EFFECTS OF EXOGENOUS MELATONIN IN HUMANS

The sleepiness-inducing properties of melatonin have been known since its discoverer, Lerner, reported this effect after self-administration. A substantial body of evidence indicates that melatonin, when taken during biological daytime (i.e., when endogenous melatonin is very low or absent), induces sleepiness/sleep and lowers alertness, cognitive performance, and cBT. These effects are posture dependent; individuals must be recumbent and preferably in very dim light for maximum responses to be seen. Accompanying these direct effects is the important ability of melatonin to change the timing of the internal circadian clock, as evidenced by shifts in the timing of endogenous melatonin itself, cortisol, cBT, thyroid-stimulating hormone (TSH), and sleep rhythms (Fig. 7). Administration during the (biological) afternoon/early evening leads to phase advances, whereas administration during the early morning can elicit phase delays (to

Figure 7 Diagrammatic representation of phase shifts induced by melatonin. Melatonin treatment, specifically timed according to internal circadian phase (shown here by the timing of the endogenous melatonin rhythm) can advance or delay the circadian clock, as evidenced by shifts in its own endogenous rhythm and that of core body temperature. The shift can be predicted by a “phase response curve” that describes the magnitude and direction of shift that can be obtained with specific circadian timing of treatment. Other rhythms that can be phase shifted by melatonin include sleep, alertness, cortisol, and thyroid-stimulating hormone. The oral doses used are usually in the range of 0.5 to 5.0 mg fast release. The phase shift obtained is dose dependent but individually variable.

this point, shown only for endogenous melatonin core body temperature and sleep). The existing data have been summarized as a “phase response curve” from which specific timing of administration to induce a specific shift can be predicted.

THERAPEUTIC POTENTIAL

In view of its ability to induce sleepiness, change the timing of sleep, and shift the timing of the internal clock, melatonin has been investigated extensively as a treatment for circadian rhythm-related sleep disorders. It has proved to be successful, when timed correctly, for alleviating jet lag, improving daytime sleep in shift workers, and normalizing sleep time in delayed sleep phase syndrome. It is able to synchronize free-running sleep and other rhythms of some blind subjects with suitable dose and timing of treatment (Fig. 8). It is the latter indication that underlines the importance of such treatment. Circadian sleep disorders can normally be treated with appropriate exposure to bright light to “shift the clock,” inducing a resetting to a normal or near normal pattern of melatonin secretion. In the blind, this is not possible, and so melatonin is the treatment of choice.

Figure 8 Melatonin can phase shift and, in some cases, synchronize circadian rhythms in some sighted and blind subjects with suitable timing of treatment and dose. Shown are the times of the calculated peaks (acrophases) of urinary 6-sulphatoxymelatonin (squares) and cortisol (circles) of a free-running blind subject with a period of 24.57 h treated with placebo or 5 mg melatonin daily, timed to phase advance the internal clock. Note that with melatonin, a 24-h period is maintained. Significant beneficial effects on sleep are found using melatonin treatment in non-24-h sleep disorder of the blind. Redrawn from Lockley, S. W., Skene, D. J., James, K., Thapan, K., Wright, J., and Arendt, J. (2000). Melatonin administration can entrain the free running circadian system of blind subjects. *J. Endocrinol.* **164**, R1–R6. Reproduced by permission of the Society for Endocrinology.

It is likely that SCN receptors mediate the circadian effects of melatonin, those in the mediobasal hypothalamus and pars tuberalis influence photoperiodic seasonal reproduction with regard to gonadotropin secretion and prolactin, respectively, and those in the retina mediate the retinal processes influenced by melatonin (Fig. 9). The physiological functions of the multiplicity of melatonin-binding sites in other areas remain to be clarified.

CONCLUSIONS

Melatonin acts as both an internal clock and an internal calendar to influence the timing of circadian and seasonal rhythms. It is likely that any aspect of

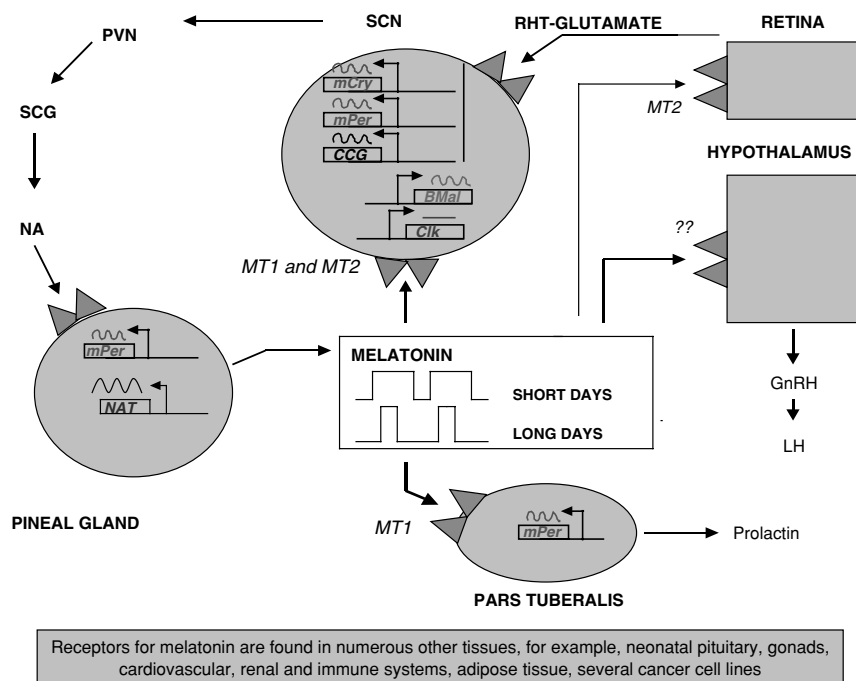

Figure 9 Diagrammatic representation of the control of production and the functions of melatonin with regard to seasonal and circadian timing mechanisms. RHT, retino-hypothalamic tract; NA, noradrenalin; SCN, suprachiasmatic nucleus; PVN, paraventricular nucleus; SCG, superior cervical ganglion; MT1 and MT2, melatonin receptor subtypes. The melatonin rhythm is generated by a closed-loop negative feedback of clock gene expression in the SCN. *Ctk* and *BMal*, positive stimulatory elements; *Per* and *Cry*, negative elements; *CCG*, clock controlled genes. *Per* and *NAT* mRNA oscillate in the pineal, although posttranscription control is evident in some species. Melatonin influences SCN activity via two or more receptors. MT2 appears to be the phase-shifting receptor in rodents, whereas MT1 is associated with suppression of SCN electrical activity. The MT2 receptor was first characterized in the retina and influences dopamine release. Melatonin conveys photoperiodic information influencing the pattern of *Per* expression in the pars tuberalis for the control of seasonal prolactin variations via an MT1 receptor. Melatonin target sites in the hypothalamus influencing seasonal variations in reproductive hormones have yet to be fully defined. Based (with permission) on an original diagram by Elisabeth Maywood, MRC Laboratory of Molecular Biology, Neurobiology Division, Cambridge, United Kingdom.

physiology that depends on perception of daylength change, and/or that is driven by the master circadian clock in the SCN, is susceptible to the effects of melatonin. These effects may be modulatory and complementary to the effects of light in the case of the adult circadian system. During the perinatal period, maternal melatonin may serve to set the timing of circadian rhythms in the offspring.

Suitable timing of melatonin administration is critical for therapeutic benefit in rhythm disorders. The acute effects of melatonin on sleep, in particular, reinforce the therapeutic potential of melatonin. The possible clinical applications of antioxidant activity remain to be explored.

The effects of melatonin on photoperiod-dependent functions are critically important and include, for example, the timing of pubertal development in photoperiodic species. Melatonin is used commercially in

agriculture to modify the timing of breeding and seasonal changes in pelage.

Current research focuses on the mechanisms of action, with particular emphasis on receptor mechanisms and modification of gene expression in target tissues. Melatonin is the marker rhythm of choice for the investigation of disturbed circadian rhythms in, for example, sleep disorder, shift work, and jet lag.

GnRH or gonadotropin injections. Development of secondary sexual characteristics can be attained with appropriate hormone replacement.

Pulsatile release of GnRH appears to be an innate characteristic of neurons in the arcuate nucleus. *In vitro* experiments have shown that these neurons have pulsatile activity even when isolated from their normal surrounding structures and microenvironment.

A growing body of evidence has revealed intricate interactions between other regions of the central nervous system and the hypothalamus. Investigators have demonstrated complex neural pathways that have led to a more sophisticated understanding of the cause and effects of hypothalamic function and dysfunction.

Environmental changes, stress, exercise, extremes of weight, and emotional distress may disrupt normal hypothalamic GnRH secretion. Patients with amenorrhea resulting from hypothalamic–pituitary dysfunction are usually hypoenestrogenic. In these cases, estrogen replacement should be considered to prevent bone loss and the possibility of osteoporosis. Hypoenestrogenic patients with amenorrhea should be screened carefully for eating disorders, which can be fatal without aggressive behavioral and nutritional therapy.

A small number of patients with hypothalamic dysfunction have neoplastic, infiltrative, or infectious lesions of the central nervous system. Structural lesions must be in the differential diagnosis of all patients presenting with primary or secondary amenorrhea of hypothalamic origin.

The Pituitary and Gonadotropin (Follicle-Stimulating Hormone and Luteinizing Hormone) Release

In response to the pulsatile release of GnRH from the hypothalamus, the anterior pituitary releases the gonadotropins luteinizing hormone (LH) and follicle-stimulating hormone (FSH) in a pulsatile fashion. The frequency and amplitude of GnRH and gonadotropin secretion play pivotal roles in oocyte development, and the alteration of either of these patterns may affect oocyte quality or ovulatory function.

The predominant function of FSH is to stimulate oocyte recruitment and development during the follicular phase of the cycle. The follicular phase is conveniently, but somewhat inaccurately, defined as beginning on the first day of menstruation. Slight but significant increases in FSH secretion can be identified 1 or 2 days before the onset of menstruation. The FSH increment is a response to declining

ovarian hormone production, especially inhibin A, during the late luteal phase.

The initial increase in FSH stimulates the development of a cohort of ovarian follicles containing immature oocytes. This FSH stimulation eventually results in the selection of a single dominant follicle destined for ovulation.

Progressively increasing estradiol secretion during the follicular phase acts to inhibit FSH release prior to the midcycle gonadotropin surge (negative feedback). This allows the dominant follicle a unique advantage over other developing follicles that will ultimately degenerate through the process of atresia. This advantage is predominantly a result of a higher density of FSH receptors, greater steroidogenic capacity, and a more profound angiogenic proliferation within the dominant follicle.

Eventually, estradiol promotes the stimulation of the midcycle gonadotropin surge that initiates the events resulting in ovulation from the dominant follicle (positive feedback). Although a surge in both LH and FSH occurs, LH plays the most significant role in the ensuing ovulation process.

The beginning of the LH surge occurs approximately 35 to 44 h prior to ovulation. The LH surge is critical in regulating the production of progesterone, prostaglandins, and other local factors that contribute to follicle rupture. In response to these conditions, the oocyte is extruded from the ovary into the fimbria of the fallopian tube en route to the uterus.

The Ovary: Response and Control

The residual follicular tissue undergoes a functional transition. Local growth factors initiate a massive angiogenic process and a drastic increase in the capacity for progesterone production. This process is known as luteinization, and the resultant collection of cells is known as the corpus luteum. Hence, ovulation signals the beginning of the luteal phase.

Pulsatile LH secretion continues to promote the production of estradiol and progesterone during the luteal phase. Progesterone secretion is essential for the induction of secretory changes within the uterine cavity. These changes are a prerequisite for proper embryo implantation.

The corpus luteum appears to have a programmed life span, rapidly regressing 9 to 11 days following ovulation in the absence of pregnancy. During early pregnancy, the conceptus produces human chorionic gonadotropin (hCG), a glycoprotein nearly identical to LH in structure and function. This sustains the steroid-producing capacity of the corpus luteum

until the placenta develops sufficient steroidogenic activity.

There is controversy regarding the effects of dysfunction in the ovary on fertility. Failure of patients to have an appropriate LH surge may inhibit ovulation. These patients can be treated with injections of hCG.

There also appears to be a subset of women who generate an LH surge but do not have rupture of their dominant follicle. The exact etiology of this process, referred to as luteinized unruptured follicle syndrome, is unknown. Because serial ultrasound monitoring is necessary to detect this disorder, the incidence is poorly described in the literature.

It is not clear whether abnormal function of the corpus luteum is a cause of infertility. A possible connection between inadequate progesterone production by the corpus luteum and early pregnancy loss has been termed luteal phase deficiency. Diagnosis and treatment of this disorder are relatively simple, although the efficacy of treatment remains a source of great conflict among experts in the field.

The remarkable coordination necessary to produce oocytes capable of establishing a successful pregnancy has been demonstrated in women receiving gonadotropins for *in vitro* fertilization. Prior to the use of GnRH analogues for pituitary suppression, approximately 20% of patients showed evidence of a premature LH surge. This untimely LH surge often resulted in the retrieval of immature oocytes that fertilized poorly *in vitro*.

Anovulatory disorders represent a large portion of the reproductive endocrinologist's daily practice. The etiology of anovulation is often obscure. Fortunately, the majority of these disorders can be treated effectively with current medical therapies.

Patients with polycystic ovary syndrome (PCOS), often referred to as chronic hyperandrogenemic anovulation, generally present clinically with amenorrhea, hirsutism, and obesity. This syndrome is extremely heterogeneous and may actually represent a pooled collection of various disorders. A strong association between PCOS and insulin resistance, with impaired glucose tolerance, has been recognized. These patients often become ovulatory in response to a strict program of exercise and dietary modification with weight loss. In addition, pharmacological intervention addressing glucose metabolism may be promising in treating anovulation and infertility in these patients.

Certain conditions are known to be associated with accelerated germ cell loss and degeneration of the ovary. Turner syndrome, an abnormality in or absence of one of the X chromosomes, is a classic example of this type of disorder. Characterized by

sexual infantilism, short stature, and streak gonads, these patients have a propensity for the development of concomitant endocrinopathies.

The cessation of ovarian function, which results in menopause, is related to the depletion of functional ovarian follicles. This process usually occurs at approximately 50 years of age. Premature ovarian failure is defined as cessation of ovarian function prior to 40 years of age. Interestingly, this condition can be associated with autoimmune diseases that can be life threatening. In addition, in the subset of women who present with premature ovarian failure prior to 30 years of age, chromosomal abnormalities are occasionally discovered.

In both Turner syndrome and premature ovarian failure, the genetic defect appears to result in an unusually rapid rate of atresia of the follicular pool. This genetic association is particularly interesting as an area for future investigations of physiology and therapeutics.

THE UTERUS AND MENSTRUATION

Distinct changes in the uterine lining are noted throughout the menstrual cycle. Anatomically, the endometrial lining may be divided into an outer functionalis layer and an inner basalis layer. The role of the functionalis layer is to respond to the alteration of hormones throughout the cycle and to prepare for implantation of the embryo. The functionalis is shed during menstruation. The basalis layer serves as a source of new endometrium after each successive menstruation.

The proliferative phase of the menstrual cycle corresponds with the follicular phase of the ovarian cycle and is marked by estrogen-dependent proliferation of glandular structures and vasculature within the endometrium. Mitotic activity is prominent, and the endometrial lining increases in thickness as much as 10-fold.

After ovulation, the thickness of the endometrium changes little. This is likely a result of inhibition from increasing progesterone production. Tortuosity of the vessels and secretory activity within the glands are the hallmarks of the secretory phase of the cycle. At the time of implantation of the blastocyst, marked edema can be seen within the stroma of the endometrium. Concomitantly, decidualization occurs. The decidua is derived from the stromal cells of the endometrium and is rich in glycogen and lipid content. This layer of cells displays the ability to produce a large number of autocrine and paracrine regulatory

peptides. The decidua is integrally involved in the processes of implantation and placentation.

In the absence of pregnancy, implantation, and the production of hCG by the trophoblasts, the demise of the corpus luteum results in the withdrawal of estrogen and progesterone. This results in apoptosis of the endometrial cells and contraction of the spiral arteries nourishing the surface of the endometrium. Hemorrhage into the stroma and infiltration of the endometrium with inflammatory mediators follow. Eventually, these combined events result in the sloughing of the endometrium, clinically recognized as menstruation.

Many factors are responsible for aberrant menstrual patterns. Patients presenting with amenorrhea, oligomenorrhea, menorrhagia, metrorrhagia, intermenstrual bleeding, or dysmenorrhea can be challenging from both a diagnostic and a therapeutic standpoint. Structural abnormalities in the uterine cavity and neoplastic conditions of the endometrium can contribute to bleeding abnormalities. In addition, alterations in any of the complex processes within the hypothalamic–pituitary–ovarian axis can result in abnormal or absent menstruation.

THE FUTURE

The next decade should bring exciting advances in our understanding of the mechanisms responsible for normal gamete function, fertilization, implantation, and early pregnancy development. Essential for the development of this growth in knowledge will be a sound basic understanding of the menstrual cycle and an appreciation of the beautifully orchestrated relationships among the brain, ovary, uterus, and other organs.

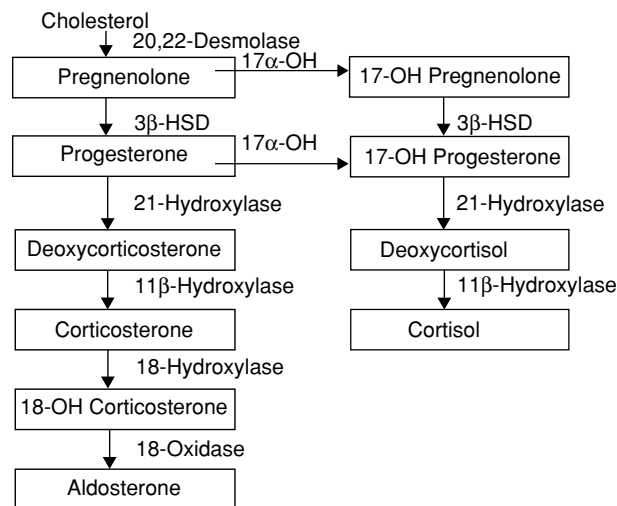

Figure 1 Steroid biosynthetic pathway.

is low-affinity binding to plasma albumin and cortisol-binding globulin. Although a specific high-affinity, aldosterone-binding protein has been reported, it is of doubtful physiological significance.

The liver is the major site of aldosterone metabolism. Aldosterone undergoes reduction by a cytosolic 5β reductase and 3α hydroxysteroid dehydrogenase to form tetrahydroaldosterone, which accounts for 40% of aldosterone urinary metabolites. Tetrahydroaldosterone is then conjugated in the liver to glucuronide to yield the major urinary metabolite of aldosterone.

REGULATION OF MINERALOCORTICOID PRODUCTION

Renin–Angiotensin System

Angiotensin II is the principal regulator of aldosterone production. The classical renin–angiotensin system (RAS) is outlined in Fig. 2. This consists of a precursor protein, angiotensinogen (produced by the liver), and two enzymes, renin (first described in the juxtaglomerular cells of the kidney) and angiotensin I-converting enzyme (ACE) (widely distributed but found predominantly in the pulmonary vascular endothelium).

Angiotensin II is an octapeptide and acts on the adrenal cortex to stimulate aldosterone secretion and also produce a direct pressor response through increased resistance vessel tone. Secretion of renin (and hence activation of the RAS) is increased under conditions of reduced sodium intake, sodium loss, or reduced extracellular fluid volume because this leads to increased angiotensin II production. Hence, the

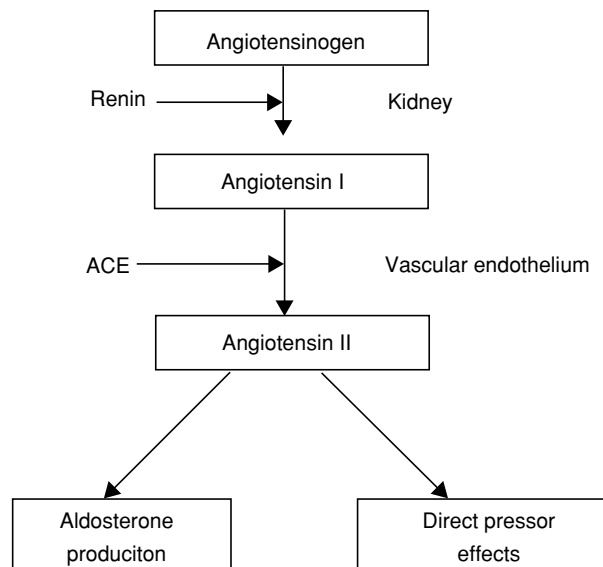

Figure 2 Classical renin–angiotensin–aldosterone system.

RAS is important in acute cardiovascular homeostasis (i.e., the response to head-up tilt or blood loss) and in the regulation of aldosterone secretion in response to salt depletion. It is noteworthy that the aldosterone response to angiotensin II is enhanced in states of classic sodium depletion and is diminished by sodium loading.

Angiotensin II produces its effect on aldosterone secretion via the type I angiotensin II receptor (ATI). Binding to this G protein-coupled receptor results in activation of phospholipase C. In turn, this leads to hydrolysis of phosphatidyl inositol biphosphate, producing inositol triphosphate (IP₃) and diacylglycerol (DAG), causing a rapid rise in intracellular calcium and activation of both early stages (transport of cholesterol into the mitochondrion) and late stages (aldosterone synthase) of aldosterone synthesis. This rise in intracellular calcium correlates well with aldosterone production.

Plasma Potassium

Potassium is a powerful direct stimulus to aldosterone secretion; very small increments, which do not alter plasma levels perceptibly, raise the aldosterone secretion rate. Potassium acts at the plasma membrane of the zona glomerulosa by modifying the membrane potential. Increasing potassium concentration leads to depolarization of the cell membrane and activation of voltage-dependent calcium channels. The resultant calcium influx leads to a sustained rise in cytosolic

calcium present for the duration of the stimulus that correlates with aldosterone production.

Adrenocorticotropin

Infusion of adrenocorticotropin (ACTH) causes a rise in circulating aldosterone levels by direct action on zona glomerulosa cells. The effect of pharmacological doses of ACTH is only temporary and is not sustained. It is hypothesized that this is due to rapid retention of sodium, with suppression of angiotensin II formation caused by the ACTH-mediated elevation of plasma levels of intermediates such as 11-DOC as well as cortisol itself. Hence, the physiological significance of the effect of ACTH on plasma aldosterone remains unclear. Patients with anterior pituitary failure, who lack ACTH, continue to secrete aldosterone responsive to potassium and angiotensin II.

Other Regulatory Factors

A variety of other peptides and amines influence aldosterone secretion in humans. Of these, atrial natriuretic peptide (ANP) may be one of the more important mechanisms that inhibit aldosterone production. Dopamine also has inhibitory effects. Stimulatory factors include catecholamines (e.g., adrenaline, noradrenaline), acetylcholine, and vasoactive intestinal peptide (VIP).

EFFECTS OF MINERALOCORTICOIDS

Mineralocorticoid Receptor

Aldosterone acts by binding to the mineralocorticoid receptor (MR). This is an intracellular receptor belonging to the steroid/thyroid/retinoid/orphan receptor superfamily. It acts as a ligand-dependent transcription factor, so that once it is bound to aldosterone (or cortisol), it will interact directly with hormone-responsive elements (HREs) in the promoter regions of regulated genes. HREs are present in many genes and fall into three groups: the glucocorticoid/progesterone/mineralocorticoid-responsive element to which aldosterone binds, estrogen-responsive element (ERE), and thyroid-responsive element (TRE).

MRs are found in epithelial tissues (renal distal nephron, colon, ducts of sweat, and salivary glands) and nonepithelial tissues (heart, brain, vascular smooth muscle, liver, and peripheral blood leucocytes). There is also evidence of a membrane-associated aldosterone receptor that subserves rapid nongenomic effects of aldosterone on vascular homeostasis.

11 β Hydroxysteroid Dehydrogenase System

The MR binds both aldosterone and cortisol with similar affinities (0.5–1 nmol/L). Because cortisol is much more abundant in plasma (100- to 1000-fold), it is clear that a mechanism is required to protect the MR against permanent occupancy by glucocorticoid hormones. This role is performed by the 11 β hydroxysteroid dehydrogenase (11 β OHSD) enzyme system. This converts cortisol into its 11-keto inactive metabolite, cortisone, and also catalyzes the opposite oxoreductase step to reform cortisol from cortisone (Fig. 3). Cortisone has no affinity for the MR.

There are two isoforms of this enzyme encoded by separate genes. The type 1 isozyme is found mainly in liver and adipose tissue; *in vivo*, it generates cortisol from cortisone. The type 2 isozyme inactivates cortisol to cortisone and so is expressed primarily in mineralocorticoid target tissues (renal distal nephron, salivary and sweat glands, and colon). Functional anomalies of the type 2 enzyme result in the clinical entity of apparent mineralocorticoid excess.

Cellular Response to Aldosterone Binding

When the MR binds aldosterone, it migrates to the cell nucleus, where it binds to an HRE. Following this, transcriptional activation occurs, and during this latent period, DNA transcription and protein

Figure 3 11 β hydroxysteroid dehydrogenase system.

translation occur. The first unequivocally aldosterone-induced protein in kidney was demonstrated in 1999. Sgk-1 (serum glucocorticoid-induced kinase, the first of three known isoforms) is regulated transcriptionally by aldosterone and is activated by insulin-regulated phosphorylation. In turn, activated Sgk-1 results in phosphorylation and activation of the epithelial sodium channel. Aldosterone activation of the MR undoubtedly leads to transcriptional regulation of other molecules, but the precise identities and functions of these are beyond the scope of this article.

Physiological Response to Aldosterone

The best-characterized physiological effect of aldosterone is to increase the reabsorption of sodium in the kidney and at other secretory epithelial sites at the expense of potassium and hydrogen ions. The major sites of aldosterone-induced sodium and potassium transport are luminal cells of the cortical-collecting tubules and the distal convoluted tubule. Aldosterone acts to increase activity of the Na/K ATPase pump on the basolateral membrane of these cells.

Aldosterone also regulates hydrogen ion excretion by the kidney in the distal nephron. Aldosterone-mediated hydrogen ion secretion occurs in the intercalated cells of the collecting tubule. This effect appears to be mediated via an increase in activity of the adenosine triphosphate (ATP)-dependent apical hydrogen ion pump and parallel regulation of the basolateral membrane Cl/HCO exchanger. Thus, aldosterone-induced natriuresis and hydrogen ion secretion appear to be independent events.

Therefore, the overall effect of aldosterone on the renal tubule is to promote sodium retention at the expense of potassium and also to promote hydrogen ion excretion. In turn, this leads to expansion of the extracellular volume as well as plasma volume.

It is likely that the rise in blood pressure reflects mechanisms other than, or in addition to, simple plasma volume expansion and associated increase in cardiac output. For example, activation of the MR in vascular smooth muscle results in alteration in pressor responsiveness to adrenergic stimulation. Moreover, evidence suggests that aldosterone binding by the MR in cardiac tissue regulates collagen formation. Therefore, it is feasible that similar action in peripheral blood vessels might result in remodeling that could sustain an elevated blood pressure. This is supported by evidence suggesting that aldosterone levels are inversely related to arterial compliance in essential hypertension.

Mineralocorticoid receptors are also present in the central nervous system (CNS) and may regulate

central sympathetic outflow as well as thirst and salt intake. Intracerebroventricular administration of aldosterone raises blood pressure without altering peripheral concentration and is independent of its effects on sodium retention. In short, sustained excess of aldosterone is likely to elevate blood pressure through a variety of mechanisms, all of which require activation of the MR.

Role of Aldosterone in Disease

Secondary hyperaldosteronism occurs due to activation of the RAS and is seen in conditions such as congestive cardiac failure (CCF), malignant hypertension, renal artery stenosis, and hepatic cirrhosis. It has generally been accepted that the pathophysiological effects of aldosterone in these conditions are mediated through sodium retention and expansion of plasma volume. This is supported by the finding that hypertension and edema do not occur in renal salt-wasting forms of secondary aldosteronism such as Bartter's syndrome.

However, recent experimental and clinical evidence suggests that excessive circulating levels of aldosterone can bring about adverse cardiovascular sequelae, such as cardiac fibrosis and left ventricular hypertrophy, independent of its effects on blood pressure or plasma volume. Several investigators have demonstrated this using rat models of renovascular hypertension. In one such experiment, uninephrectomized rats infused with aldosterone over an 8-week period developed progressive elevation of blood pressure, cardiac hypertrophy, and fibrosis. This was also seen in rats that remained normotensive due to concomitant intracerebroventricular infusion of an MR antagonist, demonstrating that these effects are humoral and not hemodynamic. The high prevalence of CCF, which is commonly associated with hyperaldosteronism, suggests a significant role of aldosterone excess as a cause of cardiovascular injury. For example, more recent studies have confirmed that aldosterone excess causes severe cardiac injury associated with perivascular inflammation (in coronary vessels), cerebral tissue damage, and nephrosclerosis. These effects are exacerbated by concomitant sodium loading and are prevented by aldosterone receptor antagonism.

SYNDROMES OF MINERALOCORTICOID EXCESS

The most common clinical form of mineralocorticoid excess reflects excess production of aldosterone;

Table 1 Classification of Mineralocorticoid Excess Syndromes

| Mechanism | Classification | Ligand |
|-------------------|---|---------------------|
| Post receptor | Liddle's syndrome | — |
| Abnormal receptor | Progesterone-induced hypertension | Progesterone |
| | Glucocorticoid resistance | Cortisol |
| Abnormal ligand | Syndrome of apparent mineralocorticoid excess | Cortisol |
| | Congenital adrenal hyperplasia | Deoxycorticosterone |
| | DOC-producing tumors | Deoxycorticosterone |
| | Ectopic ACTH syndrome | Cortisol |
| Normal ligand | Primary aldosteronism | Aldosterone |
| | GRA | |

however, there are numerous other causes and other mineralocorticoids that can be produced in excess (Table I).

Post Receptor

Liddle's syndrome was first described by Liddle in 1963 when he reported a family in which the siblings appeared to have features of aldosterone excess (early-onset hypertension and hypokalemia) but with suppressed plasma renin and aldosterone levels. It is now known that this syndrome is inherited as an autosomal dominant trait and occurs due to mutations of the genes encoding the β - or γ -subunit of the epithelial sodium channel of the distal nephron. This results in constitutive activation of this receptor (sodium retention and potassium excretion), irrespective of circulating mineralocorticoid levels (usually suppressed). Moreover, in the proband of one of Liddle's original cases, renal transplantation resulted in normalization of blood pressure and electrolyte abnormalities. However, in practice, using antagonists of the sodium channel, such as amiloride and triamterene, treats this condition effectively.

Adrenal Receptor Causes

Glucocorticoid Receptor Resistance

This rare disorder is characterized by decreased sensitivity to cortisol signaling, elevated plasma cortisol, and an absence of any stigmata of Cushing's disease. The compensatory increase in corticotropin-releasing hormone (CRH), ACTH, and cortisol production is also accompanied by increased secretion of mineralocorticoid precursors (11-DOC and corticosterone) and aldosterone as well as adrenal androgens (dehydroepiandrosterone [DHEA], androstenedione, and testosterone). Elevated plasma cortisol levels may

overwhelm the 11β OHSD system, allowing cortisol to bind at the MR.

Phenotypically, this disorder has a wide clinical spectrum ranging from fatigue, hirsutism, oligomenorrhea, infertility, and obesity to severe hypertension with hypokalemic alkalosis. In some patients, point mutations in the steroid-binding domain of the glucocorticoid receptor have been identified. However, other cases of cortisol resistance may represent abnormalities in the signaling pathway rather than in the receptor. Treatment is with sufficient dexamethasone to suppress ACTH and to lower blood pressure and adrenal androgens.

Progesterone-Induced Hypertension

Progesterone usually acts as an antagonist at the mineralocorticoid receptor. However, a mutation in the ligand-binding domain of the receptor was recently identified. This mutation allows progesterone to act as an agonist at the mineralocorticoid receptor, causing a clinical and biochemical picture indistinguishable from aldosterone excess, although aldosterone levels are suppressed. Because progesterone levels typically increase during pregnancy, affected female members of identified kindred had severe hypertension with associated hypokalemia and hyperkaliuria when pregnant.

Abnormal Ligand

Syndrome of Apparent Mineralocorticoid Excess

In this condition, the type 2 isoform of 11β OHSD is inactivated. This enzyme is important in mineralocorticoid target tissues to inactivate cortisol and prevent binding to the MR. If activity of the enzyme is reduced, cortisol binds to the MR, causing classical

mineralocorticoid-type hypertension. Clinically, this presents as hypertension, hypokalemia, and suppression of the renin–angiotensin–aldosterone (RAA) axis. Diagnosis is made by demonstration of an elevated ratio of urinary cortisol to cortisone metabolites or of urinary-free cortisol to urinary-free cortisone. This disorder is inherited as an autosomal recessive trait, and several inactivating point mutations in the type 2 gene have been identified. Dexamethasone can be used to lower plasma cortisol, and patients will also respond to spironolactone.

The same clinical and biochemical phenotype can be seen when the type 2 isoform of 11β OHSD is inhibited by large amounts of liquorice or related drugs such as carbenoxolone (the hemisuccinate derivative of the active component of liquorice, glycyrrhetic acid). Carbenoxolone was once used in the treatment of peptic ulcer disease, but mineralocorticoid side effects were seen in up to 50% of patients. Again, analysis of urine collections will reveal elevated cortisol:cortisone ratios (as urinary metabolites tetrahydrocortisol and tetrahydrocortisone), but to a lesser extent than will the congenital cases. Obviously, treatment is to stop excessive intake of liquorice or to stop the carbenoxolone.

Ectopic ACTH Syndrome

Fully 80% of patients with Cushing's syndrome are hypertensive, and this increases to 95% in the subgroup with excess pituitary ACTH production (Cushing's disease). Moreover, hypokalemic alkalosis, a hallmark of mineralocorticoid excess, is found in 95 to 100% of these cases, as compared with just 10% in other cases of Cushing's syndrome. Recent evidence suggests that saturation of 11β OHSD type 2 by the very high-cortisol concentrations that typify this condition explains the mineralocorticoid excess state. In support of this, the urinary ratios of both tetrahydrocortisol:tetrahydrocortisone and free cortisol:cortisone are elevated.

Deoxycorticosterone and Corticosterone Secretion

Excessive amounts of these mineralocorticoids are usually found only in subtypes of congenital adrenal hyperplasia. DOC excess usually occurs along with aldosterone excess in adrenal adenoma, and its contribution to the clinical phenotype is unlikely to be significant. Rarely, adenomas may produce DOC in isolation, and in these circumstances, DOC can act as an agonist at the MR, resulting in hypertension. The majority of pure corticosterone-producing adrenal tumors have been carcinomas.

Congenital Adrenal Hyperplasia

This describes a group of recessively inherited disorders arising due to mutations of enzymes involved in adrenal corticosteroidogenesis. They are described in detail elsewhere. Only two forms of congenital adrenal hyperplasia are associated with mineralocorticoid excess: 17α -hydroxylase (excess of DOC and corticosterone) and 11β -hydroxylase (excess DOC due to increased ACTH drive to the adrenal) deficiencies.

Normal Ligand: Primary Aldosteronism

Primary aldosteronism (PA) can be defined as overproduction of aldosterone independent of its normal chronic regulator, angiotensin II. Recent studies have led to a reevaluation of the apparent prevalence of PA. In particular, wider use of the aldosterone:renin ratio (ARR) as a screening and diagnostic tool has led to a substantial increase in the PA detection rate. Indeed, several groups worldwide now estimate the prevalence of PA in unselected hypertensives to be 5 to 15%. The exact prevalence remains unclear, but a reliable and reproducible study of unselected hypertensives in Dundee, Scotland, suggested a prevalence of 10% both in primary and secondary care settings. Thus, aldosterone excess may be a very important cause of cardiovascular morbidity.

Adrenal Adenoma

First described by Jerome Conn in 1955, this was previously thought to be the most common cause of PA. Aldosteronomas are usually small (<2 cm in diameter) and benign and have a golden yellow color on their cut surfaces with different adrenal cell types visible on microscopy.

In most cases, control of aldosterone secretion is altered so that the tumor responds to ACTH and not to its usual regulator angiotensin II. In this circumstance, aldosterone adopts a circadian rhythm similar to that of cortisol. However, a number of adenomas remain responsive to angiotensin II.

Bilateral Adrenal Hyperplasia

The true frequency of this is currently uncertain, but recent studies identifying patients via the ARR suggest that this is now the most common cause of PA. Histologically, it is usually associated with bilateral macro- or micronodular hyperplasia, although rarely it can occur unilaterally. Idiopathic aldosteronism is associated with enhanced adrenal responsiveness to angiotensin II. The reason for this is still unclear.

It has been suggested that this syndrome is part of the spectrum of low-renin hypertension (occurring in up to 30% of elderly hypertensives) and does not in itself constitute a distinct diagnostic entity. This is supported by the findings of adrenal hyperplasia and nodularity in postmortem series of patients with essential hypertension.

Adrenal carcinoma is a rare cause of PA.

Glucocorticoid Remediable Adosteronism

This rare autosomal dominant condition is characterized by aldosterone excess that is regulated by ACTH rather than by angiotensin II. The resulting interruption of negative feedback (aldosterone does not suppress ACTH) causes adosteronism that is suppressible by exogenous glucocorticoid, a useful therapeutic strategy.

The molecular basis of this condition was first described in 1992. The terminal steps in cortisol and aldosterone biosynthesis are catalyzed by the enzymes 11 β -hydroxylase and aldosterone synthase, respectively. These are encoded by two genes, CYP11B1 and CYP11B2, that lie in tandem on chromosome 8 and share more than 90% homology at the amino acid level. In glucocorticoid remediable adosteronism (GRA), a chimeric gene is created containing the 5' promoter sequence of CYP11B1 and functional elements of CYP11B2, resulting in aldosterone production under control of ACTH. The hybrid gene can be detected by a polymer-based chain reaction (PCR) that provides a screening test for this type of adosteronism.

Clinical Features of Primary Adosteronism

In the majority of cases, patients are asymptomatic and present simply with refractory hypertension. A few may present with symptoms related to hypokalemia with muscle weakness, tiredness, and polyuria and polydipsia related to nephrogenic diabetes insipidus. However, it should be emphasized that it is now recognized that up to 60 to 70% of patients with PA, as diagnosed by an elevated ARR, are normokalemic.

Nevertheless, spontaneous hypokalemia is rare in untreated hypertension, and its presence should raise suspicion of PA. Patients with hypokalemia on diuretic treatment should stop treatment for 2 weeks and take potassium supplements before repeat serum potassium measurements. As discussed earlier, aldosterone excess may contribute to specific humorally mediated cardiac, renal, and CNS damage. In this regard, there is evidence that patients with PA have more marked left ventricular hypertrophy than do patients with equivalent degrees of blood pressure elevation due to other causes.

Diagnosis

This remains controversial, and no consensus exists regarding an optimal diagnostic protocol. Before performing specific diagnostic tests, serum potassium should be normalized, if necessary by oral supplementation. Both aldosterone and plasma renin activity (PRA) are also affected by posture and sodium intake. Ideally, antihypertensive medications should be stopped several weeks prior to testing due to their effects on the RAA axis (Table II). In practice, this is not always possible or even advisable due to the severity of hypertension. In these circumstances, alpha blockers have been shown to have only negligible effects on the ARR and can be continued. Theoretically, calcium channel blockers are also often continued, but the possibility of false negative results should be remembered. It is simpler to consider the diagnosis of PA in two stages: confirmation of aldosterone excess initially and then investigation of the underlying cause.

Aldosterone:Renin Ratio

Given the problems of controlling posture, sodium intake, and potassium levels, many groups now advocate use of the ARR as a first step in the diagnosis of PA. This ratio appears to be more robust because it is less affected by drug administration, day-to-day and diurnal variation, and posture. However, use of this ratio is not without its problems. One concern is that

Table II Effect of Common anti Hypertensive Drugs on the RAA Axis

| Drug | Effect | Duration of washout required (weeks) |
|---|--------------------------|--------------------------------------|
| ACE inhibitors and angiotensin II antagonists | PRA \uparrow | 2 |
| Diuretics | PRA \uparrow | 2 |
| Spironolactone | PRA \uparrow | 6 |
| Beta blockers | PRA \downarrow | 2 |
| Calcium channel blockers | Aldosterone \downarrow | 2 |

whereas most laboratories around the world express plasma aldosterone as picomoles/liter, in the United States it is expressed as nanograms/deciliter. Nearly all investigators report PRA in nanograms/milliliter/hour. This means that the cutoff for a raised ARR can be approximately 25 (plasma aldosterone as ng/dl) or 750 (plasma aldosterone as pmol/L). Although this value is rather arbitrary, most groups have successfully confirmed abnormal regulation of aldosterone in patients with values equal to or greater than 750 by confirmatory testing. It is suggested that the ARR may be used as an initial screening test in individuals with resistant hypertension, hypertension with hypokalemia, and a family history of hypertension.

Postural Testing

When an abnormal ARR has been identified, confirmatory testing should be performed under more stringent conditions. Antihypertensive drug treatment (except alpha blockers) should be stopped if possible, and ideally, individuals should be on a normal to high-sodium diet. Resting and ambulant plasma aldosterone and renin (as PRA) should be measured. The rationale behind this is that in normal individuals, plasma aldosterone rises with standing. In GRA and the majority of aldosterone-producing adenomas, aldosterone is under ACTH control, resulting in diurnal variation of aldosterone levels and a loss of the normal postural response. For this reason, plasma cortisol should also be measured. In idiopathic aldosteronism due to adrenal hyperplasia and angiotensin II-responsive adrenal adenoma, aldosterone levels continue to rise on standing.

Saline Infusion/Fludrocortisone Suppression

In both tests, the rationale is that in normal individuals expansion of plasma volume will suppress plasma aldosterone concentrations, whereas in primary aldosteronism further volume expansion does not have the same suppressive effect.

Intermediary Metabolites

Both 18-hydroxy and 18-oxo cortisol are produced by the adrenal cortex by the action of aldosterone synthase on cortisol. Urinary excretion of these metabolites is increased in patients with aldosterone-producing adenomas, particularly in patients with GRA.

Adrenal Imaging

This should be performed only when aldosterone excess has been confirmed biochemically because a significant number of nonfunctioning adenomas (“incidentalomas”) can be found when the adrenals

are imaged. Although there have been no recent comparison studies, it appears that computed tomography (CT) is the preferred imaging modality. Most authors report that CT affords better spatial resolution and so is more sensitive in detecting smaller adenomas than is magnetic resonance imaging (MRI), although MRI may give more information on fat content of tumors. Nonetheless, it is estimated that CT detects only approximately 50 to 75% of aldosterone-producing adenomas and is of value in the identification of large (> 2.5 cm) adrenal masses that warrant discussion for excision based on their malignant potential.

Adrenal Vein Sampling

Although technically difficult and potentially hazardous, this remains the gold standard for diagnosis of adrenal adenomas. Given its risks, it is generally reserved for those in whom adrenal surgery is being considered, but it may be performed in others in whom there is diagnostic doubt. Diagnosis of adrenal adenoma can be made if aldosterone levels are elevated in one adrenal vein compared with the other. Simultaneous cortisol measurements ensure correct positioning of the cannula in the adrenal vein; a gradient of at least 300% between peripheral and central cortisol measurements confirms that this is the case.

In summary, the diagnosis of primary aldosteronism is problematic in that there are a number of potential diagnostic tests, many of which are affected by posture, electrolyte balance, and medications. [Figure 4](#) outlines a possible approach to the initial investigation of mineralocorticoid excess and PA.

Management

Aldosterone-Producing Adenoma

Surgical excision in suitably fit individuals can be curative. Preoperatively, patients should be treated with spironolactone to lower blood pressure and normalize plasma potassium. Spironolactone also reduces the risk of postoperative hypoaldosteronism because it allows recovery of the RAA axis, resulting in stimulation of the previously atrophic contralateral zona glomerulosa. After removal of an aldosterone-producing adenoma, serum potassium returns to normal in 100% of cases and blood pressure is normalized in 60% within a month and 75% within a year. Laparoscopic techniques keep morbidity to a minimum.

In patients who are unfit for or decline surgery, medical treatment is preferred.

Idiopathic Aldosteronism

The most appropriate treatment for idiopathic aldosteronism is blockade of the MR with aldosterone

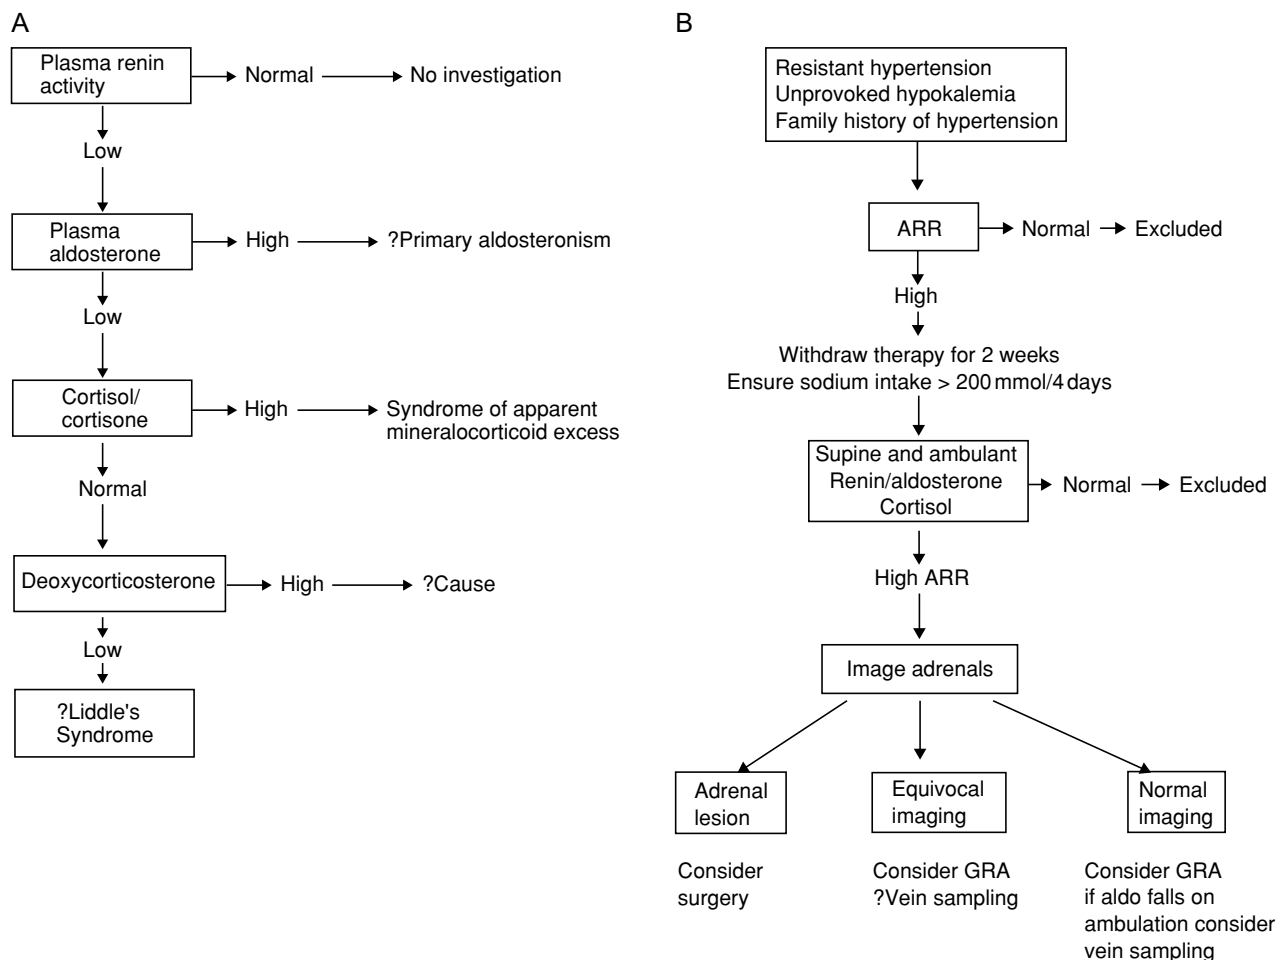

Figure 4 (A) Approach to mineralocorticoid excess. (B) Investigation of primary aldosteronism.

receptor antagonists such as spironolactone. Patients may require relatively high doses (occasionally up to 400 mg/day), although many do show a good response to much lower doses. There is evidence that patients with high ARRs, who do not have distinct adenomas, respond well to a relatively low dose of spironolactone. Dose titration is limited by dose-dependent side effects, including nausea, painful gynecomastia, and menstrual irregularities. The selective aldosterone receptor antagonist (SARA) eplerenone may offer considerable advantages, although results comparing the blood pressure lowering efficacy of this with spironolactone in PA are not yet available. Alternatives include the potassium-sparing diuretics, amiloride and triamterene, which act on the distal tubule of the nephron, inhibiting sodium-potassium exchange.

In practice, combination drug therapy using spironolactone or amiloride with one or more agents is

usually required for optimal blood pressure control. Additional agents include calcium channel blockers, angiotensin-converting enzyme (ACE) inhibitors, and angiotensin II antagonists.

Glucocorticoid Remediable Aldosteronism

Suppression of ACTH with dexamethasone provides a possible long-term therapeutic option. Patients can often be well controlled using small doses (e.g., 0.25 mg/day). Spironolactone is an alternative treatment.

Other Uses of Selective Aldosterone Receptor Antagonists

The occurrence of secondary aldosteronism in other circumstances, such as CCF, was discussed earlier. The concept of aldosterone-mediated cardiac injury has led to studies that explored the use of SARAs in patients with cardiac disease. The Randomized

Aldactone Evaluation Study (RALES) reported substantial benefit (30% reduction in mortality) in patients with advanced cardiac failure who were given spironolactone in addition to conventional treatment. More recently, the Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS) showed that eplerenone could provide substantial benefit (15% reduction in mortality) in patients following acute myocardial infarction. These are new and exciting data that illustrate the key importance of MR antagonism in cardiovascular pathophysiology and identify important therapeutic opportunities.

CONCLUSION

PA is now recognized as the most common cause of secondary hypertension and is thought to exist in up to 10% of unselected hypertensives. Aldosterone-producing adenomas are no longer the most common cause of PA but remain an important diagnosis as surgical removal offers the prospect of cure of hypertension. The majority of patients with PA are now thought to have bilateral adrenal hyperplasia. Development of new, more selective aldosterone receptor antagonists is the major therapeutic challenge to optimize blood pressure control and minimize side effects in this increasing number of patients.

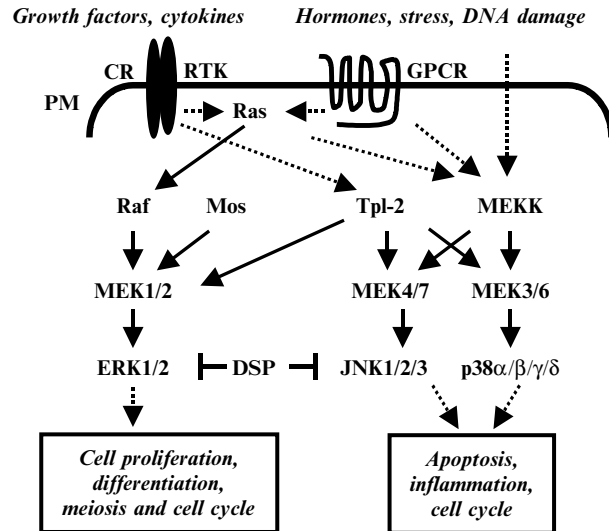

Figure 1 Schematic of the three major MAP kinase signaling pathways. Growth factors, cytokines, and other hormones activate receptor tyrosine kinases (RTK), cytokine receptors (CR), or G protein-coupled receptors (GPCR) on the plasma membrane (PM) and downstream MAP kinase pathways. Cell stress or DNA-damaging agents may activate signaling pathways independent of a receptor. Inactivation of MAP kinases occurs through dephosphorylation by dual-specificity phosphatases (DSP). Solid and dashed lines indicate direct and indirect interactions, respectively.

regulate gene expression and protein translation. Following activation, a fraction of ERK1/2 translocates to the nucleus and directly regulates gene expression by phosphorylating several transcription factors, including the p62 ternary complex factor (p62TCF; also called Elk-1), Myc, and proteins belonging to the Ets family. ERK proteins can also regulate the shape and motility of cells by phosphorylating structural proteins associated with microtubules, which are important determinants of the cell shape and architecture. Following activation, ERK proteins may also inhibit their own activity by phosphorylating the signaling protein son of sevenless (SOS), which inhibits further growth factor receptor activation of the ERK signaling pathway.

ERK Structure and Activation

The ERK proteins contain both N- and C-terminal lobes with a conserved catalytic region containing the regulatory phosphorylation sites in the activation loop (Fig. 2). These regions are important for ATP nucleotide and substrate binding as well as phosphoryl transfer onto substrate proteins. Currently, the upstream kinases, MAP or ERK kinases-1 and-2 (MEK1/2), are the only known activators of ERK1/2.

MEK1 (44 kDa) and MEK2 (45 kDa) are dual-specificity kinases that can phosphorylate both the threonine and the tyrosine residues, which are separated by a glutamate residue within the tripeptide activation motif on ERKs. Although full activation of ERK proteins requires dual phosphorylation of both threonine and tyrosine residues, single phosphorylations on either of these residues may confer partial ERK protein activity. The MEK proteins are also activated through dual phosphorylation of two serine residues primarily by Raf kinases in somatic cells and the Mos kinase in germ cells. However, the MEK proteins may also be activated by other MEK kinases, including the tumor progression locus-2 (Tpl-2) serine/threonine kinase, which is involved in inflammatory responses; the MEK kinase-1, which is involved in apoptotic responses; and mixed lineage kinase-3, which may function as a promoter of proliferation or cell death depending on the extracellular stimulus.

Raf kinases are activated through phosphorylation by a variety of serine/threonine and tyrosine kinases and by recruitment to the cell membrane through interactions with Ras G proteins. Additional phosphorylations of Raf proteins may result in inhibition

Figure 2 Diagram of the 3D structure of ERK2 showing the spatial relationship of the ERK2 N- and C-terminal lobes. The regulatory threonine and tyrosine residues within the activation loop are shown as spheres on the left. The ATP-binding region resides in the N-terminal lobe. Docking domains important for substrate interactions are represented by aspartate residues as depicted by the darker spheres on the right, and threonine residues as depicted by the lighter spheres on the right. This bilobed structure is common to many kinases.

of Raf catalytic activity and downstream ERK pathway signaling. For example, protein kinase B (also called Akt) proteins phosphorylate a serine residue in the Raf-1 catalytic domain and inhibit Raf activation of MEK and ERK. Ras proteins are coupled to the activated membrane receptors through adaptor proteins and provide a major link between plasma membrane receptors and activation of the ERK signaling pathway.

The activity of the Raf–MEK–ERK signaling module is also regulated through interactions with other binding proteins. For example, a protein called kinase suppressor of Ras may act as a scaffolding protein that binds to Raf, MEK, and ERK in a complex and determines the degree of ERK activation depending on the stimulus. In addition, a specific MEK-binding protein, MEK partner-1, may be important for directing MEK1 interactions with ERK1 but not ERK2. Lastly, a Raf-interacting protein, the Raf kinase inhibitor protein, may function by preventing Raf activation of MEK1/2. Although these and other ERK pathway binding proteins have been identified, their functional role in regulating ERK signaling events and biological functions remains largely unknown.

JNK/SAPK MAP KINASES

The c-jun NH₂-terminal kinase (JNK) proteins are an evolutionarily conserved family of serine/threonine protein kinases. The events leading to the identification and cloning of this family began in 1990, when a mammalian stress-activated protein kinase (SAPK) was discovered. These experiments identified a 54-kDa protein kinase that was activated in cells that were treated with the protein synthesis inhibitor cycloheximide. At the same time, a protein was discovered that had affinity for the transcription factor *c-jun* and phosphorylated *c-jun* on N-terminal residues when cells were exposed to ultraviolet (UV) radiation. In 1994, isolation and cloning experiments confirmed that the JNK and SAPK proteins were identical and belonged to the MAP kinase superfamily. Three isoforms, JNK-1,-2, and -3 (also known as SAPK- α , SAPK- β and SAPK- γ), have been shown to exist as at least 10 alternatively spliced variants. Whereas JNK-1 and JNK-2 are ubiquitously expressed, JNK-3 has a restricted expression pattern and is found mainly in the brain, heart, and testis.

The JNK proteins have multifunctional roles and have been proposed to be involved in tumor development, cell growth and differentiation, apoptosis, survival, and cytokine production. JNK proteins may also

mediate cardiac hypertrophic responses during hypertension and ischemia injury in the heart and kidney, and they may be involved in several neurodegenerative diseases. The JNK signaling pathway therefore represents a potential target for therapeutic intervention.

JNK Structure and Activation

JNKs have a similar core structure as that of ERK proteins but there are differences in the conformation of their activation loop, resulting in differences in the mechanism of regulation. The small N-terminal lobe helps in the orientation and binding of ATP, whereas the large C-terminal lobe aids in substrate recognition. JNKs, like ERK proteins, are activated by phosphorylation on threonine and tyrosine residues, which are separated by a proline within the tripeptide activation loop in the kinase domain.

Mammalian JNK proteins are activated by various extracellular stimuli, including growth factors, cytokines, and cellular stresses such as heat shock, hyperosmolarity, UV radiation, and ischemia/reperfusion. Although the stress-mediated activation mechanism is not clear, it has been hypothesized that stress factors induce receptor clustering and internalization, which lead to JNK activation. The organization of the JNK activation cascade is conserved between the other MAP kinase members, beginning with receptor activation and followed by recruitment of adaptor molecules and activation of small GTP-binding proteins. This is followed by three to four tiers of dual-specificity protein kinases, which culminate in the activation of the JNK proteins. Similar to the ERK proteins, JNK proteins target a variety of substrates and can translocate to the nucleus, where they regulate gene expression by phosphorylating transcription factors.

JNK proteins are activated through dual phosphorylation on threonine and tyrosine residues by MEK4 (also called SEK1 or MKK4) or MEK7 (also called MKK7). Three MEK4 and six MEK7 isoforms have been identified. These different isoforms demonstrate selectivity depending on the extracellular stimulus. For example, MEK7 is primarily activated by cytokines such as tumor necrosis factor (TNF) and interleukins (ILs). In contrast, MEK4 is primarily activated by environmental stress stimuli such as osmotic changes and DNA-damaging agents. Although both MEK4 and MEK7 proteins can activate JNK proteins, MEK4 can also activate the p38 MAP kinases. Another difference is in the specificity of the two MEKs toward the threonine and tyrosine residues within the activation site of JNK; MEK4

preferentially phosphorylates the tyrosine residue, whereas MEK7 has a higher affinity toward phosphorylating the threonine residue on JNK. The JNK-specific MEK proteins are activated by dual phosphorylation of a serine and threonine residue in their activation loop, and they are found in both the nucleus and the cytoplasm. Thus, the JNK proteins may be activated in both the nucleus and the cytoplasm.

A wide variety of upstream kinases phosphorylate the MEK proteins responsible for activating both the JNK and p38 MAP kinases. Some of these kinases include proteins belonging to the MEK kinases (MEKK1–4), the mixed lineage protein kinases (MLK1–3, DLK, and LZK), the apoptotic stimulating kinase (ASK1 and -2), and transforming growth factor- β (TGF- β)-activating kinase (TAK1) and Tpl2, which also activate MEK1/2. These proteins are in turn activated by the p21-activated kinases (Paks), the germinal center kinases (GCKs), and the hematopoietic progenitor kinases (HPKs). The activity of Paks, GCKs, and HPKs is regulated by G proteins in a manner analogous to Ras G protein activation of Raf kinases in the ERK MAP kinase pathway. In the case of the JNK and p38 MAP kinases, members of the Rho family of G proteins are involved in the initiation of the signaling cascades.

Similar to the ERK MAP kinases, several JNK pathway binding proteins have been identified that function in regulating the assembly and activation of the JNK pathway. Two such proteins have been identified as JNK-interacting proteins (JIPs), which lack enzymatic activity but act as important organizers of JNK pathway complexes. JIP1 and JIP2 are closely related proteins that can bind to JNK proteins, MEK7, and MLK proteins. JIP proteins may be involved in potentiating JNK activation in response to activation by MLK proteins.

P38 MAP KINASES

The p38 MAP kinase [also known as the cytokine suppressive anti-inflammatory drug-binding protein (CSBP), reactivating kinase (RK), or SAPK] pathway is responsible for mounting a cellular response to many types of stress signals. Stress stimuli that activate p38 MAP kinase include osmotic and temperature shock, proinflammatory cytokines, hypoxia, reactive oxygen species, and irradiation. In some circumstances, p38 may be activated in response to certain growth factors. There are at least six isoforms of p38 that have alternative names, which are given in parentheses: p38 α_1/α_2 (CSBP1/2, Mpk2, RK, and

SAPK2a), p38 β_1/β_2 (SAPK2b), p38 γ (ERK6 and SAPK3), and p38 δ (SAPK4). The p38 proteins α_1 , β_1 , γ , and δ are encoded by four separate genes, whereas the α_2 and β_2 isoforms are the result of alternative splicing of the messenger RNA of the α_1 and β_1 isoforms. Although all of these isoforms are similar enough to be considered members of the p38 family, they are expressed at different levels depending on cell type and have different affinities for p38 substrates. Thus, expression of these isoforms in varying amounts in different cell types may allow cells and tissues to fine-tune their responses to various stimuli.

p38 Structure and Activation

The topological structure of p38 MAP kinase is similar to that of the ERK proteins, although some differences exist in the activation loop, substrate-binding regions, and the ATP binding site, which helps explain the differences in activation and regulation between the various MAP kinases. The direct activators of p38 MAP kinases, through dual phosphorylation of threonine and tyrosine residues, include primarily MEK3 and -6 and, in some cases, MEK4. Activators of MEK3, -4, and -6 were previously described. Like the ERK and JNK MAP kinase pathways, activation of p38 MAP kinase proteins occurs through a kinase cascade, which is often initiated by activated membrane receptors.

Upon activation, p38 MAPK phosphorylates other kinases in the cytosol and translocates to the nucleus, where it phosphorylates and activates transcription factors as well as proteins that modify the topological structure of DNA. Downstream targets of p38 MAP kinases regulate the expression of genes responsible for the inflammatory response, including cytokines such as TNF- α , IL-1 β , and IL-6. Because of its key role as a regulator of the inflammatory response, p38 is currently the target of anti-inflammatory drugs designed to treat acute and chronic inflammatory diseases, such as rheumatoid arthritis and osteoarthritis.

MAP KINASE ACTIVATION BY RECEPTOR TYROSINE KINASES

The ERK MAP kinase pathway is activated by several growth factor ligands that stimulate RTK activity, including epidermal growth factor (EGF), fibroblast growth factor, hepatocyte growth factor, insulin or insulin-like growth factors, platelet-derived growth factor (PDGF), and vascular endothelial growth factor. Ligand binding induces receptor dimerization

and the activation of intrinsic tyrosine kinase activity, which causes autophosphorylation of tyrosine residues in the cytoplasmic domain. The phosphorylated tyrosine residues of the receptors provide docking sites for Src homology-2 (SH2) domain-containing adaptor proteins, such as SH2-containing collagen-related proteins and growth factor receptor-bound protein-2 (Grb2). Grb2 recruits the guanine nucleotide exchange factor protein SOS, which promotes the active GTP-bound form of Ras and subsequent activation of the MAP kinase signaling pathways.

The JNK and p38 MAP kinases are activated mainly under cellular stress conditions, such as heat shock, irradiation, or hyperosmolarity. Although it is not clear which mechanisms are involved in mediating the stress response and activation of the JNK and p38 pathways, it has been proposed that cell stress may induce membrane receptor clustering and internalization, which could facilitate receptor activation. Nonetheless, similar to the ERK proteins, activation of the JNK and p38 MAP kinases pathways may also be through RTKs or cytokines such as TNF and IL-1 β . RTK stimulation of Ras G protein, in addition to activating Raf-1 kinase and the ERK pathway, may activate MEK kinases involved in activating the JNK and p38 pathways.

ACTIVATION OF MAP KINASES THROUGH G PROTEIN-COUPLED RECEPTORS

G protein-coupled receptors (GPCRs) are integral membrane proteins that contain regions that pass through the membrane seven times; thus, the GPCRs are also referred to as the seven-transmembrane spanning or serpentine receptors. GPCRs are coupled to heterotrimeric G proteins that contain α , β , and γ subunits that determine which signaling pathways will be used. The G protein α subunit binds to GTP and contains the GTP-hydrolyzing activity, whereas the β and γ subunits contain regulatory information. A wide variety of GPCRs, including the adenosine A₁, α -adrenergic, and muscarinic acetylcholine receptors, as well as endothelin, angiotensin, histamine, glucagon, and thrombin receptors, initiate physiological responses through activation of MAP kinase pathways.

GPCR activation of MAP kinases may occur through G protein activation of phospholipases, which hydrolyze membrane phospholipids and generate second messengers such as diacylglycerol (DAG) and inositol triphosphate (IP₃). IP₃ stimulation of

intracellular Ca²⁺ and DAG can activate protein kinase C, which phosphorylates and activates Raf kinase. Alternatively, activated GPCRs may transactivate RTKs, which feed into downstream MAP kinase signaling pathways. For example, MAP kinase activation by endothelin or thrombin receptors is coupled to coactivation of the EGF receptor family of RTKs, and the RTK activity is required for endothelin- or thrombin-induced MAP kinase activity.

Other mechanisms for activating MAP kinase pathways may be through the G protein β and γ subunits, which can activate nonreceptor tyrosine kinases belonging to the Src protein family. Src kinases can phosphorylate tyrosine residues on the cytoplasmic domains of receptors and enhance Ras activity or directly phosphorylate and regulate Raf kinase activation. Activation of JNK and p38 MAP kinases by GPCRs has been shown to involve the G α and the G $\beta\gamma$ subunits as well as the activation of the Rho and Ras families of GTPases. Depending on the cell type and the receptor stimulated, G α or G $\beta\gamma$ or both may be involved in the activation of the MAP kinase pathways.

OTHER MECHANISMS FOR ACTIVATING MAP KINASES

Activation of the MAP kinase signaling pathways may occur through cell-permeable factors such as steroid hormones, which bind to soluble cytoplasmic and nuclear receptors. For example, estradiol, progesterone, and testosterone activate MAP kinase indirectly through steroid receptor interactions with membrane-associated receptors. One proposed mechanism is that estradiol receptors are coupled to membrane-bound receptors such as the EGF receptor, which then facilitate the activation of the MAP kinase signaling pathway in a manner similar to transactivation by GPCRs described previously. Moreover, GPCRs may mediate steroid hormone activation of RTK and MAP kinase signaling.

Some membrane-bound receptors belonging to the receptor serine/threonine kinase (RSTK) family that undergo serine or threonine autophosphorylation on the cytoplasmic domains regulate MAP kinase signaling pathways. For example, the TGF- β receptors are RSTKs that regulate a wide variety of biological responses, including cell proliferation, differentiation, extracellular matrix production, and cell death, through the p38 MAP kinases. Activated TGF- β receptor stimulates TAK1, which is a novel MEK kinase that stimulates MEK3/6 and p38 and may inhibit cell proliferation.

MAP KINASE PHOSPHATASES

Inactivation of MAP kinase signaling pathway is accomplished largely through dephosphorylation of threonine and tyrosine residues by unique protein tyrosine phosphatases called dual-specificity phosphatases (DSPs). Of the DSP family, at least six MAP kinase phosphatases (MKPs) have been identified. The MKP proteins show some specificity toward the MAP kinase family members. For example, although MKP1 and MKP2 can target activated ERK, JNK, and p38, MKP3 and MKP4 are specific toward ERK proteins, and MKP5 and MKP6 specifically dephosphorylate JNK and p38. Growth factor activation of the ERK proteins stimulates the expression of MKP1, thus providing a mechanism by which ERK proteins down-regulate their own activity. Other phosphatases belonging to the serine/threonine phosphatases may also play an important role in down-regulating MAP kinases. For example, protein phosphatase 2A (PP2A) is able to inhibit MEK1/2 and ERK1/2 activity in the absence of growth factor-induced DSPs. Similarly, PP2A has been identified as a JNK phosphatase. MAP kinase pathways are also regulated by protein serine/threonine phosphatases of the type 2C (PP2C) family. At least two members of the PP2C family, PP2C α and - β , dephosphorylate and inactivate the JNK MAP kinases.

CONCLUSION

The MAP kinase signaling pathways regulate most physiological functions throughout the life span of a diverse range of organisms, from yeast to humans.

Activation of MAP kinases occurs through plasma membrane receptor-dependent and -independent mechanisms in response to a variety of extracellular stimuli. Importantly, dysregulation of MAP kinase pathways is involved in many human diseases. Therefore, understanding of how MAP kinases are regulated and function is an important goal for the development of new therapies.

particles that contain apo's B100, CII, CIII, and E. After coupling to VLDL receptors in extrahepatic tissues, the triglycerides in VLDL undergo lipolysis by lipoprotein lipase (LPL), which requires apoCII as a cofactor. The liberated free fatty acids (FFA) are taken up by muscle or adipose tissue (through CD36) for oxidation or energy storage, respectively. In this process, VLDL remnants become intermediate density lipoproteins (IDL) that are enriched with apoE and then low-density lipoproteins (LDL). The latter step is also mediated by hepatic lipoprotein lipase (HL), which is attached to the endothelial surface in the liver by heparan sulphate proteoglycans (HSPG) and is facilitated by apoE. VLDL remnants and IDL are removed from the circulation by the low-density lipoprotein receptor (LDLR) and LDLR-related protein (LRP), largely through recognition of apoE. LDL is removed by the LDLR through recognition of apoB100.

In the exogenous pathway, dietary cholesteryl esters and triglycerides are secreted from the intestines in chylomicrons containing apoB48, A-I, and A-IV. They lose A-I and A-IV but acquire apo's CII, CIII, and E. As in VLDL, chylomicron triglycerides are hydrolyzed by LPL in the circulation and the chylomicron remnants are removed from the circulation by LDLR and LRP mainly in the liver through recognition of apoE.

In the reverse cholesterol transport pathway, cholesterol is removed from peripheral tissues by high-density lipoprotein (HDL), which binds to cholesterol-rich cells, at least partly through the SRB1 receptor. The uptake of cholesterol from these cells by HDL is facilitated by the recently characterized ABC1 transporter. HDL-associated cholesterol is then esterified by plasma lecithin cholesterol acyltransferase (LCAT), enlarging the size of the HDL particle. Cholesterol from HDL can be transported into the liver through the action of HL, by the action of the SRB1 receptor, or by the uptake of entire HDL particles. Alternatively, cholesteryl ester transfer protein (CETP) mediates HDL cholesteryl ester to triglyceride-rich particles instead of triglycerides, which are then removed from the circulation by liver LDLR and LRP. In the liver, cholesteryl ester is hydrolyzed and the cholesterol is excreted in the bile as bile acids or free cholesterol.

LIPID-LOWERING DRUGS

Hydroxy-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors inhibit the rate-limiting step in hepatic cholesterol synthesis, causing an increase in LDL receptor levels in hepatocytes and enhancement

of remnant and LDL cholesterol removal from the circulation. In addition to lowering LDL cholesterol, they lower triglyceride levels (by decreased hepatic apoB production) and increase HDL cholesterol. Large intervention trials have demonstrated the potency of these drugs in primary or secondary prevention of cardiovascular disease in patients with or without lipid disorders.

Fibric acids stimulate the activity of the liver transcription factor PPAR α that increases LPL activity, thereby enhancing VLDL degradation. PPAR α stimulation also reduces apoCIII, which facilitates VLDL remnant uptake. VLDL production may also be reduced. Stimulation of peroxisomal fatty acid oxidation by fibrates may also contribute to the triglyceride-lowering actions. In addition to reducing triglycerides, fibrates increase HDL cholesterol levels. In several intervention trials, fibrates have been demonstrated to reduce CHD events, but conflicting data on mortality are reported.

Nicotinic acid derivatives decrease both total and LDL cholesterol, reduce VLDL cholesterol levels, and raise HDL cholesterol levels. The mechanism of action is not fully understood, but it appears to inhibit the secretion of apoB-containing lipoproteins from the liver as well as lipolysis in peripheral adipose tissue. In the Coronary Drug Project, niacin significantly reduced CHD events.

PRIMARY MIXED LIPEMIAS

Type III Hyperlipoproteinemia (Familial Dysbetalipoproteinemia)

Type III hyperlipoproteinemia is a lipoprotein disorder with a prevalence of 1 to 4 in 10,000. The disorder is usually diagnosed in adults and has a male predominance. Individuals have increased plasma cholesterol and triglyceride levels resulting from increased triglyceride-rich remnant concentrations. Plasma LDL levels are usually reduced, and HDL levels are usually normal. A typical clinical feature is the presence of planar xanthomas at the palmar surface. Patients with familial type III hyperlipoproteinemia have increased susceptibility to CHD and peripheral vascular disease. The typical disorder is caused by a mutation in the apoE gene. The apoE gene has three alleles coding for E4, E3, and E2 that occur in Caucasians with frequencies of 15, 77, and 8%, respectively. The apoE polymorphisms account for approximately 10% of the population variance in LDL cholesterol levels. More than 95% of type III hyperlipoproteinemia individuals have the E2/E2

phenotype. This common E2 mutation, representing an Arg158Cys mutation, causes a nearly total defect of apoE in LDLR binding. The result is a less efficient clearance of VLDL and chylomicron remnants in the liver, leading to increased triglyceride and cholesterol levels. LDL is decreased as a result of the decreased conversion of IDL to LDL. Individuals with heterozygosity for the E2 mutation do not exhibit the phenotype, indicating that the disease is inherited in an autosomal-recessive fashion. Interestingly, only 1 to 4% of individuals with the E2/E2 genotype have the typical phenotype. Hence, type III hyperlipoproteinemia with E2/E2 homozygosity displays a low rate of penetrance. Additional factors that are associated with increased VLDL or chylomicron production or with decreased clearance, such as gender, obesity, hypothyroidism, diabetes mellitus and certain dietary factors, are thought to contribute to manifesting the disease.

The autosomal-dominant inheritance pattern of type III hyperlipoproteinemia has been described for some rare apoE variants. For instance, individuals with heterozygosity for apoE2Lys146Gln or apoE3-Leiden exhibit the phenotype. Nearly all carriers of these rare alleles have the hyperlipoproteinemic phenotype, indicating that this dominant inheritance pattern associates with a high rate of penetrance. In the treatment of this disorder, a thorough search for underlying disorders should be made. Usually, dietary measures (restriction of calories) may normalize lipid levels. If this cannot be achieved, drug therapy may be necessary. HMG-CoA reductase inhibitors have been applied successfully, and fibric acid derivatives may also be useful.

Familial Combined Hyperlipidemia

Familial combined hyperlipidemia (FCH) is a common lipid disorder affecting 0.5 to 2.0% of the population. The disease occurs in both adults and children. Biochemically, FCH is characterized by familial occurrence of increased cholesterol and triglyceride levels. The FCH lipoprotein pattern includes elevated apoB and LDL cholesterol levels, diminished HDL cholesterol levels, and the presence of small dense LDL. The phenotype may vary within one affected family and even within one individual. Xanthomas are not observed in FCH. Patients with FCH have an increased risk for CHD. FCH is associated with increased body mass index (BMI), waist/hip ratio, and fasting glucose and insulin levels, which are (together with the lipid abnormalities) characteristics of the metabolic syndrome (syndrome X). Thus,

knowledge of the pathogenesis of FCH will provide insight into the metabolic syndrome and vice versa.

Initially, the dominant mode of inheritance was thought to indicate a monogenetic cause. Several candidate genes or chromosomal regions have been suggested. The apoA-I/CIII/A-IV gene cluster, LCAT (chromosome 16q22.1), and 11p were found in Dutch FCH families. However, this could not be confirmed in Finnish FCH families. In contrast, Finnish studies identified candidate regions on chromosomes 1q, 2q, 10p, 10q, and 21q, but in turn, the strong chromosome 1 locus was not found in the Dutch families. These varying results suggest that FCH is a complex disorder where many genes are involved and a large heterogeneity in gene-gene and gene-environment interactions is present.

In the treatment, dietary and lifestyle interventions should be attempted and may be combined with drugs when necessary. Drug therapy should be aimed at the predominating lipid disorder. HMG-CoA reductase inhibitors are a logical choice, and fibric acid derivatives and niacin may be useful as well. Bile acid sequestrants should be avoided because they tend to raise triglyceride levels.

SECONDARY MIXED LIPEMIAS

Diabetic Dyslipidemia

Worldwide, diabetes mellitus (DM), and especially type 2 DM, is a rapidly expanding health problem, with estimates suggesting a doubling of its prevalence during the coming years. Cardiovascular disorders are the major cause of mortality in DM. Cardiovascular disorders, in turn, are considered the result of the combined effects of hypertension and alterations in lipid and carbohydrate metabolism, the fibrinolytic system, and inflammatory cascades. The importance of lipid abnormalities in DM is underscored by the fact that in large studies of type 1 and type 2 DM, optimization of glycemic control could prevent microvascular complications but not macrovascular ones. In contrast, in large lipid intervention studies, subgroup analyses revealed favorable effects of lipid-lowering drugs on CHD risk. Lipoprotein disorders in DM are related primarily to abnormalities in triglyceride metabolism, and this may be explained in part by the role of insulin in lipid metabolism. In the absence of insulin action (e.g., insulin deficiency in untreated type 1 DM or insulin resistance), lipolysis from adipose tissue is increased by the action of hormone-sensitive lipase. The increased FFA flux to the liver and the decreased degradation of apoB, also a

result of decreased insulin action, lead to enhanced VLDL production. As insulin facilitates LPL activity, VLDL (and chylomicron) remnant clearance is decreased when insulin action is reduced, thereby further increasing triglyceride (and VLDL-derived) cholesterol levels. Although LDL levels are expected to be lower (due to decreased conversion of VLDL remnants), LDL clearance may also be decreased.

In the presence of triglyceride-rich lipoproteins, enhanced CETP activity may result in a net transfer of cholesteryl ester from LDL and HDL to VLDL remnants. As a result, LDL particles become smaller and denser, and this is thought to be unfavorable with respect to atherosclerosis. The removal of cholesteryl ester from HDL leads to reduced plasma HDL cholesterol measurements. In addition, HDL clearance in the liver is enhanced. Another factor in decreased HDL is the diminished transport of surface lipids from VLDL to nascent HDL caused by decreased LPL activity; this impairs HDL maturation. Decreased HDL cholesterol is associated with increased risk for CHD.

Lipoprotein abnormalities in type 1 DM are the result of insulin deficiency and can be corrected completely by insulin therapy. The situation in type 2 DM is complex; in contrast to type 1 DM, lipid abnormalities usually are not corrected completely with glycemic control. Moreover, this dyslipidemia is often found in patients with insulin resistance without overt diabetes and is one of the features of the metabolic syndrome. Abnormalities in insulin action rather than hyperglycemia are associated with this lipid abnormality, and evidence suggests that a pathological FFA flux from visceral fat to the liver even precedes defective insulin action. Given the high CHD risk in DM, aggressive lipid-lowering therapy is of major importance. Apart from dietary intervention, from a theoretical point of view, HMG-CoA reductase inhibitors, fibrates, and nicotinic acid are rational. Because HMG-CoA reductase inhibitors have been demonstrated to reduce CHD risk in DM patients in large randomized studies, this category of drugs should be the first choice.

Nephrotic Syndrome

The nephrotic syndrome is almost always accompanied by hyperlipidemia. Plasma VLDL, IDL and LDL cholesterol, and total triglycerides may be increased, whereas HDL cholesterol is decreased. Mortality from CHD is particularly high in the nephrotic syndrome. The increased VLDL and IDL concentrations

may result from decreased clearance due to reduced LPL activity on the vascular endothelium that, in turn, may result from either decreased synthesis or inadequate binding of this enzyme by HSPG to endothelial surfaces. The mechanism of the increased LDL levels is not clear. Synthesis of apoB100 is not related to that of albumin, suggesting a mechanism different from the increased synthesis of nonlipoproteins. HDL concentrations in the nephrotic syndrome are normal, but maturation is impaired, leading to a shift from the larger HDL2 to the smaller HDL3 and resulting in decreased plasma HDL cholesterol concentrations. Because of the high CHD risk, lipid-lowering therapy—with HMG-CoA reductase inhibitors as first choice—must have high priority.

Hypothyroidism

Because thyroid hormone plays a role in the LDLR expression, clinical or subclinical hypothyroidism is associated with decreased LDL clearance and, consequently, increased LDL cholesterol levels; few patients with hypothyroidism have normal lipid profiles. In addition, hypothyroidism is present in approximately 5% of patients who present primarily with lipid disorders. Hypothyroidism may also be associated with increased triglyceride levels, and this is thought to be the result of decreased LPL activity. Whether hyperlipidemia in hypothyroidism is associated with increased risk for CHD is still being debated. Substitution with thyroid hormone usually corrects the lipid abnormalities.

Other Conditions

Hypopituitarism

In patients with hypopituitarism, mixed lipemia may be present. This is likely the result of the combined contribution of hypothyroidism and growth hormone deficiency, the latter of which is accompanied by increased LDL cholesterol levels.

Glucocorticoid Excess

Excess of glucocorticoids, either in the context of Cushing's syndrome or by steroid hormone therapy, may be associated with increased LDL and VLDL concentrations. Increased VLDL production and increased conversion of VLDL to LDL appear to play a role. Because glucocorticoid excess is also associated with impaired glucose tolerance, lipoprotein abnormalities (as observed in DM) may also be present.

Cushing's syndrome is associated with increased CHD risk; however, the independent contribution of dyslipidemia has not been identified.

Human Immunodeficiency Virus

Patients with human immunodeficiency virus (HIV) infection who are treated with HIV-1 protease inhibitors can develop hyperglycemia, hypertriglyceridemia, or hypercholesterolemia. The mechanism appears to be multifactorial, but data indicate that this effect may be at least partly accounted for by decreased degradation of apo-B and, hence, increased VLDL synthesis. Decreased PPAR α activity may lead to effects opposed to those of fibrates, whereas accumulation of the active portion of sterol regulatory element-binding protein-1c are also involved.

in Merck's laboratories followed a different strategy by first cloning and sequencing a large variety of G protein-coupled receptors and then looking at the nature of ligands for these receptors. Starting from an orphan receptor found in the thyroid with a structure close to that of the receptor for the growth hormone secretagogue (GHS), mass screening of more than 500 peptide and nonpeptide molecules was performed to obtain positive results for motilin. Much of our knowledge of the motilin receptor has been derived from structure-activity studies of peptide analogues and binding of radioactive ligands on various tissue membranes prepared *in vitro*.

Nuclear magnetic resonance showed that the motilin molecule (Fig. 1) is shaped like a golf club or pastoral staff. Its N-terminal portion is responsible for receptor binding and *in vitro* bioactivity. Peptide fragments containing the first 12 amino acids of the molecule have demonstrated full binding capacity *in vitro*, whereas removal of its first amino acid is enough to abolish its activity. Amino acids 4 and 7 also seem to play a major role in this N-terminal sequence. Interestingly, the C-terminal structure, not required for

in vitro bioactivity, was found to be essential for *in vivo* bioactivity. N-terminal fragments of 15 amino acids, fully active *in vitro*, were indeed inactive *in vivo*, whereas longer fragments with 19, 20, or 21 amino acids could mimic the motor activity of the 22-amino acid peptide. This is an interesting concept in the field of peptide pharmacology, where the α -helix-shaped C-terminal structure seems to be important in protecting the whole molecule, probably against circulating degrading enzymes.

Receptors have been studied in membrane solutions prepared from various species (mostly humans or rabbits) and from neural or muscle elements of the intestinal wall. The binding of motilin analogues was different in membranes prepared from the human or rabbit antrum, suggesting that motilin receptors' structure is, as for the motilin substance discussed previously, different among species. Solutions enriched in muscle or in neural elements of the intestinal wall have allowed the identification of specific and distinct responses to various motilin synthetic analogues, indicating the existence of structurally heterogeneous motilin receptor subtypes specific to muscle or neural elements (M and N receptor subtypes).

Figure 1 Structure of the 22-amino acid motilin peptide revealed by nuclear magnetic resonance. The N-terminal curved sequence binds to the receptor, whereas the α -helix C-terminal structure protects the molecule for *in vivo* bioactivity.

PHARMACOLOGICAL ACTION

As its name implies, motilin acts on digestive motility. Figure 2 shows the expected effect in humans after the administration of motilin or motilin receptor agonists. Stimulation of antro-duodenal motility remains the dominant action of the peptide.

Initial *in vitro* studies with intestinal tissues from rabbits and humans revealed that motilin can stimulate smooth muscle contraction by a direct effect on muscle cells; the peptide action was seen despite the addition of all neural blockers, including tetrodotoxin. Experiments with isolated muscle cells have confirmed the presence of motilin receptors on muscle cell membranes. However, *in vivo* studies in dogs and humans clearly indicated that the motor action of motilin is mediated by muscarinic transmitters. As discussed previously, binding experiments supported the existence of motilin receptor subtypes (M and N) that are functionally and structurally different. Currently, the most interesting hypothesis proposes that the interdigestive motor action of motilin (induction of phase III contraction) is elicited at low doses through an action via neural cholinergic receptors, whereas postprandial stimulation of antral motility is evoked at higher doses via muscle receptors.

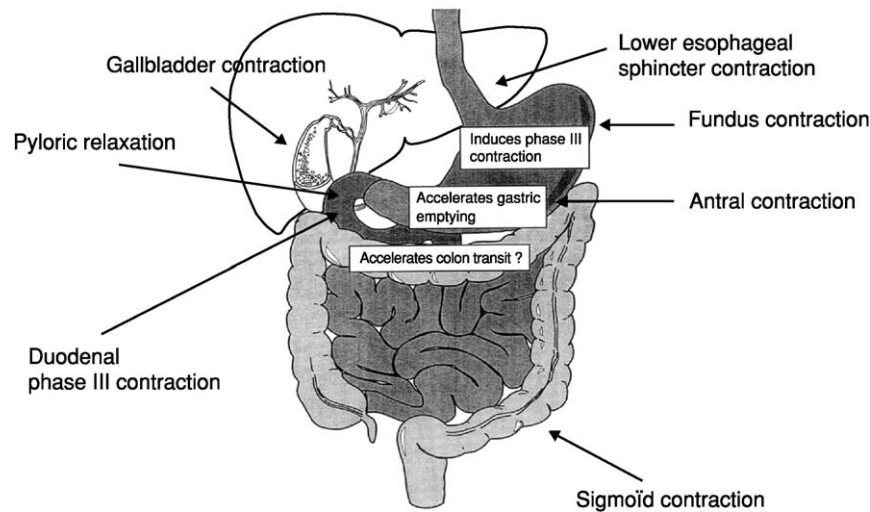

Figure 2 Biological effects obtained in the human gastrointestinal tract in response to the injection of motilin or a motilin receptor agonist such as erythromycin.

PHYSIOLOGICAL ROLE

The characteristic action of motilin is the induction of phase III contraction of the migrating motor complex (MMC). The MMC is the basic organization of motor activity of the gut during the fasting interdigestive period. It lasts 80 to 120 min and consists of three successive phases. During phase I, no significant contraction is seen for 20 to 60 min. During phase II, intermittent and irregular contractions start to occur 20 to 60 min before phase III, during which strong peristaltic contractions, lasting 3 to 10 min, start from the stomach and lower esophagus to migrate distally to the duodenum, jejunum, and ileum until the colon. This phase III peristaltic wave has been proposed to clean, from the GI tract, bacteria or nutrients that could accumulate during the digestive period, with deleterious effects on gut (e.g., bacterial overgrowth). Feeding interrupts the intermittent cyclical fasting motility (MMC) and induces a more constant motor activity of moderate amplitude to allow the optimal absorption of ingested nutrients; accelerated transit during phase III would impair nutrient absorption.

Regulatory peptides can exert their influence via different pathways: endocrine (hormonal), neurocrine, paracrine, or autocrine. Motilin is in the unique position, as a GI regulatory peptide, of being an interdigestive hormone. This has been well identified in the dog, where all of Morton Grossman's criteria establishing the endocrine contributions of peptides have been fulfilled. First, regulation of the cyclical pattern of the MMC is under the control of circulating

factors, as shown in various experiments where the MMC persisted in animals when their stomachs had been completely denervated. Second, there is a perfect correlation between circulating peak levels of motilin and the initiation of phase III contractions from the stomach or proximal duodenum. Third, exogenous motilin, given in small doses reproducing physiological plasma variations, induces phase III contraction of the MMC. Fourth, inhibition of circulating motilin by the administration of specific motilin antisera blocked phase III contractions from the upper gut. Although the situation could not be explored under such perfect experimental conditions in humans, most evidence suggests that circulating motilin also plays a key role in the regulation of phase III initiated from the antrum of our species.

RELEASE MECHANISMS

Most gastrointestinal hormones are released after a meal to allow or facilitate the digestion and absorption of nutrients. Motilin is a unique hormone. It is released periodically during the interdigestive fasting period, and its cyclical release is abolished after a meal, as shown schematically in Fig. 3. Therefore, a "biological clock" somewhere in the organism periodically signals motilin cells to release the peptide into the circulation. *In vitro* preparations of intestinal mucosal cells enriched in motilin cells showed that muscarinic receptors are present on the motilin cell membrane and that protein kinase C activators are the most potent

Figure 3 Schematic representation of plasma motilin variations in dog. During the fasting interdigestive period, motilin is released cyclically every 80 to 120 min (lower panel) to induce phase III contraction of the migrating motor complex from the stomach to the ileum (indicated by clear boxes in the upper panel). After eating, the motilin cyclical peak increases are abolished for 2 to 8 h (depending on the content and nature of the meal) while the fed pattern motility profile is taking place.

second messengers eliciting motilin release. In the *ex vivo* perfused canine intestine, bombesin has been identified as a direct stimulant of motilin release, whereas the effect of opiates is mediated by acetylcholine. Phenylephrine and somatostatin appear to act on M-cell membrane receptors to block release of the peptide. In humans, meal ingestion is followed by a very early and brief increase in plasma motilin before the interdigestive release cycle is interrupted. This early release can be mimicked by central stimulation with modified sham-feeding and by distension of the fundus with an air-filled balloon. The contribution of this postprandial motilin release (not present in the dog) in the process of nutrient digestion remains to be characterized.

CONTRIBUTION TO CLINICAL MEDICINE

Some GI hormones, such as gastrin and vasointestinal polypeptide (VIP), are important to clinicians because of the disease symptoms they can generate. Up to now, there is no clinical phenotype attributed to motilin hypersecretion. High levels of circulating motilin have been documented in some patients with pancreatic tumors and Zollinger-Ellison syndrome as well as in patients with carcinoid tumors of the gut. Although it could be tempting to speculate on the

role of motilin in the diarrhea found in these patients, its contribution to the biological alterations remains unknown.

Because motilin hypersecretion could be expected to generate GI hypermotricity and hypersecretion with probable diarrhea, it is logical to expect that hypomotilinemia will induce GI hypomotility. Some investigators have indeed found low levels of plasma motilin in patients with idiopathic intestinal pseudo-obstruction and idiopathic or postoperative gastroparesis. To this point, however, plasma motilin measurement has not been shown to be useful for inclusion in the workup diagnoses of any clinical situations.

On the other hand, motilin was recently of major interest to medical clinicians because of the capacity of motilin receptor agonists to act as powerful stimulants of GI motor activity in patients with hypokinetic disorders. Itoh was the first to observe that erythromycin could mimic the motor effect of motilin when injected in dogs. It was soon established that erythromycin was in fact acting on motilin receptors, and Janssens and colleagues made the capital observation that erythromycin was the most potent gastrokinetic ever tested to stimulate gastric emptying in diabetic patients with gastroparesis. Since then, erythromycin, whether administered intravenously (i.v.) or by mouth (p.o.), is used by many clinicians for the treatment of patients with gastroparesis or intestinal pseudo-obstruction. Motilides, or motilin receptor agonist substances derived from the erythromycin macrolide and with improved gastrokinetic activity but devoid of antibiotic properties, have been developed by many pharmaceutical companies. At least three motilides have been tested in humans, but for various reasons (e.g., rapid tachyphylaxis, no significant clinical benefit, potential side effects), clinical trials with these newly derived molecules have failed to substantiate the impressive pharmacological potential seen with i.v. erythromycin. Whether the gastrokinetic capacity of motilin receptor agonists will be amenable to commercial development and clinical exploitation remains to be seen.

THE CENTRAL NERVOUS SYSTEM AND THE PEPTIDE FAMILY

Most GI peptides are found in the brain and/or act as neuropeptides, but the situation remains unclear for motilin. Motilin mRNA has been identified in brain tissues, but RIA determination of motilin content brought ambiguous results. Motilin administration in

this organ induced actions (suggesting the existence of motilin receptors in the brain) that were quite unexpected: appetite stimulation, growth hormone (GH) release, anxiety suppression, and so forth. Yet no valid data support its role as a neuropeptide.

Most peptides are members of a “peptide family” that includes structurally related compounds; gastrin-CCK, and secretin-VIP are typical examples. Motilin remained alone; however, recently a new peptide discovered in the gastric mucosa shows 25% similitude to motilin. This new peptide has been called motilin-related peptide (MTL-RP) by some, but it is more often recognized as ghrelin because of its effect on GH release. Interestingly, ghrelin administration induces central actions that are similar to those described previously for motilin (e.g., GH release, appetite stimulation). Peripherally, ghrelin mimics motilin and appears to be the most potent gastrokinetic agent we have ever tested in the rodent. Future studies should

tell us more about the importance of this new family of peptides.

female genitalia. Evidence indicates that ALK2 is the MIS type I receptor. Expression of ALK2 in coelomic epithelium as well as in the circumferential mesenchyme of the Müllerian duct may explain the antineoplastic effects of MIS on epithelial ovarian cancers, which are derivatives of the coelomic epithelium.

Receptor or R-SMADs, the co-SMAD SMAD-4, and the inhibitory or I-SMADs function downstream of the TGF- β superfamily type I receptors. Once phosphorylated, R-SMADs dimerize with SMAD-4 and translocate to the nucleus, where they modulate SMAD-responsive gene expression either directly or through recruitment of additional DNA-binding proteins, such as CREB, CBP/p300, or FAST-1. The repressors of SMAD signaling such as SNIP1 interfere with the interaction between SMAD-4 and CBP/p300; I-SMADs 6/7 impair phosphorylation/activation of R-SMADs.

MIS DURING DEVELOPMENT

In males, serum MIS is present at birth, peaks in infancy, and declines at puberty. Excluding a short time period after birth, serum MIS and testosterone are reciprocally related. This is best illustrated in male puberty, when a precipitous decline in MIS occurs during the characteristic increase in testosterone. In contrast, female ovaries produce low levels of MIS at birth, increasing slightly at puberty to levels similar to those of the adult male.

OBSERVATIONS FROM TRANSGENIC MICE AND HUMAN SYNDROMES WITH MIS DEFECTS

Human Müllerian duct regression is complete 51 days after ovulation. Failure of MIS signaling in males results in persistent Müllerian duct syndrome (PMDS), in which affected individuals show normal male external/internal genitalia development but manifest a retained cervix, uterus, and Fallopian tubes. In PMDS, findings of crossed ectopia of the contralateral gonad and Müllerian structures contained within an inguinal hernia are common. Unilateral or bilateral testicular maldescent is also common and many PMDS patients are infertile. The phenotype seen in MIS and MIS RII knockout mice recapitulates that seen in human PMDS. Approximately half of human PMDS patients have undetectable MIS levels and harbor MIS gene mutations; most of the remaining patients show

normal/elevated serum MIS levels and have MIS RII gene mutations.

Normally virilized MIS-deficient mice develop focal Leydig cell hyperplasia and tumors. In contrast, transgenic mice overexpressing MIS show undervirilization and cryptorchidism secondary to the effect of MIS on Leydig cell function. Interestingly, in addition to the expected Müllerian regression, female overexpressors develop masculinized ovaries with seminiferous tubules, Sertoli cells, and a paucity of germ cells. MIS is also expressed in the granulosa cells surrounding the small and preantral follicles where MIS activity may function in oocyte development.

EXTRA-MÜLLERIAN EFFECTS

Antiproliferative Effects

Human ovarian epithelium derives from the coelomic epithelium, which expresses both type I and type II receptors, suggesting MIS as a potential therapeutic for the most common ovarian cancers that originate from these cells. Preclinical *in vitro* and *in vivo* studies of a human ovarian cancer cell line transplanted beneath the renal capsule of immunosuppressed mice showed that delivery of highly purified human recombinant MIS (hrMIS) via intraperitoneal injection or MIS-producing tissue implants could suppress tumor growth. We found that human breast cancer cells also express the MIS type II receptor, as does the normal involuting but not rapidly growing lactating breast. Furthermore, growth of human breast cancer lines is inhibited by hrMIS *in vitro*. Similar observations have been made of MIS growth inhibition against human prostatic cell lines, indicating additional targets for MIS as a cancer therapeutic against other reproductive tumors expressing MIS RII.

Regulation of Steroidogenesis

The role of MIS as a modulator/regulator of Leydig cell differentiation/function was suggested by the phenotypes of transgenic mice that either over- or under-express MIS or MIS RII. The highest MIS-producing male transgenics were undervirilized, had Leydig cell hypoplasia with low testosterone, and ultimately developed gonadal exhaustion. Conversely, those mice underexpressing MIS or MIS RII showed Leydig cell hyperplasia and high testosterone. A plausible explanation was derived when it was shown that Leydig cells express MIS RII and that

MIS suppresses testosterone production and Cyp17 expression, which catalyzes the committed step of testosterone synthesis. Cyp17 mRNA levels were highest in the gonads of mice with the lowest MIS levels and Cyp17 mRNA decreased after MIS treatment. When added to cAMP-stimulated MA-10 cells, a mouse Leydig cell line, MIS inhibited testosterone biosynthesis 10-fold, coincident with a decrease in the transcriptional activity at the Cyp17 promoter. MIS suppression of androgens as well as the detection of MIS type II receptor in normal prostate and prostatic cancers indicate that testing MIS in the setting of benign prostatic hypertrophy and prostate cancers may be warranted. MIS inhibition of aromatase activity has also been documented in cultured fetal gonads. It is of interest to determine if MIS has a therapeutic role in hyperandrogenic women with polycystic ovarian syndrome.

DIAGNOSTIC APPLICATIONS

Normal human gender-specific MIS levels have been established from virtually all developmental stages using an enzyme-linked immunoabsorbant assay, and this assay is helpful in the evaluation of gonadal abnormalities and tumors. MIS is an excellent marker of testicular activity, specifically of the Sertoli cell compartment. Accordingly, in prepubertal boys with nonpalpable gonads, MIS can be used to differentiate anorchia from intraabdominal testes. MIS is also a useful diagnostic tool in intersex states, with levels correlating with the mass of testicular tissue. Consequently, MIS is abnormally low in gonadal dysgenesis, in which functional testicular tissue is subnormal. In androgen-insensitivity syndromes, MIS is elevated; thus, MIS levels can differentiate abnormal testicular determination from defects in androgen biosynthesis or sensitivity. MIS is also extremely valuable as a marker of tumor burden or recurrence in patients with granulosa or sex-cord tumors.

CONCLUSION

MIS plays an important role in normal sexual development and differentiation, and it has proven diagnostic value for intersex disorders, undescended testis, and gonadal tumors. Furthermore, MIS may have important therapeutic applications in a number of common reproductive tumors in both sexes. The success of these applications will likely depend on the efficiency and cost-effectiveness of MIS production. A complete understanding of MIS downstream signaling pathways and the induced gene products essential for its effect may lead to the development of therapeutics capable of modulating this pathway, which could be of benefit.

CLINICAL DESCRIPTION OF APS TYPES I AND II

In 1980, Michael Neufeld, Noel Maclaren, and Robert Blizzard presented data from a survey of patients with APSs and proposed a classification for the syndromes observed:

APS type I was defined as present in patients who have at least two of the triad of Addison's disease, hypoparathyroidism, and chronic mucocutaneous candidiasis. Other associated autoimmune disorders were also allowed to be present.

APS type II was defined as Addison's disease with autoimmune thyroid disease and/or type 1 diabetes mellitus. Autoimmune disorders other than hypoparathyroidism and candidiasis were also sometimes present.

APS type III was defined as patients presenting with thyroid autoimmune disease and any other autoimmune disease except Addison's disease or hypoparathyroidism. APS type III could be grouped separately or together with type II.

APS type IV was defined as patients presenting with two or more organ-specific autoimmune diseases that do not otherwise fall into the category of type I, II, or III. This form of APS is frequently present in patients with non-endocrine autoimmune disorders. In this article, we consider APS type IV to be part of APS type III.

APS TYPE I

Prevalence

APS type I is a rare disorder. The highest prevalence, 1 in 9000, has been reported in the Iranian Jewish population. It is also more common in the Finnish and Sardinian populations, with prevalences of 1 in 25,000 and 1 in 14,500, respectively. APS type I may appear in a sporadic or familial form and is now known to be an autosomal recessive disease caused by mutations of the autoimmune regulator (AIRE) gene. According to Michael Neufeld and colleagues, females exceed males at all ages in a ratio of 1.6 to 1.

Presentation

Of the classic features, chronic mucocutaneous candidiasis occurs at the youngest age, often during infancy. Hypoparathyroidism may occur shortly thereafter, usually before adolescence. Addison's disease tends to appear after the onset of hypoparathyroidism and as late as the fourth decade of life. Chronic active

hepatitis and malabsorption due to celiac disease tend to occur in APS type I and not in APS type II. Chronic active hepatitis is particularly important because it has been reported as the cause of death in a significant number of patients with APS type I. In addition, gonadal failure and diffuse vitiligo may be found in patients with APS type I, and in 1985, it was recognized that hypopituitarism and diabetes insipidus also occur. In 1990, P. Ahonen and colleagues reviewed their data from 68 patients in 54 families in Finland (coining the term "autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy [APECED]) and found that all of their patients had candidiasis at some time with hypoparathyroidism (79%), adrenocortical failure (72%), and/or gonadal failure (60% in females and 14% in males). Several of their patients also had dental enamel hypoplasia (77%) and/or keratopathy (35%) that was not attributable to hypoparathyroidism and whose endocrine dysfunction did not manifest until the fifth decade of life. These observations underscored the need for lifelong surveillance for new components of the disease. In 1998, Corrado Betterle and colleagues from Italy published their experience following 41 patients for 20 years (1967–1996). They compared the clinical manifestations in their patients with those of Neufeld and Ahonen. The occurrence of clinical manifestations and the age of onset were similar. They reported calcifications of the basal ganglia in 17 of their patients, most likely secondary to hypoparathyroidism. As in earlier published reports, Betterle and colleagues showed that 20% of their patients had chronic active hepatitis, again emphasizing the importance of continued surveillance of liver function in these patients (Table I).

Genetics of APS Type I

APS type I is the only autoimmune disease known to be caused by a defect in a single gene. This disease is inherited as a simple recessive Mendelian trait. It occurs primarily in the familial form but can occur sporadically. The defective gene in this disorder was identified by positional cloning and was called AIRE (Fig. 1). The AIRE (autoimmune regulator) gene is located on chromosome 21q22.3. More than 40 mutations have been described. All of the mutations described are localized to the coding portion of the gene and are present in all ethnic populations, with the exception of one mutation that was found only in the homozygous form of APS type I in Iranian Jewish patients. The Iranian Jewish population also seems to have a milder clinical expression of this disorder.

Table I Autoimmune Polyglandular Syndrome (Percentages)

| Type I | |
|--------------------------------------|-----|
| Endocrine disorders | |
| Hypoparathyroidism | 90 |
| Addison's disease | 60 |
| Gonadal failure | 45 |
| Autoimmune thyroid disease | 10 |
| Type 1 diabetes mellitus | 1 |
| Hypopituitarism | |
| Diabetes insipidus | |
| Nonendocrine disorders | |
| Mucocutaneous candidiasis | 75 |
| Malabsorption syndromes | 25 |
| Alopecia | 20 |
| Pernicious anemia | 15 |
| Chronic active hepatitis | 10 |
| Vitiligo | 5 |
| Sjörge's syndrome | |
| Dystrophy of nails and dental enamel | |
| Progressive myopathy | |
| Type II | |
| Endocrine disorders | |
| Addison's disease | 100 |
| Autoimmune thyroid disease | 70 |
| Type 1 diabetes mellitus | 30 |
| Gonadal failure | 10 |
| Hypopituitarism | <1 |
| Nonendocrine disorders | |
| Alopecia | |
| Pernicious anemia | |
| Chronic active hepatitis | |

This group of patients rarely has any of the mucocutaneous candidiasis or ectodermal disorders common in all of the other affected populations.

The protein encoded by the AIRE gene is localized to the cell nucleus and acts as a transcription factor that regulates autoimmunity by promoting the ectopic expression of peripheral tissue-restricted antigens in medullary epithelial cells of the thymus. AIRE-deficient thymic medullary epithelial cells showed a specific reduction in ectopic transcription of genes encoding peripheral antigens. Animals lacking a functional AIRE protein in the thymus exhibit a defined profile of autoimmune diseases. AIRE is expressed not only in the thymus but also in the spleen, lymph

nodes, peripheral leukocytes, testes, and adrenal gland. There is no good genotype-phenotype correlation of the mutations with the syndrome. However, Maria Halonen and colleagues reported an association between the most common mutation of the AIRE gene, R257X, and a higher prevalence of candidiasis than with other mutations.

Antibodies that cross-react with steroid-producing cells have been commonly observed in patients with APS type I. Mark Leshin reported that although steroid antibodies were observed in both males and females, a considerably greater number of females manifested clinical hypergonadotropic hypogonadism secondary to gonadal failure. Studies describe adrenal cortex autoantibodies and steroid-producing cell autoantibodies associated with autoimmune Addison's disease and premature ovarian failure. Betterle and colleagues also showed that a number of these autoantibodies, detected by indirect immunofluorescence, reacted with steroidogenic enzymes. The prevalence of these antibodies has varied depending on the techniques used to detect them. The fact that epitope-specific autoantibodies are expressed against a number of tissues in APS type I indicates a polyclonal immune response. In addition, the T-cell dysfunction results in localized infections with *Candida albicans*.

All of the autoantigens in the adrenal cortex and gonads are cytochrome P450 enzymes involved in steroid synthesis. Usually, the appearance of these antibodies signals a high risk of developing failure of the target organs. In Addison's disease, the three major autoantigens are the 21-hydroxylase (P450c21) and 17-hydroxylase (P450c17) enzymes and the cholesterol side chain cleavage enzyme (P450scc). Patients with APS type I might not express antibodies to all of the P450 enzymes. The most commonly expressed antibody is to P450c21. All three P450 enzymes are expressed in the adrenal cortex, and P450c17 and P450scc are also expressed in the gonads. In addition, their expression in the brain and skin has been described (Table II).

In most autoimmune diseases, including APS type II, there is an association with certain human leukocyte antigen (HLA) alleles, incurring higher susceptibility to the autoimmune disease. The association is particularly strong with the occurrence of tissue-specific antibodies. APS type I was not known to have any correlation with HLA class II haplotypes until recently, when Addison's disease was associated with HLA-DRB1*03, alopecia was associated with HLA-DRB1*04-DQB1*0302, and type 1 diabetes correlated negatively with HLA-DRB1*15-DQB1*0602. The same HLA associations have been established previously for the isolated endocrine disorders.

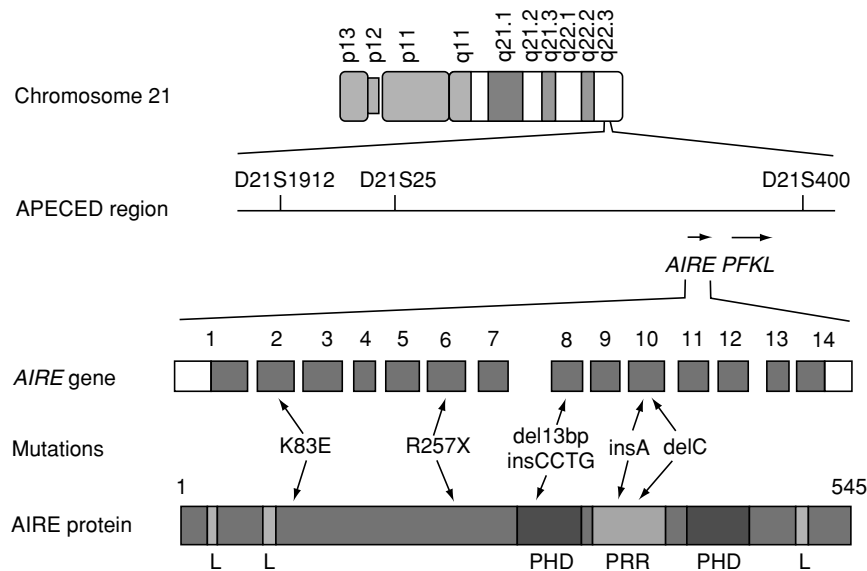

Figure 1 Schematic of chromosome 21 showing the physical map of the APECED region (top) and the genomic structure of the AIRE gene, features of its protein product, and mutations found in APECED patients (bottom). The AIRE gene maps proximal to the 5' end of the PFKL (phosphofruktokinase of liver type) gene between DNA markers D21S25 and D21S400 and has 14 exons. The most common mutation found in APECED patients was the Arg change to a stop codon (R257X) in exon 6. Three other mutations were also detected: deletion of 13 nucleotides (del13bp) and insertion of a 4-nucleotide repeat CCTG (insCCTG) in exon 8, resulting in a truncated AIRE protein product; insertion of A (insA) and deletion of C (delC) nucleotides in exon 10, again resulting in a truncated AIRE protein product; and a missense substitution of amino acid Lys to Glu (K83E) in exon 2. The location of mutations in gene exons and respective sites in the protein are shown by arrows. The AIRE protein (545 amino acids) contains three LXXLL motifs (L), two PHD-type zinc fingers (PHD), and a proline-rich region (PRR), suggesting that it functions as a transcriptional factor or coactivator. APS TYPE II

Prevalence

In 1980, a report of familial Schmidt's syndrome was published. The report described 17 offspring of a common father. Endocrine abnormalities were documented in 8 of the 12 siblings studied and one of the two mothers in this kindred. The age of clinical onset ranged from 18 to 38 years. Adrenal and thyroid hypofunction with organ-specific antibodies were found. Pernicious anemia, vitiligo, and alopecia were reported as well. This familial study helped to elucidate the variable presentation of adrenal, thyroid, and other autoimmune abnormalities in Schmidt's syndrome (Fig. 2).

The occurrence of primary Addison's disease in the general population is 40 to 50 per 1 million. Recent studies have suggested an increasing prevalence, or greater recognition, of the disease. In 40% of the patients with idiopathic Addison's disease, a second or third endocrine disease is present. The female-to-male

predominance is approximately 1.8 to 1. Other non-endocrine autoimmune disorders have been described as well, sometimes classified separately as APS type III or IV. Although a clear relationship exists, the current recommendation is that it might not be necessary to evaluate all patients with clinically latent adrenal insufficiency. The prevalence of adrenal insufficiency among patients with Hashimoto's thyroiditis is low. Only if other evidence of APS type II is present, such as type 1 diabetes mellitus either in the patient or in a first-degree family member, should the possibility of adrenal insufficiency be investigated more thoroughly.

Presentation

The initial description of APS type II included the concurrent appearance of adrenal insufficiency and autoimmune thyroid disease or type 1 diabetes mellitus. For the purpose of this discussion, we include all associated autoimmune disorders as also being variable expressions

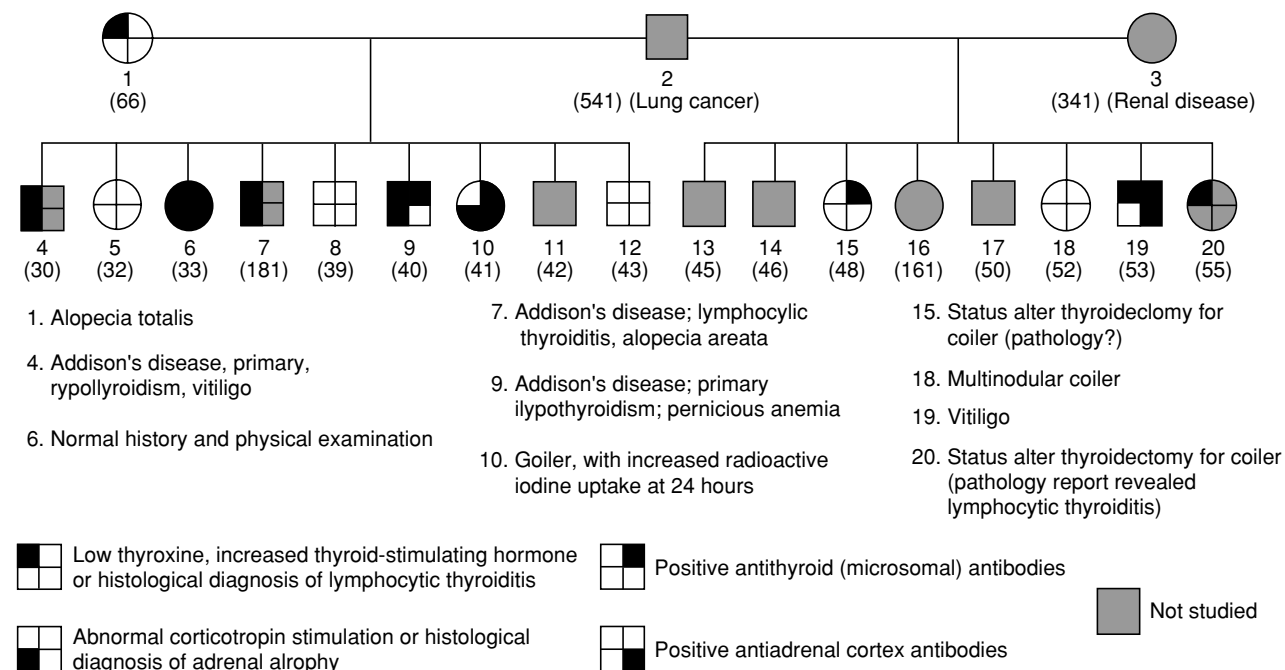

Figure 2 Family pedigree. Numbers in parentheses indicate ages in years; daggers indicate deceased. Adapted with permission from Anderson, P. B., Fein, S. H., and Frey, W. G., III. (1980). Familial Schmidt's syndrome. *J. Am. Med. Assoc.* **244**, 2070.

of APS type II as proposed by Neufeld and colleagues, where not all of their patients with APS type II had Addison's disease. The age of onset was much more varied when compared with their APS type I patients, occurring during childhood to late adulthood with peak incidence during midlife. Chronic mucocutaneous candidiasis and hypoparathyroidism were not present in any of their patients with APS type II. Chronic active hepatitis and malabsorption were also essentially non-existent in their patients, although these were common in the patients with APS type I. Fully 69% of patients had autoimmune thyroid disease, which was overactive as well as underactive. In addition, 52% of patients had type 1 diabetes mellitus. In a group of older patients, Betterle and colleagues demonstrated atrophic gastritis by biopsy in 95% of older patients with vitiligo. They concluded that 95% of all patients with vitiligo would have pernicious anemia and/or gastric atrophy. Vitiligo, alopecia, and premature graying of the hair are relatively common and should alert the physician to the possible presence of other diseases (Table I).

Genetics of APS Type II

The inheritance of APS type II is poorly defined, and the familial aggregation does not follow Mendelian inheritance. Hence, in contrast to APS type I, APS

type II is a more complex disease that results from the interaction of an even greater variety of genetic and environmental influences. Many members of affected families were noted to have an increased frequency of the HLA B8/DR3 haplotype, indicating that HLA was one susceptibility gene. More recent studies have focused on the cytotoxic T-lymphocyte antigen 4 (CTLA4) gene, which confers susceptibility to autoimmunity. CTLA4 is a negative regulator of T-cell activation, and the association of CTLA4 with APS type II was variable (OR = 1.73) depending on the specific autoimmune disease being studied.

APS TYPE III

APS type III consists of a diverse group of multiple autoimmune endocrine disorders developing in the same patient over time. There are a few considerations to keep in mind. Approximately 3 to 8% of patients with type 1 diabetes mellitus or autoimmune thyroid disease have celiac disease. Measuring auto-antibodies to tissue transglutaminase is now the typical method for screening for celiac disease. The frequency of frank or latent pernicious anemia is increased among patients with autoimmune thyroid disease who are over 40 years of age. Atrophic gastritis with achlorhydria but normal B12 absorption is

Table II Circulating Antibodies to Endocrine Antigens in Autoimmune Polyglandular Syndromes

| | Autoantigen | Tissue/Cells |
|--|---|---|
| Addison's disease | 21-OH, P450scc 17-OH | Enzymes of the adrenal cortex |
| Hypogonadism, premature menopause | CYP450scc 17-OH | Ovary: granulosa/theca cells Testis: Leydig cells Placenta: syncytiotrophoblasts |
| Hashimoto's thyroiditis/ hypothyroidism | Thyroid peroxidase Thyroglobulin TSHr (blocking) | Thyroid enzyme Thyroid-secreted protein Thyrocytes |

also frequent in patients with autoimmune thyroid disease. Approximately 20 to 30% of patients with autoimmune thyroid disease have circulating parietal cell antibodies, compared with a frequency of 60 to 90% of patients with the APS syndrome.

The clinical and epidemiological characteristics of the group of patients with diabetes mellitus and coexistent autoimmune thyroid disease differ from those of patients with diabetes alone. The frequency of insulin dependence is 60%, and the median age of diagnosis of patients with insulin-dependent diabetes and thyroid disease (36 years) is greater than the mean age of patients with insulin-dependent diabetes alone (25 years). The female-to-male predominance of patients with type 1 diabetes mellitus and thyroid disease is much greater (6.4 to 1) than the ratio for patients with diabetes alone (1 to 1).

Over the past 20 to 30 years, an increasing incidence of hypophysitis has also been reported in patients with Hashimoto's thyroiditis. This pituitary autoimmune disorder, as well as diabetes insipidus, has also been recognized in patients with APS type II.

One-fifth (20%) of patients with generalized myasthenia gravis have been reported to have clinical autoimmune thyroid disease, with a higher incidence of clinical endocrine disease described in patients with onset of myasthenia after 40 years of age than before (35 vs 17%).

TREATMENT

There are some special considerations for patients with APS. For example, thyroxine therapy with untreated adrenal insufficiency may precipitate an adrenal crisis. In addition, a decreased insulin requirement or increased hypoglycemia in a patient with type 1 diabetes mellitus may be one of the many signs of adrenal insufficiency or hypothyroidism. On the other hand, increased hyperglycemia may be an early sign of autoimmune hyperthyroidism. Therefore, it is necessary to be vigilant of the possible development of thyroid, adrenal, and other autoimmune diseases when considering appropriate therapy and management of endocrine autoimmune disorders.

or a pentagastrin-stimulated calcitonin value is >100 pg/ml. A basal calcitonin value of >30 pg/ml or a stimulated value >200 pg/ml is highly predictive of MTC (positive predictive value 93%, sensitivity 80%). Hypercalcitonemia also occurs in other disease states, such as other neuroendocrine tumors, renal failure, chronic lymphocytic thyroiditis, and follicular thyroid adenomas. False-positive test results for abnormal calcitonin values in individuals suspected to have MTC occur in 5–10% of the tests, as determined by retrospective testing for *RET* germ-line mutations in these individuals. Fifty percent of patients with a negative pentagastrin test but a positive test for *RET* mutation had already developed MTC. MTC can also give rise to ectopic hormone production, such as ectopic adrenocorticotrophic hormone syndrome.

Before thyroidectomy is performed, the physician should always screen for pheochromocytoma by measuring fractionated urinary metanephrines and/or plasma free-metanephrines. This is especially important since MEN2-associated pheochromocytomas are “adrenergic”; i.e., they cause symptoms such as palpitations rather than sustained hypertension. Before prophylactic thyroidectomy was routinely performed in individuals at risk for MTC (e.g., carriers of a *RET* germ-line mutation), MTC rarely was at stage 1 but instead was usually at an advanced stage (stages 3 and 4) when it was discovered in a patient. Therefore, prophylactic thyroidectomy with central lymph node dissection has been recommended for individuals with a *RET* germ-line mutation. This has lowered the mortality rate from hereditary MTC to $<5\%$. Multifocal hyperplasia of parafollicular C cells has been regarded as a precursor lesion for hereditary MTC. Metastases usually develop in the cervical and mediastinal lymph nodes as well as in lung, liver, or bone. Calcitonin is an excellent tumor marker in postsurgical follow-up. In addition, carcinoembryonic antigen is helpful. Diarrhea from humoral factors may develop and can be improved by reducing the tumor burden. For instance, patients with MTC metastatic to the liver, high calcitonin values, and diarrhea may experience cessation of diarrhea and a fall in calcitonin levels to near normal after partial liver resection. For disseminated metastatic MTC, no good therapeutic measures exist. None of the different chemotherapeutic regimens has proven beneficial nor has radiation therapy has proven beneficial in these relatively insensitive tumors.

Pheochromocytoma develops in approximately 50% of patients with MEN2A during their lifetime. The true prevalence can be determined by autopsy studies of such patients. Typically, MEN2 pheochromocytomas

predominantly produce epinephrine and metanephrine; i.e., they are adrenergic. Affected patients develop adrenergic symptoms, such as palpitations, sweating, and paroxysmal hypertension. Screening for pheochromocytoma in patients at risk for MEN2 should start at the age of approximately 6 years. MEN2 pheochromocytomas can be unilateral but are often bilateral, typical for a hereditary syndrome. Rarely ($<5\%$ of cases), MEN2 pheochromocytomas are metastatic. Once the presence of a pheochromocytoma has been confirmed by a more than threefold elevation of metanephrines from baseline values, an imaging study such as high-resolution (thin cuts, 1–2 mm) computed tomography or magnetic resonance imaging of the adrenal glands should be performed. Before surgery, a metaiodobenzylguanidine (MIBG) scan should also be performed to rule out extra-adrenal lesions. The sensitivity of MIBG is approximately 80%, whereas the specificity is 100%. All individuals scheduled for adrenalectomy for a biochemically confirmed pheochromocytoma or an adrenal “incidentaloma” should be treated with an alpha-blocker, such as phenoxybenzamine, and/or a beta-blocker for 7–10 days prior to surgery. The preferred surgical approach is laparoscopic adrenalectomy—if possible, adrenal cortical-sparing laparoscopic adrenalectomy.

Primary hyperparathyroidism in patients with MEN2A develops in approximately 25% of cases and usually is mild; i.e., most affected individuals have no symptoms. Screening should include serum calcium and intact parathyroid hormone. Surgical intervention should be based on the same criteria as for sporadic primary hyperparathyroidism, i.e., serum calcium elevation >0.25 mmol of the upper limit of normal, 24 h urinary calcium >400 mg, creatinine clearance reduced by 30%, *T* score of bone mineral density (radius, femur, spine) minus 2.5 SD, and age less than 50 years. Surgical procedures should be similar to those in patients with other hereditary hyperparathyroidism, such as multiple endocrine neoplasia type 1.

Familial Medullary Thyroid Carcinoma

In a few families with *RET* germ-line mutations (probably fewer than 20 kindreds), affected individuals are known to develop only medullary thyroid carcinoma during their lifetime. Whether such patients indeed do not have pheochromocytoma can be proven only by autopsy studies. Rigorous criteria for familial medullary thyroid carcinoma (FMTC) patients have been established to avoid incorrect designations and

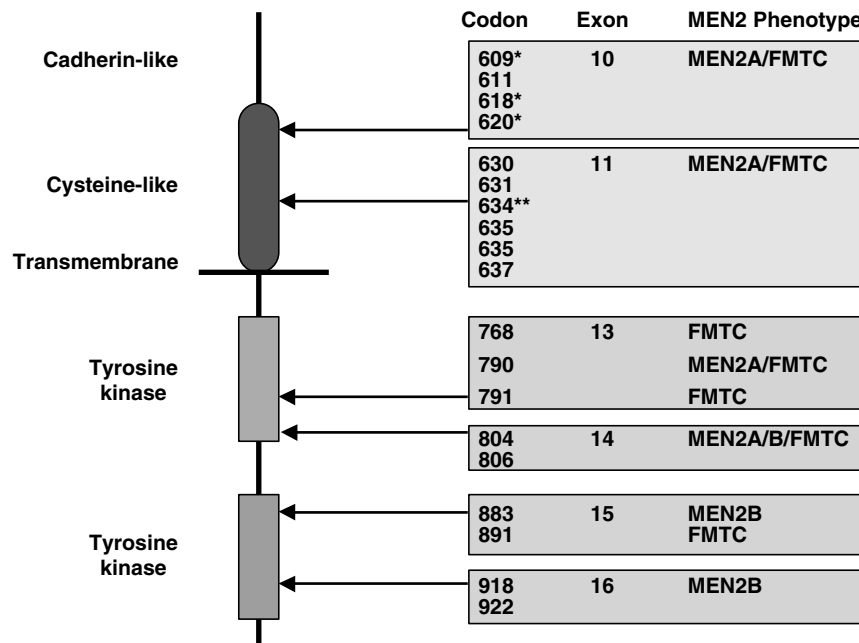

Figure 1 Genotype–phenotype correlations for *RET* mutations in patients with MEN2. *, Associated with Hirschsprung’s disease. **, cutaneous lichen amyloidosis (CLA).

include the following: an adequate medical history, particularly in older family members, multiple carriers, or affected members over the age of 50 years; and more than 10 carriers in the kindred. Late onset of familial medullary thyroid carcinoma commonly occurs in patients with *RET* germ-line mutations in codons 790, 791, and 804 (Fig. 1). Often, basal and stimulated pentagastrin calcitonin values are used in deciding when to perform thyroidectomy. Some authorities recommend waiting no longer than until age 10 in individuals with negative calcitonin testing and *RET* mutations in the aforementioned codons.

Multiple Endocrine Neoplasia Type 2B

MEN2B is the most aggressive form of all MEN2 subforms. It affects approximately 5% of all MEN2 patients. MTC can occur in the first weeks of life. Therefore, some authorities recommend prophylactic thyroidectomy with central lymph node dissection in patients with *RET* germ-line mutations in exon 16 within the first months of life. Similarly, pheochromocytoma becomes manifest earlier (by approximately 10 years) than in individuals with MEN2A and therefore should be screened for earlier. On the other hand, MEN2B patients usually do not develop hyperparathyroidism. Instead, they have a

characteristic habitus with marfanoid features and intestinal and mucosal ganglioneuromas.

MOLECULAR ASPECTS

The RET Receptor Tyrosine Kinase

RET denotes “rearranged during transfection” and was discovered in 1985 during transfections assays. It has been classified as a proto-oncogene located at chromosome 10q11.2 with activating mutations leading to MEN2. Interestingly, so-called inactivating *RET* mutations have been found in patients with Hirschsprung’s disease or intestinal aganglionosis. In addition, some kindreds with *RET* germ-line mutations in codons 618 and 620 have MEN2 and Hirschsprung’s disease. *RET* is expressed in neural crest-derived cells, such as the parafollicular C cells in the thyroid gland and the chromaffin cells in the adrenal medulla. *RET* consists of 21 exons and encodes a receptor tyrosine kinase. Six exons, exons 10, 11, 13, 14, 15, and 16, are called hot spots, since germ-line mutations in these exons are found in approximately 97% of patients with MEN2. The most common affected exon is exon 11 including codon 634, which is mutated in approximately 80% of patients with MEN2A. More than 94% of patients with MEN2B have *RET* germ-line mutations in exon 16, most

commonly in codon 918. There are strong genotype–phenotype correlations (see Fig. 1). Ligands for the *RET* receptor include glial cell line-derived neurotrophic factor, neurturin, persephin, and artemin. *In vitro* studies indicate that certain *RET* germ-line mutations can lead to autophosphorylation and/or dimerization with constitutive activation of RET. The RET receptor consists of several domains, a cadherin-like domain, a cysteine-rich domain, a transmembrane domain, and an intracellular tyrosine kinase domain (see Fig. 1).

RET Downstream Signaling

A complex array of downstream interactions mediates RET's functions in normal and tumorigenic cells. For instance, RET stimulates the RAS pathway, including activation of the mitogen-activated protein kinase pathway, which is necessary for differentiation and neuronal survival. RET also can activate phosphatidylinositol 3-kinase (PI3-kinase), which has been implicated in cell proliferation and motility. Furthermore, through PI3-kinase activation, RET can activate protein kinase B, also leading to cell proliferation and survival. Through activation of the c-jun N-terminal kinase pathway, RET may contribute to tumorigenesis.

Model for Tumorigenesis of MEN2

Transgenic mice heterozygous for the M918T *RET* mutation develop hyperplasia of C cells and

adrenomedullary hyperplasia without progression to medullary thyroid carcinoma or pheochromocytoma. On the other hand, mice homozygous for this *RET* mutation not only have an earlier onset of C cell and adrenomedullary hyperplasias but also progression to medullary thyroid carcinoma and pheochromocytoma. It is puzzling that related and unrelated patients with the same heterozygous germ-line mutation in *RET* develop the respective tumor (MTC or pheochromocytoma) at widely different ages, i.e., at age 1 and at age 81, and that only a few cells in the target organs develop into tumors. In an attempt to answer this question *in vivo*, studies showed evidence of a so-called second hit in tumors of patients with heterozygous *RET* germ-line mutations, leading to tumor formation. In MEN2-associated pheochromocytomas, overrepresentation of mutant RET through duplication of mutant RET in trisomy 10 or loss of wild-type RET was found. Similarly, such an allelic imbalance between mutant and wild-type *RET* could also be demonstrated in MEN2-associated medullary thyroid carcinoma (Fig. 2). In addition, in the stable and commercially available TT cell line, which is derived from medullary thyroid carcinoma with a *RET* germ-line mutation in codon 634, a tandem amplification of mutant RET was found, leading to the overrepresentation of mutant RET. Selected C cells in the thyroid gland and selected chromaffin cells in the adrenal gland may undergo such a second-hit event, giving these cells a growth advantage and making them prone to more replication errors. Somatic *RET* mutations in MEN2-associated MTC

Figure 2 Model for tumorigenesis in MEN2-associated pheochromocytomas. In an individual with MEN2, each cell of the target organs (e.g., adrenal medulla) carries a *RET* germ-line mutation in the heterozygous state with one intact wild-type *RET* allele. Selected chromaffin cells undergo a second hit through duplication of the mutant *RET* allele in trisomy 10 or loss of the wild-type allele, giving these cells an overrepresentation of mutant RET and a growth advantage with subsequent tumor formation. M, mutant *RET* allele; WT, wild-type *RET* allele; C10, chromosome 10. Modified from Koch *et al.* (2002), *J. Clin. Endocrinol. Metab.* 87, 5367–5384, with permission.

or pheochromocytoma are rare and may represent a tumor progression phenomenon. A few patients have double germ-line mutations in *RET*; the functional significance of this finding has yet to be determined. A subset of MEN2-associated pheochromocytomas have somatic *VHL* gene alterations, possibly leading to tumorigenesis or representing events of tumor progression.

RET Mutation Testing

All cases of sporadic MTC should be tested for *RET* germ-line mutations, since approximately 7% of patients with apparently sporadic MTC have germ-line mutations in *RET*. Also, all patients presenting with pheochromocytoma should be tested for germ-line mutations in *RET*, since a study including 271 patients found that up to 24% of these patients with apparently nonsyndromic/sporadic pheochromocytoma had germ-line mutations in the *VHL*, *RET*, *SDHD*, or *SDHB* genes. Patients with apparently sporadic primary hyperparathyroidism without other features of MEN2, such as MTC, should not routinely be tested for *RET* germ-line mutations. If one of the so-called hot spot exons does not reveal a *RET* mutation, especially in members of MEN2 families, the other 15 exons of *RET* should be tested. Prophylactic thyroidectomy with central lymph node dissection within the first 6 months should be recommended for children with *RET* mutations in codons 883, 918, or 922. For children with mutations in codons 611, 618, 620, or 634, this surgical procedure should take place before 5 years of age. Children with mutations in codons 609, 768, 790, 791, 804, or 891 also should undergo prophylactic thyroidectomy but the recommendation for the exact age at which the child should undergo surgery varies between the ages of 5 and 10, especially for children with mutations in codons 790 and 791.

LABORATORY DIAGNOSIS

As in uncomplicated hypothyroidism, a significantly elevated thyroid-stimulating hormone (TSH) with very low or undetectable thyroid hormone levels is seen. The degree of TSH elevation can vary a lot between patients; a TSH level seen in a patient with mild signs and symptoms of hypothyroidism could be comparable to that seen in another patient with myxedema coma. Similarly, it is not unheard of for patients to be functional with undetectable levels of thyroid hormone (at least for some period of time).

An exception to the rule of an elevated TSH level may be the patient with central hypothyroidism, although even in this case it is possible for the TSH to be in the normal range or even somewhat elevated, possibly reflecting bioinactive TSH.

TREATMENT

Given the high mortality associated with myxedema coma, treatment must be instituted as soon as diagnosis is strongly suspected. Thyroid hormone therapy alone might not be enough in the presence of the multiple system organ dysfunction associated with myxedema coma. Ventilatory support is often required and helps to prevent respiratory failure, a common cause of death in these cases. An intensive care unit is always the best place in which to care for these patients. Mechanical ventilation and empirical antibiotic therapy are often indicated together with monitoring of blood gases. It is important to realize that prolonged ventilatory support may be required despite adequate therapy of the hypothyroidism.

Correction of hyponatremia is of equal importance. This can easily contribute to the altered mental status of these patients, especially if the serum sodium concentration is less than 120 mEq/L. Intravenous saline and dextrose are used to correct any volume depletion and to provide minimal nutritional support. If serum sodium concentration is less than 120 mEq/L, use of small amounts of hypertonic saline may be indicated; however, this requires very close monitoring of sodium concentration changes to avoid central pontine myelinolysis. The intravenous fluids may be warmed to help correct hypothermia. Thyroid hormone will ultimately restore body temperature, and external heat with warming blankets must be used with great caution because they may act to cause vasodilation and provide too precipitous a fall in peripheral vascular resistance. Rather than external warming, it would be more prudent to use ordinary blankets or increase the ambient room temperature.

If there is any suspicion of adrenal insufficiency, stress dose steroids should be given after a baseline cortisol level is drawn. The presence of signs such as hypoglycemia, hyponatremia, hyperkalemia, and hypotension is highly suggestive. This can be of extreme importance because correction of the hypothyroidism without correction of adrenal insufficiency can precipitate an adrenal crisis. Rarely, these patients require vasopressor support for hemodynamic stability.

The most important part of therapy is the replacement of the thyroid hormone deficiency. Which regimen of thyroid hormone administration to use remains controversial. Administration of levothyroxine (T4) by itself may result in insufficient levels of triiodothyronine (T3) because of inadequate mono-deiodination of T4 to T3 in sick patients. On the other hand, T4 therapy provides a steady smooth rise of the hormone level and is less likely to be associated with any adverse effects. A commonly used dosing regimen involves administration of a high dose (300–600 µg) intravenously the first day to replete the body's stores and then about 50 to 100 µg daily intravenously or orally after that.

Administration of T3 has the advantage that its onset of action is much faster than that of T4, an advantage that can be very important for patients' survival. The drawback is that there may be potential for an increased incidence of complications, especially in those patients who have primary cardiac diseases or who are at risk for arrhythmias or ischemia. Intravenous preparations of T3 are available, and common doses for myxedema coma are 10 to 20 µg intravenously every 4 h for the first day and then 10 µg every 6 h for 1 to 2 days. Oral administration is usually possible after that.

Another approach is to administer both T4 and T3 initially. T4 is given at a dose of 4 $\mu\text{g}/\text{kg}$ lean body weight (approximately 200–300 μg) followed by 100 μg 24 h later and then 50 μg daily either intravenously or orally as tolerated. The initial T3 dose is 10 μg intravenously every 8 to 12 h until the patient is able to tolerate oral intake. The response to therapy can be quite variable, and close monitoring of all such patients is extremely important.

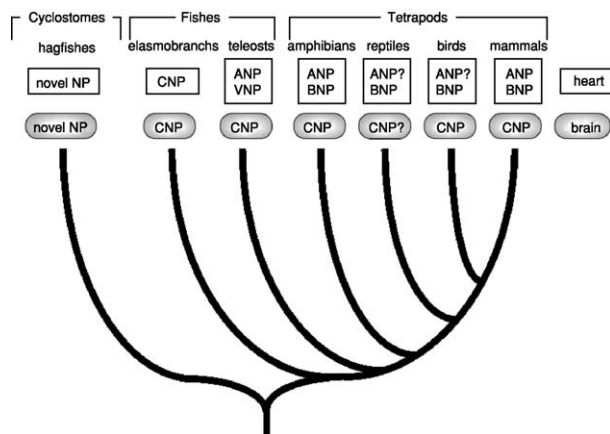

Figure 1 Phylogenetic distribution of natriuretic peptides in vertebrates. NPs in rectangles are circulating hormones secreted from the heart. NPs in ellipses are paracrine factors synthesized mainly in the brain.

and ventricular natriuretic peptide (VNP) secreted from the heart and paracrine CNP synthesized and stored most abundantly in the brain (Fig. 1). In nonmammalian vertebrates, BNP and CNP are identified in birds, whereas ANP, BNP, and two types of CNP are identified in amphibians (Fig. 3). Thus, ANP, BNP, and CNP appear to be common members of the NP family in tetrapods. However, in fishes, ANP, CNP, and VNP are identified in teleost fish. VNP has a uniquely long C-terminal tail sequence that extends from the intramolecular ring structure (Fig. 3). In elasmobranchs, CNP is the only NP in the heart and brain. In cyclostomes (hagfish), a novel NP that displays a chimerical structure sharing all features of NPs is the sole NP in the heart and brain (Fig. 1). It remains undetermined whether CNP or hagfish NP is an ancestral form of the NP family.

CNP is structurally the most conserved peptide in the NP family (Fig. 3), whereas BNP is highly variable even in mammals (Fig. 3). ANP exhibits high sequence identity in mammals but has low identity among various classes of vertebrates. VNP is well conserved in teleosts; its sequence is more than 80% identical between eel and rainbow trout that are phylogenetically distant and is completely identical between rainbow trout and chum salmon.

MOLECULAR EVOLUTION OF NATRIURETIC PEPTIDE RECEPTORS

Cloning of NP receptors in nonmammalian species is still scanty. In tetrapods, NPR-A and NPR-B have been cloned in two species of frogs (*Xenopus laevis* and

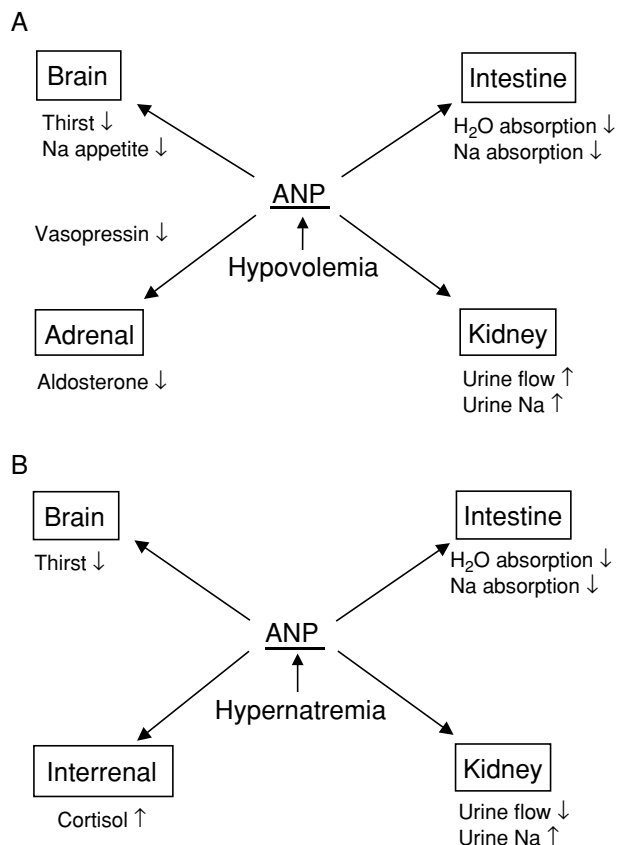

Figure 2 Secretory stimulus and biological actions of ANP on water and sodium metabolism in mammals (A) and seawater fish (B).

Rana catesbeiana), whereas no NPR has been cloned in birds and reptiles. In fishes, NPR-A and NPR-B have been cloned in eel (*Anguilla japonica*) and medaka (*Oryzias latipes*), and NPR-C has been cloned in eel. In addition, a new receptor that lacks a cytosolic guanylyl-cyclase domain, named NPR-D, has been cloned in eel. Unlike clearance-type NPR-C that is scattered ubiquitously in various tissues in large numbers, however, NPR-D is localized selectively in the brain. Thus, NPR-D may serve as a good model to pursue biological functions of guanylyl cyclase-deficient receptors. NPR-D is a tetramer as NPR-A and NPR-B that also differs from dimeric NPR-C.

FUNCTIONAL EVOLUTION OF THE NATRIURETIC PEPTIDE SYSTEM

In birds, as in mammals, rat ANP is diuretic and natriuretic in the chicken, indicating that ANP is a volume-regulating hormone. However, chicken BNP stimulates the secretion of hypertonic NaCl solution

from the nasal salt gland of seawater-adapted ducks (*Anas platyrhynchos*), suggesting a specific role for sodium extrusion in marine birds. In reptiles, mammalian ANP is vasodepressor, but no osmoregulatory actions have been examined. In amphibians, homologous ANP is without effect on NaCl absorption by the skin, but it inhibits vasotocin-stimulated NaCl absorption in the bullfrog. Collectively, NP peptides seem to decrease body sodium in tetrapods in general.

In teleost fish (eel), ANP secretion caused by an increase in plasma osmolality is more prominent than that caused by an increase in blood volume (Fig. 2). ANP secretion occurs after transfer of eels from fresh water to sea water when blood volume decreases and plasma sodium concentration increases. Thus, ANP secretion after seawater transfer is stimulated solely by hypernatremia even with an inhibitory signal

by hypovolemia. The stimulation of ANP secretion occurs *in vitro* from the isolated eel atrial tissue when sodium concentration in the medium is increased.

Consistent with the secretory stimulus, ANP specifically decreases sodium ions from the body, resulting in a decrease in plasma sodium concentration in seawater-adapted eels. This is exemplified by the fact that ANP decreases urine volume but increases urine sodium concentration (Fig. 2). With respect to the intake, ANP inhibits drinking in seawater eels and inhibits intestinal absorption of sodium from the ingested sea water. ANP also seems to increase sodium excretion by the gills of seawater fish. Furthermore, ANP stimulates the secretion of cortisol, which acts as a mineralocorticoid as well as a glucocorticoid in teleost fish to facilitate long-term adaptation to sea water (Fig. 2). Most of these ANP

actions are observed only in seawater fish. Therefore, ANP is an important hormone that promotes seawater adaptation in teleost fish (Fig. 4).

In contrast, CNP appears to be a hormone important for freshwater adaptation (Fig. 4). Unlike mammals in which CNP is principally a paracrine factor, CNP circulates in the blood of freshwater fish. The CNP-specific receptor, NPR-B, is expressed more abundantly in the gills and other osmoregulatory organs of freshwater fish than in those of seawater fish. Furthermore, CNP infused into freshwater fish promote sodium uptake from the environment, resulting in an increase in plasma sodium concentration. This is in contrast to the decrease caused by ANP infusion in seawater fish. These results, together with seawater-adapting effects of ANP, indicate that the NP system is a key hormonal system that governs the diverse environmental adaptability of euryhaline fish (Fig. 4).

Figure 4 Effects of natriuretic peptides (ANP and CNP) on adaptation to sea water (SW) and fresh water (FW) in euryhaline fish.

In the shark, where CNP is the only NP in the heart and brain, CNP stimulates hypertonic NaCl secretion from the rectal gland of marine species. Because CNP is a circulating hormone in the shark, as is the case with ANP in teleosts and tetrapods, CNP may take over the role of ANP in marine elasmobranchs. Taken together, it seems that the essential action of ANP is sodium extrusion throughout vertebrate species. This is particularly eminent in marine fishes, but it becomes a volume-regulating hormone in mammals, probably because sodium and water are regulated together in the same direction in terrestrial species. This illustrates the functional evolution of the NP system during the course of landward migration in the vertebrate phylogeny.

Figure 1 Amino acid sequences of human ANP-28 (α -ANP), BNP-32, and CNP-22. Shaded amino acids are common to the three natriuretic peptides.

The third member, CNP, is present in the human brain, but in contrast to ANP and BNP, little CNP is detected in the heart. The two molecular forms, CNP-53 and CNP-22, were processed from the pro-hormone CNP(1–103). The major molecular form circulating in human blood is CNP-22 (Fig. 1), although the level is much lower than those of ANP and BNP. The vascular endothelium also produces CNP, probably contributing to plasma CNP. The endothelial production is augmented by growth-promoting factors of the vascular smooth muscle, such as thrombin and transforming growth factor- β , and by factors involved in the pathogenesis of sepsis, such as tumor necrosis factor- α and lipopolysaccharide.

BIOLOGICAL ACTIONS

Natriuresis and diuresis occur with a reduction of blood pressure following intravenous infusion of ANP in humans (Fig. 2). The natriuretic peptides exert an endothelium-independent vasodilator effect by acting directly on the vascular smooth muscle cells to elevate the intracellular cyclic guanosine 3',5'-monophosphate (cGMP) level. Despite the reduced blood pressure, the increase in heart rate is relatively small due to an inhibitory effect on sympathetic nerve activity. ANP lowers plasma renin activity and inhibits aldosterone secretion from the adrenal glomerulosa. According to *in vitro* experiments, the natriuretic peptides inhibit

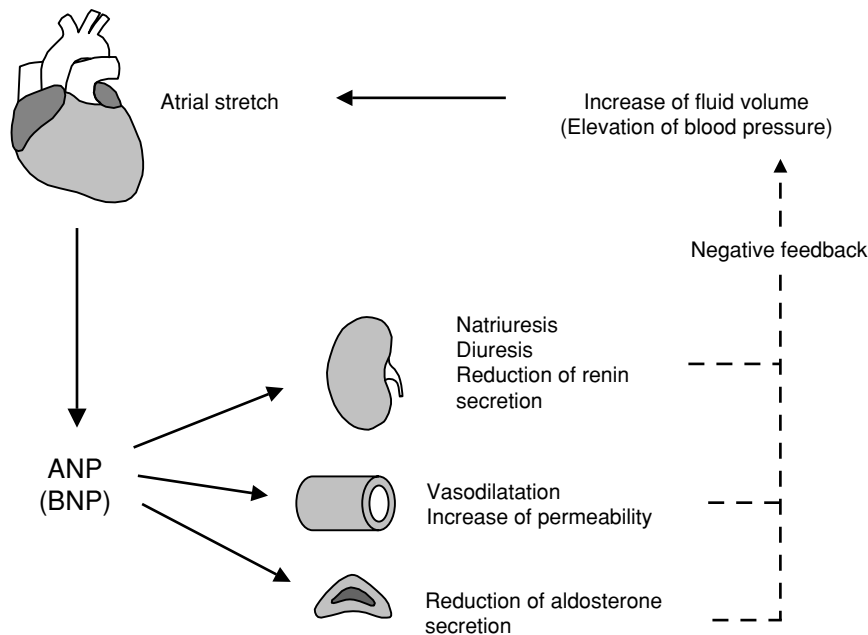

Figure 2 Schematic representation of the actions of ANP (and BNP) and fluid volume regulation by ANP.

cellular proliferation of the vascular smooth muscle and renal mesangial cells.

The natriuretic peptides induce natriuresis and diuresis largely by acting on the glomeruli and inner medullary collecting ducts of the kidney. ANP dilates the afferent arterioles with little effect or constrictor effect on efferent arterioles, leading to an increase in intraglomerular capillary pressure that elevates the glomerular filtration rate (GFR). ANP relaxes the mesangial cells of the glomerulus in a cGMP-dependent manner, and this relaxation also increases the GFR. Another important site of action appears to be the inner medullary collecting duct, where the natriuretic peptides inhibit sodium and water reabsorption. In addition, increased blood flow to the renal medulla partly contributes to natriuresis and diuresis induced by the natriuretic peptides. Fluid volume is reduced by their actions not only on the kidneys but also on vascular permeability. ANP increases the vascular permeability, thereby shifting fluid volume to the extravascular space.

Both the natriuretic peptides and their receptors are present in the central nervous system (CNS). When infused to the lateral ventricles of the rat brain, ANP inhibits salt appetite and water drinking and lowers blood pressure, suggesting roles of the natriuretic peptides in the CNS. Centrally infused ANP reduces the secretion of antidiuretic hormone (ADH) and adrenocorticotrophic hormone (ACTH). These central actions appear complementary to the systemic roles of the natriuretic peptides in reducing fluid volume and blood pressure.

RECEPTOR AND INTRACELLULAR MECHANISM OF THE ACTIONS

The biological actions discussed previously are mediated by binding of the natriuretic peptides to specific receptors on the cell surface. Three subtypes of natriuretic peptide receptors (NPRs) have been identified. The two subtypes NPR-A and NPR-B are transmembrane proteins that have similar structures: an extracellular ligand-binding domain and an intracellular domain containing protein kinase-like and guanylate cyclase portions. The third type of receptor is a "clearance" receptor (NPR-C), the main function of which is clearance of the natriuretic peptides from the bloodstream.

Most of the natriuretic peptide actions are mediated by elevation of the intracellular cGMP level. Binding of the natriuretic peptides to the extracellular domain of NPR-A or NPR-B activates guanylate

cyclase of the intracellular domain, increasing the conversion of guanosine triphosphate (GTP) into cGMP. The cellular response occurs by the cGMP-dependent cascades, including activation of protein kinase G, although the precise mechanisms of cGMP actions appear to be complex. In contrast, NPR-C has neither a protein kinase-like nor a guanylate cyclase domain in its short intracellular portion. Following binding of the natriuretic peptides to NPR-C, the receptor-ligand complex is internalized to the cytoplasm, where the peptides are degraded by lysosomal enzymes. Thus, NPR-C participates in the metabolism of natriuretic peptides.

The modes of action of ANP, BNP, and CNP depend on the specificity and distribution of their receptors. ANP activates NPR-A most potently, followed by BNP, whereas CNP has a much lesser affinity. On the other hand, CNP is highly specific for NPR-B, compared with ANP and BNP, in terms of cGMP generation. Both NPR-A and NPR-B are present in a number of tissues, such as the kidney, adrenal gland, and vascular smooth muscle, where the natriuretic peptides exert their effects. The affinity of NPR-C for BNP seems to be less than that for ANP or CNP, suggesting a lower clearance rate of BNP. NPR-C is widely distributed in many tissues, including the vascular endothelium and smooth muscle.

METABOLISM

Circulating natriuretic peptides are metabolized by two mechanisms: clearance by NPR-C and enzymatic cleavage by neutral endopeptidase (NEP)-24.11. Both mechanisms seem to be important for the metabolism of natriuretic peptides. NEP-24.11 is widely distributed in many tissues and organs, including the kidney and lung. The natriuretic peptides filtered through the glomerulus of the kidney are metabolized by NEP expressed on the brush border membrane of renal tubules. NEP-24.11 cleaves the ringed structure of ANP, an essential portion for the biological action, but is rather a nonspecific enzyme and hydrolyzes not only the natriuretic peptides but also other bioactive peptides such as bradykinin and endothelin.

PLASMA LEVELS

In healthy adults, the plasma levels of ANP, BNP, and CNP are in the ranges 20 to 40, 2 to 4, and 1 to 2 pg/ml, respectively. Both the ANP and BNP levels increase with aging and are transiently elevated by physical exercise. In patients with congestive heart

failure, the plasma ANP levels progressively increase in relation to severity of the disease. Because atrial stretch is the major stimulus of ANP secretion, the plasma ANP level can be a marker of volume retention or a preload to the heart. Compared with ANP, the plasma level of BNP is lower in healthy individuals but increases to a much greater degree in heart failure as well as in myocardial infarction. BNP is a hormone produced mainly by cardiac ventricles responding to stress to the heart, and its plasma level is clinically used as a sensitive indicator to evaluate cardiac function. Based on the inhibitory actions of ANP and BNP on the renin-angiotensin system and sympathetic nerve activity, the elevated plasma level is thought to be involved in the mechanism counteracting excessive volume retention and vasoconstriction in heart failure (Fig. 2). The plasma levels of ANP and BNP also increase in patients with hypertension and renal failure. These increases appear to be responses against blood pressure elevation and volume retention. In patients with renal failure, reduced clearance of ANP and BNP partly contributes to the increased plasma levels. In contrast to ANP and BNP, little change is observed in the plasma level of CNP in heart failure or hypertension, but the CNP level rises markedly in sepsis, and this increase appears to be due to increased production in the vascular endothelium by various cytokines.

THERAPEUTIC IMPLICATIONS

The therapeutic potential of the natriuretic peptides has been considered for various diseases in which either fluid volume retention or excessive vasoconstriction occurs such as heart failure, hypertension, and renal failure. When infused intravenously to patients with congestive heart failure, ANP exerted favorable effects—reductions in pulmonary capillary wedge pressure and peripheral vascular resistance and an increase in cardiac output. ANP is currently

used as an intravenous agent for heart failure patients in Japan, and BNP has become available in the United States. On the other hand, because the natriuretic peptides are metabolized by NEP-24.11, substantial efforts have been made to develop orally available drugs that inhibit the enzymatic activity of NEP-24.11. Indeed, the NEP inhibitors elevate the plasma level of endogenous ANP when administered intravenously or orally in patients with congestive heart failure. This elevation leads to natriuresis, diuresis, reductions in pulmonary capillary wedge pressure and right atrial pressure, and a reduction in plasma renin activity. Orally active NEP inhibitors could be useful in the treatment of not only congestive heart failure but also hypertension.

deriving from bowel, pancreas, kidneys, placenta, thyroid, pituitary, and hypothalamus. Within the stomach, ghrelin is produced by the enteroendocrine cells, probably the X/A-like cells, a major endocrine population in the oxyntic mucosa, the hormonal product of which was previously unknown.

Ghrelin is the first peptide isolated from natural sources in which the hydroxyl group of one of its residues (namely, serine 3) is acylated by *n*-octanoic acid. The acylation seems critical for the peptide to be able to cross the blood-brain barrier and is essential for binding GHS-R type 1a and for endocrine actions. In fact, nonacylated ghrelin, which circulates in far greater amounts than the acylated form, does not bind GHS-R type 1a and has no endocrine activities. However, nonacylated ghrelin exerts some nonendocrine actions including cardiovascular and anti-proliferative effects, probably binding different GHS-R subtypes or other receptor families. It should be noted that it is possible that ghrelin is not the sole natural GHS-R ligand and that GHS-R type 1a is one of a group of receptors for such ligands. Indeed, GHS-R is also bound by other molecules, such as Des-Gln14-ghrelin, which is a gastric homologue of ghrelin, with the exception that one glutamine is missing, and which has the same biological activities as ghrelin; adenosine, which binds but does not activate the receptor; and cortistatin, which is a neuropeptide that is homologous to somatostatin, which is in turn unable to recognize GHS-R type 1a.

Moreover, there is strong evidence suggesting the existence of additional receptor subtypes. Specific binding sites for peptidyl GHS only, with very low binding affinity for ghrelin and nonpeptidyl GHS, have been shown in a wide range of nonendocrine peripheral human tissues.

Circulating ghrelin levels mostly reflect gastric secretion. The regulation of ghrelin secretion is still largely unknown, but it has already been shown that circulating ghrelin levels are increased by fasting and decreased by food intake and glucose but not by gastric distension. In agreement with the critical influence of nutrition on ghrelin secretion, circulating ghrelin levels are increased in anorexia and cachexia but reduced in obesity.

The functional relationship between ghrelin and insulin is still unclear. Indeed, there is a negative association between their circulating levels, and insulin administration has been reported to decrease ghrelin secretion independent of glucose variations.

Though ghrelin drives the GH response to fasting in humans, a feedback regulatory mechanism between ghrelin and GH seems unlikely. On the other hand,

both somatostatin and cortistatin exert a potent inhibitory effect on ghrelin secretion in humans.

Thus, all these data clearly indicate that ghrelin represents a true turning point in understanding the control of the GH-insulin-like growth factor-I (IGF-I) axis but, indeed, in addition to potent GH-releasing actions, ghrelin and synthetic GHS have other remarkable endocrine and nonendocrine actions that are often unrelated to their GH-releasing activity.

ENDOCRINE ACTIONS OF GHRELIN

GH-Releasing Action

Ghrelin and synthetic GHS possess a strong and dose-related GH-releasing effect, which synergizes with that of GH-releasing hormone (GHRH), indicating at least partially different mechanisms of action. Nevertheless, GHS need GHRH activity to fully express their GH-releasing effect. In humans, the GH response to GHS is strongly inhibited by GHRH receptor deficiency or antagonists as well as by hypothalamus-pituitary disconnection, accordingly with the assumption that the most important action of GHS takes place at the hypothalamic level.

In both animals and humans, ghrelin and synthetic GHS act as functional somatostatin antagonists at both the pituitary level and the hypothalamic level. In fact, the GH response to ghrelin and GHS is refractory to the modulatory effects of substances enhancing or inhibiting somatostatin secretion or action.

In humans, the GH-releasing effect of ghrelin and GHS undergoes marked age-related variations increasing at puberty, persisting in adulthood, and decreasing with aging. The mechanisms underlying the age-related variations in the GH-releasing action of GHS differ according to age and could involve variations in estrogenic levels, GHRH and/or somatostatin expression, and GHS-R and/or endogenous ghrelin expression.

PRL- and ACTH-Releasing Action

In humans, the stimulatory effect of ghrelin and GHS on PRL secretion is slight, independent of both gender and age, and probably comes from direct stimulation of somatomammotroph cells.

The acute stimulatory effect of ghrelin and GHS on the hypothalamus-pituitary-adrenal axis in humans is remarkable and similar to that of naloxone, arginine-vasopressin (AVP), and even corticotropin-releasing hormone (CRH) but probably vanishes during prolonged treatment. Under physiological

conditions, the ACTH-releasing action of GHS totally depends on central nervous system-mediated mechanisms including AVP-, neuropeptide Y (NPY)-, and/or γ -aminobutyric acid-mediated actions.

The ACTH response to GHS is generally sensitive to the negative feedback action of cortisol but is surprisingly exaggerated (and higher than the response to CRH) in patients with pituitary ACTH-dependent Cushing's disease as well as in some patients with ectopic ACTH-dependent Cushing's syndrome. Interestingly, ghrelin and GHS-R are expressed in abnormal human pituitary and in other neuroendocrine tumors including ACTH-secreting tumors; GHS also stimulate ACTH release from human ACTH-secreting pituitary adenomas but not from normal human pituitary.

Influence on Endocrine Pancreatic Function

Ghrelin and GHS-R type 1a are also present in normal and neoplastic endocrine pancreas. In agreement with these data, an increasing number of studies suggest that ghrelin plays a significant role in the fine-tuning of insulin secretion and glucose metabolism, integrating the hormonal and metabolic response to fasting.

In humans, a clear relationship between ghrelin and insulin secretion has been found and ghrelin has been shown to induce a significant increase in plasma glucose levels that is surprisingly followed by a reduction in insulin secretion. Specifically, ghrelin may likely block the inhibitory effects of insulin on gluconeogenesis and have a direct, non-GHS-R type 1a-mediated, stimulatory effect on glycogenolysis, since this activity is not shared by synthetic GHS.

Influence on Gonadal Function

GHS-R are present in the testis and in the ovary. Leydig cells synthesize ghrelin, which, in turn, induces a significant inhibition of human chorionic gonadotropin (HCG)- and cyclic AMP-stimulated testosterone secretion *in vitro* coupled with a significant decrease in HCG-stimulated expression levels of steroid acute regulatory protein and synthetic enzymes. These data, together with evidence that intracerebroventricularly injected ghrelin inhibits pulsatile luteinizing hormone secretion in rats, provide evidence for a possible action of ghrelin in the regulation of the gonadal axis and of testicular function.

NONENDOCRINE ACTIONS OF GHRELIN

Regulation of Energy Balance

Exogenous ghrelin induces weight gain in rodents by increasing food intake and reducing fat utilization. These actions are GH independent and are mediated by a specific central hypothalamic network of NPY- and Agouti-related protein neurons that is also modulated by leptin; ghrelin and leptin might actually be complementary players of one regulatory system that informs the central nervous system about the status of energy balance.

A premeal rise in circulating ghrelin levels suggests its role as a hunger signal triggering meal initiation and this action would be mediated by GHS-R non-type 1a subtypes, as suggested by evidence that GHS analogues devoid of any GH-releasing effect stimulate food intake.

Peripheral ghrelin could reach GHS-R in the hypothalamus through the general circulation to regulate food intake and energy homeostasis. Ghrelin-containing cells are also present in the mediobasal hypothalamus, where GHRH-secreting neurons and the neuroendocrine network regulating energy balance are located.

Effects on Behavior

In mice, ghrelin induces anxiogenic activities after both intracerebroventricular and intraperitoneal administration, an effect that is significantly inhibited by the administration of a CRH receptor antagonist. These findings suggest that ghrelin may play a role in mediating neuroendocrine and behavioral responses to stressors and that the stomach could play an important role, not only in the regulation of appetite, but also in the regulation of anxiety.

Gastro-entero-pancreatic Actions

It is not surprising that, as a gastric hormone, ghrelin acts at the gastro-entero-pancreatic level, where GHS-R type 1a have been demonstrated. Interestingly, there is also a close structural and functional similarity between motilin and ghrelin. Also, the gastrointestinal motilin receptor 1A and the GHS-R type 1a show a high degree of structural homology.

Ghrelin stimulates gastric acid secretion and motility. Interestingly, these actions are mediated by the cholinergic system, at least partially, at the central level.

Moreover, ghrelin exerts a potent inhibitory effect on pancreatic cholecystokinin-induced exocrine secretion in rats via modulation of intra-pancreatic neuron activities.

It should be noted that the endocrine cells of the stomach may undergo both hyperplastic and neoplastic phenomena and even silent gastric carcinoids often synthesize ghrelin. These might represent conditions of ghrelin hypersecretion, whereas gastrectomy is associated with a 65% reduction in circulating ghrelin levels. The clinical impact of ghrelin hyper- and hyposecretion is still unknown.

Cardiovascular Actions

In the cardiovascular system, both GHS-R type 1a and specific binding sites for only peptidyl GHS have been reported, suggesting the coexpression of different GHS-R subtypes.

Peptidyl GHS markedly protects against cardiovascular ischemic damage and improves cardiac performance in normal rats and in different animal models of GH deficiency, ischemic heart disease, or dilated cardiomyopathy. On the other hand, acute administration of high-dose peptidyl GHS induces transient coronary vasoconstriction via activation of the binding glycoprotein CD36.

In humans, hexarelin, a peptidyl GHS, increases the left ventricular ejection fraction in normal subjects, in hypopituitary patients with severe GH deficiency (GHD), and in patients with ischemic dilated cardiomyopathy. Although ghrelin has been reported to be devoid of cardioprotective effects, its chronic administration has been shown to improve cardiac contractility and to reduce systemic vascular resistance in GHD rats and in rats with chronic heart failure.

In humans, independent of GH-IGF-I and nitric oxide systems, ghrelin significantly decreases systemic vascular resistance and mean arterial pressure and increases cardiac index and stroke volume index in normal subjects and in patients with chronic heart failure. The vasodilating activity of ghrelin has been attributed to antagonism of endothelin-1.

Antiproliferative Actions

GHS-R have been also found in neoplastic endocrine and nonendocrine tissues even from organs that do not express these receptors under physiological conditions, such as the breast.

Both normal and neoplastic thyroid tissues express GHS-R and ghrelin, at least in parafollicular cells.

Both ghrelin and synthetic GHS inhibit cell proliferation of thyroid follicular, papillar, and anaplastic tumor cell lines.

GHS-R was also shown in breast tumors but not fibroadenomas and normal mammary parenchyma. Both ghrelin and synthetic GHS inhibit cell proliferation in different human breast (estrogen-dependent and estrogen-independent) carcinoma cell lines. The same effect is shared by nonacylated ghrelin, indicating that this is a non-GHS-R type 1a-mediated action.

Neuroendocrine carcinoid tumors and even adenocarcinomas of the lung express specific GHS-binding sites. Synthetic peptidyl GHS, but not ghrelin, inhibit human CALU-1 lung cancer cell line proliferation.

On the other hand, the prostate cancer cell line PC-3 shows increased cell proliferation *in vitro* after exposure to ghrelin, suggesting that autocrine-paracrine pathways involving ghrelin might be capable of stimulating cell proliferation (at least of this cell line).

CLINICAL PERSPECTIVES

GHS have been considered to represent a potential diagnostic and therapeutic tool based on their strong and reproducible GH-releasing effect even after oral administration.

Particularly when combined with GHRH, GHS represent one of the most potent and reliable tests to evaluate the pituitary GH-releasable pool for the diagnosis of GHD, provided that appropriate cutoff limits are assumed.

On the other hand, the promise of GHS as growth-promoting factor in children with GHD and as an anti-aging drug has not been fulfilled thus far.

Due to evidence that ghrelin possesses other relevant endocrine and nonendocrine actions, the possibility that ghrelin and/or GHS analogues, acting as either agonists or antagonists on different GH-unrelated activities, might have clinical impact in internal medicine, metabolism, gastroenterology, immunology, oncology, and cardiology has been suggested and is receiving increasing attention.

CONCLUSIONS

Ghrelin, a 28-residue acylated peptide predominantly produced by the stomach, displays strong GH-releasing action but also shows other central and peripheral endocrine and nonendocrine actions via the activation of the GHS-R. Indeed, ghrelin isolation helped elucidate GH-IGF-I physiology but also

opened new promising perspectives in other medical fields, such as internal medicine, gastroenterology, immunology, oncology, and cardiology. Researchers are working on the possibility that ghrelin and/or GHS analogues may have potential diagnostic or therapeutic application.

The neuroendocrine theory of aging evolved from observations that animals exhibit predictable and progressive impairments in a number of physiological processes with time, including, but not limited to, decreases in reproductive and immune function, decreases in muscle mass and function, accumulation of adipose tissue, and decreases in glucose utilization and cognitive function. The role of the neuroendocrine system in these processes was related to the observations that many of the hormones regulated by the neuroendocrine system had an important trophic and integrative role in maintaining tissue function and that withdrawal of hormonal support mimicked some of the phenotypes observed in aging animals and humans.

The neuroendocrine system includes the hypothalamus and associated brain structures as well as the pituitary gland. This system includes neurotransmitters and neuropeptides within the brain that regulate hypothalamic-releasing and-inhibiting hormones secreted into hypophysial portal blood that reaches the pituitary gland. The release of these hormones influences the secretion of anterior pituitary hormones into the bloodstream and subsequently regulates tissue function. The posterior pituitary is also an important part of the neuroendocrine system; however, in contrast to the anterior pituitary gland, it is composed of long axons from specific hypothalamic nuclei. The hypothalamus and pituitary gland have the capacity to detect neural activity and/or humoral secretions from target tissues and adjust activity to maintain an optimal internal environment or "milieu" for tissue function. It is well established that the neuroendocrine system has critical roles in regulating tissue growth and metabolism through the release of growth hormone and thyroid-stimulating hormone; reproductive function through the release of luteinizing hormone (LH), follicle-stimulating hormone (FSH), and prolactin; and plasma electrolytes and responses to stress through secretion of vasopressin and adrenocorticotropin (ACTH), respectively. In addition, the hypothalamus also has an important role in the integration of parasympathetic and sympathetic nervous system activity and can thereby affect a wide variety of functions, including heart rate, blood pressure, vascular responses, and glucose metabolism. The hypothalamus also regulates biological rhythms. Recently, fat metabolism and food intake were shown to be regulated through the hypothalamus by its response to leptin and the synthesis of neuropeptide Y and other orexigenic peptides. Unfortunately, the categorization of hormones and their primary function noted previously is an overly simplistic view of the neuroendocrine system since critical interactions

occur between hormones that contribute to the regulation of cellular function. Because many of the early events of aging include alterations in systems regulated by the neuroendocrine axis, it was proposed (and subsequent studies supported the conclusion) that age-dependent alterations in the neuroendocrine system result in a progressive series of events that are manifest as biological aging.

Although the etiology of the age-related changes in the neuroendocrine system is unknown, it has been proposed that cellular and molecular events in specific subpopulations of neurons within the hypothalamus and brain and/or supporting structures are a contributing factor in the dysregulation of this system. The cause of the specific perturbations may be related to genetic errors or increased free radicals that lead to progressive aberrations in tissue function. As a result, the neuroendocrine theory of aging is unique compared to other theories of aging in that alterations in this system are not considered the primary causative factor in biological aging but rather are important mediators of aging initiated by cellular changes in specific subpopulations of neurons or systems that closely interact with hypothalamic neurons. In this article, the major alterations within the neuroendocrine axis are discussed, with emphasis on the regulation of growth hormone since it exhibits some of the more important physiological changes that occur with age.

GROWTH HORMONE AND INSULIN-LIKE GROWTH FACTOR-I

Since the early 20th century, it was known that a substance present in blood promotes growth, but it was only after the isolation of pure bovine growth hormone from the pituitary gland in 1945 that the biological effects of the hormone became evident. It was subsequently shown that growth hormone stimulates cellular amino acid uptake and DNA, RNA, and protein synthesis, and that it has a role in cellular division and hypertrophy.

Plasma levels of growth hormone reveal a pattern of discrete pulses that increase after the onset of sleep. Although the precise function of this ultradian pattern remains unknown, the pulsatile release of growth hormone has been confirmed in every species examined and is closely related to the biological actions of the hormone. Growth hormone in humans is characterized by relatively low-amplitude pulses throughout the day and a large pulse after the onset of sleep. In rats, growth hormone is characterized by an ultradian rhythm with high-amplitude secretory pulses every

3–3.5 h; between pulses, growth hormone decreases to almost undetectable levels. This secretory pattern is regulated by two hormones released from the hypothalamus: growth hormone-releasing hormone (GHRH), which increases growth hormone release, and somatostatin, which inhibits growth hormone release. The results of several studies suggest that both hormones are secreted in a phasic manner, with GHRH contributing to high-amplitude growth hormone pulses and somatostatin to trough levels. A dynamic interrelationship between these hypothalamic hormones is necessary for pulsatile secretion. A number of other factors either within the hypothalamus or circulating in plasma contribute to the regulation of growth hormone release either by acting directly on the pituitary gland or by regulating hypothalamic somatostatin and GHRH secretion. Both growth hormone and insulin-like growth factor-1 (IGF-1) inhibit growth hormone secretion in a typical feedback relationship: These hormones increase somatostatin and decrease GHRH release from the hypothalamus.

Recently, there has been increased interest in small peptides that stimulate the release of growth hormone. One of these peptides, Ghrelin, is produced in the stomach and stimulates growth hormone release. Although it does not interact with the GHRH receptor, it has been shown to act synergistically with GHRH to regulate both growth hormone release and possibly food intake. This peptide is particularly important since oral administration of peptide and non-peptidyl analogs of Ghrelin increase growth hormone secretion.

Although growth hormone is one of the most potent anabolic factors in the body, most of the anabolic actions of the hormone are regulated through the secretion of another hormone, IGF-1. IGF-1 binds with high affinity to the type 1 IGF receptor found in tissues throughout the body. The IGF-1 receptor shares 50% amino sequence homology with the insulin receptor, and competitive binding and affinity cross-linking studies have demonstrated that IGF-1 binds to the insulin receptor with 100 times lower affinity than the IGF-1 receptor. IGF-1 is synthesized mainly in the liver under the regulation of growth hormone but is also synthesized in smaller quantities in almost all tissues. Although regulation of local IGF-1 production or paracrine activity is poorly understood, this represents an important source of the hormone that also appears to be regulated by growth hormone.

IGF-1 secreted from liver circulates in the blood either free or bound to specific binding proteins that prolong the half-life of the peptide. At least six binding

proteins have been identified and constitute an intricate transport system for the IGFs that regulate their availability to specific tissues. It is clear that IGF binding proteins are important regulators of IGF-1 activity and may have actions independent of IGF-1.

The actions of growth hormone are not entirely mediated through IGF-1, and in muscle and adipose tissue growth hormone can have direct effects. Specifically, growth hormone decreases insulin sensitivity by direct effects on skeletal muscle and increases free fatty acids (and decreases fat mass) by increasing the activity of hormone-sensitive lipase in adipose tissue. These findings have led to the concept that the primary anabolic actions of growth hormone are mediated through IGF-1 (through either endocrine or paracrine regulation) and that the effects of growth hormone on fuel utilization are mediated by direct actions on muscle and adipocytes.

Alterations in the neuroendocrine axis and specifically in the regulation of growth hormone have an important role in the physiological and biochemical changes normally associated with aging. Early studies in humans indicated that the amplitude of growth hormone pulses and the increase in the concentrations of growth hormone were blunted after insulin-induced hypoglycemia. Subsequent studies demonstrated a prominent decrease in the amplitude of growth hormone pulses in aged animals, although there were no changes in either the basal concentrations or the ultradian rhythm of growth hormone. The decline in growth hormone results in a progressive reduction in plasma concentrations of IGF-1 in both animals and humans. Subsequent studies in various strains of rats and mice, nonhuman primates, and humans have consistently confirmed the decline in growth hormone and IGF-1 concentrations with age and suggest that these are a robust marker of biological aging in mammalian species.

Traditionally, endocrinologists investigated the impact of hormone deficiency by replacement therapy. Initial investigations demonstrated that purified growth hormone preparations reversed the age-related decline in protein synthetic capacity. Although these studies did not address the question of whether tissue response to growth hormone diminished with age, they clearly indicated that cellular protein synthesis decreases with age in an environment of reduced growth hormone and IGF-1 levels and that growth hormone and/or IGF-1 replacement have the capacity to increase protein synthesis in aged animals. Thus, the age-related decline in tissue function results, at least in part, from deficits within the neuroendocrine system.

Subsequent studies demonstrated that growth hormone or IGF-1 administration could partially reverse the decline in immune function; increase the expression of aortic elastin, lean body mass, skin thickness, and vertebral bone density; and improve cognitive function in aged animals and humans. Although the beneficial effects of growth hormone administration have been repeatedly confirmed, deleterious side effects of growth hormone replacement severely limit its usefulness as a treatment to modulate physiological changes with age. For example, growth hormone increases cartilage growth and contributes to carpal tunnel syndrome, increases glucose levels contributing to diabetes, and, in several cases, has been found to increase pathology. In fact, elevated IGF-1 levels are a risk factor for breast, gastrointestinal, prostate, and lung cancer. Nevertheless, it is evident that decreases in growth hormone and IGF-1 have clinical significance and are a contributing factor in the genesis of tissue dysfunction in aged animals and humans, although replacement therapy in the elderly population is currently unwarranted.

ACTH, CORTISOL, AND ADRENAL FUNCTION

One of the controversies regarding neuroendocrine aging is whether the regulation of ACTH and cortisol is altered in aged animals and humans and the significance of these changes for the development of the aged phenotype. ACTH released from the pituitary gland is regulated by a synergistic action between corticotropin-releasing hormone and vasopressin on the pituitary. ACTH released into the blood subsequently stimulates activity of an enzyme within the adrenal gland that results in the conversion of cholesterol to pregnenolone, initiating the biosynthetic pathway for the synthesis of cortisol (in humans and nonhuman primates) or corticosterone (in rodents). These hormones have a diurnal rhythm, with highest levels usually observed at the end of the dark phase of the light–dark cycle. Cortisol and corticosterone exert a major role in response to stress and the regulation of immune function but are also important factors in fat metabolism and glucose regulation. Increased blood levels result in an increase in free fatty acids through their actions on hormone-sensitive lipase in adipocytes and glucose levels by stimulating gluconeogenesis and glycogenolysis and decreasing tissue sensitivity to insulin. Furthermore, elevated levels of cortisol or corticosterone result in protein degradation in skeletal muscle that causes a muscle-wasting condition similar to that found in aged animals and humans.

The similarities between the physiological changes that accompany excess cortisol secretion and the aging phenotype have led to the hypothesis that cortisol secretion increases with age (the glucocorticoid hypothesis of aging). However, the results from analyses of basal corticosterone and cortisol levels have been controversial, with investigators reporting either no change or increased basal levels of the hormones. Since ACTH and cortisol levels can be dramatically influenced by environmental variables, it is probable that many of these differences can be reconciled by differences in time of blood sampling and/or variations in animal housing conditions that produce minor stresses that differentially affect young and old animals. Similarly, in humans, there appear to be few differences in the diurnal levels of ACTH or cortisol. Perhaps the most important differences between these hormones occur when animals and humans are assessed under conditions of mild stress. In response to stressors, similar acute increases in hormone levels are noted with age but the levels of the hormones remain elevated for longer periods of time in older subjects, leading to the conclusion that relatively small but important increases in cortisol and corticosterone occur. The consequences of the potential age-related increases in corticosterone or cortisol for the development of tissue impairments associated with age are unknown. Certainly, high levels of these hormones (independent of age) have been associated with atrophy of brain structures linked to learning and memory (e.g., the hippocampus), loss of muscle and bone mass, and diminished insulin sensitivity, whereas a reduction in the levels of these hormones has been reported to delay or prevent age-related changes in the hippocampus. Whether blood levels of glucocorticoids or alterations in brain response to glucocorticoids are an important part of the normal cognitive decline with age remains to be determined.

Interestingly, there are several reports of a reduced ability of ACTH to stimulate adrenal hormone synthesis and release with age, consistent with the reduction of other adrenal hormones indirectly regulated by ACTH. Aldosterone (involved in sodium regulation) decreases modestly with age, whereas there is a profound decrease in the weak androgen, dehydroepiandrosterone (DHEA). Age-related changes in these latter hormones appear to be the result, at least in part, of a reduced response to ACTH (in the case of aldosterone) and a profound loss of specific cells in the adrenal gland that produce DHEA. The significance of alterations in these hormones is beyond the scope of this article and is detailed elsewhere in this encyclopedia.

LH/FSH/PROLACTIN AND REPRODUCTIVE FUNCTION

Although it is well recognized that the primary cause of reproductive decline in women is an age-related loss of follicles from the ovary, alterations in hypothalamic and pituitary regulation of reproductive function play an important role in reproductive decline in both genders. Similar changes within neuroendocrine structures responsible for regulating reproductive function have been noted in nonhuman primates and rodents. In both males and females, reproductive function is regulated by the secretion of gonadotropin-releasing hormone (GnRH) from the hypothalamus, which stimulates the release of the gonadotropins, FSH and LH, from the anterior pituitary gland. These hormones are secreted in a pulsatile manner to regulate gonadal function. In the male, FSH regulates spermatogenesis and LH stimulates testosterone production within specific cells of the testis. Sex steroids and other gonadal-derived hormones inhibit the secretion of GnRH from the hypothalamus and LH and FSH release from the pituitary gland. In the female, FSH regulates folliculogenesis and estrogen secretion, whereas LH stimulates luteinization of the mature follicle as well as estrogen and progesterone secretion. The cyclical release of hormones in the female requires a complex interaction between steroid secretion from the ovary, the detection of alterations in hormone levels by the hypothalamus and pituitary, the integration of physiological responses that lead to a midcycle surge of gonadotropins, and the preparation of estrogen-responsive tissues (e.g., oviduct and uterus) for fertilization and implantation.

Because of the complex interrelationships between hormone secretion and physiological responses that are necessary to maintain the female menstrual cycle, it is not surprising that alterations in the regulation of this system are some of the most consistent age-related events noted. Prior to the decline in ovarian follicles that is responsible for the onset of menopause in humans, there are decreases in the release of GnRH from the hypothalamus and impaired sensitivity of the pituitary to GnRH stimulation. These changes undoubtedly contribute to irregular menstrual cycles several years before the onset of menopause and may be a contributing factor in the acceleration of follicular loss in the premenopausal years. The resulting decline in estrogen levels leads to atrophy of estrogen-sensitive tissues and appears to be a risk factor for a number of other diseases (e.g., atherosclerosis and osteoporosis).

In rodents, decreased secretion of GnRH from hypothalamic neurons, rather than loss of follicles, is the primary factor leading to a decline in gonadotropins and the loss of reproductive cycles. Rodents typically proceed from regular cycles to irregular cycles, a state of constant estrus, repetitive pseudopregnancy, followed by an anestrus state later in life. Administration of GnRH and several other factors that act through the hypothalamus reinitiate estrous cycles in aged animals. Although the manifestations of reproductive aging are clearly different in human and rodent models, the neuroendocrine alterations (e.g., GnRH release and pituitary response) appear to share common mechanisms. Recent studies suggest that the absence of GnRH release with age may result from lack of plasticity within the hypothalamus and/or interactions between neurons and glia.

In the male, decreased GnRH secretion also contributes to a decline in gonadotropins and subsequently androgen levels, with a corresponding loss of skeletal muscle mass and reproductive function. Although this decrease appears to be consistent in animal models, the decline in humans exhibits greater variability, with many older men demonstrating relatively minor decreases in total or free androgen levels throughout life. Nevertheless, testosterone replacement in androgen-deficient individuals has been shown to reverse the age-related decline in muscle mass and other aspects of reproductive function.

Prolactin secretion from the anterior pituitary is tonically inhibited by dopamine release from tuberoinfundibular neurons within the hypothalamus. This hormone has a role in the maintenance of luteal function during the menstrual cycle of the female and is responsible for milk production in the postpartum female. With increasing age, the production of dopamine is decreased, resulting in hypertrophy and hyperphasia of prolactin-secreting cells within the pituitary. In rodent models, prolactin levels generally increase in plasma, which may contribute to the genesis of mammary tumors. In many strains, prolactin-secreting pituitary tumors develop that may suppress reproductive function (through actions on GnRH release) and/or interfere with the secretion of other anterior pituitary hormones by mechanical displacement. Although the specific etiology of the decrease in dopamine release with age is poorly understood, data suggest that high levels or prolonged estrogen treatment may damage tuberoinfundibular neurons. In humans, prolactin microadenomas are commonly observed in the elderly at autopsy, but the increase in prolactin levels is not sufficient in many cases to produce significant pathology.

THYROID-STIMULATING HORMONE, TRIIODOTHYRONINE, THYROXINE, AND THYROID FUNCTION

Metabolism is regulated by plasma levels of triiodothyronine (T_3) and thyroxine (T_4). T_3 has greater biological activity than T_4 , and tissues express enzymes that convert T_4 to T_3 (e.g., deiodinase). Levels of these hormones regulate the basal metabolic activity and function of numerous tissues. T_3 and T_4 are controlled by feedback regulation of thyroid-stimulating hormone released from the anterior pituitary gland. Apart from specific thyroid diseases, there appear to be subtle changes in the levels of thyroid hormones with age. There appears to be a reduction in deiodinase activity, which may lead to a reduction in levels of T_3 within target organs, but the significance of these changes for the development of physiological changes in tissue function has not been determined.

POSTERIOR PITUITARY HORMONES

The posterior pituitary hormones, oxytocin and vasopressin (also known as antidiuretic hormone), regulate myometrial and myoepithelial contractions in the female and water balance in both genders, respectively. In response to decreased blood volume/pressure or increased plasma osmolality, vasopressin constricts arterioles and increases water transport in the kidney. Both oxytocin and vasopressin have a diurnal rhythm that diminishes with age, but the significance of this decrease is ill defined. In response to water deprivation, studies suggest that there are no major impairments in either rodent models or humans with age. However, the results of other studies suggest an attenuated response to oropharyngeal factors that regulate vasopressin and/or alterations in kidney response to vasopressin with age. The significance of these changes for the regulation of water balance in the elderly population remains to be determined.

CONCLUSION

Alterations in the neuroendocrine system contribute to physiological manifestations of aging. Decreases in growth hormone and IGF-1, for example, are important factors in the accumulation of body fat mass, the reduction in cellular protein synthesis, and impairments in some aspects of immune function with age. Similarly, alterations in the neuroendocrine regulation of reproductive function are responsible for cessation of cyclicity in female rodents, whereas in humans the

decline in reproductive function is related primarily to a loss of follicles that is exacerbated by neuroendocrine impairments. In the male, neuroendocrine alterations are a contributing factor to the decline in androgens with age. Although the specific etiology of the age-related neuroendocrine dysfunctions is unknown, increases in oxidative damage in specific hypothalamic nuclei, impairments in neurotransmitter levels and turnover, and diminished plasticity within hypothalamic nuclei are some of the potential mechanisms.

An alternative explanation for the alterations within the neuroendocrine system is that an active regulation of hypothalamic function exists throughout the life span. Decreases in growth hormone and IGF-1, for example, are initiated immediately after puberty and decline progressively with age. In fact, age-related events within this system may be consistent with a model of antagonistic pleiotropy, a recently described theory on the evolution of aging that suggests that the expression of particular genes is beneficial early in life but becomes detrimental as the organism ages. Certainly, the beneficial actions of growth hormone and IGF-1 on muscle mass early in life would be expected to increase general as well as reproductive fitness, whereas continued high levels may increase pathology and limit life span. Thus, the age-related decrease in growth hormone and IGF-1 may be a physiologically regulated, adaptive process rather than the result of damage to specific hypothalamic nuclei. The potential significance of such changes for this and other systems regulated by the neuroendocrine axis awaits further investigations.

Table I Diagnostic Criteria for NF1

Two or more criteria are necessary for a diagnosis of NF1:

- Six or more café-au-lait spots >5 mm in greatest diameter in prepubertal individuals and >15 mm in greatest diameter in postpubertal individuals
- Two or more neurofibromas of any type or one or more plexiform neurofibromas
- Freckling in the axillary or inguinal region
- Two or more Lisch nodules (iris hamartomas)
- Optic pathway glioma
- A distinctive osseous lesion, such as sphenoid dysplasia or thinning of long bone cortex, with or without bowing and pseudoarthrosis
- A first-degree relative (parent, sibling, or offspring) with NF1 according to the preceding criteria

of Schwann cells, perineural fibroblasts, endothelial cells, and mast cells.

Dermal Neurofibromas

Dermal neurofibromas are cutaneous or subcutaneous tumors that originate from terminal nerve branches in the skin (Fig. 2). Cutaneous neurofibromas are characteristically reddish-bluish, soft, and nearly gelatinous to touch. Subcutaneous neurofibromas are discrete spherical or ovoid shaped and often firm to touch; they are more often tender or painful. Both types generally appear prior to puberty and develop mainly on the trunk. During adulthood, these benign tumors may become a major cosmetic burden. A large study on pregnancy outcome in NF1 patients reported growth of new neurofibromas in 60% of cases and enlargement of existing neurofibromas in 52%.

Table II Diagnostic Criteria for NF2

Individuals with the following clinical features definitely have NF2:

- Bilateral (VS) *or*
- Family history of NF2 (first-degree relative) *plus*
- Unilateral VS < 30 years *or*
- Any two of the following: meningioma, glioma, schwannoma, juvenile posterior subcapsular lenticular opacities/juvenile cortical cataract

Individuals with the following clinical features possibly have NF2:

- Unilateral VS < 30 years *plus* at least one of the following: meningioma, glioma, schwannoma, juvenile posterior subcapsular lenticular opacities/juvenile cortical cataract
- Multiple meningiomas (two or more) *plus* unilateral VS < 30 years *or* one of the following: glioma, schwannoma, juvenile posterior subcapsular lenticular opacities/juvenile cortical cataract

Note. VS, vestibular schwannomas.

Figure 1 Café-au-lait spots and skin fold freckling in the axilla.

Plexiform Neurofibromas

Plexiform neurofibromas originate from major peripheral nerves and, as a consequence, may cause severe complications (Fig. 3). They are present in approximately one-third of the NF1 population and are congenital, although they may present later due to growth. The overlying skin may be abnormal, with signs of hypertrophy, hyperpigmentation, or hypertrichosis. Two types of plexiform neurofibromas have been described. Diffuse plexiform neurofibromas are soft subcutaneous swellings with ill-defined margins. Nodular plexiform neurofibromas are ovoid or spherically shaped, feel firm, and are well circumscribed. Extension into adjacent tissues must always be suspected because particularly diffuse plexiform neurofibromas grow with numerous finger-like fronds.

Lisch Nodules

Lisch nodules are small pigmented benign hamartomas of the iris, presenting at slit lamp presentation. They are seen in 92% of NF1 patients over 6 years of age. As a consequence, these iris hamartomas are of great diagnostic importance for NF1.

Optic Pathway Glioma

Optic pathway glioma (OPG), or pilocytic astrocytoma of the optic pathway, is an important complication of NF1 during childhood. In general, OPG associated with NF1 is less progressive than OPG without NF1. Symptomatic OPG seldom appears after 6 years of age. Listerick and colleagues reported OPG in 33 of 176 (19%) NF1-affected children after routine screening with magnetic resonance imaging (MRI). However, only half of these children developed glioma-associated signs or symptoms, and

progression of tumor growth and deteriorating vision were observed in only 3 children (9%).

Osseous Lesions

Osseous lesions specific for NF1 are sphenoid wing dysplasia and congenital bowing or thinning of long cortical bones with or without pseudoarthrosis. Sphenoid wing dysplasia is rare in NF1 patients but occasionally may present with pulsatile exophthalmia. Congenital bowing is generally located in the tibia or fibula. It is reported in 3% of NF1 patients. However, NF1 has been implicated in more than half of cases of congenital pseudoarthrosis of the tibial bone.

Minor Disease Features

Physical Characteristics

In addition to the diagnostic signs, physical characteristics such as macrocephaly (53%), hypertelorism

(63%), thorax abnormalities (e.g., pectus excavatum, pectus carinatum) (38%), and short stature (25%) are observed more frequently than in the general

Figure 2 Dermal neurofibromas.

Figure 3 Plexiform neurofibroma located on the upper left arm.

population. The “facies neurofibromatosis,” as described by Lin, encompasses hypertelorism, a broad nasal bridge or root, pigmentary abnormalities (“dirty skin”), and facial asymmetries. Furthermore, a variety of mild to severe learning difficulties, including motoric speech and behavioral problems such as attention deficit hyperactivity disorder, are common.

Hyperintense Regions on T2-Weighted MRIs

An additional minor disease feature is the “increased intensity” lesions on T2-weighted MRIs or “unidentified bright objects” that are typically seen in the basal ganglia, thalamus, cerebellum, and brainstem regions of the brain in up to 79% of NF1 patients. Some discussion has evolved to include these typical lesions as a diagnostic criterion. They present as well-circumscribed, hyperintense foci, nonenhancing after administration of contrast medium, without mass effect, and resolving with increasing age (average age of presentation: 7 years). Histopathologically, the hyperintense regions on T2-weighted MRIs correspond to areas of vacuolar or spongiotic change. Correlations have been found between these lesions and learning difficulties. However, studies are not decisive. These lesions should be carefully differentiated from brainstem tumors that cause focal or diffuse brainstem enlargement, present with mass effect, and cause gadolinium enhancement.

COMPLICATIONS AND MANAGEMENT

Complications in NF1 patients may occur in every organ or tract and may cause severe morbidity or even mortality. It does not seem possible to differentiate

between patients at high risk for complications and those at low risk for complications as risk factors for development of complications have not been identified and incidence rates of complications do not differ significantly between groups of children with complications at presentation and those without complications at presentation. Therefore, regular screening by an experienced team (every 1–2 years), even in groups without complications, seems justified.

Plexiform Neurofibromas

Depending on their localization and symptomatology, plexiform neurofibromas may cause considerable morbidity such as functional disturbances, neurological deficits, and cosmetic disfigurement. Moreover, malignant degeneration into a malignant peripheral nerve sheath tumor (neurofibrosarcoma or malignant schwannoma) occurs in 5% of plexiform neurofibromas. Alarming signals include growth and tenderness. In those cases where surgery is indicated, complications as bleeding and recurrence of the tumor are well-known problems. In general, excessive bleeding is caused by vascular abnormalities and the presence of mast cells within plexiform neurofibromas. Total excision of a plexiform neurofibroma is usually impossible due to finger-like fronds that insinuate themselves into adjacent tissues.

Optic Pathway Gliomas and Other Ophthalmological Abnormalities

The NF1 OPG task force recommends annual ophthalmological examinations by an experienced ophthalmologist until 6 years of age, supplemented by visual field evaluations when possible and, most important, visual-evoked potentials (VEPs) given the fact that they monitor the functioning of the optic pathway (Table IV). Evidence of dysfunction of the optic nerve should be followed by MRI of the brain, with contrast enhancement and special attention to the orbits (Table V). Management of children with OPG depends on the localization of the tumor; chiasmatic tumors have been reported to progress more frequently and may be accompanied by hormonal disturbances. If clinical progression is observed, treatment may be indicated and may include chemotherapy or (less commonly) radiation therapy or surgery.

Other ophthalmological problems, such as congenital ptosis, cornea abnormalities, strabismus, and myopia, do not seem specific to NF1.

Table IV Ophthalmological Screening Protocol According to the NF OPG Task Force

All children under 6 years of age: once yearly complete examination
 All newly diagnosed NF1 patients: complete examination
 Follow-up schedule of children over 6 years of age:
 Ages 8, 13, 20 years: short examination
 Ages 10, 16, 25 years: complete examination
 Complete ophthalmological examinations should be performed whenever signs or symptoms suggest an ophthalmological abnormality

Note. Complete examination = visual acuity, color vision, visual fields (when possible) and visual-evoked potentials, eye movements, papillary light responses, refractive status, fundoscopy, (indirect and direct), and slit lamp examination. Short examination = visual acuity, color vision, and slit lamp examination.

Orthopedic Problems

In addition to the earlier described osseous lesions, scoliosis and hemihypertrophy are associated with NF1 and occur in 2.0 and 2.5% of patients, respectively. Congenital bowing must be monitored by an orthopedic surgeon with experience in NF1 as prevention of bone fractures and pseudoarthrosis is essential. Atlantoaxial dislocation in patients with abnormalities of the cervical spine is a severe complication in NF1 patients undergoing situations associated with traction and hyperextension of the spine such as intubation during general anesthesia. Bidirectional cervical vertebral column X rays, and supplementary flexion–extension imaging in case of abnormalities, is recommended.

Neurological Symptoms

Mental retardation has been reported in 3 to 15% of NF1 patients. Many of these studies are biased in that they consist of a high frequency of severely affected patients. A slightly increased risk of epilepsy, which is

Table V Ophthalmological Follow-up Protocol for Children with OPG According to the NF1 OPG Task Force

| Time interval following diagnosis | Complete ophthalmological examination | MRI |
|-----------------------------------|---------------------------------------|----------------|
| First year | Every 3 months | Every 6 months |
| Second year | Every 6 months | Every 6 months |
| Thereafter | Yearly | Yearly |

Note. If there is no evidence of progression 2 years after diagnosis, the interval may be increased gradually.

only partly accounted for by macroscopic abnormalities, has been reported. Also, it has been suggested that headache of various types (e.g., tension headaches, migraines) may be more common in NF1 patients than in the general population. Although high prevalences of psychiatric illness have been reported, these have not been confirmed by others.

Endocrinological Abnormalities, Short Stature, and Hypertension

Precocious puberty, delayed puberty, and growth hormone (GH) deficiency are more frequent in children with NF1 than in the general population. Therefore, deviations from the growth curve and premature manifestations of puberty should be recognized as possible complications of NF1. Although central precocious puberty (CPP) in NF1 patients may be associated with OPG, several studies have reported children with NF1 and CPP or GH deficiency without OPG. Possible mechanisms may be slow-growing hamartomas, undetectable at the neuroimaging level, or abnormalities at the cellular level given that the protein encoded by the NF1 gene, neurofibromin, plays a regulating role in signal transduction pathways. No adverse side effects of treatment with luteinizing hormone-releasing hormone (LHRH) analogues or recombinant human GH have been reported, although continuous monitoring is recommended.

Short stature is observed in 25% of NF1 patients and is often without endocrinological basis. Hypertension in NF1 patients may be associated with either renal artery stenosis or pheochromocytoma. In children with NF1, pheochromocytoma is quite rare. However, 5 to 25% of adult patients with pheochromocytoma are reported to have NF1.

Malignancies

A descriptive analysis by Friedman and Birch of nearly 1800 NF1 patients observed malignancies (excluding OPG) in approximately 7.0% of probands and 4.5% of affected relatives. In addition to malignant peripheral nerve sheath tumors that may arise in preexisting plexiform neurofibromas, astrocytomas, juvenile chronic myeloid leukemia, rhabdomyosarcoma, adenocarcinoma of the ampulla Vater, and duodenal somatostatinoma have been reported to be associated with NF1. Moreover, secondary tumors develop in 21% of NF1 patients with primary malignancies in comparison with 4% of the general population. Brainstem tumors have been described as being less

aggressive in NF1 patients than in those not affected by NF1.

MOLECULAR GENETICS

Gene, Protein, and Mutation Analysis

In 1990, the NF1 gene was mapped to chromosome 17q11.2. The gene spans a region of about 350 kb of genomic DNA, contains approximately 60 exons, and encodes an 11- to 13-kb mRNA that is markedly expressed in neurons, oligodendrocytes, and nonmyelinating Schwann cells. Three genes are embedded within intron 27: EV12A, EV12B, and OMGP. Interestingly, these genes are transcribed in the opposite direction of the NF1 gene (Fig. 4).

The protein encoded by the NF1 gene, neurofibromin, consists of 2818 amino acids with a predicted molecular mass of 327 kDa. Various studies report that neurofibromin is involved in microtubule-mediated signal transduction pathways. In addition, a certain region of the predicted protein product shows homology to the GTPase-activating protein (GAP) family in yeast and mammals. The GAP-related domain (NF1-GRD) of neurofibromin is the only known functional domain of the NF1 gene and plays a role in the regulation of cellular proliferation and differentiation through hydrolysis of active RAS-GTP into inactive RAS-GDP (Fig. 5).

Mutations in the NF1 gene are spread throughout and are of different types and sizes. Most unrelated patients have their own unique mutation. Genotype-phenotype relationships have not been found with the exception of correlations between large deletions, encompassing the entire NF1 gene, and a severe phenotype with mental retardation and possibly early presentation of dermal neurofibromas. Modifying

Figure 4 The NF1 gene location and size, with embedded genes. Illustration shows the NF1 gene transcript and protein with only known functional domain, NF1-GRD.

Figure 5 (A) Hydrolysis of active RAS-GTP into inactive RAS-GDP by neurofibromin. Cell proliferation is regulated. (B) Loss of function of neurofibromin, leading to high levels of active RAS-GTP. Cell proliferation is no longer regulated.

genes may play a role in the extreme clinical variability of the disease. Candidate genes have not been identified.

Mutation Rate and Mosaicism

The high mutation rate of 1×10^{-4} per gamete per generation of the NF1 gene is impressive and cannot be explained by the large size of the gene alone. Various biological mechanisms may be responsible, including the presence of many NF1 pseudogenes in the genome, a high frequency of methylatable CpG residues within the NF1 gene that are prone to mutations, and particular sequence patterns predisposing toward insertions and/or deletions.

Genetic mosaicism may occur more often in NF1 than in other genetic diseases due to the high mutation rate. Genetic mosaicism is a condition in which genetically distinct cell populations are observed within one individual. Mutations during early embryonic development, before the determination of the germ line, will cause gonosomal mosaicism (affecting both somatic tissues and the germ line). Mutations occurring later may affect either the germ cells alone (germ line mosaicism) or the somatic cells alone (somatic mosaicism). This phenomenon has important implications for mutation analysis and genetic counseling in NF1 because risks for affected offspring are higher when germ line cells are affected.

Tumor Suppressor Gene

Characteristic of an autosomal dominant disorder (mosaics are not taken into account) is that all body cells have one wild-type (normal) allele and one mutated allele of the disease gene. If the gene involved is a tumor suppressor gene, tumor formation takes place when a mutation or “second hit” occurs in the wild-type allele. This leads to complete lack of functional

protein and loss of “tumor suppression.” Such is the case in NF1; absence of neurofibromin leads to defective regulation of proliferation and differentiation of the cell, causing cellular proliferation or tumor growth. A number of symptoms and complications in NF1 (e.g., neurofibromas, malignancies) seem to follow this second hit model by Knudson. This phenomenon has been confirmed at the molecular genetic level. However, other symptoms in NF1 patients, such as learning difficulties, cannot be explained by this model and are more likely due to haploinsufficiency of the gene.

GENETIC COUNSELING

Consultation of a clinical genetics center is highly recommended as information on the inheritance of NF1, its natural history, and the possibilities and limitations of molecular genetic analysis and prenatal diagnosis is essential for patients and family members. Prenatal diagnosis may be offered to NF1 families in which a gene mutation has been detected or the tested intragenic polymorphic markers have proved to be informative (the mutated allele can be followed within an NF1-affected family). Because the probability of genetic mosaics within the NF1 population is high, prenatal diagnosis should be considered and offered to the parents of a *de novo* NF1 patient with an identified mutation. In practice, parents at risk for NF1 in their offspring rarely request prenatal testing. Presumably, the extreme clinical variability of the disorder and the low mortality of the disease, in combination with the fact that mainly familial NF1 patients are eligible for

prenatal testing, leads to a low uptake of prenatal testing.

activities. Dissociation could also be performed by acetic acid dialysis, trichloroacetic acid precipitation, and countercurrent distribution (Fig. 1). From the cathodic fraction obtained by electro dialysis, two

peptides migrating like pure oxytocin and pure vasopressin and having their respective amino acid compositions and activities were isolated by paper zone electrophoresis. On the other hand, the inactive

Figure 1 Dissociation of the “mother molecule,” a noncovalent complex, into vasopressin, oxytocin, and neurophysins by counter-current distribution.

protein, for which we suggested the name neurophysin, was later shown to include two highly homologous components termed MSEL-neurophysin (M, methionine-2; S, serine-3; E, glutamic acid-6; L, leucine-7) and VLDV-neurophysin (V, valine-2; L, leucine-3; D, aspartic acid-6; V, valine-7), according to the residues in positions 2, 3, 6, and 7.

The complex was purified from posterior pituitary glands of ox, sheep, pig, horse, rat, guinea pig, and whale and was revealed to be a four-component assembly containing oxytocin, vasopressin, MSEL-neurophysin, and VLDV-neurophysin. Because of the rough stoichiometry between vasopressin and MSEL-neurophysin, on the one hand, and oxytocin and VLDV-neurophysin, on the other, the hypothesis that each tandem hormone-neurophysin derived from a common precursor was suggested.

The Four-Component Neurohormone-Neurophysin Complex

The first direct data on the common neurohormone-neurophysin precursors were obtained by Sachs and collaborators, who injected [35 S]cysteine into the third ventricle of dogs and removed the hypothalamus 1.5 h later. One-half of the tissue, examined right away, contained proteins but practically no vasopressin, whereas the other half, incubated for 4.5 h in a medium containing puromycin and unlabeled cysteine, yielded a significant amount of a labeled vasopressin. Sachs was able to identify a neurophysin in the dog hypothalamus and to show that biosynthesis and secretion of vasopressin and of this neurophysin are parallel events. Later, Brownstein and colleagues showed that [35 S]cysteine injected into the supraoptic nucleus of the rat is incorporated into 20,000-Da proteins (pI 5.4 and 6.1) that are in time converted into 12,000-Da-labeled proteins reacting with rat neurophysin antiserum. The vasopressin precursor was found to be glycosylated, whereas the oxytocin precursor was not. On the other hand, a glycosylated 39-residue peptide found in the human neural lobe in proportions approximately equivalent to those of neurophysins was suspected of being a constituent of the vasopressin precursor. Finally, in 1982–1983, the amino acid sequences of preprovasopressin and prooxytocin were deduced through cDNA technology by Richter and co-workers. Aside from a signal peptide, provasopressin is organized into three domains and is comprised of vasopressin linked by a processing sequence Gly-Lys-Arg to MSEL-neurophysin, itself linked by an arginine residue to a glycopeptide or copeptin (Fig. 2). Prooxytocin has two domains and is comprised of oxytocin linked by the tripeptide Gly-Lys-Arg to VLDV-neurophysin.

Thus, in approximately a century, a neurohypophysial multiactive compound first was supposed to be a

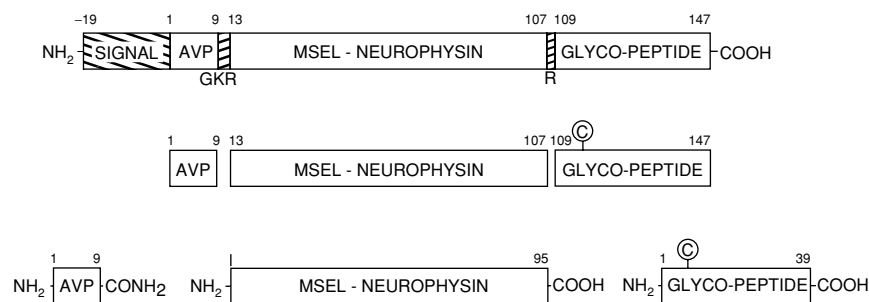

Figure 2 Domain organization and processing of bovine preprovasopressin. Signal, signal peptide; AVP, arginine vasopressin; C, carbohydrate. GKR and R are the enzymatic processing sites.

single protein, the “mother molecule; then was dissociated into four components, two active peptides (oxytocin and vasopressin) and two inactive protein carriers (neurophysins); and finally was shown to originate from two neurohormone–neurophysin tandem precursors. Progressive advances in techniques led to elucidation of the biological status of oxytocin and vasopressin. However, it remains to be explained why these hormones are stored in the glands of most mammals in approximately equal molar amounts despite their very distinct physiological functions. The finding that the human vasopressin gene is closely linked to the oxytocin gene on the same chromosome, the two genes being transcribed on opposite DNA strands, might suggest some relationship in their expressions.

The Two Precursor Genes

The genes of mammalian neurohypophysial hormones, namely those of oxytocin and vasopressin of man, rat, ox, and mice, have been identified by Sausley, Richter, Schutz, and Gainer, respectively, along with their collaborators. They are built in the same way, namely, with the same three-exon organization, with the first exon encoding the signal peptide, the hormonal nonapeptide, the processing tripeptide sequence, and the first 9 residues of neurophysin; the second exon encoding the central part of neurophysin (residues 10–76); and the third exon encoding the C-terminal part of neurophysin (residues 77–93/95) and, for vasopressin genes, an arginine processing site linking to a 37/39-residue glycopeptide or copeptin. The gene product, preprovasopressin, is a four-domain protein (Fig. 2), and this organization is preserved in the nonmammalian tetrapod preprovasotocin. On the other hand, preprooxytocin and its nonmammalian tetrapod counterpart, prepromesotocin, are three-domain proteins, with copeptin extension being absent.

The promoters and the regulatory elements of these genes, as well as their expressions in the central nervous system and the peripheral tissues, have been investigated intensively. Because of a striking similarity in the nucleotide sequences of the second exons of oxytocin and vasopressin genes in all mammalian species investigated, it is assumed that recent gene conversion events occurred. In contrast, the third exons are clearly different. The three exons, and therefore the corresponding encoded peptide sequences, have likely undergone distinct evolutionary fates (composite evolution). Furthermore, mutations in the regions coding for hormones in the first exons should have been limited by the need of the mature peptides to fit specific receptors, whereas the constraints on

neurophysins, if any, seem to be determined by particular interactions, either with endoplasmic reticulum (ER) chaperones or with specific trans-Golgi sequences.

Neurohypophysial hormone genes are also known in lower vertebrates. In nonmammalian tetrapods, mesotocin and vasotocin replace oxytocin and vasopressin, respectively. The chicken vasotocin gene has been identified by Ivell's team; its organization is comparable to that of mammalian vasopressin genes. In the bony fishes, isotocin and vasotocin correspond to mammalian oxytocin and vasopressin. Isotocin and vasotocin genes of a tetraploid catostomid fish, the white sucker *Catostomus commersoni*, and of the tetraodontoid Japanese pufferfish, *Fugu rubripes*, have been characterized by Richter's and Venkatesh's groups, respectively. Whereas in the first species the two vasotocin genes appear to be built essentially like the mammalian neurohypophysial genes (i.e., with a three-exon organization), the two isotocin genes are revealed to be intronless. It is still premature to integrate this unusual feature and to deduce that evolution operated by insertion of introns. The Fugu is remarkable because its genome has been subjected to compaction, with a large part of the usual intergene sequence being deleted and very few repetitive sequences being present. With 400 Mb, the Fugu genome is approximately 7.5 times smaller than the human genome, but it has a gene repertoire similar to that of the human. The two genomes apparently are syntenic. Whereas in mammals the vasopressin and oxytocin genes are closely linked in a tail-to-tail orientation, Fugu vasotocin and isotocin genes are linked head-to-tail and are separated by five genes. A possible peculiar evolution of fish neurohypophysial hormone genes, derived from an ancestral vasotocin gene through an inverted duplication and differentiation of the two copies into isotocin and vasotocin genes and then a fragment of DNA containing the vasotocin gene, has undergone inversion in the *Fugu* lineage. Interestingly, Venkatesh's experiments with transgenic rats reveal functional conservation of regulatory controls between the Fugu isotocin and rat oxytocin genes. Finally, in the vasotocin gene of the Pacific hagfish *Eptatretus stouti*, belonging to the most primitive vertebrate class, Cyclostomes, not only are the two usual introns found at positions similar to those in the mammalian vasopressin and oxytocin genes, but also a third one is detected interrupting the 5'-untranslated region.

In summary, the general organization of neurohypophysial precursor genes is remarkably preserved during evolution, with some punctual secondary

variations in a few species. The discovery of “neurohypophysial-like” precursors in invertebrates displaying the four-domain structure suggests that this type of protein antedates the vertebrate–invertebrate divergence (some 700 million years ago) and so is very ancient. The physiological functions that these molecules could fulfill in the primitive organisms are still unknown, but they should have been involved in the early evolutionary shaping of the neurohypophysial-like peptide conformations.

Structures and Conformations of Neurohypophysial Peptides

Precursor Self-Folding and Domain Organization

The precursor polypeptide chain, emerging from the ribosome, is translocated into the rough ER through the signal recognition particle (SRP) and the SRP receptor. Whereas the signal prepeptide is removed by a signalase, the translocated polypeptide folds in the lumen to take its native conformation. The right folding is subjected to quality control in the ER and may be helped by a chaperone. This folding allows the 16 cysteine residues of the precursor to pair in eight precise disulfide bridges. In both vasopressin and oxytocin precursors, there is one disulfide in the hormonal moiety and seven disulfides in the neurophysin moiety. It can be stated that the hormonal nonapeptide domain folds first and that the sequence connecting the hormone to the neurophysin moiety adopts a conformation allowing the accessibility for the specific processing endopeptidase. The crucial processing site is a Gly–Lys–Arg sequence (Fig. 2). The 93/95-residue neurophysin domain is likely folded in a second step. In the vasopressin or vasotocin precursor, there is a third additional domain, a 39-residue glycopeptide or copeptin, devoid of disulfide bridges and cut off, in the case of provasopressin only, during the processing at a monobasic site, an arginine residue (Fig. 2). Prooxytocin has only two domains, oxytocin and VLDV–neurophysin, but the maturation of the hormone moiety is virtually identical to that of vasopressin. However the fish proisotocin owns an additional C-terminal domain similar to the one found in provasopressin or provasotocin.

Precursor Processing and Mature Conformations

The Processing Enzyme Cascade

Most of hormonal peptides have a C-terminal amidated residue, and this feature—essential for biological activities—is the result of a four-enzyme

processing machinery very likely operating in the last compartment of the secretory pathway, the secretory granules. Sequentially, the four enzymes are (1) a dibasic endopeptidase, Ca²⁺ dependent, often termed PC1/PC3 and PC2 (prohormone convertases); (2) a carboxypeptidase B-like enzyme termed carboxypeptidase E or H, which removes the two basic residues; (3) a peptidylglycine mono-oxygenase giving a peptidylhydroxyglycine; and (4) an alpha-amidating lyase that splits the hydroxyglycine into the amide group and glyoxylic acid. The last two enzymes share a common precursor and may operate like a two-domain single protein (PAME), as shown by Eipper and Mains. The four enzymes are likely granule membrane bound and work as machinery. They have pH optima between 5 and 6, and we have identified them in the neurohypophysial secretory granules of the ox and rat. The pH in these granules is 5.5 to 5.8. With enzymes purified from secretory granules, we have reconstituted the processing *in vitro* using vasopressinyl–Gly–Lys–Arg converted into vasopressin, identified by chromatography with the synthetic peptide and its specific rat pressor activity. It can be assumed that all neurohypophysial amidated nonapeptides are produced from protein precursors through this multienzyme mechanism.

In the case of mammalian provasopressin, a second cleavage (specific monobasic endopeptidase) occurs in the precursor, separating the neurophysin domain from the copeptin domain. Release of mature mediators in circulating blood involves regulated fusion mechanisms of secretory vesicles with the plasma membrane and subsequent exocytosis.

The Conformation-Shaping Mechanisms

The processing machinery not only tailors the proper size of the peptide but also secures the right conformation necessary for recognizing and binding to the specific receptor. After being detached from the precursor by the processing endopeptidase, the intermediate dodecapeptide, and particularly its terminal tail, self-folds in a way that is different from the one it exhibits within the prohormone. Its conformation becomes flexible. Removal of the last three residues and building of the C-terminal carboxamide group of the hormone through the alpha-amidating lyase are crucial for shaping the active conformation able to bind the specific receptor (Fig. 3). Alpha-deamidation entails complete loss of the biological activity.

In anuran Amphibia, an adaptive differential processing of provasotocin involving a down-regulation of either carboxypeptidase E, leading to vasotocinyl–Gly–Lys–Arg (hydrin 1) in *Xenopus laevis*, or the

Figure 3 Three-dimensional structure of deamino-oxytocin: (A) the space filling model and (B) the equivalent stick model. Reprinted with permission from Wood, S. P., *et al.* (1986). Crystal structure analysis of deamino-oxytocin conformational flexibility and receptor binding. *Science* 232, 633-636. Copyright 1986, American Association for the Advancement of Science.

alpha-amidating enzymes, giving vasotocinyl-Gly (hydrin 2) in frogs and toads, has been discovered in our laboratory. These intermediates have conformations different from that of mature vasotocin, not only because of the hindrance due to the extension

but also because the C-terminal negative carboxyl induces a different folding. They display hydro-osmotic activities on frog urinary bladder and skin but not on the kidney, in contrast to vasotocin, and may act through distinct receptors, playing an essential role in the rehydration of the animal.

Neurohypophysial Hormones

The Vertebrate Neurohypophysial Hormones

Since the chemical characterization in 1953 of bovine oxytocin and arginine vasopressin by Du Vigneaud, Tuppy, and our laboratory, we have isolated 10 distinct neurohypophysial peptides from marsupials and nonmammalian vertebrates (Table II). About 80 species belonging to the seven vertebrate classes have been investigated. There is a great evolutionary stability in the structures given that species within the same class of vertebrates, with the exception of cartilaginous fishes, almost always possess the same hormones. Furthermore, two peptides, one oxytocin-like and the other vasopressin-like, are usually found in

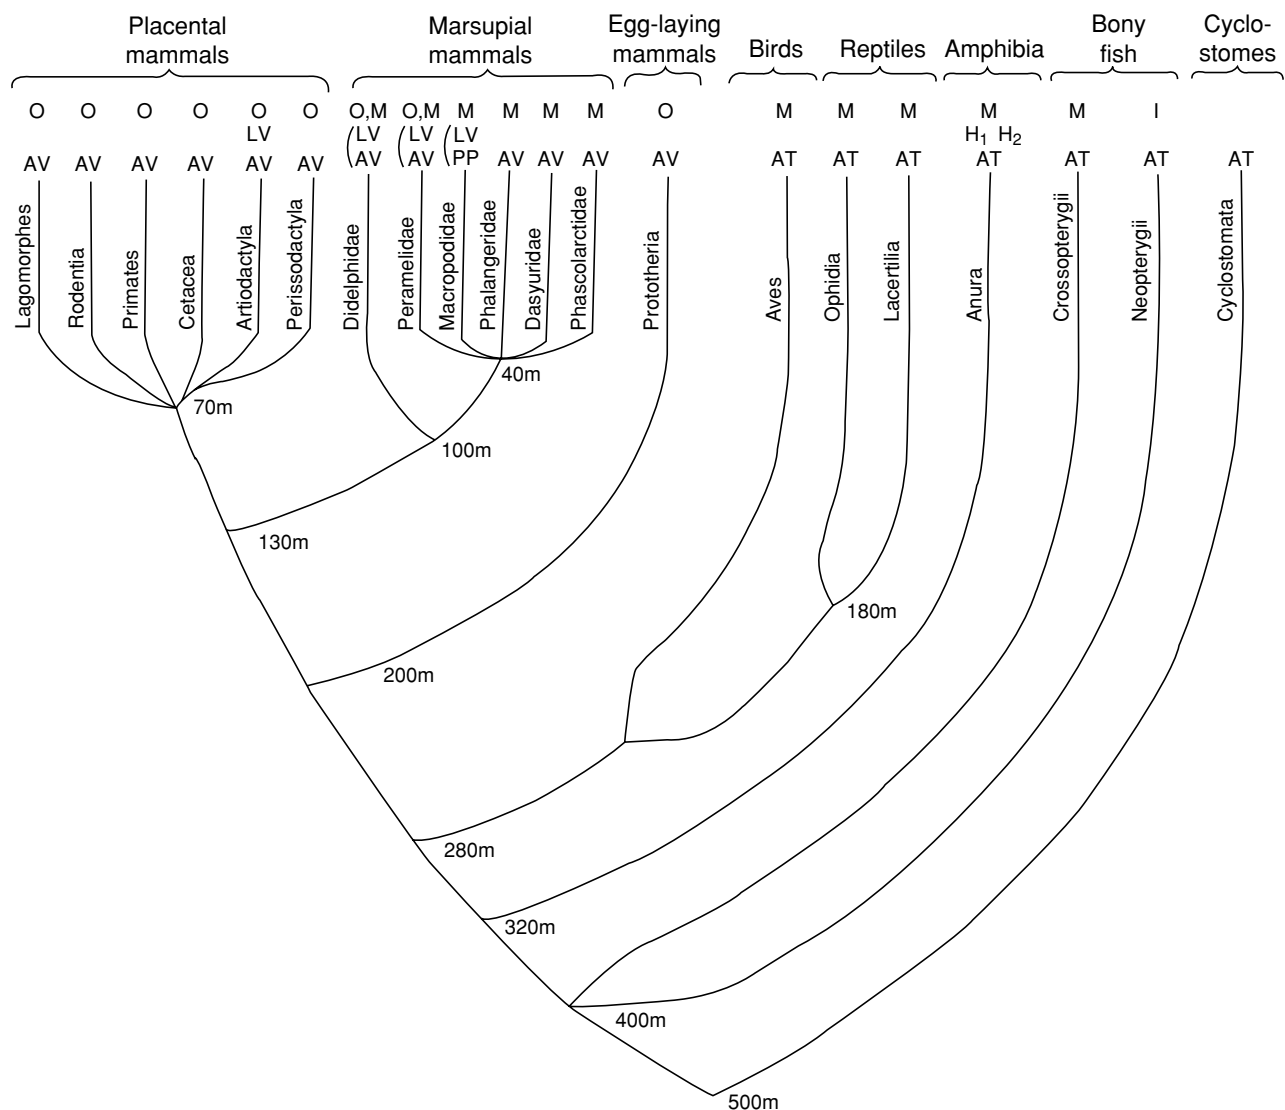

Figure 4 The two evolutionary lineages of vertebrate neurohypophysial hormones. The peptides identified in cartilaginous fishes are not included because these fishes are not located in the evolutionary pathway from bony fishes to mammals and were subjected to a separate evolution. O, oxytocin; AV, arginine vasopressin; LV, lysine vasopressin; M, mesotocin; PP, phenylpressin; AT, arginine vasotocin; I, isotocin; H₁, hydrin 1; H₂, hydrin 2. The line connecting LV and AV or connecting LV and PP means that both peptides exist in the same species. The numbers give the time in million years (m) since the divergence.

each species, so that two paralogue lineages can be traced from Cyclostomes to mammals (Fig. 4). The vasopressin-like hormones are characterized by a basic residue, arginine or lysine, in position 8, a key position for receptor recognition, whereas oxytocin-like peptides almost always have a neutral aliphatic hydrophobic residue in this position.

The preservation of the hexacyclonapeptide pattern with invariant residues in positions 1, 6, 7, and 9 and C-terminal amidated glycine strongly suggests, on the one hand, that the general conformation of

the molecule (Fig. 3) has been largely conserved in the course of evolution and, on the other hand, that the two lineages likely originated from a primordial duplication of a common ancestral gene. This latter assumption is reinforced by the fact that the most primitive vertebrates, the Cyclostomes, have a single neurohypophysial peptide, namely vasotocin. Table II gives the names, structures, and origins of the 13 vertebrate neurohypophysial peptides chemically identified. Whereas mesotocin ([Ile⁸]-oxytocin) has been chemically identified in two species of

African lungfish (*Protopterus annectens* and *Protopterus dolloi*) and in two individuals of the Australian lungfish (*Neoceratodus forsteri*), Hyodo and colleagues have deduced the occurrence of a variant, Phe2–mesotocin, from a cDNA of an Australian lungfish.

Most species have the two types of neurohypophysial hormones, but secondary duplications of either or both can be observed in some groups. In marsupial mammals, duplication of the vasopressin-like peptide is found in Australian macropodids (lysiipressin and phenyppressin), in Australian peramelids (lysiipressin and vasopressin), and in American didelphids (lysiipressin and vasopressin). In the same way, duplication of the oxytocin-like peptide, namely oxytocin and mesotocin, is observed in Australian peramelids and in American didelphids. Occurrence of additional neurohypophysial hormone duplications in both American and Australian marsupials can be explained by common ancestors living at the time of the association of South America and Australia in Gondwanaland and their later separation through the continental drift. Curiously, the nonmammalian vasotocin has been replaced completely by the vasopressin-like hormone in Metatherians, whereas the nonmammalian mesotocin is still present. In the cartilaginous fishes, which form a heterogeneous class, duplication of the oxytocin-like peptide has also been detected in sharks, namely valitocin and aspartocin in the spiny dogfish and asvatocin and phasvatocin in the spotted dogfish (Table II). It is likely that secondary duplications of the genes have led to duplications of the protein precursors and finally to duplications of the processed hormones. Apparently, these secondary duplications were random and restricted to limited groups. It will be of great interest, when the genomes are sequenced, to check whether “silent” duplications with unexpressed genes exist in the other classes of vertebrates.

When substitutions in the oxytocin/vasopressin superfamily are examined (Table II), it is clear that whereas some positions are invariant (e.g., positions 1, 6, 7, and 9), others are particularly affected (e.g., positions 4 and 8). Substitutions in position 4 are always polar, and those in position 8 are virtually always aliphatic hydrophobic in the oxytocin family and always basic in the vasopressin family. Position 3 is occupied by an aliphatic hydrophobe (isoleucine) in the oxytocin family and by an aromatic hydrophobe (phenylalanine) in the vasopressin family except in vasotocin. Position 2 is usually occupied by tyrosine, but occasionally phenylalanine replaces tyrosine (phasvatocin and phenyppressin).

The biological significance of the substitutions is not clearly understood except for the replacement of

vasotocin by vasopressin in mammals (replacement of Ile3 by Phe3) that leads to a peptide that acts only on kidney and vascular receptors and no longer on uterus and mammary gland receptors, as does nonmammalian vasotocin. On the other hand, replacement of mesotocin by oxytocin in placental mammals (replacement of Ile8 by Leu8) could be neutral given that the two peptides have roughly equal uterotonic and milk-ejecting activities in rat and rabbit, respectively, and given that mesotocin was conserved in marsupial mammals with the same function as oxytocin in placentals.

The finding of oxytocin in the ratfish, a holocephalian fish (cartilaginous fishes), is very puzzling. Cartilaginous fishes display a great diversity of oxytocin-like peptides because rays, sharks, and chimera have different peptides. It has been suggested that this apparent freedom for mutations might be related to the fact that these fishes regulate their osmoregulation with urea rather than with salts. Simultaneously, the amount of vasotocin stored in neurohypophysis is dramatically reduced when compared with that in other nonmammalian vertebrates.

The Invertebrate Neurohypophysial Hormone-like Peptides
“Neurohypophysial hormone-like” peptides have been discovered in various tissues of some invertebrates: locupressin in the brain of *Locusta migratoria* (insects); Lys–conopressin and Arg–conopressin in the venom of two marine *Conus* species, the freshwater snail *Lymnaea stagnalis* and the seawater snail *Aplysia kurodai* (gastropod molluscs); cephalotocin in the “neurosecretory system of the vena cava” of *Octopus vulgaris* (cephalopod molluscs); and annetocin in the body of the earthworm *Eisenia foetida* (Table III). When present, there is always a single neurohypophysial hormone-like peptide in invertebrate species, in contrast to two neurohypophysial hormone-like peptides in virtually all vertebrates. The possible physiological functions of these peptides are poorly known, except for locupressin, the dimer of which would be a diuretic hormone.

Whatever their functions, the occurrence of neurohypophysial hormone-like peptides in invertebrates indicates that the ancestral gene antedates the single preprovasotocin gene of Cyclostomes and was present before the invertebrate–vertebrate divergence at least some 700 million years ago.

The Neurophysins

Mammalian Neurophysins

Neurophysins are small proteins initially found to be stoichiometrically associated with neurohypophysial hormones in noncovalent complexes. Mammalian

Table III Structures of Invertebrate Neurohypophysial Hormone-like Peptides

Note. Residues identical to those of vasopressin are indicated by dashes.

neurophysins are 93/95 residues long and contain seven disulfure bridges, so that a reticulated conformation can be suspected. When neurophysin amino acid sequences from several mammalian species are compared (Table IV), it is clear that three segments have different variabilities. The N-terminal part (residues 1–9), which permits the two types to be distinguished, is rather constant in each family; the central part (residues 10–76) is strongly preserved within the family and between the two families; and the C-terminal part (residues 77–93/95) is subject to many variations. The near identity between the central parts of MSEL- and VLDV-neurophysins from man, ox, and rat has been explained by gene conversion events, with the oxytocin and vasopressin genes being closely linked on the same chromosome and transcribed on opposite DNA strands.

In the case of provasopressin, the precursor has a third domain, a 39-residue C-terminal glycopeptide extension termed copeptin, which is cut off from MSEL-neurophysin at the level of an arginine residue (Fig. 2). This glycopeptide has no disulfide bridge and may be proteolytically truncated during the extraction. It is also encoded by the third exon of the provasopressin gene, as is the C-terminal part (residues 77–93/95) of neurophysin, and displays the same high evolutionary variability. In mammals, copeptin is usually detached from MSEL-neurophysin and found separated in the secretory granules. However, in the guinea pig, about 20 % of the initial domains remain

linked, so that an intermediate having 132 residues can be isolated along with separate neurophysin and copeptin. The separation does not occur in nonmammalian tetrapods, so that MSEL-neurophysins reach 129 to 132 residues (“big” neurophysin) (Table IV).

Avian and Amphibian Neurophysins

In nonmammalian tetrapods, oxytocin and vasopressin are replaced by mesotocin and vasotocin, respectively. These hormones are processed from protein precursors similar to those of mammalian hormones, and the two types of neurophysins (VLDV type [mesotocin associated] and MSEL type [vasotocin associated]) can be recognized. The numbers of amino acid substitutions increase when avian, amphibian, and fish neurophysins are compared with their mammalian counterparts (Table IV).

In all neurophysins, the seven disulfide bridges occupy the same location, so that the general three-dimensional structure, as determined by X ray for bovine MSEL-neurophysin (Fig. 5), is very likely preserved. However, for the avian and amphibian MSEL-neurophysins, the presence of the additional extension copeptin might modify to some extent the conformation of the C-terminal neurophysin domain.

Fish Neurophysins

In bony fishes, isotocin and vasotocin replace the mammalian oxytocin and vasopressin, respectively. Bony fish neurophysins have not been chemically

Figure 5 Three-dimensional structure of the neurophysin (ribbon representation)-oxytocin (stick model) complex dimer. Reprinted with permission from Rose, J. P., *et al.* (1996). Crystal structure of the neurohypophysin-oxytocin complexes. *Nature Structural Biology* 3, 163-169.

characterized extensively. Partial sequence information is available for pollack (*Pollachius virens*) MSEL- and VLDV-neurophysins. Amino acid sequences of the two types of neurophysins have been deduced from cDNA or genes for the white sucker *C. commersoni* by Richter's group and the chum salmon *Oncorhynchus keta* by Hyodo and colleagues. Catostomids and salmonids are tetraploid fishes, so that two MSEL-neurophysins (vasotocin-associated neurophysins) and two VLDV-neurophysins (isotocin-associated neurophysins) have been detected. The two types of neurophysins have also been sequenced in the Japanese puffer fish *Fugu rubripes* by Venkatesh and Brenner. The numbers of substitutions increase when compared with the bovine counterparts. The new features are a shortening of the C-terminal copeptin extension in provasotocins and, conversely, the occurrence of a copeptin extension in proisotocins, so that the two precursors have approximately the same numbers of residues. In Cyclostomes, a single neurohypophysial peptide, vasotocin, has been chemically identified in the lamprey *Petromyzon marinus*; the provasotocin sequence has been deduced from the provasotocin gene of the Pacific hagfish *Epastretus stouti*. The length of the neurophysin-copeptin domain (127 residues) is nearly similar to that of white sucker neurophysins (121/123 residues), assuming that copeptin extensions are not cut off. Sequence comparison with other vertebrates shows that the hagfish vasotocin-associated neurophysin contains 14 conserved cysteine residues at identical positions and

suggests a similar polypeptide chain folding with seven disulfide bridges.

Composite Evolution and the Two Phylogenetic Lineages

Because neurohypophysial hormone-neurophysin precursors are usually encoded by three-exon genes, with the first coding for the hormone moiety, the tripeptide processing signal, and the first 9 residues of neurophysin; the second coding for the central part (residues 10-76); and the third coding for the C-terminal part (residues 77-93/95 or 77-135), three autonomous evolutions can be considered (Fig. 6).

For the first exon, it is plausible that the hormone moiety, subjected to coevolution with its receptor, has its specific structural constraints in each lineage. Whereas the processing signal is perfectly preserved with a strict conservation of the Gly-Lys-Arg sequence, with all hormones being nonapeptides, amino acid substitutions in the hormone moiety may be regarded either as selective (Ile3/Phe3 for the change of vasotocin into vasopressin) or as neutral (Ile8/Leu8 for the change of mesotocin into oxytocin). For the first 9 residues of neurophysins, the relative preservation of the four tracer residues in each lineage (MSEL or VLDV) may be explained by the proper folding of the processing region. However, variations in these nine positions are more numerous than those in the nine positions of the hormone moiety (Table IV).

The central part of neurophysins encoded by the second exon appears to be strongly invariant in mammals and, furthermore, nearly identical in the two types of a given species due to gene conversion. It is difficult to explain the particular evolutionary stability within each lineage, but it may be a requisite for proper folding.

The C-terminal part of the precursors encoded by the third exon is very variable, either for the last part of the neurophysin domain (residues 77-93/95) or for the copeptin domain (95/97-133/135). Moreover, copeptin, present in fish proisotocins, disappears in avian/amphibian promesotocins and mammalian prooxytocins (Fig. 6).

MOLECULAR MACHINERIES WITHIN THE NEUROHYPOPHYSEAL HORMONE TARGET CELLS: SYSTEMIC FUNCTIONS

Neurohypophysial hormone target cells contain G protein-coupled receptors that are associated with

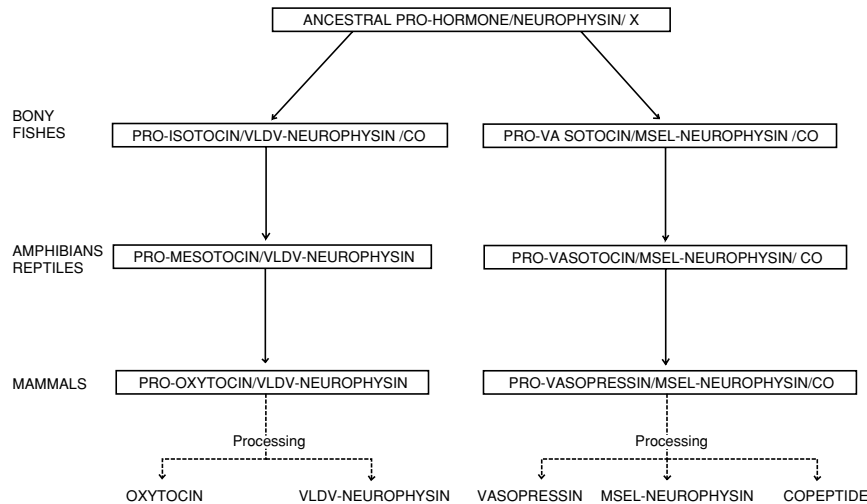

Figure 6 The two evolutionary lineages of vertebrate neurohypophysial hormone precursors. The three domains (hormone, neurophysin, and copeptin [CO]) are likely present in the ancestral prohormone. After gene duplication, they remain at the level of the two bony fish precursors, but copeptin disappears in the prooxytocin lineage from the tetrapods onward. In the provasopressin-like lineage, neurophysin and copeptin remain linked in amphibians and birds, whereas the complete processing into three fragments appears at the level of mammals.

either $G_{\alpha s}$ proteins and the adenylate cyclase–protein kinase A cascade or $G_{\alpha q}$ proteins and the phospholipase C–protein kinase C cascade (cf. Fig. 7). The physiological specificities of the hormones depend essentially on the nature of the effectors. A number of biological or pharmacological functions have been ascribed to the vasopressin-like hormones (Table V) as well as to the oxytocin-like peptides. Diversification of functions has been generated in the course of evolution by recruitment of novel effectors rather than by changes in the structures of hormones or receptors.

Figure 7 A hydro-osmotic principal cell of the nephron-collecting duct involved in water reabsorption through the vasopressin (ADH) action. Water uptake occurs by the vasopressin-regulated aquaporin 2 (AQP2), water output occurs by aquaporins 3 and 4 (AQP3 and AQP4), and return to blood occurs by the capillary aquaporin 1 (AQP1). G_s , heterotrimeric G_s protein; AC, adenylate cyclase; Aggrephore, cytoplasmic vesicles containing AQP2 targeted to apical membrane through PKA activation.

Vasopressin/Vasotocin Receptors

On the basis of pharmacological and functional studies, Mitchell in 1979 proposed the occurrence of two types of vasopressin receptors. Activation of vasopressin receptors in the liver triggers an increase in inositol triphosphate and diacylglycerol, leading to activation of protein kinase C. Mitchell suggested the term V1 for this type of receptor. Renal vasopressin receptors involved in water reabsorption activate adenylate cyclase and are called V2. The vasopressin receptor present in anterior pituitary corticotropes has a pharmacological profile different from that of the hepatic/vascular receptors, so these receptors were subdivided into V1a and V1b subtypes, respectively. Mammalian vasopressin receptors were sequenced by Brownstein, Brinbaumer, and their colleagues in 1992 through molecular biology.

Table V Pleiotropic Effects of Vasopressin

| | |
|----------------------|--|
| Antidiuresis | Blood volume |
| Antinatriuresis | Blood osmolality |
| Urea reabsorption | Renal regulation |
| Vasoconstriction | Vascular tone |
| Corticotrope action | Adrenocorticotrophic hormone secretion |
| Glycogenolysis | Hepatic metabolism |
| Platelet aggregation | Coagulation |
| Coagulation factors | Factors release |
| Neurotransmission | Synaptic action |
| Mitogenesis | Cell proliferation |

V1a Vasopressin Receptors

The hepatic/vascular V1a vasopressin receptors have been identified through complementary DNAs from the rat and human. They comprise 394 and 418 residues, respectively, with 72% sequence identity between them, and they possess seven putative transmembrane segments. Measurements of vasopressin-induced inositol trisphosphate production and calcium mobilization in COS-7 cells and Chinese hamster ovary cells where the cloned receptors have been expressed indicate that these receptors are coupled to phospholipase C via a pertussis toxin-insensitive pathway. A coupling with phospholipase D, leading to the breakdown of phosphatidylcholine into phosphatidic acid, diacylglycerol, and choline, has also been observed in hepatocytes and smooth muscle cells. These receptors mediate different physiological effects in vascular smooth cells (vasoconstriction) and in hepatic cells (glycogenolysis), despite identical second messengers, because of the differentiated molecular environment and different interaction cascades. V1a receptor transcripts are also present in the larger renal blood vessels, including the interlobular arteries and branches. V1a receptors have been detected by *in situ* hybridization histochemistry in many brain areas, suggesting a neurotransmitter function for vasopressin.

V1b Vasopressin Receptors

The corticotrope V1b vasopressin receptors of the rat and human have been cloned. These receptors (424 residues for the human receptor) display a high percentage sequence identity with their V1a and V2 vasopressin receptor counterparts (53 and 43%, respectively, for rat receptors and 45 and 39% for human receptors). They also show a high degree of sequence identity with oxytocin receptors (49% for rat and 45% for human), so that a superfamily of oxytocin/vasopressin receptors can be defined.

corticotropin-releasing factor (CRF) and vasopressin are found colocalized in parvocellular cells of the paraventricular nucleus. A cooperation between CRF action through its specific receptor and vasopressin action through the V1b receptor seems involved in corticotropin secretion. Vasopressin, in contrast to CRF, does not increase pro-opiomelanocortin mRNA transcription but induces corticotropin release (secretagogue activity), perhaps by a separate secretory pathway.

V2 Vasopressin Receptors

The renal V2 vasopressin rat and human receptors have also been cloned and characterized. They comprise 370 and 371 residues, respectively, and display

significant sequence identity either with or between their V1a vasopressin receptor counterparts (36% for human receptors). In the transmembrane domains, the rat V2 vasopressin receptor has approximately 60% identity with the rat V1a vasopressin receptor. The transmembrane hydrophobic helices are particularly preserved in the course of evolution.

Vasotocin Receptors

In all nonmammalian vertebrates, vasopressin is replaced by vasotocin ([Ile3]vasopressin). Whereas vasotocin is the antidiuretic hormone of nonmammalian tetrapods, its function in fishes is not yet clearly clarified. A vasotocin receptor from a bony fish, the white sucker *C. commersoni*, has been cloned by Richter. It comprises 435 residues and has the seven stretches of hydrophobic residues that are assumed to span the membrane, as found for mammalian vasopressin receptors. This receptor is present in various teleost tissues such as pituitary, liver, gills, swim bladder, and lateral line. The pharmacological properties of the vasotocin receptor expressed in *X. laevis* oocytes seem to indicate an ancestral nonapeptide receptor; vasotocin, vasopressin, oxytocin, mesotocin, and aspartocin activated the receptor, but isotocin ([Ser4,Ile8]oxytocin), the second neurohypophysial hormone of the white sucker, did not. This receptor belongs to the V1-type vasotocin receptor.

Oxytocin-like Hormone Receptors

Oxytocin Receptor

Identification of the human oxytocin receptor has been performed through complementary DNA isolated by expression cloning. Messenger RNAs have been isolated from breast, ovary, uterine endometrium, and myometrium. The mRNA level in the myometrium is very high at term of labor, with a dramatic increase in the number of oxytocin receptors. Both oxytocin and vasopressin elicit electrophysiological responses on the oxytocin receptor expressed in *X. laevis* oocytes, but a vasopressin V1 receptor agonist ([Phe2,Ile3,Orn8]vasopressin) has no effect at high concentration (10^{-5} M). A specific oxytocin antagonist ([d(CH2)5,Tyr(OMe)2-Orn8]-vasotocin) markedly decreases the membrane current at 10^{-6} M concentrations.

Mesotocin Receptor

Mesotocin ([Ile3]-oxytocin) is the oxytocin-like hormone of nonmammalian tetrapods (lungfishes, amphibians, reptiles, and birds) and in most marsupials,

particularly macropodids (kangaroos and wallabies). The cloning and functional characterization of the cDNA for the mesotocin receptor from the urinary bladder of the toad *Bufo marinus* has been carried out by Farhenholz. The cloned cDNA encodes a polypeptide of 389 amino acids and shows great similarities to the mammalian oxytocin receptor (70 % sequence identity) and to the teleost fish isotocin receptor (66 % sequence identity). When expressed in COS cells, it exhibits the following relative order of ligand affinity: mesotocin > vasotocin = oxytocin > vasopressin > hydrin 1, isotocin, hydrin 2. This receptor is coupled to the inositol phosphate/calcium pathway. It is found not only in bladder but also in kidney, muscle, and brain of the toad.

Isotocin Receptor

Teleost fish possess a specific oxytocin-like hormone, isotocin ([Ser4,Ile8]-oxytocin) that can be regarded as the evolutionary precursor of nonmammalian tetrapod mesotocin. The isotocin receptor of the white sucker *C. commersoni* has been cloned by Richter. The isotocin receptor can also be activated by vasotocin, mesotocin, oxytocin, and arginine vasopressin, although these have lower potencies than does isotocin.

The general conclusion can be drawn that there is a high evolutionary conservation in the structures of both the hormones and the receptors.

Evolution of Oxytocin/Vasopressin-like Peptide Receptors

An Ancestral Invertebrate Lys-Conopressin Receptor

In invertebrates, cooccurrence of vasopressin- and oxytocin-related peptides has never been demonstrated in the same species. Lys-conopressin, a hormone first characterized in *Conus geographicus* and then found in other molluscs, controls reproductive functions that are analogous to oxytocin functions in vertebrate reproductions despite its being structurally related to vasopressin (Table III). Geraerts and colleagues have identified in *L. stagnalis* a G protein-coupled receptor (LSCPR) mediating both vasopressin- and oxytocin-like functions in this freshwater snail. The receptor is a classical seven-helix transmembrane protein consisting of 462 amino acids. LSCPR may represent an ancestral receptor to both vertebrate vasopressin and oxytocin receptors.

Evolution of Vertebrate Neurohypophysial Hormone Receptors

Because the most primitive vertebrates, the Cyclostomes, have a single neurohypophysial peptide,

vasotocin, it can be assumed that the first vertebrate receptor was a vasotocin receptor and that successive gene duplications have allowed diversification of receptors in the more evolved vertebrate classes. We can suppose that two main lineages of receptors, namely oxytocin- and vasopressin-like hormone receptors, correspond to the two main neurohypophysial hormone lineages. A phylogenetic tree depicting a possible evolution of the receptors of the neurohypophysial hormone family derived from a single ancestral gene is proposed.

CONCLUSIONS

The described neurohypophysial endocrine regulatory cascade outlines the general features of any intercellular communication mediated by a peptide messenger. The precursor biosynthesis and the mediator storage in the hypothalamic secretory neurons are regulated by both systemic effects and neural signals, for instance, for vasopressin by signals originating from osmoreceptors and baroreceptors.

The physiological function can now be analyzed as a cascade of protein-protein interactions occurring partly in soluble medium and partly in membrane-bound systems (Table I). From a mechanical viewpoint, the key factor is the elasticity of proteins (i.e., the reversible change of conformation) through covalent or noncovalent actions. The succession of specific recognitions is ordered by the conformational shift at each level. However, dynamic events, such as the translocation of the precursor into the rough ER, its transport, and its processing along the secretory pathway; the exocytotic secretion of the mediator in blood; the hormone fishing by a target cell membrane receptor; the transduction signaling with release of a second messenger; and the intracellular cascade leading to effector mobilization, cannot be explained only by static-specific interactions. These events involve energy consumption such as adenosine triphosphate (ATP) or guanosine triphosphate (GTP) hydrolysis. On the other hand, a regulated network of cascades, with each one triggered by a specific hormone, must ensure the fine-tuning of the physiological function.

The array of surface membrane receptors make, in part, the identity of the cells. Emission and treatment of the hormonal message are dependent on the differentiated intracellular machineries of the two cell partners: the messenger secretory cell and the target cell.

The duplication propensity of genomic DNA determines the occurrence of multigene families and,

therefore, multiprotein families. As a result, several sequence-related messengers, receptors, and effectors exist in evolved organisms, allowing for diversification of the regulatory cascades through combinatorial mechanisms. The two mammalian neurohypophysial hormones, oxytocin and vasopressin, very likely derived from an ancestral duplication in early vertebrates. Each peptide can stimulate a variety of sequence-related receptors, themselves originating from gene duplications. For example, vasopressin in mammals has at least three types of receptors—V1a, V1b, and V2—displaying high-identity percentages among them and between them and oxytocin receptors. Each receptor, in turn, activates a set of effectors: water channels, amiloride-sensitive Na⁺ channels, inward rectifier potassium channel, and urea transporters for the V2-type and smooth muscle myosin regulatory light chain; glycogenolytic enzymes; and corticotrope secretory vesicles for the V1 type. So, diversity of physiological functions was achieved by evolution, with a limited number of molecules interacting in cascades ordered through precise conformation recognitions.

Adaptation may involve a switch from one cascade to another, and a peptide messenger, whose initial function became obsolete in the frame of organismal evolution, can recruit a new receptor and (indirectly) new effectors. The deciphering of the biological roles of invertebrate neurohypophysial peptides should shed light on the evolutionary molecular flexibility of neuroendocrine systems.

Acknowledgments

The author is deeply indebted to researchers and technicians of his laboratory who worked enthusiastically over the past decades in obtaining some of the results described in this article. He is grateful

to many colleagues from Africa, Asia, Europa, North and South America, and Oceania who, by providing pituitary glands from approximately 80 vertebrate species, permitted him to partly decipher the evolutionary history of neurohypophysial hormones. The research received financial support from the Ministère de l'Enseignement Supérieur et de la Recherche, the CNRS, and the INSERM.

in the guinea pig ileum was much more sensitive to NKB than to other tachykinins.

BIOSYNTHESIS OF NEUROKININS

The synthesis of the tachykinins in mammals is directed by two separate genes termed preprotachykinin A and preprotachykinin B, each of which includes seven exons. Sequence analysis of cloned cDNAs from various human tissues have identified mRNAs directing the synthesis of four biosynthetic precursors of SP (α -, β -, γ -, and δ -preprotachykinin A) that arise from the preprotachykinin A gene by an alternative RNA splicing mechanism. As shown in Fig. 2, the mRNA encoding β -preprotachykinin A is derived from transcription of all seven exons of the gene, so that β -preprotachykinin A contains SP, NKA, and its 36-amino acid residue, NH₂-terminally extended form, NPK. The mRNA encoding γ -preprotachykinin A lacks exon 4, so that γ -preprotachykinin A contains the sequence of SP, NKA, and its 21-amino acid residue, NH₂-terminally extended form, NP γ . The mRNA encoding α -preprotachykinin A lacks exon 6, which precisely specifies the NKA region, and the mRNA encoding δ -preprotachykinin lacks exons 4 and 6, so that these biosynthetic precursors contain the sequence of SP only. The organization of the preprotachykinin B gene is similar to that of the preprotachykinin A gene, suggesting evolution from a common ancestral gene, but preprotachykinin B contains the sequence of NKB only.

TACHYKININ RECEPTORS

The biological effects of the tachykinins are mediated through interaction with three discrete and fully

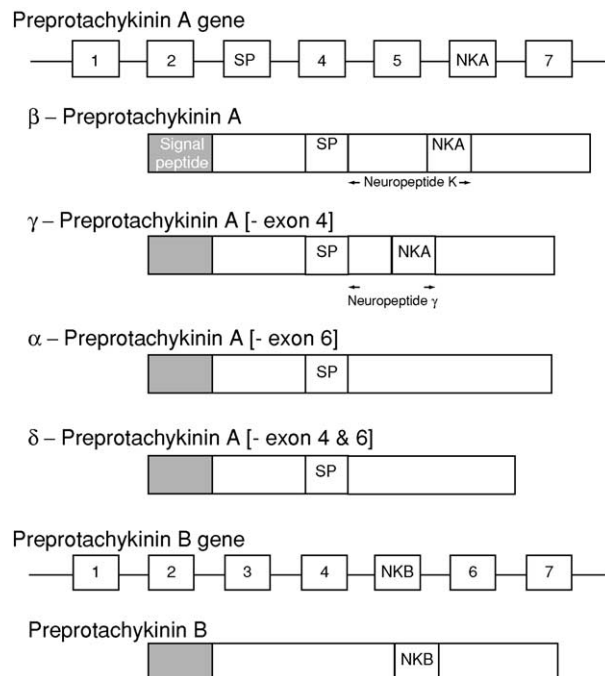

Figure 2 A simplified schematic representation of the organization of the preprotachykinin A and preprotachykinin B genes and the biosynthetic precursors of the mammalian tachykinins.

characterized receptors. The original nomenclature used to describe these receptors (SP-P, SP-E, and SP-N) has now been replaced by NK₁, NK₂, and NK₃. The receptors are defined pharmacologically in terms of the binding affinities of their endogenous ligands, so that SP may be regarded as the preferred agonist of the NK₁ receptor (rank order of potency SP > NKA > NKB), NKA is the preferred agonist of the NK₂ receptor (NKA > NKB > SP), and NKB is the preferred agonist of the NK₃ receptor (NKB > NKA > SP). The N-terminally extended forms of NKA, neuropeptide K, and neuropeptide γ bind with highest affinity to the NK₂ receptor.

Molecular cloning studies have confirmed unequivocally the existence of three classes of tachykinin receptor in mammalian tissues. Nucleotide sequence analysis demonstrates that the receptors are homologous (high sequence identity within and between species) and belong to the extensive family of rhodopsin-type (seven transmembrane domains), G protein-coupled receptors. Binding of ligand results in activation of phospholipase C with a subsequent rise in inositol 1,4,5-trisphosphate and diacylglycerol concentrations, although in some systems activation of adenylate cyclase, leading to an elevation in intracellular concentrations of cyclic AMP (cAMP), has also been reported.

DISTRIBUTION OF THE NEUROKININS AND THEIR RECEPTORS

Neurokinins

Because SP and NKA are biosynthetically related, the tissue distribution of the two peptides within the central and peripheral nervous systems overlaps closely and colocalization within primary C-afferent sensory neurons has been reported. However, the distribution of the mRNAs encoding the different preprotachykinin A precursors is both tissue and species dependent. In the rat, the relative abundance $\gamma > \beta > \alpha$ is common to all tissues, whereas in the ox, α -preprotachykinin A predominates in the brain and β -preprotachykinin A predominates in the intestine. All four mRNA isoforms (α , β , γ , and δ) have been identified in human mononuclear phagocytes and lymphocytes. NKB has been detected by immunohistochemistry in several regions of the brain, with the highest concentrations in the hypothalamus, substantia nigra, and olfactory tubercle as well as in the dorsal horn of the spinal cord. *In situ* hybridization immunohistochemistry reveals a similar, but not identical, distribution pattern of preprotachykinin B mRNA compared with preprotachykinin A mRNA in most regions of the brain. NKB is present in extracts of the intestines of those mammalian species examined, but the concentrations are low (< 1 pmol/g tissue). Selective expression of preprotachykinin B mRNA in human neuroblastomas has been reported.

Neurokinin Receptors

Few if any mammalian tissues contain a single homogeneous population of tachykinin receptors, and all natural tachykinins act as full agonists at the three receptor subtypes, and so pharmacological data must be interpreted in this light. The tissue distribution of the NK₁ receptor was described earlier. NK₂ receptors have a wide distribution, particularly on the smooth muscle of peripheral tissues, and rat gastric fundus and uterus, endothelium-denuded rabbit pulmonary artery, and hamster trachea and bladder have been used as a source of NK₂ receptors in pharmacological studies. In contrast, NK₃ receptors are found primarily in tissues of the central nervous system, with abundant expression in rat cerebral cortex, cerebellum, and hypothalamus. *In situ* hybridization studies have shown that the levels of NK₃ receptor mRNA in the gastrointestinal tract are much lower than the levels of NK₁ and NK₂ receptor mRNAs. Expression of NK₃ receptor mRNA and preprotachykinin

B mRNA in the uterus of pregnant rats has suggested a role for NKB in the regulation of uterine functions.

PHYSIOLOGICAL AND PATHOPHYSIOLOGICAL ROLES

In general, the diverse biological actions displayed by SP are mimicked by NKA with a greater or lesser potency depending on the relative levels of NK₁ and NK₂ receptors in the target tissue. For example, NKA is approximately 10-fold more potent than SP in producing contraction of the rat stomach but is more than 10-fold less potent in stimulating secretion of rat salivary secretion. NKA is also more potent than SP in stimulating the motility of the urinary bladder and in activating the micturition reflex. Exposure of the airways to mechanical or chemical irritants such as cigarette smoke produces reflex responses such as bronchoconstriction, vasodilatation, and increased vascular permeability, mucous secretion, and mucociliary activity. There is strong evidence that tachykinins released from capsaicin-sensitive afferent fibers plays an important role in mediating these responses. NKA is appreciably more potent than SP in humans with respect to bronchoconstrictor action, whereas SP is more potent in vascular and secretory regulation. Inappropriate release of tachykinins may be involved in the pathogenesis of allergic reactions in the respiratory system and in the hyperresponsiveness of the airways in asthma.

The metabolic clearance rate of NKA, like SP, is extremely high, whereas the half-lives of the N-terminally extended forms (NPK and NP γ) in the circulation are appreciably longer. Consequently, intra-arterial infusions of NPK and NP γ produce hypotensive and bronchoconstrictor responses that are of enhanced magnitude and duration compared with NKA. Similarly, NPK is appreciably more potent than NKA in stimulating adrenal corticosterone release in rats. Elevated concentrations of NPK have been measured in the circulation of patients with metastatic carcinoid tumors. The powerful vasodilator and bronchoconstrictor actions of this peptide are consistent with a role in the etiology of the flushing and bronchoconstriction observed in patients with carcinoid syndrome. Data have demonstrated that the human placenta is an abundant source of NKB, and enhanced release of placental NKB into the maternal circulation during the third trimester of pregnancy has been found in women suffering from preeclampsia.

PATHOGENESIS OF DIABETIC AUTONOMIC NEUROPATHY

Hypotheses concerning the multiple etiologies of diabetic autonomic neuropathy include a metabolic insult to nerve fibers, neurovascular insufficiency, auto-immune damage, and neurohormonal growth factor deficiency. Several different factors have been implicated in this pathogenic process. Hyperglycemic activation of the polyol pathway leading to the accumulation of sorbitol and potential changes in the NAD:NADH ratio may cause direct neuronal damage and/or decreased nerve blood flow. Activation of protein kinase C induces vasoconstriction and reduces neuronal blood flow. Increased oxidative stress, with increased free radical production, causes vascular endothelium damage and reduces nitric oxide bioavailability. Alternatively, excess nitric oxide production may result in the formation of peroxynitrite and damage to the endothelium and neurons, a process referred to as nitrosative stress. In a subpopulation of individuals with neuropathy, immune system mechanisms may also be involved. Reduction in neurotrophic growth factors, deficiency of essential fatty acids, and formation of advanced glycosylation end-products also result in reduced endoneurial blood flow and nerve hypoxia with altered nerve function. The result of this multifactorial process may be the activation of poly(ADP) ribosylation depletion of ATP, resulting in cell necrosis and the activation of genes involved in neuronal damage.

CLINICAL MANIFESTATIONS OF DIABETIC AUTONOMIC NEUROPATHY

The metabolic disorders of diabetes lead to diffuse and widespread damage of nerves and small vessels. Clinical manifestations of autonomic dysfunction frequently occur concurrently but in inconsistent patterns (Table I). Diabetic autonomic neuropathy is typically assessed by focusing on symptoms or dysfunction attributable to a specific organ system. Cardiac autonomic neuropathy is the most prominent focus because of the life-threatening consequences of this complication and the availability of direct tests of cardiovascular autonomic function. However, neuropathies involving other organ systems should also be considered in the optimal care of patients with diabetes.

Table I Clinical Manifestations of Autonomic Neuropathy

| |
|---|
| Cardiovascular |
| Resting tachycardia |
| Exercise intolerance |
| Orthostatic hypotension |
| Silent myocardial ischemia |
| Gastrointestinal |
| Esophageal dysmotility |
| Gastroparesis diabeticorum |
| Constipation |
| Diarrhea |
| Fecal incontinence |
| Genitourinary |
| Neurogenic bladder |
| Erectile dysfunction |
| Retrograde ejaculation |
| Female sexual dysfunction (loss of vaginal lubrication) |
| Metabolic |
| Hypoglycemia unawareness |
| Hypoglycemia-associated autonomic failure |
| Sudomotor |
| Anhidrosis |
| Heat intolerance |
| Gustatory sweating |
| Dry skin |
| Pupillary |
| Argyll-Robertson pupil |
| Decreased diameter of dark-adapted pupil |

Cardiac Autonomic Neuropathy

Cardiac autonomic neuropathy results from damage to the autonomic nerve fibers that innervate the heart and blood vessels and results in abnormalities in heart-rate control and vascular dynamics. The 5-year mortality rate from this serious complication is five times higher for individuals with cardiac autonomic neuropathy than for individuals without cardiovascular autonomic involvement. Autonomic dysfunction can impair exercise tolerance. The severity of cardiac autonomic neuropathy has been shown to correlate inversely with an increase in heart rate at any time during exercise and with the maximal increase in heart rate. Cardiac autonomic neuropathy also leads to a reduced cardiac ejection fraction, systolic dysfunction, and decreased diastolic filling. There is a consistent association between cardiac autonomic neuropathy and the presence of silent myocardial ischemia. The

perception of angina is severely impaired in diabetic patients, allowing these individuals to exercise longer after the onset of myocardial ischemia with dire consequences. Chest pain in any location in a patient with diabetes should be considered to be of myocardial origin until proven otherwise; however, of equal importance, unexplained fatigue, confusion, tiredness, edema, hemoptysis, nausea and vomiting, diaphoresis, arrhythmias, cough, or dyspnea should alert the clinician to the possibility of silent myocardial infarction. Mortality rates after a myocardial infarction are also higher for diabetic patients than for nondiabetic patients. This may be due to regional differences in autonomic nerve damage within the heart, increasing the tendency for the development of ventricular arrhythmia and cardiovascular events after infarction.

Orthostatic hypotension, another sign of autonomic neuropathy, is a fall in systolic blood pressure of greater than 30 mm Hg on standing. It is aggravated by peripheral vascular pooling of blood such as occurs with hot baths or drugs used to treat hypertension. Patients with orthostatic hypotension typically present with lightheadedness and presyncopal symptoms. Symptoms such as dizziness, weakness, fatigue, visual blurring, and neck pain also may be due to orthostatic hypotension.

Gastrointestinal Autonomic Neuropathy

Gastrointestinal symptoms are relatively common among patients with diabetes and often reflect diabetic gastrointestinal autonomic neuropathy. Esophageal dysfunction results at least in part from vagal neuropathy; symptoms include heartburn and dysphagia for solids. Gastroparesis in diabetes is usually clinically silent and may be the most important cause of "brittle diabetes." Severe diabetic gastroparesis is one of the most debilitating of all diabetic gastrointestinal complications. Via the use of radioisotopic techniques that quantify gastric emptying, it appears that ~50% of patients with longstanding diabetes have delayed gastric emptying. Major clinical features of this disorder are early satiety, anorexia, nausea, vomiting, epigastric discomfort, and bloating. Episodes of nausea or vomiting may last for days to months or occur in cycles. Even with mild symptoms, gastroparesis interferes with nutrient delivery to the small bowel and therefore disrupts the relationship between glucose absorption and exogenous insulin administration. These changes may result in wide swings in glucose levels and unexpected episodes of postprandial hypoglycemia and apparent brittle diabetes. Gastroparesis should therefore always be

suspected in patients with erratic glucose control. Diarrhea is evident in 20% of diabetic patients, particularly those with known diabetic autonomic neuropathy. Diarrhea is typically intermittent, but bowel movements may occur 20 or more times per day with urgency, and the stools are often watery. Individuals with constipation may have less than three bowel movements per week and these may alternate with diarrhea. Fecal incontinence due to poor sphincter tone is common in individuals with diabetes and may be associated with severe paroxysmal diarrhea or constitute an independent disorder of anorectal dysfunction.

Genitourinary Autonomic Neuropathy

Neurogenic Bladder

The earliest bladder dysfunction is a sensory abnormality that results in impaired bladder sensation, an elevated threshold for initiating the micturition reflex, and an asymptomatic increase in bladder capacity with urinary retention. Overflow incontinence occurs because of denervation of the external and internal sphincters. Individuals with bladder dysfunction are predisposed to the development of urinary tract infections, including pyelonephritis, which may accelerate or exacerbate renal failure.

Erectile Dysfunction

Erectile dysfunction is the most common form of organic sexual dysfunction in males with diabetes, with an incidence estimated to be between 35 and 75%. It is defined as the consistent inability to attain and maintain an erection adequate for sexual intercourse. Erectile dysfunction may be the presenting symptom of diabetes and more than 50% of men with diabetes notice the onset of erectile dysfunction within 10 years of onset of the diabetes. Erectile dysfunction is a marker for the presence and development of generalized vascular disease and for premature demise from a myocardial infarct. Penile failure may portend an upcoming and possibly preventable, cardiovascular event. Erectile dysfunction should alert physicians to perform cardiovascular evaluations for these patients. Retrograde ejaculation into the bladder also occurs in diabetic males.

Hypoglycemic Unawareness

The counterregulatory hormone responses and awareness of hypoglycemia are reduced in patients with diabetes mellitus. Unawareness of hypoglycemia and unresponsiveness to it are serious problems that

hamper the patient's ability to manage his or her diabetes. In most diabetic patients, catecholamine release, triggered by low glucose levels, produces noticeable symptoms, such as tremulousness and cold sweat, that alert the patients to eat and take other measures to prevent coma. Diabetic autonomic neuropathy impairs catecholamine release and prevents the warning signs of hypoglycemia, leaving the patient unaware of it. The related problem of hypoglycemic unresponsiveness occurs when impaired autonomic responses derange glucose counter-regulation during fasting or periods of increased insulin activity. In healthy people and in patients with early-stage diabetes, these autonomic responses result in the release of glucagon and epinephrine for short-term glucose counter-regulation and in the release of growth hormone and cortisol for long-term regulation. Failure in glucose counter-regulation can be confirmed by the absence of glucagon and epinephrine response to hypoglycemia induced by a controlled dose of insulin. The glucagon response becomes impaired after 1 to 5 years of type 1 diabetes. After 15 to 30 years, the glucagon response is almost undetectable, and it is absent in patients with autonomic neuropathy. The difficulty is in distinguishing the loss of counter-regulation due to autonomic neuropathy from that due to the dampening effects of intensive glycemic control and recurrent hypoglycemia, called "hypoglycemia-associated autonomic failure."

Neurovascular Disturbances

Skin blood flow is important in maintaining nutrition, maintaining regional and whole body temperature, and healing traumatized skin. The apical (glabrous) skin is present in the palmar surface of the hand, the plantar surface of the foot, and the face. It contains a large number of arteriovenous anastomoses or shunts and functions in thermoregulation. In contrast, non-apical (hairy) skin is present over most of the body surface. There are relatively few arteriovenous shunt vessels and blood flow is primarily nutritive in function. Microvascular skin flow is under the control of the autonomic nervous system and is regulated by both the central and peripheral components. In diabetes, the rhythmic contraction of arterioles and small arteries is disordered. Microvascular blood flow can be accurately measured noninvasively using laser Doppler flowmetry. Defective blood flow in the small capillary circulation is found with decreased responsiveness to mental arithmetic, cold pressor, handgrip, and heating. The defect is associated with a reduction in the amplitude of vasomotion and

resembles premature aging. There are differences in the glabrous and hairy skin circulations. In hairy skin, a functional defect is found before the development of neuropathy; it occurs in family members and it may precede the development of diabetes. The clinical impact is dry skin, loss of sweating, and the development of fissures and cracks that are portals of entry for microorganisms leading to infectious ulcers and ultimately gangrene. The effect of autonomic neuropathy on the risk of developing a foot ulcer is independent of other measures of sensory neuropathy. Autonomic neuropathy may also lead to hyperperfusion of bone with increased osteoclastic activity, resulting in reduced bone density. Thus, a hot foot should alert the physician to impending Charcot's neuroarthropathy.

DIAGNOSTIC TESTS OF DIABETIC AUTONOMIC NEUROPATHY

Assessing Cardiovascular Autonomic Function

Tests of cardiovascular reflexes are sensitive, reproducible, simple, and noninvasive and they allow extensive evaluation of diabetic cardiovascular autonomic neuropathy. These include measurements of the resting heart rate, beat-to-beat heart-rate variation, blood pressure response to the Valsalva maneuver, changes in heart rate and systolic blood pressure in response to sustained exercise, and the QT interval. An increased resting heart rate and loss of heart-rate variation in response to deep breathing are primary indicators of parasympathetic dysfunction. Tests for sympathetic dysfunction include measurements of changes in heart rate and blood pressure in response to standing, exercise, and handgrip. Reduced 24h heart-rate variability (HRV), a newer test, is believed to be more sensitive than standard reflex tests and can detect cardiac autonomic neuropathy earlier. A 24h recording of HRV can reveal abnormal circadian rhythms regulated by sympathovagal activity. In vagal dysfunction, the high-frequency (HF) component of HRV is reduced; in sympathetic dysfunction, the low-frequency (LF) and very low-frequency components are reduced. Furthermore, in advanced cardiac autonomic neuropathy, all three components are reduced, as is the LF:HF ratio, which represents sympathovagal balance.

HRV should be assessed during deep breathing, the Valsalva maneuver, and standing. It may be used to diagnose the cause, for example, of gastroparesis or erectile dysfunction, to give an incentive for intensive

glycemic control, to quantitate the risk of a macrovascular event, and to monitor the response to therapy. Abnormalities in two or more of these tests suggest a diagnosis of autonomic neuropathy. Some centers recommend that patients with type 1 diabetes be tested 5 years after diagnosis and yearly thereafter and that patients with type 2 diabetes be tested at diagnosis and yearly thereafter. The sympathetic innervation of the heart can also be visualized and quantified by single-photon emission computed tomography with metaiodobenzylguanidine in a research setting.

Assessing Gastrointestinal Autonomic Function

The finding of retained food in the stomach after an 8 to 12 h fast in the absence of obstruction is diagnostic of gastroparesis. Basic diagnostic tests include upper gastrointestinal (GI) endoscopy or barium series to rule out structural or mucosal abnormalities of the GI tract. Gastric emptying can be visualized by scintigraphic imaging after the patient consumes radio-nuclide-labeled food, but the scintigraphic results do not always correlate with the severity of the symptoms. The blood glucose should be normal at the time of testing because hyperglycemia decreases gastric motility. Gastroduodenal manometry may be helpful in patients with symptoms but apparently normal emptying because it can help identify pylorospasm or incoordinate gastric and duodenal motility.

Before attributing constipation to diabetic autonomic neuropathy, the clinician should rule out other causes of constipation such as hypothyroidism, side effects of drugs such as amitriptyline or calcium channel blockers, and colonic carcinoma. All patients should have a careful digital rectal examination and women should have a bimanual pelvic examination. Three stool specimens should be tested for occult blood. Anorectal manometry may be used to assess the rectal anal inhibitory reflex, which can distinguish rectosigmoid dysfunction and outlet-obstructive symptoms from colonic hypomotility.

Assessing Genitourinary Autonomic Function

A thorough workup for erectile dysfunction in men should include a medical and sexual history, physical and psychological evaluations, blood tests for testosterone, prolactin, and thyroid hormones, a test for nocturnal erections, tests to assess penile, pelvic, and spinal nerve functions, and tests to assess penile blood supply and blood pressure. Physical examination must

include an evaluation of the autonomic nervous system, vascular supply, and hypothalamic–pituitary–gonadal axis. Autonomic neuropathy that causes erectile dysfunction is usually accompanied by loss of the HRV, ankle jerk reflex, and absent or reduced vibration sense over the large toes. To determine the integrity of sacral parasympathetic divisions, the physician should assess perianal sensation, sphincter tone, and the bulbocavernous reflex. Stenosis of the internal pudental artery is another potential cause of impotence. A penile/brachial index of less than 0.7 indicates diminished blood supply. A venous leak manifests as unresponsiveness to vasodilators and must be evaluated by penile Doppler sonography. In simple terms, unresponsiveness to intracavernosal injection of a direct vasodilator means arterial or venous insufficiency and requires inflatable devices, prostheses, or vascular reconstruction. A response to the vasodilator indicates autonomic insufficiency or a psychogenic cause that can be further defined using the HRV.

TREATMENT OF AUTONOMIC NEUROPATHY

Intensive glycemic control is critical to preventing the onset of diabetic autonomic neuropathy and slowing its progression. The Diabetes Control and Complications Trial (DCCT) provided extensive clinical evidence that good metabolic control reduces diabetic complications. Specifically with regard to cardiovascular autonomic function, the DCCT showed that intensive glycemic control prevented the development of abnormal HRV and slowed the deterioration of autonomic dysfunction over time in individuals with type 1 diabetes. The Steno Memorial Study emphasized a multifactorial approach including blood pressure, lipid, and glucose control and the use of vitamins and antioxidants and the researchers were able to reduce the likelihood of development of autonomic neuropathy by 68%. Early identification of cardiac autonomic neuropathy permits the timely initiation of therapy with the antioxidant α -lipoic acid, which appears to slow or reverse the progression of neuropathies in some studies. The use of cardioselective (e.g., atenolol) or lipophilic (e.g., propranolol) beta-blockers may also modulate the effects of autonomic dysfunction. By opposing the sympathetic stimulus, they may restore the parasympathetic–sympathetic balance. Studies using graded exercise, angiotensin-converting enzyme inhibitors, and aldosterone antagonists as a means to improve HRV have resulted in suggestive results in small populations in

research studies. Cardiovascular evaluation should include macrovascular risk factors and their elimination.

Orthostasis is best treated by avoiding precipitating factors such as hot baths and drugs that accentuate the fall in blood pressure. Patients should stand slowly and useful drugs include clonidine, midodrine, and somatostatin. The use of fludrosterone and the liberalization of salt intake usually result in weight gain edema and inadequate control of the orthostatic symptoms.

Neurovascular dysfunction requires the use of emollient creams, scrupulous attention to foot care, vasodilators, and bisphosphonates for impending Charcot's neuroarthropathy.

Treatment of gastroparesis should stress improvement of glycemic control and correction of other metabolic abnormalities. It also includes dietary modification, gastric suction, and prokinetic agents such as metoclopramide, domperidone, or erythromycin. In some severe cases, jejunostomy may be needed to provide for nutrient intake and to allow the stomach to rest until such time that it recovers its function.

The severe and intermittent nature of diabetic diarrhea makes treatment difficult. Because afferent denervation may contribute to the problem, a bowel program that includes restriction of soluble fiber and regular effort to move the bowels is indicated. In addition, trials of a gluten-free diet and restriction of lactose, cholestyramine, clonidine, somatostatin analogue, pancreatic enzyme supplements, and antibiotics, such as metronidazole, may be indicated. Treatment of constipation should begin with an emphasis on good bowel habits, including regular exercise and maintenance of adequate hydration and fiber consumption. Sorbitol and lactulose may be helpful.

A grossly overdistended bladder should be drained by catheter to improve contractility and the patient should be instructed to void by the clock rather than waiting for the sensation of bladder distension. Cholinergic agents or clean intermittent self-catheterization may also be used to facilitate emptying.

Treatment of erectile dysfunction may include withdrawal from offending medications coupled with psychological counseling, medical treatment, or surgery. Medical treatment may include the 5'-phosphodiesterase inhibitors, such as sildenafil, tadalafil, or vardenafil. A lower dosage is needed for individuals with renal failure or liver dysfunction. It may, however, take several doses to achieve an effect in patients

with diabetes. These drugs should not be taken by individuals with unstable ischemic heart disease or those using nitroglycerin or other nitrate-containing medications. Alternative treatments include suction devices with or without a constriction ring, injections of vasodilators into the corpus cavernosum, and ultimately prostheses.

Prospects for the Future

With improved understanding of the pathogenesis of autonomic neuropathy, agents that have the potential for treating the underlying biologic defect rather than purely symptomatic therapy are being investigated. The situation is much less gloomy than the 1994 *Lancet* editorial that stated, "all we can do is make the diagnosis and commiserate with the patient."

receptors in general elicit a similar signaling response as other receptors coupling to $G_{i/o}$ proteins.

NPY AND METABOLIC FUNCTION

NPY is one of the most powerful stimulators of food intake. Endogenously, this appears to involve neurons from the arcuate nucleus that project to the paraventricular nucleus and act on a combination of Y_1 and Y_5 receptors. Increases in body weight have been demonstrated in a variety of animal models upon central NPY administration. Since food intake, body weight homeostasis, and thermogenesis are closely linked, it is noteworthy that central NPY administration reduces brown adipose tissue thermogenesis. Thus, it has been proposed that NPY may play a role in obesity. This is further supported by the finding that alterations in the hypothalamic NPY system precede the disturbances in feeding in genetically obese animals, such as *ob/ob* and *db/db* mice or the *fa/fa* Zucker rat, that are characterized by hyperphagia and hyperinsulinemia.

Central administration of NPY raises levels of circulating insulin independent of the availability of food, whereas peripheral NPY administration was reported to lower blood glucose without accompanying alterations of insulin levels. Alterations of circulating insulin, on the other hand, can markedly affect hypothalamic expression of NPY, as observed in animal models of genetic and acquired diabetes. The pathophysiological importance of these findings remains to be determined.

NPY AND PITUITARY FUNCTION

NPY can lower circulating levels of growth hormone, possibly via the release of somatostatin, which can be stimulated in the hypothalamus by low NPY doses. Correspondingly, pathophysiological conditions associated with elevated NPY tone in the hypothalamus, such as obesity, are associated with reduced growth hormone levels.

NPY can stimulate the release of corticotrophin-releasing factor to enhance the secretion of ACTH from the anterior pituitary and hence plasma levels of corticosterone. This appears to be part of a regulatory feedback loop since glucocorticoids can regulate NPY gene expression.

NPY can also facilitate luteinizing hormone (LH) secretion, an effect that is dependent on the presence of sex steroids. Although acute facilitatory effects on LH secretion are well documented, the chronic

effect of NPY is less well understood due to possible interference by concomitant alterations of food intake.

NONENDOCRINE NPY EFFECTS

In both the central and the peripheral nervous systems, NPY can inhibit transmitter release via prejunctional receptors, usually belonging to the Y_2 subtype. This can occur as autoinhibition (i.e., in neurons releasing NPY, such as sympathetic neurons) or as heteroinhibition (i.e., in neurons not releasing NPY, such as parasympathetic neurons). For a number of central NPY actions, it is not yet known whether they occur directly (i.e., via postjunctional receptors) or indirectly (i.e., via prejunctional receptors).

In addition to its effects on metabolism and neuroendocrine regulation, NPY can also cause other central nervous system (CNS) effects such as anxiolysis, which apparently occurs via Y_1 receptors. An anti-seizure activity of NPY has also been demonstrated. A greater susceptibility to seizures in NPY knockout mice suggests the endogenous importance of this effect, which seems to occur via Y_5 receptors. Various types of stress-related behaviors as well as the regulation of voluntary alcohol intake are also prominent CNS-based NPY effects.

The most prominent peripheral nonendocrine effect of NPY is vasoconstriction. This involves a direct effect on vascular smooth muscle cells and also a potentiation of the effects of other vasoconstricting agents; in most cases, both parts of the enhancement of vascular smooth muscle tone occur via Y_1 receptors. Although NPY-induced vasoconstriction is also present in the renal circulation, NPY has repeatedly been shown to induce diuresis and natriuresis. However, the exact localization of the receptor, which modulates tubular function and resembles a Y_5 receptor, is not known. NPY can also modulate the contractility of nonvascular smooth muscle cells, including those of the gut.

While all of these peripheral effects occur acutely, extended NPY exposure can also affect cell growth by causing, for example, cardiomyocyte hypertrophy or vascular smooth muscle cell proliferation and angiogenesis. Data from studies of knockout mice indicate that NPY may also be a neuroproliferative factor.

GENE STRUCTURE AND MECHANISMS OF GENE DUPLICATION

The genes for NPY, PYY, and PP all have three introns in equivalent positions. This confirms evolution from a common ancestral gene by duplication followed by sequence divergence. The genes for NPY and PYY are located on different human chromosomes close to the HoxA and HoxB gene clusters, respectively. Many other gene families have members on both of these chromosomes, suggesting that the entire chromosome was duplicated, after which the NPY and PYY genes accumulated sequence differences and became differentially expressed. This duplication probably took place very early in vertebrate evolution (Fig. 2). The PP gene is located only 11 kb from the PYY gene and in the same orientation, suggesting that it arose by a local tandem duplication. Because PP is known only in tetrapods, this gene duplication probably occurred in the common ancestor of tetrapods (Fig. 2). Fish PY and the second lamprey PYY-like peptide probably arose by independent gene duplications.

EVOLUTION OF FUNCTIONS

The functions of NPY have primarily been studied in mammals, where NPY influences a very large number of physiological parameters. The effects include stimulation of food intake, vasoconstriction, release of pituitary hormones, influence on circadian rhythms, and modulation of neuronal activity in the hippocampus. Beyond mammals, the functions of NPY are less well known. The most studied effect is that on food intake, which is stimulated in virtually all vertebrates

investigated, including chicken, garter snake, and goldfish.

EVOLUTION OF NPY RECEPTORS

The NPY family peptides have at least five distinct receptor subtypes in mammals, all of which belong to the superfamily of G protein-coupled receptors. The subtypes Y1, Y2, and Y5 probably arose before the origin of vertebrates, and these receptors display only approximately 30% overall amino acid sequence identity to each other. The genes for these three subtypes are located in close proximity to each other on chromosome 4 in the human genome, and the genes for Y1 and Y5 even seem to overlap in their regulatory

Figure 2 Probable gene duplication events for the NPY family of peptides shown in a schematic tree for vertebrates, hagfishes, and amphioxus.

regions. This gene cluster was probably duplicated as part of a chromosome duplication during early vertebrate evolution, in analogy with the NPY–PYY gene duplication mentioned previously, forming the two Y1-like genes: Y4, which is the primary receptor for PP, and y6, which is a pseudogene in human and several other mammals (hence indicated with lower-case “y”) but appears to be functional in mouse, rabbit, chicken, and a shark. A Y2 duplicate exists in teleost fishes and frogs but has probably been lost in mammals. Little is yet known about the functional evolution of the receptor subtypes, but both Y1 and Y5 seem to stimulate food intake in response to NPY in the species that have been investigated. Receptor subtypes Y2 and Y4 inhibit food intake in response to PYY(3–36) and pancreatic polypeptide, respectively.

| Chicken Lys Asp NT6 (LANT6) | | | | | | | | Lys | Asn | Pro | Tyr | Ile | Leu |

regulatory peptides, such as cholecystokinin, to influence gastrointestinal functions. Neurotensin is also secreted from neurosecretory cells in the hypothalamus and nerve terminals in the median eminence, with elevated levels seen in hypophyseal-portal blood of the rat. In contrast, the neurotensin originating from the gonadotropes and thyrotropes of the anterior pituitary probably functions as paracrine/autocrine agents.

RECEPTORS

Following the first demonstration of neurotensin-binding sites in rat brain synaptic terminals in 1977, there have been many biochemical and autoradiographic studies on the nature and distribution of neurotensin-binding sites. These have culminated with the cloning of three receptor subtypes, all of which recognize the C-terminal, biologically active part of neurotensin.

Neurotensin Type 1 (NTR1)

The cDNA clone was obtained from the rat brain cDNA library using an electrophysiological assay in *Xenopus* oocytes as the end point. The cDNA encodes a 424-amino acid protein (similar in size to that reported earlier by chemical isolation) and, as suggested by pharmacological studies, is a member of the G protein-coupled receptor family. The human receptor has been cloned from the colonic adenocarcinoma cell line HT29. The receptor has a high affinity (0.2 nM), is insensitive to levocabastine, and is expressed in the intestine and brain. Signal transduction mechanisms are primarily intracellular Ca and inositol 1,4,5-trisphosphate.

Neurotensin Type 2 (NTR2)

This is a low-affinity (5–7 nM) receptor that shares about 60% homology with NTR1 and is sensitive to levocabastine. Although it has the characteristics of a

G protein-coupled receptor, the transduction mechanisms have not been completely characterized and appear to be system and species specific. Furthermore, neurotensin antagonists have paradoxical agonist functions in some species. The receptor is expressed mostly in the brain, but in a distribution pattern different from NTR1, so that there is rarely coexpression.

Neurotensin Type 3 (NTR3)

A third neurotensin-binding site was isolated by affinity cross-linking of brain extracts and following cloning shown to have 100% homology with the previously cloned human gp95/sortilin receptor. This protein has a large luminal domain, a single transmembrane domain, and a short cytoplasmic tail. The signal transduction mechanism and biological role remain to be determined.

BIOLOGICAL EFFECTS

Neurotensin has a variety of biological effects, with more than 30 different *in vitro* and *in vivo* effects known. Peripheral effects include vasodilation, cyanosis, increased histamine release, stimulation of the endocrine and exocrine pancreas, effects on gastrointestinal tract smooth muscle activity and motility, stimulation of intestinal secretion, and inhibition of blood flow to adipose tissue. Centrally, neurotensin has hypothermic and antinociceptive effects, and it modulates brain dopamine systems, luteinizing hormone (LH), and prolactin release.

Gastrointestinal Effects

Neurotensin secretion is stimulated by a fat-containing meal and has been postulated as the mediator of many of the effects of fat ingestion. These include inhibition of gastric acid secretion and motility, stimulation of pancreatic and intestinal secretions, decrease in adipose tissue blood flow, and increase in small intestinal blood flow. Neurotensin potentiates

the actions of secretin, cholecystokinin, and the vagus on pancreatic secretion and acts in concert with other enterogastrones, such as secretin, to inhibit gastric acid secretion.

Central Effects

The neuroendocrine effects of neurotensin are extremely complex and dependent on the route of administration, the sex steroid status, and the species. Furthermore, there are outstanding issues of separating the physiological effects from the pharmacological effects and the mode of action (neurocrine, autocrine, paracrine, or endocrine). In this regard, the development of specific receptors and the use of anti-neurotensin antiserum have been most useful. SR48692 blocks NTR1-mediated effects, such as potassium-evoked dopamine release and turning behavior but not analgesia or hypothermia. These latter effects appear to be mediated by the NTR2 and are blocked by R142948A, an inhibitor of both NT1 and NT2. However, recent studies using NTR1 knockout mice suggest that this receptor does contribute to the analgesic and hypothermic responses.

As detailed in a recent review by Binder and colleagues, there are intimate and multiple anatomical and functional relationships between neurotensin and dopamine throughout the central nervous system, often with reciprocal modulation of their activities. Neurotensin activates hypothalamic dopaminergic and noradrenergic activity in the basal state but not in the fasted state. Central administration increases plasma adrenocorticotrophic hormone (ACTH) and corticosterone by enhancing the release of corticotrophic releasing factor (CRF) into the hypophyseal portal system. Studies with neurotensin antagonists implicate neurotensin in the stress-initiated activation of the hypothalamic pituitary adrenal axis. In ovariectomized animals (but not in male ones), injection of neurotensin in the preoptic area stimulates LH secretion, whereas injection of NT into the cerebral ventricular system inhibits LH secretion. However, no effect is seen in humans following intravenous administration.

As for gonadotropin release, the route of administration and the experimental conditions are critical in determining the effects of neurotensin on prolactin release. Intracerebroventricular administration decreases circulating prolactin, whereas intravenous administration increases prolactin concentrations. These effects appear to be specific in that they can be reversed by the administration of anti-neurotensin serum. Interestingly, estrogen increases neurotensin mRNA in specific regions of the hypothalamus, further

implicating hypothalamic neurotensin in the estrogen-dependent prolactin secretion. In contrast, estrogen decreases anterior pituitary levels of neurotensin. Despite some conflicting data, studies comparing the effects of neurotensin and neurotensin antiserum administration are consistent with a stimulatory effect of neurotensin on thyroid-stimulating hormone (TSH) secretion via an autocrine or paracrine mode of action.

In summary, neurotensin regulates anterior pituitary function both by its release from the nerve terminal from the median eminence and by autocrine/paracrine effects from neurotensin synthesized within the anterior pituitary. The expression of hypothalamic and pituitary neurotensin is under the regulation of gonadal and steroid hormones.

PATHOLOGY

Pancreatic tumors producing neurotensin have been reported, but these tumors often produce excess amounts of other peptides, particularly vasoactive intestinal peptide. Because vasoactive intestinal peptide and neurotensin both stimulate intestinal secretion, it is difficult to assess the role, if any, of neurotensin in gastrointestinal symptoms of pancreatic tumors. No clinical syndromes that could be attributed to neurotensin were evident in patients with either lung or hepatic fibrolamellar tumors containing neurotensin as the only detected bioactive peptide. However, the presence of neurotensin in some types of tumors may be of some relevance given that, in experimental studies, neurotensin promotes gastric and colonic carcinogenesis and stimulates the growth of small cell lung cancer cell lines. Neurotensin antagonists inhibited basal and neurotensin stimulated small cell lung cancer growth. Neurotensin is absent from normal prostate but is synthesized and secreted from primary prostate cancers. The proliferative effect of neurotensin may be of theoretical benefit in patients who have atrophy of the bowel associated with long-term parenteral feeding. However, this has not been tested in the human. Neurotensin has been implicated in the pathogenesis of schizophrenia, and a subset of schizophrenic patients have low cerebrospinal fluid neurotensin concentrations that are restored by effective antipsychotic drug treatment.

GABA

GABA was recognized as a unique chemical component of brain in 1950, long before its functions were understood. Its neurotransmitter properties were first validated for the inhibitory nerves of crustacean (lobster) limb muscles, in which GABA content was shown to account for the inhibitory effects of extracts of these nerve fibers, and release of GABA with increased firing of the nerve fibers correlated with the inhibitory effects on the muscle.

In the mammalian CNS, GABA is considered the major mediator for local interneurons and for presynaptic inhibition within the spinal cord. Presumptive GABAergic inhibitory synapses have been demonstrated most clearly between cerebellar Purkinje neurons and their targets in Deiter's nucleus; between small interneurons and the major output cells of the cerebellar cortex, olfactory bulb, cuneate nucleus, hippocampus, and lateral septal nucleus; and between the vestibular nucleus and the trochlear motoneurons. GABA also mediates inhibition within the cerebral cortex and between the caudate nucleus and the substantia nigra. GABAergic neurons and nerve terminals have been localized with immunocytochemical methods that visualize glutamic acid decarboxylase, the enzyme that catalyzes the synthesis of GABA from glutamic acid. GABA-containing neurons have frequently been found to coexpress one or more neuropeptides. The most useful selective antagonists for demonstration of likely GABAergic synapses are bicuculline and picrotoxin.

GABA receptors exist in two main molecular forms, each with a functional representation. The more prominent GABA receptor subtype, the GABA_A receptor, is a ligand-gated Cl⁻ ion channel that opens in the presence of GABA. As a typical ion channel receptor, akin to the classical cholinergic nicotinic receptor, the GABA_A receptor is composed of four or five subunits, each of which is composed of proteins that exhibit four transmembrane domains and cluster to form the ion channel for Cl⁻. Although there are four main classes of subunits, there are multiple variations, providing for an enormous number of possibly similar but distinct classes of GABA receptors. Many neuroactive drugs, such as benzodiazepines, ethanol, and barbiturates, act on GABA_A receptors. The GABA_B receptor is a G protein-coupled receptor able to activate second-messenger signal transduction pathways, and like other receptors of this class, it exhibits a structure composed of seven transmembrane domains. Many of the features described for the GABA_A receptor family also apply to the glycine receptor, which appears to be

the major inhibitory neurotransmitter in the brainstem and spinal cord.

Glutamate and Aspartate

Glutamate and aspartate are both abundant in brain, and both are powerful excitants for neurons in every brain region of the CNS, where they are considered the principal fast ("classical") excitatory transmitters. Glutamate receptors, like GABA receptors, exist in two forms—as ligand-gated ion channel receptors with multiple possible combinations of a few isoforms of subunits or as G protein-coupled receptors. The ligand-gated glutamate ion channel receptors are further classified according to the agonists that selectively activate them, including α -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA), kainate, and *N*-methyl-D aspartate (NMDA) receptors, each of which has selective agonists and antagonists. The diversity of gene expression and, consequently, of the protein structure for glutamate receptors also arises by alternative splicing and RNA editing.

AMPA and kainate receptors mediate fast depolarization at most glutamatergic synapses in the brain and spinal cord. NMDA receptors are also involved in normal synaptic transmission, but activation of NMDA receptors is more closely associated with the induction of various forms of synaptic plasticity. AMPA or kainate receptors and NMDA receptors coexist at many glutamatergic synapses. Activation of NMDA receptors is obligatory for the induction of the form of plasticity known as long-term potentiation. Activation of NMDA receptors requires both the binding of glutamate and the simultaneous depolarization of the postsynaptic membrane to displace a Mg²⁺ normally bound within the channel. High concentrations of glutamate are lethal to neurons because of elevation of intracellular Ca²⁺ levels and induction of apoptosis. Studies suggest that local depletion of Na⁺ and K⁺, as well as small increases in extracellular Zn²⁺, will activate both necrotic and proapoptotic cascades of neuronal death. Disordered glutamatergic transmission has been postulated as a mechanism of chronic neurodegenerative diseases and schizophrenia.

AMINE TRANSMITTERS

In the following sections, all the neurotransmitters that are chemically amines are discussed, including the monoamines dopamine, norepinephrine, and epinephrine (which together comprise the catecholamines);

5-hydroxytryptamine (or serotonin); the diamine histamine; and the quaternary amine acetylcholine. However, all of these have been studied for far longer than their chemical similarities have been apparent.

Acetylcholine

Acetylcholine (ACh) became the first established chemical neurotransmitter when it was demonstrated to be the substance released by the vagus nerve to slow the heart rate as the terminal step in the parasympathetic control of heart rate. ACh was later identified as the transmitter at both neuromuscular and parasympathetic neuroeffector junctions, as well as at the major synapse within autonomic ganglia. Eventually, ACh received recognition as a central neurotransmitter, based on its irregular distribution within the CNS and the behavioral effects exerted by cholinergic drugs after central administration. The first established cholinergic central synapse was the recurrent excitatory synapse from Renshaw interneurons to spinal motoneurons.

As for the amino acid receptors, the classical pharmacological forms of the cholinergic receptors were also shown by molecular cloning and sequence determinations to be represented by ligand-gated ion channels (nicotinic receptors) and by G protein-coupled forms (muscarinic receptors). As is the case for the amino acids, nicotinic receptors have multiple combinations of four transmembrane domain subunits, whereas the muscarinic receptors, like all known G protein-coupled receptor forms, exist as a single seven-transmembrane domain. In most regions of the CNS, the effects of ACh, assessed either by iontophoresis or by radioligand receptor-displacement assays, appear to be generated by interaction with a mixture of nicotinic and muscarinic receptors. Several sets of presumptive cholinergic pathways have been described in addition to that of the nicotinic spinal Renshaw cell to motoneuron. Eight major clusters of ACh neurons and their pathways have been characterized, with four separate groups of cell bodies located in the basal forebrain, two groups in the upper pons provide the major cholinergic innervation of thalamus and striatum, and there are two groups for the mid-brain and brainstem. The intense cholinergic projections to neocortex and hippocampal formation are dependent on the trophic growth factors provided to them by retrograde axonal transport from their target neurons, and their loss has been the sole target of treatments for Alzheimer's disease through inhibition of the central catabolic enzyme, acetylcholinesterase.

Catecholamines

The brain contains separate neuronal systems that use three different catecholamines—dopamine, norepinephrine, and epinephrine. These monoamines are derived from the common precursors tyrosine and L-dihydroxyphenylalanine (L-DOPA), and they form a three-step synthetic metabolic pathway. Tyrosine is converted to L-DOPA by tyrosine hydroxylase, L-DOPA is converted to dopamine by DOPA decarboxylase, dopamine is converted to norepinephrine by dopamine β -hydroxylase, and norepinephrine is converted to epinephrine by the synthetic enzyme phenylethanolamine *N*-methyl transferase. When these enzymatic steps were determined, antibodies raised against these proteins were found to be useful cellular markers and defined three catecholamine-containing neuronal systems: Tyrosine hydroxylase defined dopamine- and norepinephrine-synthesizing neurons, antibodies to dopamine β -hydroxylase revealed exclusively the norepinephrine-synthesizing neurons, and antibodies to phenylethanolamine *N*-methyl transferase defined the epinephrine-synthesizing neurons. Each system is anatomically distinct and serves separate but similar functional roles within their fields of innervation.

Dopamine

Originally, dopamine was considered to be only a precursor for norepinephrine; however, assays of distinct regions of the CNS eventually revealed that the distributions of dopamine and norepinephrine are markedly different. In fact, more than half the CNS content of catecholamine is dopamine, and extremely large amounts are found in the basal ganglia (especially the caudate nucleus), the nucleus accumbens, the olfactory tubercle, the central nucleus of the amygdala, the median eminence, and restricted fields of the frontal cortex. The anatomical connections of the dopamine-containing neurons are categorized into three major morphological classes: (i) ultrashort neurons within the amacrine cells of the retina and periglomerular cells of the olfactory bulb; (ii) intermediate-length neurons within the tuberobasal ventral hypothalamus, critical for many endocrine regulatory processes within the median eminence and intermediate lobe of the pituitary, that connect the dorsal and posterior hypothalamus with the lateral septal nuclei and other hypothalamic nuclei; and (iii) long projections between the major dopamine-containing nuclei in the substantia nigra (named for the black pigment that these neurons exhibit in the postmortem human and monkey brain and that is lost

when these neurons die in Parkinson's disease) and the ventral tegmentum. These dopamine neurons project to precise targets in the striatum, in the cerebral cortex, and in other major limbic structures except the hippocampus. All dopamine receptors are represented by two functional classes of G protein-coupled receptors—those that activate adenylate cyclase (D1 and D5) and those that inhibit the activation of adenylate cyclase (D2–D4). The D2 receptors couple to multiple effector systems, including the inhibition of adenylate cyclase activity, suppression of Ca^{2+} currents, and activation of K^{+} currents. D2 dopamine receptors have been implicated in the pathophysiology of schizophrenia and Parkinson's disease.

Norepinephrine

The noradrenergic innervation of the forebrain, including the hypothalamus, cortex, hippocampus, and olfactory bulb, arises from the major cluster of noradrenergic neurons in the pontine nucleus called the locus ceruleus because of the blue pigment they contain in the brains of primates. There are relatively large amounts of norepinephrine within the hypothalamus and in certain zones of the limbic system, such as the central nucleus of the amygdala and the dentate gyrus of the hippocampus. However, norepinephrine is also present in significant but lesser amounts in most brain regions. Detailed mapping studies indicate that most noradrenergic neurons arise either in the locus ceruleus of the pons or in neurons of the lateral tegmental portion of the reticular formation. From these neurons, multiple branched axons innervate specific target cells in a large number of cortical, subcortical, and spinal fields. The pharmacological properties of such synapses are complex, with evidence of mediation by both α - and β -adrenergic receptors (both G protein-coupled receptors; the β -adrenergic receptors activate adenylate cyclase, whereas α -adrenergic receptors inhibit cyclic AMP synthesis, and each form has three or more subtypes). For example, stimulation of the locus ceruleus depresses the spontaneous activity of target neurons in the cerebellum mediated by a slowly developing hyperpolarization and a decrease in membrane conductance. However, activation of the locus ceruleus also enhances the higher firing rates produced by stimulation of excitatory inputs to these convergent target neurons to a lesser degree. The afferent circuits innervating the locus ceruleus neurons include medullary cholinergic neurons, opioid peptide neurons, raphe (5-HT) neurons, and corticotropin-releasing hormone neurons from the hypothalamus. Tricyclic antidepressant drugs act on noradrenergic

neurons, augmenting levels in the extracellular space by inhibiting the norepinephrine transporter.

Epinephrine

Epinephrine-containing neurons are found in the medullary reticular formation and make restricted connections to a few pontine and diencephalic nuclei, such as the paraventricular nucleus of the dorsal midline thalamus. Their physiological properties have not been established.

5-Hydroxytryptamine

The early history of this neurotransmitter brought together two sets of previously unconnected work on factors extracted from serum (serotonin) and gut (enteramine) identified chemically as 5-hydroxytryptamine (5-HT), which is functionally detected in large amounts in brain. Through various cytochemical approaches, 5-HT-containing neurons have been characterized in nine pontine and medullary nuclei lying in or adjacent to the midline (raphe). The more rostral raphe nuclei innervate forebrain regions, whereas the caudal raphe nuclei project within the brainstem and spinal cord with some overlap. The median raphe nucleus makes a major contribution to the innervation of limbic cortical structures, and the dorsal raphe nucleus makes a similar contribution to the cerebral cortex and the neostriatum.

Molecular biological approaches have led to the identification of more than 12 distinct mammalian 5-HT receptor subtypes, all of which are G protein-coupled receptors linked to a variety of signal transduction cascades except for the 5HT₃ receptor, which is a ligand-gated ion channel receptor. These subtypes exhibit characteristic ligand-binding profiles, couple to different intracellular signaling systems, exhibit subtype-specific distributions within the CNS, and mediate distinct behavioral effects of 5-HT. The 5-HT_{1A} receptors are abundantly expressed on 5-HT neurons of the dorsal raphe nucleus, where they are thought to be involved in temperature regulation. They are also found in regions of the CNS associated with mood and anxiety, such as the hippocampus and amygdala. 5-HT_{1D} receptors are potently activated by the drug sumatriptan, which is prescribed for acute management of migraine headaches.

The 5-HT₂ receptor class has three recognized subtypes: 5-HT_{2A}, 5-HT_{2B}, and 5-HT_{2C}. 5-HT_{2A} receptors are enriched in forebrain regions such as neocortex and olfactory tubercle as well as in several brainstem nuclei, including most cranial motoneurons. The 5-HT_{2C} receptor, which is very similar in

sequence and pharmacology to the 5-HT_{2A} receptor, is expressed abundantly in the choroid plexus, where it regulates cerebrospinal fluid production. The hallucinogen LSD interacts through the 5-HT₂ receptors. Serotonin-containing pathways have been implicated in sleep disturbances, appetitive problems, pain, and depression. The class of drugs termed serotonin selective reuptake inhibitors is very effective in some patients with major depression.

Histamine

Although not recognized as a neurotransmitter for much of the recent history of such signaling molecules, histamine and antihistaminic drugs were long known to possess potent effects on animal behavior. The subsequent biochemical detection of histamine synthesis by neurons, as well as direct cytochemical localization of these neurons, established the existence of a histaminergic system in the CNS. Most histaminergic neurons are located in the ventral posterior hypothalamus and give rise to long ascending and descending tracts to the entire CNS. Histaminergic neurons function in the regulation of arousal, body temperature, and vascular dynamics.

PEPTIDES

During the 1980s, numerous novel peptides were discovered in the CNS, each capable of regulating one or another aspect of neural function. Furthermore, certain peptides previously thought to exist only in gut or endocrine glands were also found in the CNS. Most CNS peptides are thought to act mainly in concert with coexisting transmitters, both amines and amino acids. Each neuropeptide system has significant implications for endocrinology and endocrine diseases. Three general approaches to the continuously growing families of neurons containing one or more neuropeptides are discussed here.

Organization by Peptide Families

Peptides can be grouped into families based on the possession of significant homology in amino acid sequences, with each having its own genetic representation through evolutionary gene duplication and subsequent divergence of functions. Such relationships are well illustrated by the tachykinin or the vasotocin (vasopressin/oxytocin) families, in which species differences can be correlated with modest

variations in peptide structure. The multiple members of the tachykinin/substance P family coexist within mammalian neurons in the brain and in the intestines and may account for the apparent existence of subsets of receptors for each of these peptides. The mammalian representatives of the vasotocin family show two concurrent products, vasopressin and oxytocin, each having evolved to perform separate functions once executed in amphibia by a single vasotocin-related peptides and receptor. A different divergent evolutionary pathway is illustrated by the endorphin and by the glucagon–secretin peptide families. In the endorphin superfamily, three major genetically distinct systems of endorphin peptides (proopiomelanocortin, proenkephalin, and prodynorphin) exist in independent neuronal circuits. These natural opioid peptide families have emerged from independent but homologous genes. The peptides all share some actions at receptors once classed generally as “opioid” but that are undergoing progressive refinement with molecular resolution of their structures, functions, and cellular expression patterns. In the glucagon–secretin family, multiple and somewhat homologous peptides are found simultaneously in different cells of the same organism but in separate organ systems: glucagon and vasoactive intestinal polypeptide (VIP) in pancreatic islets; secretin in duodenal mucosa; VIP and related peptides in enteric, autonomic, and central neurons; and growth hormone-releasing factor in central neurons only. The general metabolic effects produced by this family lead to increased blood glucose.

Organization by Anatomic Pattern

Some peptide systems follow consistent anatomical organizations. Thus, the hypothalamic peptides oxytocin, vasopressin, proopiomelanocortin, gonadotropin-releasing hormone, and growth hormone-releasing hormone all tend to be synthesized by single large clusters of neurons that give off multibranching axons to several distant targets. Others, such as systems that contain somatostatin, cholecystokinin, and enkephalin, can have many forms, with patterns varying from moderately long, hierarchical connections to short-axon, local-circuit neurons that are widely distributed throughout the brain.

Organization by Function

Since almost all peptides were initially identified on the basis of bioassays, their names reflect these biologically

assayed functions (e.g., thyrotropin-releasing hormone and vasoactive intestinal polypeptide). These names will become trivial if more ubiquitous distributions and additional functions are discovered. Some general integrative role might be hypothesized for widely separated neurons (and other cells) that make the same peptide. However, a more parsimonious view is that each peptide has unique messenger roles at the cellular level and that these are used repeatedly in functionally similar pathways within large systems that differ in their overall functions. Cloning of the major members of the opioid-peptide receptors revealed unexpected and unexplained conservation of sequences with receptors for somatostatin, angiotensin, and other peptides.

Comparison with Other Transmitters

Peptides differ in several important respects from the monoamine and amino acid transmitters considered earlier. Synthesis of a peptide is performed in the rough endoplasmic reticulum, where mRNA for the propeptide can be translated into an amino acid sequence. The propeptide is cleaved (proteolytically processed) to the form that is secreted as the secretory vesicles are transported from the perinuclear cytoplasm to the nerve terminals. Another major difference between neuropeptides and other neurotransmitters is that no active reuptake mechanisms for peptides have been described. Thus, peptidergic nerve terminals are dependent for their signaling on distant sites of synthesis. Much progress has been made in the development of drugs that act as antagonists for neuropeptides and that are orally active and not peptides, thereby advancing roles for neuropeptides in human diseases such as stress and depression.

OTHER REGULATORY SIGNALS

In addition to the previously discussed major families of neurotransmitters, other endogenous substances have also gained attention as interneuronal signaling molecules that, if valid, will expand the definition of this process. For example, the purines adenosine monophosphate, adenosine triphosphate, and free adenosine have helped define a purinergic signaling system with two large families of purinergic receptors. ATP-regulated responses have been linked pharmacologically to a variety of supracellular functions, including anxiety, stroke, and epilepsy.

Although all the classical neurotransmitters described previously were detected on the basis of the ability to extract them as factors from their storage sites in brain, gut, or other organ systems, studies have revealed potent classes of signaling molecules that are apparently synthesized on demand and act at significant distances from their sites of synthesis and release through diffusion. Arachidonic acid, normally stored within the cell membrane as a glycerol ester, can be liberated when phospholipases are activated by a variety of neurotransmitter receptors and then converted to highly reactive signals by one of three enzymatic pathways: cyclooxygenases (leading to prostaglandins and thromboxanes), lipoxygenases (leading to the leukotrienes and other transient catabolites of eicosatetraenoic acid), and cytochrome P450 (which is inducible but expressed at low levels in brain). These arachidonic acid metabolites have been implicated as diffusible modulators in the CNS, particularly for long-term potentiation and other forms of plasticity, and include the anandamides, which are endogenous lipid signals identified on the basis of their interactions with the cannabinoid receptors.

Last, nitric oxide was initially recognized as an important regulator of vascular and inflammatory mechanisms and was later recognized to play analogous signaling roles in the brain after determination of the various forms of the enzyme nitric oxide synthase (NOS), through which NO is made and released. At least four isoforms of this biosynthetic enzyme have been identified in the brain: a constitutive form present in some neurons, capillary endothelial cells, and macrophages, as well as inducible forms of the enzyme. The availability of potent activators of NOS has led to reports of the presumptive involvement of NO in a host of phenomena in the brain, including long-term potentiation, guanylyl cyclase activation, neurotransmitter release and reuptake, and enhancement of glutamate (NMDA)-mediated neurotoxicity.

DIAGNOSIS OF AMBIGUOUS GENITALIA IN THE NEWBORN

When a genital defect is discovered during the neonatal period, complementary clinical, hormonal, genetic, molecular, and radiographic investigations are needed first to diagnose the intersex state and then to determine the etiology and orient the therapeutic approach.

Clinical Investigations

Thorough physical examination is key to diagnosis. Methodical general inspection will establish whether the genital defect is a sign of a malformation syndrome. Careful genital inspection will define the extent of the ambiguity by determining the presence, number, size, symmetry, and position of gonads. In some cases, the sexual ambiguity is evident. For example, the genital tubercle may show development that is midway between that of a penis and a clitoris (however, the length and diameter should be evaluated); the genital folds may be completely fused, with a bifid scrotum; the penis may appear abnormally bent and buried or sunken inward; or the urethral orifice may open toward the inner side of the penis, indicating hypospadias. Other signs include posterior fusion of the labia majora and a single perineal orifice at the base of the genital tubercle, between the genital folds, signaling the existence of a urogenital sinus.

However, the genital malformation often is less obvious. When the malformation is not easy to determine, the clinician's attention should be drawn to the following: an association of cryptorchidism and hypospadias, bilateral cryptorchidism, true clitoral hypertrophy of the gland and not of the hood, and an oblong mass in the inguinal position in a newborn with a female phenotype. Precise measurement of the penis should be made. The mean stretched penile length in the normal full-term newborn male is 3.5 cm (± 0.5).

Once the examination has been completed, the clinician should be ready to classify the degree of ambiguity of the external genitalia (the genital tubercle and folds and the urogenital sinus). Prader's five stages may be used, but Quigley's six stages are used more often because they offer the advantage of greater descriptive detail:

- Grade 1:* individuals with normal male external genitalia such as infertile males with azoospermia and hormonal features of androgen resistance and those with reduced virilization at puberty (so-called minimal androgen resistance)
- Grade 2:* individuals who have a univocally male phenotype but who have mildly defective fetal masculinization, manifested by defects such as isolated hypospadias and/or micropenis
- Grade 3:* individuals with a predominantly male phenotype but with more severely defective masculinization *in utero*, as evidenced by perineal hypospadias, small penis, and cryptorchidism and/or bifid scrotum
- Grade 4:* individuals with an ambiguous phenotype and severely limited masculinization, as evidenced by a phallic structure that is intermediate between a clitoris and a penis, generally accompanied by a urogenital sinus with perineal orifice and labioscrotal folds
- Grade 5:* individuals with an essentially female phenotype (i.e., minimal fetal androgen action), including separate urethral and vaginal orifices, with minimal androgenization, as evidenced by mild clitoromegaly or a small degree of posterior labial fusion
- Grade 6:* individuals with a normal female genital phenotype (i.e., no fetal androgen action) who develop androgen-dependent pubic and/or axillary hair at puberty

Careful palpation to locate gonads below the genital folds or in the inguinal region provides the first element for diagnostic orientation. If the gonads are absent, a diagnosis of female pseudohermaphroditism seems to be advisable. If a gonad or gonads are palpated, a diagnosis of male pseudohermaphroditism is indicated. However, one should bear in mind that cases presenting with very similar clinical expression may be quite different diagnostically (e.g., a masculinized female newborn with congenital adrenal hyperplasia [CAH] and an undervirilized male newborn).

A careful family history should be obtained from the parents. Detailed information on ambiguous genitalia in other siblings or family members, history of neonatal death, and consanguinity all should be sought. Cases of amenorrhea or infertility in the family will be important elements, and careful attention should be paid to clues of maternal ingestion of drugs or exposure to chemical environmental disruptors during pregnancy. Questions about "salt losing" in the family should also be raised.

A differential diagnosis should be formulated by the end of the clinical examination (Fig. 1). A certain number of complementary investigations will then need to be carried out, although perhaps not all need

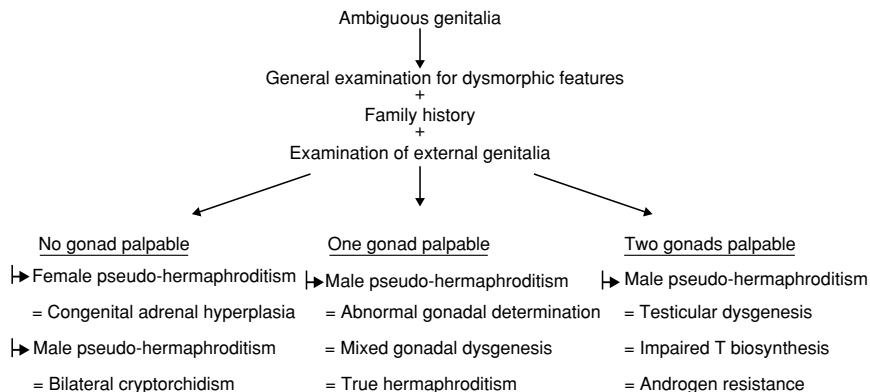

Figure 1 Diagnosis of ambiguous genitalia.

be done in a systematic fashion. However, testing for salt losing is mandatory.

Cytogenetic and Molecular Investigations

Buccal smears reveal the presence of Barr bodies (chromatin positive) equal to the number of X-1. In practice, this screening test is easy and rapid but insufficiently reliable; thus, it is being increasingly replaced by molecular studies of the X or Y chromosome. Karyotyping is systematic, but results are often not available until several days later. Because of the urgent need for sex assignment—it is intolerable for parents to wait several weeks to know whether their baby is a boy or a girl—many hospitals are now also performing polymerase chain reaction (PCR) analysis of the SRY gene on the Y chromosome given that the results are available within 1 day.

Hormonal Investigations

Hormonal investigations should be based on the clinical and cytogenetic orientation. Although most are generally easy to perform, they can be quite complex at times. Certain hormones should be measured on an urgent basis—immediately. Other measurements should be made as quickly as possible, and still others can be made within a few days.

Substantial elevation in 17-hydroxyprogesterone (17-OHP), as well as in plasma testosterone (which is of lower amplitude), will confirm the diagnosis of CAH, which in most cases is due to a deficiency in 21-hydroxylase.

Basal plasma testosterone levels evaluate the presence of functional Leydig cells. Testicular stimulation

with human chorionic gonadotropin (hCG) (1000 U/day for 3 days or 1500 U/every 2 days for 2 weeks) is required to determine the functional value of testicular tissue. An insufficient response (< 3 ng/ml) suggests a final diagnosis of gonadal dysgenesis. This same test is also needed to show evidence of an inborn error of testosterone biosynthesis by an augmentation in the precursors (e.g., 17-OHP, dehydroepiandrosterone, Δ^4 androstenedione), which contrasts with the absence of variation in the plasma testosterone.

In all cases of undermasculinization of the external genitalia that are associated with an often elevated secretion of testosterone, peripheral androgen receptivity must be investigated. Depending on the group, this is accomplished either by evaluation of the clinical response of the genital tubercle to exogenous testosterone or by measurement of the concentration of receptor sites in the external genitalia.

There is no consensus regarding the dose, method of administration, timing, or duration of therapeutic trials in the newborn with micropenis and ambiguous genitalia. To test for a clinical response to testosterone, an intramuscular injection of either 25 or 100 mg every 4 weeks for 3 months should bring about an augmentation in length, diameter, and the cavernous bodies of the genital tubercle. An augmentation in phallic length less than 35 mm is insufficient. Failure to respond implies end organ resistance to the action of androgens and introduces uncertainty concerning the appropriate sex of rearing.

For the evaluation of androgen receptor (AR) concentration, the number of receptors and their affinity for testosterone are measured on cultured genital skin fibroblasts. Concentrations less than 300 fmol/mg of DNA suggest partial androgen insensitivity.

Imaging Investigations

Exploration of the genitourinary axis is carried out principally by ultrasound and genitography. In certain cases, ultrasound confirms the presence of a uterus and ovaries. Genitography can accurately detect the level of implantation of the vaginal cavity on the urethra, an essential consideration in the choice of therapeutic strategy. One of three cases can be found: the vagina opens the length of the vertical urethra, forming a long urogenital sinus; the vaginal opening is in the subvesicle position; or the vagina is located at the junction of the horizontal and vertical portions of the urethra.

ETIOLOGY OF AMBIGUOUS GENITALIA IN THE NEWBORN

In general, the medical team has a final diagnosis and has determined the etiology of the intersex state by the end of 3 weeks.

The XX Newborn

In the XX newborn, gonads are not palpable, and this classically leads to the diagnosis of female pseudohermaphroditism. Excessive androgen production can be traced back to the mother (excessive maternal androgen production or maternal exposure to androgens or progestins), the placenta (placental aromatase deficiency), or the fetal adrenal gland (CAH) (Fig. 2).

Excessive Maternal Androgens

Any maternal source of elevated androgens can induce virilization in the female fetus. Maternal ingestion of androgens, progestins, or other drugs is a notable cause. For example, several oral progestational compounds given to prevent spontaneous abortion in the past, such as 19-nor testosterone, have been

implicated. Exogenous steroids administered during pregnancy may cause posterior fusion of the labia, clitoridal enlargement, or even increased degrees of androgenization. Other drugs that are also used in pregnancy, such as danazol, have been associated with abnormalities of sexual differentiation. Ovarian tumors include luteoma of pregnancy, arrhenoblastoma, hilar cell tumor, masculinizing ovarian stromal cell tumor, and Krukenberg tumor. Untreated maternal virilizing CAH is another potential cause, although androgen-secreting adrenal tumor in the mother is rare. In both cases, investigation of abnormal androgen production by the mother must be performed immediately after delivery. A discrepancy between marked virilization in the mother and a minimal androgen effect in female offspring indicates placental aromatase activity, which converts androgens to estrogens, or androgen metabolism, which becomes less active.

Excessive Placental Androgens

Female pseudohermaphroditism due to placental aromatase deficiency, which has been reported by several investigators, illustrates the critical role of placental aromatization in protecting the fetus from excess androgen exposure. A defect in the placental conversion of androgens to estrogens causes virilization in female offspring. In the absence of aromatase, androgens cannot be converted to estrone, estradiol, or estriol, and large quantities of androstenedione and testosterone are transferred to the maternal and fetal circulation, resulting in masculinization of the urogenital sinus and external genitalia of the female fetus. The mother may undergo virilization during gestation as well. Cloning and sequencing of the CYP19 aromatase gene has provided new opportunities for identifying mutations. Detection of mutations in this gene has confirmed the fundamental role of aromatase for the fetal-placental unit and for sexual differentiation of the female fetus.

Figure 2 The XX newborn.

Management of excessive androgens in the female fetus is somewhat difficult and will differ, for example, if there is a family history of female pseudohermaphroditism or if androgen excess is suspected from ultrasonography.

Excessive Fetal Androgens

CAH is the most frequent cause of androgen excess and ambiguous genitalia in the female newborn, and the various forms of CAH are due to defects in the biosynthesis of cortisol, with the subsequent excessive adrenocorticotropic hormone (ACTH) production leading to an accumulation of adrenal androgens and steroid precursors. Adrenal androgens undergo peripheral conversion to testosterone and dihydrotestosterone, and steroid precursors produce specific findings depending on the exact enzyme deficiency. The enzymatic defects causing female virilization involve 3β -hydroxysteroid dehydrogenase (3β -HSD)/ Δ^5 - Δ^4 isomerase, P450C21 hydroxylase (21-OH), and P450C11 hydroxylase (11-OH). The association of ambiguous genitalia and salt loss at birth signals an enzymatic block of the adrenal glands. The differential diagnosis is made by the marked accumulation of the steroid above the enzymatic block: 17-OHP for 21-OH deficiency, 11-deoxycortisol for 11-OH deficiency, and pregnenolone and other Δ^5 precursors for 3β -HSD deficiency. The molecular genetics of these defects has been studied extensively. More than 90% of CAH is due to 21-hydroxylase deficiency, and during the newborn period salt losing is present in 75% of patients. Glucocorticoid treatment should be started as soon as possible and adjusted on the basis of length, weight, and steroid levels. Mineralocorticoid should be added if salt losing is documented. 11 β -OH deficiency is associated with hypertension. 3β -hydroxylase dehydrogenase is exceptional.

Prenatal diagnosis of these defects is possible in high-risk families, and prenatal treatment can be offered to the mother of a 21-OH-deficient girl for future pregnancies. In preterm infants, differential diagnosis with the exceptional clitoridal hypertrophy associated with a high concentration of adrenal androgen should be considered.

True Hermaphroditism

The true hermaphrodite has both testicular and ovarian tissues present in either the same or opposite gonads. Both the external genitalia and the internal duct structures display gradations between male and female. The initial manifestation is ambiguous genitalia in 90% of the cases. More rarely, isolated clitoromegaly or penile hypospadias is seen. Two-thirds of

true hermaphrodites are raised as males. Among those raised as females, two-thirds will have clitoromegaly. Virtually all patients have a urogenital sinus, and in most cases a uterus is present. The most common peripheral karyotype is 46,XX, but mosaicisms are observed (XX/XY). The SRY gene is present in 10 to 30% of patients, suggesting that true hermaphroditism is a heterogeneous condition in terms of its genetic background.

The most critical factor in managing true hermaphroditism is gender assignment. A decision of male sex of rearing should be based on both the findings at laparotomy and the potential for adequate penile length. Another important consideration is that true hermaphrodites have the potential for fertility.

The XY Newborn

In the XY newborn, gonads are usually palpable and the diagnosis will be male pseudohermaphroditism (Fig. 3).

Normal Testosterone Increases

If testosterone rises normally after hCG stimulation, a defect in androgen sensitivity or 5α -reductase deficiency (5α -RD) is indicated. Androgen resistance is the most common cause of ambiguous genitalia in male pseudohermaphroditism.

Complete Androgen Insensitivity

Complete androgen insensitivity is characterized by an unambiguous female phenotype with a blind vagina pouch and no uterus. Underdevelopment of the clitoris and labia minora may also be observed. The development of an inguinal hernia signals the possibility of complete androgen insensitivity during infancy, whereas this diagnosis is evoked by primary amenorrhea during puberty. However, pubertal breast development is normal or augmented in the majority of cases, in contrast to absent or scanty axillary and pubic hair. Patients with complete androgen insensitivity develop female habitus. The major treatment decision for complete androgen insensitivity syndrome primarily concerns the optional timing of gonadectomy. Our group performs gonadectomy before puberty and prescribes estrogens during puberty.

Partial Androgen Insensitivity Syndrome

Partial androgen insensitivity syndrome (PAIS) covers a wide spectrum of clinical phenotypes, from patients with a predominantly female phenotype (i.e., mild clitoromegaly) to an undervirilized male phenotype. In

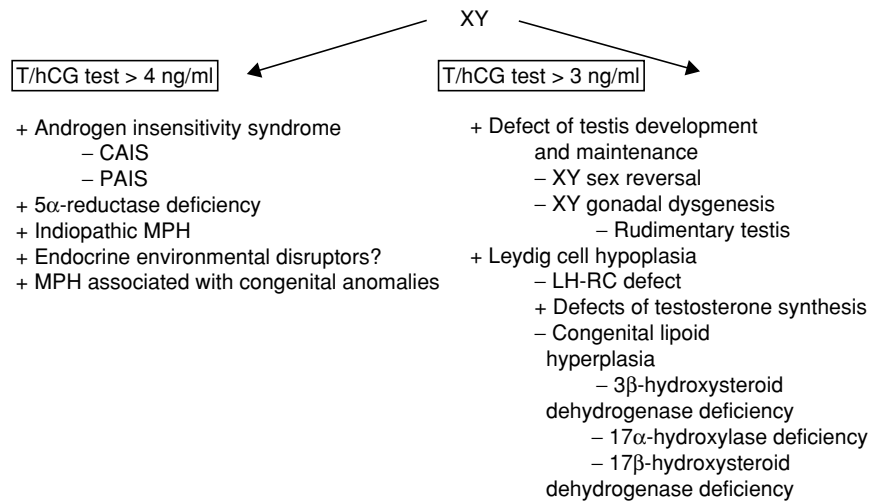

Figure 3 The XY newborn. MPH, male pseudohermaphroditism.

addition, the Wolffian duct may develop to a variable extent. Simple hypospadias or micropenis in children, or undervirilization and gynecomastia in adolescent boys, should also come to medical attention.

Newborns with PAIS have increased luteinizing hormone (LH) and testosterone secretion, whereas estrogen production is also higher (serum sex hormone-binding globulin [SHBG] concentrations are intermediate between those of normal male and normal female). The SHBG response to the increase in serum testosterone induced by an hCG stimulation test has been used as an aid in the differential diagnosis between PAIS and other forms of male pseudohermaphroditism.

Androgen binding in genital skin fibroblasts has revealed that defects are heterogeneous in that they range among reduced capacity, reduced affinity, thermolability, increased ligand dissociation rate, and altered ligand specificity. However, no research group has been able to report any consistent correlation between the concentration of AR and the degree of undervirilization.

Since the AR gene was cloned, the tools of molecular biology have made it possible to identify mutations within the gene from patients with different phenotypes of PAIS. Screening procedures with sequencing of the AR gene allow identification of subtle changes responsible for missense or nonsense mutations. Measurements of AR mRNA have been useful in identifying mutations that cause PAIS by altering the state levels or the size of the mRNA. Transfection of constructs expressing the mutant AR in mammalian cells is the main approach for demonstrating the

causative role of the mutation in the development of the androgen insensitivity.

The management of patients with partial androgen insensitivity syndrome must be individualized depending on the degree of genital ambiguity, the growth response of the penis to supraphysiological doses of testosterone, and the type of AR mutation. Although certain AR defects may be amenable to androgen therapy, multiple reconstructions of external genitalia and azoospermia are good arguments to prefer a female sex of rearing.

5α-Reductase Deficiency

Patients with 5α-RD are characterized at birth by an undervirilized phenotype. Affected newborns exhibit ambiguous genitalia with a hypospadiac phallus resembling a clitoris, a bifid scrotum that is labial-like, and a urogenital sinus opening on the perineum. It is worth noting that the testes have been found in the inguinal canal, labia majora, or scrotum.

The clinical presentation can actually range from a nearly normal female phenotype to a clear-cut male phenotype with isolated hypospadias, but in all cases Wolffian ducts have been differentiated normally into vas deferens, epididymis, and seminal vesicles.

The main characteristic of patients with 5α-RD is the virilization of the external genitalia that occurs at puberty along with the acquisition of male genetic identity in these patients usually raised as females.

Diagnosis should be based on physical examination, pedigree analysis, analysis of basal and post-hCG stimulation plasma T and DHT levels, 5β/5α urinary steroid metabolite ratio, measurement of

5 α -RD activity in cultured genital skin fibroblasts, and analysis of the 5 α -R2 gene.

The characteristic endocrine features of 5 α -RD are as follows: normal male to high levels of plasma T and low levels of plasma DHT, an elevated ratio of the concentration of plasma T to DHT during adulthood and after stimulation with hCG during childhood, and elevated ratios of urinary 5 β - to 5 α -metabolites of androgen and C21 steroids. The biological diagnosis of 5 α -RD is supported mainly by an increased plasma T/DHT ratio.

From a biochemical point of view, the decrease in 5 α -reductase activity in the intact genital skin fibroblasts supports the diagnosis of 5 α -RD, but enzymatic activity is sometimes in the normal range. The decreased activity in sonicated cell extracts at acidic pH provides strong evidence that the mutation resulted in a loss of type 2 enzyme activity.

Isolation and sequencing of the cDNA encoding 5 α -reductase type 2 provides the molecular tools required for definition of the gene abnormalities responsible for 5 α -RD.

The management of 5 α -RD is primarily dependent on the phenotypic findings and gender at the time of diagnosis. Given the severe defect of the external genitalia, most newborns are raised as female. Gonadectomy should be performed early to prevent masculinization along with vaginoplasty and clitoral reduction. If the diagnosis is made during puberty, one can consider raising the child as male.

When Testosterone Does Not Increase

If testosterone does not rise after the therapeutic trial, either testicular dysgenesis (which is an anomaly in testicular determination) or a disturbance in testicular biosynthesis may be responsible. Genitography is useful for differential diagnosis. When a vagina and uterine cavity are found, the diagnosis of testicular dysgenesis is likely. When a blind vagina without a uterine cavity is found, the diagnosis of disturbance in testicular biosynthesis is made.

Abnormal Testicular Determination

- *Dysgenetic testis.* Newborns with dysgenetic testis present with bilateral dysgenetic testes, persistent Müllerian structures, cryptorchidism, and inadequate virilization. This disorder shows wide clinical heterogeneity. Because the uterus is present, the sex of rearing should be female and gonadectomy is recommended, as for mixed gonadal dysgenesis. These patients should be screened routinely for tumor.

- *Defect of testis maintenance.* Bilateral vanishing testis (or embryonic testicular regression) is characterized

by an XY karyotype and absent or rudimentary testes. The syndrome entails the presence of testes that vanish during embryogenesis, although the etiology is unclear. The regression of the testes *in utero* may be due to genetic mutation, a teratogen factor, or bilateral torsion. Clinically, the syndrome encompasses a spectrum of phenotypes, ranging in severity from genital ambiguity to a male phenotype with an empty scrotum. Patients with a defect in testis maintenance will be managed according to their position in the clinical spectrum of the disorder. In true agonadism, external genitalia are ambiguous and Müllerian derivatives are absent or rudimentary due to complete or partial anti-Müllerian hormone secretion without secretion of testosterone. Patients with rudimentary testis have a male phenotype with micropenis and small atrophic testis with pre-Sertoli and Leydig cells. Some patients present with perineal hypospadias and persistent Müllerian duct structures. Congenital anorchia is characterized by the complete absence of testicular tissue at birth but with normal male sexual differentiation without Müllerian structures. Patients with ambiguous genitalia require meticulous assessment to determine the optimal sex of rearing. In the absence of palpable gonads, measurement of basal- or hCG-stimulated testosterone secretion above the female range is informative, but laparotomy or celioscopy followed by histological analysis of the gonads is absolutely essential. In general, the sex of rearing should be male with testosterone replacement therapy, which will lead to normal puberty and sexual function. Phenotypic males require long-term androgen replacement, beginning at the time of expected puberty.

Leydig Cell Hypoplasia

Male pseudohermaphrodites with Leydig cell hypoplasia have impaired Leydig cell differentiation and testosterone production. The phenotype is usually female, although it may be ambiguous. In all cases, Müllerian structures are absent. Inhibiting mutations in the LH receptor gene have been reported in these patients.

Defect in Testosterone Synthesis

Decreased androgen production caused by an alteration in the enzymes involved in the testosterone biosynthesis pathway is another cause of male pseudohermaphroditism. On the other hand, increased fetal production of androgens results in female pseudohermaphroditism.

- *Congenital lipoid adrenal hyperplasia.* Congenital lipoid adrenal hyperplasia (CLAH) is a rare disease

characterized by a defect in the synthesis of the three classes of steroid hormones, resulting in severe salt wasting and a female phenotype. Few mutations in humans have been found in the gene encoding for P450scc, which is the principal candidate gene. Recently, the gene responsible for CLAH was cloned and validated by nonsense mutation. This gene encodes for the StAR (steroidogenic acute regulatory) protein, which is thought to be responsible for the transport of cholesterol to the inner membrane of mitochondria and, thereby, to the P450scc enzyme complex.

- *17 α -hydroxylase deficiency.* Defects in P450c17 lead to male pseudohermaphroditism with various degrees of ambiguous genitalia. This is frequently a severe form and is most often diagnosed at puberty, with a female phenotype associated with hypertension. Cytochrome P450c17 catalyzes the transformation of progesterone and pregnenolone into 17-OH progesterone and 17-OH pregnenolone (17 α -hydroxylase activity), respectively, and then into dehydroepiandrosterone and Δ^4 -androstenedione (17-20 lyase activity). The gene encoding for this enzymatic complex, CYP17, is located on chromosome 10q24-q25. Several different mutations have been reported in the CYP17 gene leading to either a complete or partial form of the disease.

- *3 β -hydroxysteroid dehydrogenase deficiency.* Defects in the function of 3 β -HSD result in 46,XY individuals with male pseudohermaphroditism who sometimes show salt wasting in the classic form. Nearly 15 mutations of the type II 3 β -HSD enzyme have been reported. However, no mutation of type I has been found, and this explains how virilization can occur in 46,XX individuals by peripheral nonsteroidogenic conversion of elevated testosterone precursors.

- *17 β -hydroxysteroid dehydrogenase deficiency.* Type 3 17 β -HSD deficiency is a rare autosomal recessive cause of male pseudohermaphroditism. The typical patient is a 46,XY male born with female external genitalia and testes located in the inguinal canals or labia majora. This disorder is particularly puzzling. The deficiency in testosterone synthesis and the defect in virilization, both of which are usually more complete during embryogenesis than in later life, contrast with the well-differentiated Wolffian duct structures, suggesting that androgen acts *in utero* by an alternate mechanism in these tissues. Substantial virilization is seen at puberty in association with elevated levels of androstenedione but low to normal plasma levels of testosterone. As in the case of 5 α -RD, pubertal virilization may result from extraglandular testosterone formation due to peripheral conversion of

increased testicular androstenedione by unaffected 17 β -HSD isoenzymes. Missense and nonsense mutations, splice junction abnormalities, and a small deletion resulting in a frame shift have been described, among other gene alterations. Expression of mutant enzymes after site-directed mutagenesis showed that the missense mutations caused nearly complete loss of enzymatic activity.

Although affected newborns are generally considered to be female, the choice of sex of rearing will be greatly influenced by family values and cultural background. When female sex of rearing is maintained, we strongly urge that orchidectomy be carried out during infancy or childhood. When diagnosis is not made before puberty, a gender change to male at that time is acceptable.

Male pseudohermaphroditism may, in some cases, be part of a multiple malformation syndrome. In other cases, etiology cannot be determined, and the so-called idiopathic pseudohermaphroditism should raise the suspicion of environmental contamination by pesticides during gestation.

The 46,XY/XO Newborn

For the 46,XY/XO newborn, the diagnosis is mixed gonadal dysgenesis. The most common karyotype in mixed gonadal dysgenesis is 45,XO/46,XY, but other mosaics have been reported with structurally abnormal or normal Y chromosome. The characteristics include a unilateral testis that is often intra-abdominal, a contralateral streak gonad, and persistent Müllerian duct structures. Because affected patients are at great risk for gonadal tumor, the gonads should be removed so that the patients can be reared as females. However, when the abnormality of the external genitals is minor, parents may perceive their children as boys. Male sex of rearing will then impose lifelong surveillance of the gonads. In any case, mixed gonadal dysgenesis is associated with varying degrees of inadequate masculinization, and such males would be infertile. It should be remembered that the distinction between mixed gonadal dysgenesis and Turner syndrome with Y material is unclear.

SEX ASSIGNMENT OF THE INTERSEX CHILD AT BIRTH

When a child is born with ambiguous genitalia, the medical team must mobilize for a neonatal emergency. In addition to the urgent need to rule out life-threatening conditions such as salt wasting, determination of the most appropriate sex for rearing must be made as rapidly as possible. It cannot be emphasized enough

that the parents desperately need to know whether their baby is a girl or a boy. The unambiguous designation of a baby's sex is a key step in the birth process, and for the parents of an intersex neonate, the period of waiting to learn their baby's sex is often agonizing. Birth is the meeting of parents' dreams and a real infant, alive and present in the world. When a child is born, one of the first announcements is whether the mother has delivered a boy or a girl. We can easily imagine the profound distress and helplessness of parents who are confronted with the intersex status of their newborn.

The clinical examination provides an assessment of the degree of undervirilization and the presence of gonads. Biological assessments are mandatory for plasma 17-OHP and the SRY gene.

Once the investigations have been concluded, the medical team should be ready to undertake its greatest responsibility: the assignment of sex for rearing. This decision must be guided by three parameters: the anatomical condition and functional abilities of the genitalia, the etiology of the genital malformation, and family considerations (e.g., cultural factors, religious convictions). The choice of declared sex must be—and this bears repeating—the result of full discussion among all protagonists.

In cases of female pseudohermaphroditism, the newborn with ambiguous genitalia should always be declared to be of the female sex. With normal ovaries and uterus, the female pseudohermaphrodite is potentially capable of bearing children.

In cases of male pseudohermaphroditism, great care should be taken in the declaration of the male sex. Major considerations will be the potential for reconstructive surgery, the probability of pubertal virilization, and the “programmed” response of the external genitalia to exogenous and endogenous testosterone. On the other hand, the presence of testicular tissue is not an essential factor in this decision.

In cases of gonadal dysgenesis, sex assignment will be based on several criteria. A defect in 5 α -reductase is an indication for male sex for rearing because pubertal virilization will lead to penile development (although it will be subnormal), normal pubic hair development, and the acquisition of male sexual identity. In contrast, for inborn errors of testosterone biosynthesis, female orientation is advisable if effective male reconstructive surgery appears to be highly unlikely. When a vagina and uterus are present, female orientation is also preferable if it appears that vaginoplasty can be easily accomplished.

In cases of androgen resistance, a female orientation is unquestionably correct for complete resistance, and

it is preferable in cases of partial resistance confirmed by therapeutic testing.

In true hermaphroditisms, which are very rare, female sex assignment is to be preferred because ovarian function may be preserved.

Castration is indicated for male pseudohermaphrodites reared as girls. When they are reared as boys, careful gonadal follow-up throughout life is crucial. Because the cumulative risk of gonadal tumor in the intersex child is present even before puberty, we advocate castration in the XY intersex infant with testicular dysgenesis.

CONCLUSION

A methodical clinical examination and hormonal, radiographic, molecular, and genetic investigations are the bases for determining the diagnosis, etiology, and optimal management of ambiguous genitalia in the newborn. In conversations with family members, terms such as “ambiguous genitalia” and “pseudohermaphrodite” should be avoided and more neutral terms such as “genital malformation” should be substituted. The family should be informed of the various difficulties and therapeutic options, but excessive detail is unnecessary. Once a decision for the assignment of sex is made, it should be definitive for the parents. The baby will hereafter be referred to by name and as either “he” or “she” by all staff to help the parents fix their child's gender firmly in their minds.

Because of the far-ranging consequences, the assignment of sex for rearing should never be the decision of a single physician. The entire multidisciplinary team should remain involved in every step of the diagnostic procedure, the choice of sex for rearing, and the treatment strategy. The team also has an important role in guiding the family and ensuring family agreement with and support for the decision, which is the sole means of guaranteeing that the child will be raised with an unambiguous sexual identity.

of one or both of the *nervi recurrentes*, and it will result in hoarseness and dyspnea. Paralysis of the *nervus phrenicus* and Horner's syndrome are rare complications of goiters.

Laboratory Tests

The level of thyroid-stimulating hormone (TSH) in blood should be measured for all patients with goiter to either determine or exclude (subclinical) hyperthyroidism or hypothyroidism. If the TSH concentration is low, it is necessary to measure the level of free thyroxine (T₄) to distinguish between subclinical or manifest hyperthyroidism. If the concentration of TSH is low and the concentration of free T₄ is normal, triiodothyronine (T₃) toxicosis must be excluded by measuring the serum level of T₃. If the concentration of TSH is high and the concentration of free T₄ is low, chronic autoimmune thyroiditis should be considered as a possible cause of the thyroid enlargement. This diagnosis can be confirmed by measuring the level of antibodies against microsomes (thyroperoxidase) in serum and/or by fine-needle aspiration biopsy.

Imaging Diagnostics and Lung Function Tests

The presence of tracheal compression and intrathoracic growth of the goiter should be considered in all patients with goiter, especially in the case of a large goiter. Taking X-rays of the thorax and trachea is a simple but not very sensitive screening method for trachea compression. Lung function tests can provide additional indications for tracheal compression, especially tests with so-called flow-volume loops. Computed tomography (CT) and magnetic resonance imaging (MRI) are relatively expensive but very sensitive methods to demonstrate tracheal compression and intrathoracic growth of a goiter. Iodine-containing contrast agents should not be used for CT because of the risk of inducing hyperthyroidism. If it is absolutely necessary to use iodine-containing contrast agents in order to show venous obstruction with phlebography or CT, pretreatment with a thyrostatic drug or perchlorate is needed. Ultrasonography of the thyroid gives detailed information about the number and size of the nodules within the goiter, but this investigation is not indicated routinely. X-rays of the esophagus can show esophageal compression by a goiter, but these are rarely necessary. Thyroid scintigraphy is also not indicated routinely. Thyroid scintigraphy and the measurement of radioiodine uptake in the thyroid are useful when radioiodine treatment is considered to reduce the goiter volume. If radioiodine uptake in the thyroid is low or if large parts of the thyroid hardly take up any radioiodine, treatment with radioiodine is not very effective.

Fine-Needle Aspiration Biopsy

In patients with nontoxic goiter, clinically significant thyroid carcinoma is rare, given the high prevalence of nontoxic goiter and the very low incidence of thyroid carcinoma in the population. For this reason, fine-needle aspiration biopsy is not indicated routinely. Biopsy is needed, however, if nodules are fast growing or if they have a significantly firmer consistency than other nodules.

THERAPY

Nontoxic goiters usually grow slowly. The presence of a diffuse or multinodular goiter is not an indication for treatment. The most important indications for treatment are compression of the trachea and esophagus and obstruction of the large veins. Treatment should also be considered in the case of progressive

growth of either the whole goiter or individual nodules, particularly when the goiter shows significant intrathoracic growth. Indeed, it is not possible to palpate the intrathoracic part of the goiter or take a biopsy from it. In addition, bleeding within a nodule or a cyst can result in acute and life-threatening compression of the trachea. Sometimes, treatment is indicated for cosmetic problems.

The main therapeutic options are thyroidectomy, administration of radioiodine, and treatment with thyroxine. Iodine supplementation can be tried for patients with a small diffuse goiter caused by iodine deficiency. Iodine supplementation is not advised for patients with multinodular goiter, even if it is caused by iodine deficiency. The administration of iodine to these patients is rarely effective and can even induce hyperthyroidism.

Thyroidectomy

Surgical treatment of goiter results in fast decompression of vital structures and provides tissue material for pathological examination. In most cases, bilateral subtotal thyroidectomy is performed, including the removal of all macroscopically abnormal tissue. Almost all nontoxic goiters can be removed through an incision in the neck, even goiters that have grown substantially into the thoracic cavity. The most common complication of thyroid surgery is tracheal obstruction caused by bleeding, damage to the *nervus recurrens*, or tracheomalacia. Other postsurgical complications are hypoparathyroidism, change in voice caused by damage to the *nervus laryngeus superior*, and hypothyroidism. The incidence of postsurgical hypothyroidism is dependent on the extensiveness of the operation. The highest morbidity is found in patients with very large goiters and those who have had secondary surgery. The mortality after thyroid surgery on patients with nontoxic goiters is less than 1%.

Radioactive Iodine

During the past decade, it has been conclusively shown that administration of radioactive iodine (radioiodine) is an effective treatment that results in reduction of the thyroid volume in more than 90% of patients with nontoxic goiter. Usually, a single dose of approximately 100 μCi (3.7 MBq) radioactive iodine (^{131}I) per gram of thyroid tissue is administered. Twelve to 18 months after treatment with radioiodine, the thyroid volume in patients with a diffuse goiter is reduced by 50–60%. Radioiodine treatment of patients with a multinodular goiter results in a reduction of thyroid volume of approximately 40% after

1 year and 50% after 3–5 years. There is a positive correlation between the reduction of the goiter volume and the administered dose of radioiodine per gram of thyroid tissue and a negative correlation between the reduction of the goiter volume and the goiter volume before treatment. In addition to the reduction in thyroid volume, the treatment also results in a reduction of compression symptoms for a majority of patients.

Early side effects, such as radiation thyroiditis or radiation esophagitis, are generally mild and temporary. Exacerbation of compression symptoms following treatment with radioiodine is rare. Therefore, the administration of glucocorticoids is not routinely indicated. The most important late complication, which appears months after radioiodine treatment in 5% of patients, is the development of autoimmune (Graves') hyperthyroidism, which is probably induced by thyroid antigens that are released as a result of radiation. The prevalence of hypothyroidism after treatment is 20–50% after 5 years. Recurrent goiter growth after 3–5 years occurs in approximately 10% of patients. A second treatment with radioiodine can be effective in these cases.

Treatment with high doses of radioactive iodine is potentially carcinogenic. Risk assessments show that the risk of developing a malignancy that is caused by treatment with a high dosage of radioiodine in patients 65 years of age or older is approximately 0.5%, which is equal to the surgical mortality after subtotal thyroidectomy.

Treatment of nontoxic goiter with radioiodine is mainly given to older patients, particularly those who have an increased surgical risk and those who refuse surgery. However, radioiodine is also a good alternative to surgery for younger patients, provided that the dosage of radioiodine is relatively low (only patients with a small goiter and sufficient radioiodine uptake).

Thyroxine

TSH is the most important growth stimulator of normal thyroid tissue. Treatment of patients with nontoxic goiter is based on the hypothesis that the growth of a goiter is also TSH dependent and that suppression of TSH secretion will result in the reduction of the goiter volume or at least prevent further growth of the goiter.

Treatment with thyroxine is an effective method to reduce the thyroid volume in patients with diffuse goiter. Only one placebo-controlled, randomized trial of patients with multinodular goiters has been published. In this trial, thyroid volume was reduced in

58% of patients (by an average of 25%). Only patients with relatively small goiters were treated. The effectiveness of thyroxine treatment in patients with larger multinodular goiters is probably considerably lower. Thyroxine treatment of patients with a multinodular goiter and a low serum TSH level is not advisable because this treatment can cause overt hyperthyroidism, and a reduction of the goiter volume is not to be expected in the case of low TSH levels.

Long-term thyroxine treatment with doses that reduce the serum TSH concentration to subnormal level reduces bone density, particularly in women after menopause. It also causes left ventricular hypertrophy and possibly cardiac dysfunction and arrhythmia.

Choice of Treatment

The pros and cons of the three treatments—thyroidectomy, radioiodine, and thyroxine—should be weighed carefully before advice is given about the treatment of a patient with nontoxic goiter. Thyroidectomy is the standard treatment, especially for young and otherwise healthy patients and when prompt decompression of vital structures is required. Radioiodine treatment is an attractive alternative to surgery for older patients and for patients with cardiopulmonary diseases or recurrent goiters. There are few indications for thyroxine treatment of patients with nontoxic goiters. Thyroxine treatment can be tried in young patients with small, diffuse goiter and a normal TSH level. In this case, the goal is to obtain a TSH concentration between 0.1 and 0.5 mU/liter.

test will become available. Until that time, Noonan syndrome will remain a clinical diagnosis.

Diagnosis

The diagnosis of Noonan syndrome is based on clinical findings. Characteristic facies are helpful in diagnosis but change with age. In the newborn, Noonan syndrome is difficult to diagnosis by facial appearance alone. The forehead is often sloping and the ears may be thick, broad, and posteriorly angulated. Newborns often have redundant nuchal skin and experience significant weight loss due to the edema present at birth. In infancy, from neonatal to approximately 2 years of age, the head often appears relatively large. The malar eminencies are flat and the eyes are more prominent and round. The nasal bridge is depressed. The neck appears short but is no longer webbed. At 2 years of age, the body appears more stocky and the chest deformity appears more prominent. As childhood progresses, the facial appearance becomes more coarse and assumes a more triangular shape as the chin lengthens. The eyes become less prominent and ptosis becomes more apparent. The neck appears longer and the low hair line and webbing may become more obvious. The teenager and young adult develop triangular facial features that become much sharper. The nose has a pinched root and a thin, high bridge. The older adult often has prominent nasal labial folds and a high anterior hair line, and the skin often appears transparent and wrinkle (Fig. 1).

Although the majority of patients with Noonan syndrome have an unremarkable prenatal history, in one-third of patients the pregnancy is complicated by polyhydramnios. Since fetal ultrasound has become

more widely available, a number of fetuses later diagnosed with Noonan syndrome have been reported to show increased nuchal fluid and hydrops as early as 14 weeks of gestation. Follow-up studies frequently revealed resolution of the nuchal fluid. Excessive weight loss common in the first week of life suggests fetal edema may be quite common.

Short stature is noted in more than 80% of patients with Noonan syndrome. The cause of the short stature is unknown. After an apparently normal birth history, many patients develop feeding problems in early infancy. Approximately 35% have mild to moderate feeding problems, mainly vomiting, whereas nearly 25% develop severe feeding problems, often requiring tube feedings. Studies have indicated an increased incidence of gastroesophageal reflux and poor gut motility. In general, the feeding problems resolve later in infancy.

Children with Noonan syndrome often present to the endocrinologist with short stature, delayed puberty, and undescended testes in males. Weight and length are usually normal at birth. Height drops off within the first few months. In general, there is a 2-year delay between bone age and chronological age. This results in a delay in the onset of puberty. Continued growth may occur until the early twenties. Height and weight are usually below the third percentile, with a mean final adult height of 162.5 cm in males and 151 cm in females. In approximately half of males, one or both testes fail to descend. Delayed puberty is frequent in females. Females seem to possess normal fertility, whereas males, as expected due to undescended testes, appear to have decreased fertility.

Developmental delay is frequent. Motor delay may be partially attributed to muscular hypotonia. In a study by van der Burgt *et al.*, individual IQ scores varied between 48 and 130. The overall experience suggests that approximately one-third of children will have some degree of mental retardation or learning disability. Graduation from college and achievement of Ph.D. degrees have been reported. Conductive hearing loss is relatively common, and very frequent visual problems may contribute to learning disability.

Almost every system of the body may be affected in Noonan syndrome. Eye findings are very frequent and include apparent hypertelorism, ptosis, refracted errors, strabismus, and amblyopia. An occasional patient will have a coloboma. More than 90% of patients with Noonan syndrome have a chest deformity, such as a pectus carinatum or pectus excavatum. Scoliosis occurs in 10–15%, as does talipes equinovarus. Muscular hypotonia is common and often improves

Figure 1 Mother with Noonan syndrome and her affected infant.

with time. The chest is often shield-like with widely spaced nipples. Unexplained peripheral neuropathy has been seen. Poor coordination is reported by some parents. Spina bifida occulta, tethered cord, and Arnold–Chiari malformation have all been reported.

Although curly hair is often a feature, some patients have both sparse hair and eyebrows. Nevi and freckles are common. A number of patients have findings characteristic of both neurofibromatosis and Noonan syndrome. Children have a tendency to form extensive keloids following surgical procedures. Hepatosplenomegaly, usually unexplained, is present in approximately 25%. Bleeding problems and easy bruising have been frequently noted. A variety of abnormal clotting factors have been reported, including low levels of factor 11 and factor 8, thrombocytopenia, and platelet function defects. Low levels of a wide variety of clotting factors with no specific patterns have also been reported. There may be an increased risk of leukemia in patients with Noonan syndrome, and there have been several reported cases of neuroblastoma. Lymphatic abnormalities occur in less than 20% of patients in Noonan syndrome but may cause serious problems. Intestinal lymphagectasia leading to protein-losing enteropathy has been reported as well as pulmonary lymphagectasia. Spontaneous chylothorax has been reported, and persistent pleural effusions following cardiac surgery is a known risk in patients with Noonan syndrome.

More than 80% of patients with Noonan syndrome have some kind of cardiovascular abnormality. A dysplastic, often stenotic pulmonary valve is the most characteristic lesion of Noonan syndrome, but virtually every type of cardiac defect has been described. Atrial septal defect, branch pulmonary artery stenoses, ventricular septal defect, and tetralogy of Fallot are among those that are frequently reported. Valvar aortic stenosis, subaortic stenosis, patent ductus arteriosus, and coarctation of the aorta have also been reported. In addition, hypertrophic cardiomyopathy, both obstructive and nonobstructive, occurs in 20–30% of patients. This myocardial hypertrophy may be noted at birth or may develop later in infancy or later childhood. Unlike the nonsyndromic, familial hypertrophic cardiomyopathy, patients with Noonan syndrome often have involvement of both the right and the left ventricle. Microscopic examination, however, reveals similar findings in both forms—mainly muscle disarray and thick-walled coronary arteries. In addition to dysplasia of the pulmonary valves, all valves may be dysplastic and mitral valve prolapse is relatively common, occurring with other cardiac

defects or as an isolated finding. An unusual electrocardiogram with an indeterminate left axis deviation and a dominant S wave over the entire precordium is frequent but not clearly related to any specific cardiac malformation. The cause of the electrocardiographic finding is unknown, but it supports the diagnosis of Noonan syndrome.

DIFFERENTIAL DIAGNOSIS

Differential diagnosis should include Turner syndrome, particularly for a female who has a left-sided cardiac lesion. Cardiofaciocutaneous syndrome and Costello syndrome may be very difficult to diagnose in early infancy, although with time differences become more apparent. Patients with both Watson syndrome and Leopard syndrome may be indistinguishable from those with Noonan syndrome until a specific diagnostic test becomes available. There are children who show evidence of both neurofibromatosis and Noonan syndrome. Careful history to eliminate possible alcohol abuse or other tetragons in the mother as well as chromosome studies are helpful in distinguishing Noonan syndrome from some of the other conditions that must also be considered in the differential diagnosis.

MANAGEMENT

A child with Noonan syndrome will have special needs. Fortunately, many children are mildly affected and may essentially be treated as “normal.” Because of the high incidence of abnormal eye and cardiac findings, these children should have careful eye and cardiac evaluations. In addition, hearing should be tested. Careful developmental assessment should be carried out before the child begins school so that any potential learning disabilities can be recognized early before the child develops problems in school.

Short stature is of concern to both patients and families. Some studies have been carried out to evaluate the efficacy of growth hormone therapy. No consistent abnormalities in the secretory dynamics of growth hormone have been reported in these children. There has been no consistent relationship between growth hormone studies and the response to growth hormone treatment. Studies by Romano *et al.* and Noordam *et al.* demonstrated a positive effect of growth hormone treatment on linear growth. Romano *et al.*'s study revealed sustained growth for

4 years with continued growth hormone therapy. Unfortunately, both studies demonstrated an advance in bone age relative to height age. Clearly, children treated with growth hormone therapy reach final growth earlier, but it is not clear whether their final height is significantly increased. Unfortunately, there are very limited data on final height of patients with Noonan syndrome who have been followed serially. Fortunately, studies indicate that the use of growth hormone treatment for Noonan syndrome appears to be relatively safe. There is no evidence that growth hormone adversely affects the cardiovascular system in children with hypertrophic cardiomyopathy.

monoamine oxidases, catechol-*o*-methyltransferases) and plasma membrane uptake carriers, to lower extracellular concentrations and terminate the action of norepinephrine.

ADRENERGIC RECEPTORS: G PROTEIN-COUPLED RECEPTORS THAT LINK VIA G PROTEINS TO EFFECTOR MOLECULES

Plasma membrane receptors that recognize and respond to norepinephrine are of three major classes: α_1 -, α_2 -, and β -adrenergic receptors (adrenoceptors), each of which has three subtypes: $\alpha_{1A,B,D}$; $\alpha_{2A,B,C}$; and $\beta_{1,2,3}$ (Figs. 2 and 3). In humans, the receptors are encoded by separate genes with distinct chromosomal locations (Table I). All of the adrenergic receptors are members of the G protein-coupled receptor (GPCR) superfamily and couple to one or more heterotrimeric (α , β , γ) GTP-binding (G) proteins (see Table II). Each of the three major classes of adrenergic receptors preferentially couples to G proteins of a particular type: α_1 -adrenergic receptors to $G_{q/11}$, α_2 -adrenergic receptors to G_i , and β -adrenergic receptors to G_s . When the G proteins are activated by norepinephrine or another agonist acting at a particular adrenergic

receptor, each of the G proteins preferentially couples to and regulates specific effector enzymes and channels: G_q couples to phospholipase C_β , which hydrolyzes phosphatidylinositol 4,5-bis-phosphate to inositol 1,4,5-triphosphate and diacylglycerol, which regulate, respectively, increases in cytosolic $[Ca^{2+}]$ via release from intracellular endoplasmic reticulum stores and activation of protein kinase C; G_i regulates the inhibition of adenylyl cyclase activity (and the decrease in intracellular cyclic AMP levels), activation of inwardly rectifying potassium channels, and inhibition of voltage-dependent calcium channels; and G_s primarily regulates the stimulation of adenylyl cyclase activity and also the increase in activity of voltage-dependent calcium channels in some tissues. All the adrenergic receptors regulate the phosphorylation state of intracellular proteins through the action of signaling kinases: protein kinase C for α_1 -adrenergic receptors and protein kinase A for α_2 - and β -adrenergic receptors. Other kinases may be more distally linked in these signaling cascades, including mitogen-activated protein (MAP) kinase/extracellular signal-regulated kinase, calcium-calmodulin kinases, and protein kinase B. In addition, cyclic AMP may regulate cellular functions through additional mechanisms, such as ion channels and guanine nucleotide exchange factors, in particular, Epac 1 and 2, for the monomeric G protein, Rap.

The effects of adrenergic receptor activation have most typically been viewed in the context of their acute regulatory effects, e.g., regulation of vasoreactivity, insulin release, lipolysis, gluconeogenesis, and glycogenolysis. These mechanisms are mostly related to the immediate effects of adrenergic receptor-stimulated kinases to modulate protein function by phosphorylation. However, more chronic effects of adrenergic receptor stimulation via the regulation of transcriptional mechanisms (including MAP kinase- and phosphoinositide 3-kinase-dependent pathways) have been increasingly appreciated.

ADRENERGIC RECEPTORS: STRUCTURE AND MECHANISMS OF ACTIVATION AND DESENSITIZATION

As is typical of GPCRs, all the adrenergic receptors have a similar general structure (Fig. 3): extracellular amino termini, seven α -helical domains that cross the lipid bilayer of the plasma membrane, resulting in three intracellular and extracellular loops and in intracellular carboxyl termini. Some of the adrenergic receptors are palmitoylated, with this fatty acid being

Figure 2 Schematic structures of the nine adrenergic receptor (AR) subtypes. Each of the receptor subtypes has an extracellular amino terminus, seven α -helical domains that cross the plasma membrane, and an intracellular amino-terminal “tail” domain. Note the similarities among members of certain types of receptors, for example, α_1 -ARs have relatively long carboxy-terminal tails and α_2 -ARs have long intracellular third loops.

Figure 3 Model of adrenergic receptor activation. Physiologic agonists (norepinephrine, epinephrine) bind to adrenergic receptors, which stimulate signaling through their action as guanine nucleotide exchange factors (GEF) that facilitate GDP release, the subsequent binding of GTP to G_α subunits, and the release of the $G_{\beta\gamma}$ dimer from heterotrimeric $G_{\alpha,\beta,\gamma}$ proteins. Both the G_α and $G_{\beta\gamma}$ subunits are able to regulate effectors and modulate the activity of signaling cascades, in large part via phosphorylation mechanisms. The activation of the G protein and the regulation of the effector are reversible, in part via intrinsic GTPase activity of the G_α subunits and, in addition, via the action of RGS (regulators of G protein signaling) proteins, which are GTPase-activating proteins (GAP). G_α and $G_{\beta\gamma}$ subunits interact with the plasma membrane via lipid modifications, which are indicated by squiggly lines. Although the agonists are shown sitting on the outside of the receptor, the binding sites for norepinephrine and epinephrine are thought to be located within the lipid bilayer. Modified from Sondak, J., and Siderovski, D. (2001). *Biochem. Pharmacol.* 61, 1329–1337, with permission.

Table I Human Adrenergic Receptors: Chromosomal Locations

| Receptor | Chromosomal location |
|-------------------|----------------------|
| α_{1A} -AR | 8p21-p11.2 |
| α_{1B} -AR | 5p23-q32 |
| α_{1D} -AR | 20p13 |
| α_{2A} -AR | 10q24-q26 |
| α_{2B} -AR | 2p13-q13 |
| α_{2C} -AR | 4p16 |
| β_1 -AR | 10q24-q26 |
| β_2 -AR | 5q31-q32 |
| β_3 -AR | 8p12-p11.2 |

added to a cysteine residue in the proximal end of the carboxy-terminal regions, thereby potentially creating a fourth intracellular loop. Adrenergic receptors are N-linked glycoproteins, i.e., with asparagine-linked carbohydrates found in the amino-terminal regions. G protein-interacting domains are predominantly in the third intracellular loop and proximal portions of the carboxy-terminal regions. The third intracellular loop and carboxy-terminal “tails” also possess residues that can be phosphorylated by various protein kinases.

Norepinephrine and other agonists of adrenergic receptors appear to bind to regions of the receptors within the lipid bilayer, apparently as a consequence of folding of the receptors so as to create a polar core region within the hydrophobic transmembrane α -helices that facilitates binding of the charged amines. Certain amino acid residues within the hydrophobic domains of adrenergic receptors have been implicated as sites that preferentially bind and complex with the hydroxyl groups of the catechol moiety and with amines of the side chain (e.g., Ser203, Ser204, and Ser207 bind the hydroxyl groups of the catechol moiety and Asp113 binds amines of the side chain,

in the β_2 -adrenergic receptor). Data indicate that at least some of the adrenergic receptors may exist as preformed (constitutive) dimers within the membrane, perhaps preferentially in certain membrane microdomains, which are enriched for cholesterol and sphingolipids. These lipid rafts can also contain the protein caveolin (caveolae) and appear to be sites in which one finds not only the receptors, but also portions of the cognate G proteins and effector enzymes and channels.

The precise mechanism whereby occupancy of adrenergic receptors by norepinephrine or other agonists leads to receptor activation is poorly understood but most evidence points to agonist-promoted conformational changes in the receptor proteins. Of key importance (Fig. 4) is the ability of agonist-occupied receptors to activate G proteins by facilitating the exchange of cytosolic GTP for G_{α} -bound GDP. In this action, the agonist-occupied receptors function as guanine nucleotide exchange factors (see Figs. 3 and 4). Subsequent to the exchange of GTP for GDP, the G protein heterotrimer dissociates into G_{α} and $G_{\beta\gamma}$ (the β - and γ -subunits of $G_{\beta\gamma}$ are tightly bound and function as a dimer) subunits, both of which are able to regulate the activity of effector molecules. The dissociated G_{α} GTP and $G_{\beta\gamma}$ subunits represent the active state of G proteins; the lifetime of G protein activation is determined by intrinsic GTPase activity of G_{α} and by accessory RGS (regulators of G protein signaling) proteins, which serve as GTPase-activating proteins (see Fig. 3). The hydrolysis of GTP and generation of GDP decrease the activity of G_{α} and facilitate the re-formation of the inactive $G_{\alpha\beta\gamma}$ heterotrimer.

Deactivation of signaling in response to norepinephrine or other agonists that activate adrenergic receptors occurs not only via the reversible activation of G proteins, but also by several mechanisms that “turn off” (desensitize) signaling (Fig. 4). These include

Table II Adrenergic Receptors: Subtypes and Their Signaling Pathways

| | Receptors | | |
|--------------------------|--|--|--|
| | $\alpha_{1A,B,D}$ | $\alpha_{2A,B,C}$ | $\beta_{1,2,3}$ |
| G proteins | G_q | G_i | G_s |
| Effectors | Phospholipase C_{β} | Adenylyl cyclase Ca^{2+} Channels K^+ Channels | Adenylyl cyclase Ca^{2+} Channels |
| Second messengers | Inositol 1,4,5-trisphosphate Diacylglycerol | Cyclic AMP Ca^{2+} K^+ | Cyclic AMP Ca^{2+} |
| Protein kinases | Protein kinase C | Protein kinase A | Protein kinase A |

agonist-promoted activation of G protein receptor kinases or second-messenger kinases that phosphorylate receptors; binding of accessory proteins, e.g., β -arrestins, to phosphorylated receptors; biochemical uncoupling and physical sequestration of receptors from G proteins; and internalization of receptors (which is facilitated by β -arrestin interaction with clathrin-coated pits); and degradation or removal of agonist-promoted second messengers and of receptors, the latter occurring at least in part by lysosomal enzymes, and perhaps by proteasomes. In some cases, internalized receptors recycle to the plasma membrane and are resensitized, events that are especially detectable after an agonist is withdrawn. In the continued presence of an agonist, the expression of surface receptors thus represents the balance between internalization and resensitization/externalization. Some results indicate that adrenergic receptor internalization may also facilitate activation of certain intracellular events and signaling pathways.

Beyond the importance of desensitization in the modulation of adrenergic receptor-activated responses, this process has important pharmacological implications. It is notable that by and large, the use of

adrenergic agonists is primarily confined to either acute or intermittent use—in part related to the impact of desensitization on their actions. In contrast, the effects of adrenergic antagonists are much more stable over time and consequently are more broadly utilized therapeutically. Moreover, antagonists can blunt the tonic desensitization and degradation of receptors that occur physiologically. This can precipitate withdrawal syndromes if administration of the antagonist is abruptly stopped and tissue levels fall, prior to the return to normal levels of the “supersensitized” receptors.

ADRENERGIC RECEPTOR EXPRESSION IN TISSUES

In addition to norepinephrine, a key physiologic agonist of adrenergic receptors is the methylated derivative, epinephrine (adrenaline) (Fig. 1), which is particularly prominent in the adrenal medulla and other chromaffin cells, as a consequence of the action of phenylethanolamine *N*-methyltransferase. Relative to norepinephrine, epinephrine shows preferential interaction, i.e., binds with higher affinity to certain

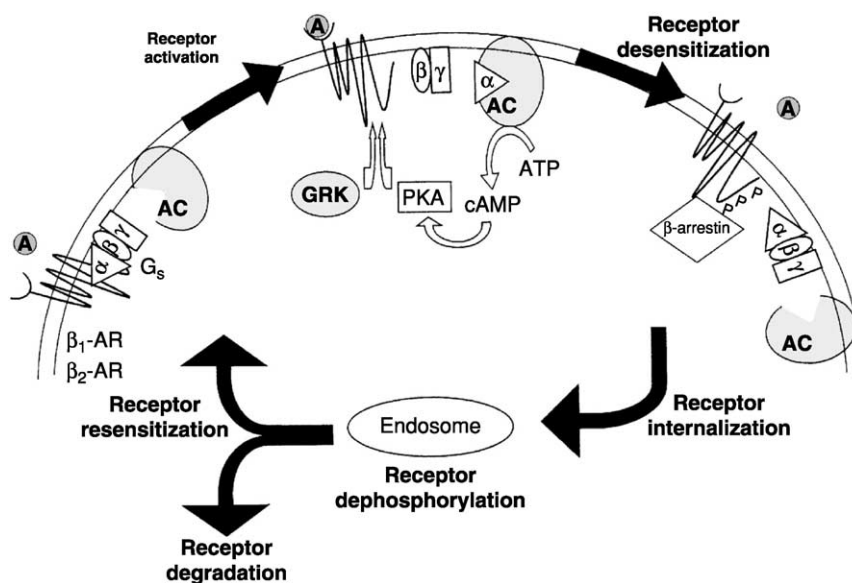

Figure 4 Schematic diagram of adrenergic receptor activation and desensitization using β_1 -adrenergic receptors and β_2 -adrenergic receptors (β_1 -AR and β_2 -AR) as examples. Occupancy of the β_1 -AR or β_2 -AR by norepinephrine, epinephrine, or other agonist (A) promotes the activation of G_s (see Fig. 3) and stimulation of adenylyl cyclase (AC) to enhance the synthesis of cyclic AMP (cAMP) from ATP. cAMP can activate protein kinase A (PKA), which promotes the phosphorylation of cellular substrates, including the β -adrenergic receptors. Agonist-occupied receptors are also phosphorylated by G protein receptor kinases (GRK). The phosphorylated receptors (which are probably phosphorylated primarily by GRK-mediated phosphorylation) subsequently interact with β -arrestin, thereby uncoupling the receptors from activation of the G_s protein. Subsequently, the receptors are internalized via a clathrin-mediated endocytic pathway. In the endosome, receptors can be dephosphorylated and recycled back to the cell surface (resensitization) or degraded by lysosomes or perhaps proteasomes. Modified, with permission, from Post, S. R., Hammond, H. K., and Insel, P. A. (1999). *Annu. Rev. Pharmacol. Toxicol.* 39, 343–360, © 1999 by Annual Reviews, www.annualreviews.org.

classes and subtypes of adrenergic receptors (e.g., β_2 -adrenergic receptors). Some data indicate that α_1 - and β_1 -adrenergic receptors, which show relatively high affinity for binding norepinephrine, are located at postsynaptic neuroeffector junctions in the sympathetic nervous system, whereas other receptors, such as β_2 -adrenergic receptors, which recognize norepinephrine with lower affinity than epinephrine, are located at extrasynaptic sites. α_{1A} receptors appear to be particularly enriched in the heart and vascular smooth muscle in humans. α_{2A} and α_{2C} receptors appear to play a key role in presynaptic feedback inhibition of norepinephrine release from sympathetic nerve endings and at central sites, whereas α_{2B} receptors are located at postsynaptic sites. Although previously it had been suggested that certain tissues exclusively contained single subtypes of adrenergic receptors (e.g., heart and fat cells, β_1 versus lung, β_2), it has become apparent that most major organs, tissues, and cells express multiple types and subtypes of adrenergic receptors. Thus, one can identify β_1 -, β_2 -, and β_3 -adrenergic receptors as well as α_{1A} - and α_{1B} -adrenergic receptors in the heart; adipocytes express multiple subtypes of α_1 -, α_2 -, and β -adrenergic receptors, including β_1 , β_2 , and β_3 in brown fat.

ADRENERGIC RECEPTORS: ROLE IN CLINICAL MEDICINE

Norepinephrine receptors are important clinically for three reasons: (1) their key role in physiology (e.g., cardiovascular, metabolic, renal); (2) the large number of drugs that target these receptors as agonists or antagonists; and (3) the contribution of these receptors in disease, including endocrine disorders. Information about physiologic actions and pharmacological derivatives is available in other reference texts. In terms of endocrine disorders, a few key disorders should be briefly mentioned: disorders of the endocrine pancreas, hyperthyroidism/hypothyroidism, and pheochromocytoma.

Endocrine diseases of the pancreas, in particular, β -cell disorders that are associated with hypoglycemia, lead to activation of the sympathetic nervous system and increases in circulating norepinephrine and epinephrine, the latter primarily as a result of adrenal medullary stimulation. Such counterregulatory responses can occur with hypoglycemia of any etiology, although excess administration of insulin or sulfonylurea drugs is probably the most common cause. Activation of receptors by neuronally released and circulating catecholamines plays a key role

in several signs and symptoms that characterize hypoglycemia, including pallor, tremor (a β_2 -adrenergic receptor response), tachycardia, and actions of adrenergic receptors in the liver, muscle, and fat to increase blood glucose concentration.

Hyperthyroidism is associated with a number of signs and symptoms that suggest a "hyperadrenergic state," e.g., tremor, tachycardia, arrhythmias, and systolic hypertension. Data in experimental animals and patients have indicated that hyperthyroidism is associated with increased β -adrenergic and decreased α_1 -adrenergic receptor activity, at least in part as a consequence of altered receptor expression in several thyroid hormone-responsive tissues and cell types. The molecular basis of these changes may relate to the ability of thyroid hormone to act as a transcriptional regulator of adrenergic receptor mRNA, but post-receptor events also appear to be altered. β -Adrenergic antagonists thus provide rational therapy to treat the signs and symptoms of hyperthyroidism that result from the enhanced β -adrenergic receptor activity.

Conversely, some of the clinical manifestations of hypothyroidism, such as bradycardia, suggest a "hypoadrenergic state." Consistent with this idea are data that indicate opposite changes to those described above for hyperthyroidism, i.e., decreased β -adrenergic receptor activities, increased α_1 -adrenergic receptor activities, and altered activity of postreceptor components.

Pheochromocytomas, chromaffin cell tumors that are most commonly found in the adrenal medulla, produce high circulating levels of catecholamines, stimulation of adrenergic receptors, and predictable effects of such stimulation in target cells. In addition to the direct activation of these receptors, the elevation of norepinephrine (and epinephrine when present) can produce desensitization and down-regulation of adrenergic receptors. These feedback responses help buffer hypertension and other effects of chronic or episodic elevations in catecholamines, but also may contribute to the hypotension that can occur, especially in settings of receptor blockade or postoperatively with removal of the catecholamine-producing tumors.

Data have suggested another potentially important aspect of adrenergic receptors in endocrine and other disorders: the role of genetic variants of these receptors. Several classes of adrenergic receptors, especially α_2 receptor subtypes, as well as β_1 , β_2 , and β_3 receptors are polymorphic, with coding sequence variants that change amino acids involved in receptor activation and desensitization or change amino acids at noncoding regions that can influence receptor expression. Of particular importance in terms of endocrine disorders are data related to the possible contribution of α_2 - and

β_3 -adrenergic receptor variants in obesity. It is likely that substantial further information will be forthcoming regarding genetic variants of adrenergic receptors or their role as disease-modifying genes in endocrine and other disorders—both genetic and acquired.

Figure 1 The noradrenergic neuron. The initial and rate-limiting step in the production of norepinephrine (NE) is the hydroxylation of tyrosine by tyrosine hydroxylase (TH) to L-dihydroxyphenylalanine (DOPA). DOPA is subsequently decarboxylated by L-aromatic amino acid decarboxylase (AADC) to dopamine (DA). Dopamine is mobilized into vesicles through vesicular monoamine transporter 2 (VMAT2), where it is subsequently hydroxylated by dopamine β -hydroxylase (DBH) to form NE. The majority of released NE is removed from the synaptic cleft through reuptake into the presynaptic neuron by the norepinephrine transporter (NET). The remaining NE diffuses away from the synapse and may be taken into other cells by extraneuronal monoamine transporter. Catechol-*O*-methyltransferase (COMT) is an extraneuronal enzyme that catalyzes the methylation of NE to normetanephrine (NMN). NE taken into the presynaptic neuron is either repackaged into vesicles or oxidized by monoamine oxidase (MAO) to dihydroxyphenylglycol (DHPG).

increased aggression in humans homozygous for the low-activity COMT allele, but more study is required on this topic.

Monoamine Oxidase

Monoamine oxidase A (MAO-A) and MAO-B are mitochondrial isoenzymes that are widely expressed among tissues; MAO-A predominates in neural tissue and catalyzes the oxidative deamination of DA to DOPAC and NE to DHPG. MAO-B is selectively expressed in platelets and has been localized to a variety of brainstem structures. MAO-B may have an important modulatory role in limbic output. Dopamine is a substrate for both subtypes. The genes encoding the two isoenzymes are distinct and in adjacent locations on the human X chromosome (Xp11.23). MAO-A-deficient animals showed increased aggressive behavior, which can be corrected by administration of serotonin (5HT) inhibitor. Developmental studies showed an uptake of 5HT by noradrenergic neurons and the animals exhibited cytoarchitectural

abnormalities in the somatosensory cortex. MAO-B-deficient mice showed a reduction in mean arterial pressure and heart rate. Elevated plasma levels of phenylethylamine, a dietary amine, have been reported after administration into MAO-B-deficient mice. Thus, humans deficient in MAO-B may exhibit an increased sensitivity to dietary amines and it brings into focus the association between MAO and migraine headache.

TRANSPORTERS

Vesicular Monoamine Transporter

NE taken up into the presynaptic neuron by norepinephrine transporter (NET) (Uptake 1) is translocated into storage vesicles or deaminated by monoamine oxidase. Vesicular monoamine transporter 2 (VMAT2) mobilizes monoamines from the neuronal cytoplasm into vesicles, where they are repackaged for release at the synapse. Reserpine effectively blocks VMAT-2 and also shuts down the conversion of DA to NE. This

prevents the recycling of NE and results in a gradual and prolonged depletion of NE from the nerve terminal and has been used therapeutically in the treatment of hypertension. VMAT2 null mutation is lethal in mice 2 weeks after birth. The absence of biogenic amine storage in the central nervous system (CNS) of neonatal VMAT2-deficient mice confirms that VMAT2 is the only functional biogenic amine vesicular transporter in the mammalian CNS and that vesicular transporter activity is required for storage. VMAT2 protein levels were reduced by 50% in mice with a single VMAT2 gene and their neural tissue contains approximately 50% of the normal amount of norepinephrine, dopamine, and serotonin. After 10 months, 28% of the mice with a single VMAT2 gene experienced sudden death. Body temperature and heart rate were normal but QT and QTc intervals were lengthened. The failure to completely compensate for the changes in NE signaling may lead to arrhythmias and consequently sudden death. VMAT2 is a potential pharmacological target in the treatment of neuropsychiatric disease in humans.

Norepinephrine Transporter

Neuronal uptake (Uptake 1) by NET accounts for inactivation of 70–90% of released NE from the synaptic cleft in the central and peripheral nervous systems. In

humans, a single gene located on chromosome 16q12.2 encodes a 617-amino-acid protein with 12 putative transmembrane domains (TMDs), and intracellular amino and carboxyl termini (Fig. 2). NET protein undergoes posttranslational N-glycosylation on a large extracellular loop between TMD3 and TMD4, before the protein is subsequently trafficked to the plasma membrane. This modification enhances NET protein stability and catalytic function. NET is expressed presynaptically on noradrenergic axons and varicosities. It is a target of many pharmacological agents including tricyclic antidepressants (TCAs).

TCAs are potent inhibitors of NE uptake and elevate circulating catecholamines. The heart is particularly dependent on reuptake of NE for its inactivation and an increase in heart rate with standing after systemic administration of desipramine, sibutramine, and reboxetine has been reported. Desipramine, which has greater activity on NE reuptake than imipramine, decreases sympathetic nerve traffic, whole body NE spillover, and renal and forearm NE spillover, whereas imipramine was associated with orthostatic hypotension. These effects are similar to those of NET deficiency.

Genetic variability in the human NET gene could contribute to altered reuptake of NE and susceptibility to diseases involving impairment of function at NE synapses, including autonomic nervous system and

Figure 2 The structure of NET encompassing 12 membrane domains is shown. The arginine to proline mutation at amino acid 457 is shown in the ninth transmembrane domain.

psychiatric disorders. Single-nucleotide polymorphisms are the most common type of genetic variability. Among the human NET variants identified thus far, a functional missense mutation in exon 9 in which guanine was replaced by cytosine at position 237 (G237C) has been described. This polymorphism results in a change from alanine to proline (A457P) within the highly conserved region of TMD9 of the NET protein. Proline residues in a transmembrane-spanning α -helix have the ability to kink the α -helix by preventing the formation of backbone hydrogen bonds, which results in disrupted surface expression and function. Transient transfection of A457P into heterologous expression systems revealed a protein with a near complete loss of transporter activity and greatly diminished cell surface expression of the mature, glycosylated form of the transporter. Furthermore, A457P exerts a dominant-negative effect on wild-type NET uptake activity and suggests that individuals heterozygous for A457P may be affected to a greater extent than predicted for harboring one mutant allele. The allele segregates with postural tachycardia, elevated plasma NE, decreased NE clearance, diminished conversion to the intraneuronal metabolite DHPG, and a blunted response to tyramine (Fig. 3).

Molecular studies showed that NET is regulated via transporter surface expression and intrinsic catalytic activity. The regulatory mechanisms involve transporter phosphorylation and regulated associations of accessory proteins. NET has been reported to complex with the catalytic subunit of protein phosphatase 2A (PP2Ac), syntaxin 1A, a presynaptic soluble N-ethylmaleimide-sensitive factor attachment protein receptor (SNARE) protein, and the scaffolding protein PICK1. NET internalization is mediated by protein kinase C through disruption of Syntaxin and PP2Ac association. NET catalytic activity is regulated by insulin- and mitogen-activated protein kinase-linked pathways through PP2Ac. It is quite possible that trafficking and catalytic function are coregulated through kinase-dependent mechanisms.

The management of NET dysfunction requires pharmacological and nonpharmacological interventions, which must be tailored to the individual patient. The pharmacological intervention is directed at attenuating tachycardia in response to standing. Clonidine, an α_2 -adrenoceptor partial agonist, could reduce NE release by stimulating α_2 -autoreceptors and reduce sympathetic outflow. It can also reduce heart rate responses to standing by binding to central α_2 -adrenoceptors involved in brainstem cardiovascular regulation. Beta-blockers can also

Figure 3 NET deficiency. The norepinephrine transporter is responsible for clearance of a majority of the released NE from the synaptic cleft. Loss of NET from the neuron results in elevated synaptic levels of NE. Furthermore, the inability to recycle NE leads to reductions in intraneuronal levels of NE and a concomitant reduction in the production of the NE metabolite DHPG.

attenuate the cardiovascular symptoms. α -Methyldopa appears to be the drug of choice in this group of patients.

Figure 1 Pathway of metabolism of norepinephrine and epinephrine. *Enzymes:* MAO, monoamine oxidase; COMT, catechol-*O*-methyltransferase; mPST, monoamine preferring sulfotransferase (SULT1A3); ADH, alcohol dehydrogenase. *Metabolites:* MHPG, 3-methoxy-4-hydroxyphenylglycol; DHPG, 3,4-dihydroxyphenylglycol; VMA, vanillylmandelic acid.

this is represented by circulating and urinary levels of NMN.

COMT is not located in neurons but is found in nonneuronal tissues, such as liver, muscles, and kidneys. An additional important location of COMT is the adrenal medulla, in which the enzyme is responsible for the conversion of EPI to MN and that of NOREPI to NMN. Circulating EPI is also subject to uptake-2, but less than 10% of MN is derived from this source. More than 90% of circulating MN and 23–40% of NMN are derived from *O*-methylation of EPI and NOREPI within adrenal medullary chromaffin cells. The importance of the adrenal medulla for production of MN and NMN reflects the fact that COMT is predominantly present in this tissue as the membrane-bound enzyme, an isoform of COMT with particularly high affinity for catecholamines. Therefore, plasma metanephrines are specific markers for extraneuronal and intra-adrenal metabolism of catecholamines, whereas plasma DHPG is a specific marker for neuronal metabolism of catecholamines. From a quantitative standpoint, the neuronal pathway of metabolism greatly predominates over extraneuronal and intra-adrenal pathways for metabolism of NOREPI, whereas the extraneuronal and intra-adrenal pathways are more important for metabolism of EPI.

KINETICS AND METABOLISM OF METANEPHRINES

Metanephrines can be measured in plasma and urine by high-pressure liquid chromatography (HPLC) with electrochemical detection (ED). In plasma, the levels of free plus conjugated metanephrines are approximately 20-fold higher than the levels of the free (unconjugated) metanephrines. In human urine, most metanephrines are in the conjugated form. Conjugation of metanephrines by the specific sulfotransferase isoenzyme, SULT1A3, represents an important route of NMN and MN metabolism (Fig. 1). This enzyme is located mainly in extraneuronal tissue of the mesenteric organs, particularly the wall of the gut. These conjugates are excreted by the kidneys. Other routes of metabolism of free metanephrines involve their conversion by MAO to MHPG. MHPG is further oxidized in the liver by alcohol dehydrogenase to the final end product of catecholamine metabolism, vanillylmandelic acid (VMA). The MHPG that is excreted in the urine is mainly conjugated to MHPG sulfate.

Plasma levels of free metanephrines in healthy subjects under resting baseline conditions average approximately 0.6 nmol/liter for NMN and 0.3 nmol/liter for MN. The plasma half-lives of free (unconjugated)

metanephrines are similar to those of catecholamines (approximate 3 or 4 min). The plasma clearances of free NMN and MN are approximately 1.5 liters/min, slightly lower than that of plasma catecholamines (2 liters/min). In contrast, the plasma half-lives of conjugated NMN and MN are much longer (>60 min) and their circulatory clearances are much lower (0.1 liters/min). Since the circulatory clearance of conjugated metanephrines is determined almost exclusively by their extraction by the kidneys, plasma levels of conjugated metanephrines do not always reflect production of free metanephrines. For example, plasma levels of conjugated metanephrines are substantially increased in patients with renal failure, whereas those of free metanephrines are minimally affected.

Plasma levels of metanephrines increase during activation of the sympathetic nervous and/or adrenomedullary hormonal systems. However, increases in plasma levels of NMN and MN above baseline levels are relatively less than those of their parent catecholamines. Even during intense adrenomedullary stimulation induced by hypoglycemia, plasma MN levels increase only 3-fold, in contrast to a 25-fold increase in plasma EPI levels. During less intense stressful conditions, such as mental stress, the responses of catecholamines are proportionally much greater than those of metanephrines. Consequently, metanephrines are inferior to catecholamines for gauging stress responses.

MEASUREMENT OF METANEPHRINES

Measurements of metanephrines in urine have been available for clinical purposes since the early 1960s. Historically, the term total metanephrines was coined to indicate the combined measurement of both NMN and MN by early spectrophotometric assays that did not allow separate measurement of NMN and MN. The development of HPLC techniques has allowed separate measurement of both amines, hence the term fractionated metanephrines. However, urinary measurements of NMN and MN are usually carried out after subjecting samples to acid hydrolysis or enzymatic deconjugation with sulfatase, which liberates the free from conjugated metanephrines. These measurements therefore reflect levels of both the free and conjugated forms of NMN and MN.

In plasma, metanephrines can be measured as free metanephrines or as free plus conjugated metanephrines by HPLC and ED (Fig. 2). In view of the

Figure 2 Chromatogram of free metanephrines in a healthy subject (top) and a patient with a pheochromocytoma (bottom) as measured by HPLC with electrochemical detection. NMN, normetanephrine; MN, metanephrine.

much lower plasma concentrations of free metanephrines, the required analytical sensitivity is much higher for free metanephrines. Many factors should be considered as potential sources of falsely high or falsely low test results. Despite the fact that plasma metanephrines are less sensitive than plasma catecholamines to sympathoadrenal excitation, sympathoadrenal excitation must still be considered a potential cause of falsely high test results. Analytical interference with the analgesic drug acetaminophen can be a problem. Several antidepressant drugs may cause pharmacokinetic interference with the measurement of plasma free metanephrines. Tricyclics can elevate NMN levels, whereas MAO inhibitors increase both NMN and MN levels. Conversely, COMT inhibitors and central sympatholytic drugs lower NMN and MN levels. Despite the availability of this high specific assay, caution for drug interference remains warranted in the interpretation of test results.

APPLICATION OF MEASUREMENT OF METANEPHRINES

In the past 10 years, a new assay for plasma metanephrines has enabled investigators to obtain more detailed and comprehensive insights into the metabolism of catecholamines. This has led to several promising applications. First, measurement of plasma free metanephrines provides a highly sensitive test for diagnosis of pheochromocytoma. The abundant presence of COMT in pheochromocytoma tumor tissue is responsible for a continuous intratumoral conversion of catecholamines to metanephrines. These metanephrines diffuse to the circulation, independently of the release of catecholamines by the tumor. More than 94% of the increased circulating levels of NMN and MN in patients with pheochromocytoma is derived from catecholamine metabolism within tumor cells. Thus, only small increases in NMN and MN levels indicate metabolism of catecholamines after their secretion by the tumor into the circulation. This largely explains why plasma free metanephrines have an approximately 100% sensitivity. Elevations of plasma metanephrines in patients with pheochromocytoma show larger relative increases above normal levels compared to the parent catecholamines. This also contributes to the higher diagnostic sensitivity of measurements of free metanephrines over catecholamines. The continuous production of metanephrines within the tumor tissue also explains why levels of plasma metanephrines are less apt to increase compared to plasma catecholamines during paroxysmal catecholamine release from a pheochromocytoma or during surgical manipulation of the tumor.

Other applications of plasma free metanephrines include a role in the assessment of COMT activity. In conjunction with measurements of plasma DHPG levels, measurements of free NMN can also be used to assess the activity of MAO: An increased NMN/DHPG ratio indicates inhibition of MAO and can also be used to establish MAO-deficiency states. Finally, since plasma free MN is almost completely derived from intramedullary conversion from

adrenomedullary EPI, plasma MN levels can serve as a marker of the adrenomedullary EPI stores.

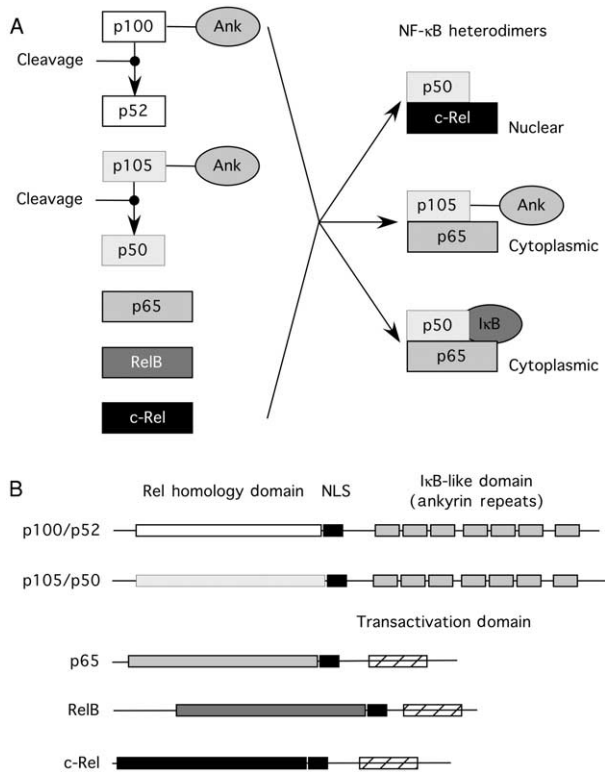

Figure 1 (A) Nuclear factor- κ B family of transcription factors and representative heterodimers between different nuclear factor- κ B proteins. (B) Schematic diagram of the primary structure and functional domains of nuclear factor- κ B proteins.

NF- κ B is considered an inducible transcription factor. In cells with inactive, cytoplasmic NF- κ B, the I κ B protein is phosphorylated by specific I κ B kinases (IKKs) in response to various endogenous and exogenous signals, including viral infection, bacterial components, DNA damage, oxidative stress, and chemotherapeutic agents. The phosphorylated I κ B is then marked for degradation by the ubiquitin-26S proteasome pathway. Degradation and removal of I κ B from the NF- κ B heterodimer exposes a nuclear localization signal, which directs the movement of NF- κ B to the nucleus. Once in the nucleus, NF- κ B binds κ B responsive elements in the promoter of various genes and stimulates transcription by interacting with other transcription factors, coactivators, and the basal transcription machinery. Full transcriptional activity of NF- κ B appears to require its phosphorylation.

Inhibitory Proteins Mask the Nuclear Localization Signal in NF- κ B

The I κ Bs are a family of proteins that play a critical role in regulating NF- κ B activity by physically

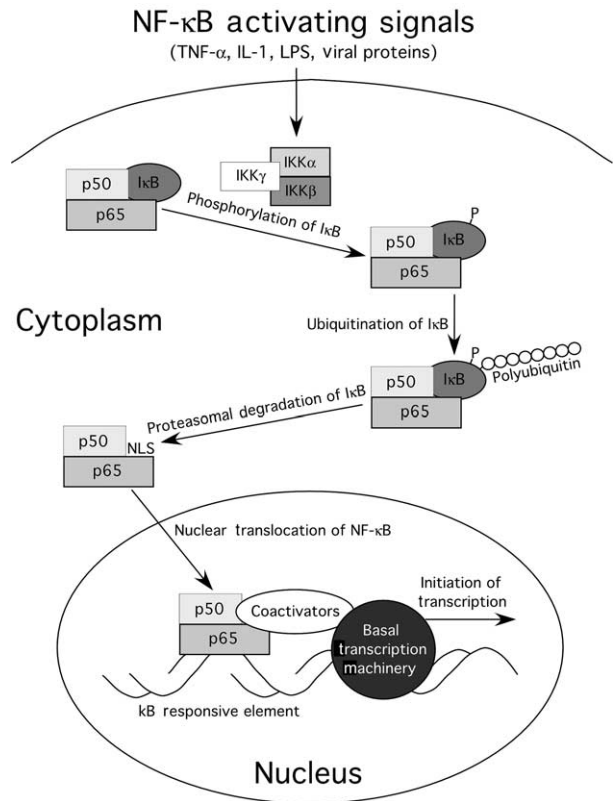

Figure 2 General mechanism of action for cytoplasmic nuclear factor- κ B proteins as described in the text.

interacting with and retaining NF- κ B in the cytoplasm. The I κ B family includes I κ B α , I κ B β , I κ B γ , I κ B ϵ , Bcl-3, p105, p100, and the homologous protein Cactus, which is found in *Drosophila*. Interestingly, different I κ Bs interact preferentially with different members of the NF- κ B family and may have specific patterns of expression in different cell types. For example, I κ B α and I κ B β have a high affinity for the p65 subunit of NF- κ B. As noted previously, ankyrin repeats are a common feature of all I κ B proteins as well as I κ B-like portions of p100 and p105. These ankyrin repeats are involved in the physical interaction between I κ B proteins and NF- κ B. This interaction essentially masks the nuclear localization signal and prevents interactions with other proteins that would transport NF- κ B to the nucleus (Fig. 2). An amino acid sequence containing acidic residues is also characteristic of the C-terminal region of I κ B family members. Evidence suggests that this acidic domain may interact with the DNA-binding and nuclear localization domains of NF- κ B. Nevertheless, the function of this region of I κ B is not as well defined as that of the ankyrin repeats.

Protein Phosphorylation Leads to Ubiquitination and Degradation of I κ B

Diverse signals activate cytoplasmic NF- κ B. Nevertheless, most signaling pathways activate a common I κ B kinase or IKK (Fig. 2). Although IKK is a multisubunit complex that contains IKK α , IKK β , and IKK γ proteins in a stoichiometric ratio, the composition of the entire IKK complex has not been completely defined. It is clear that the activated IKK complex phosphorylates conserved serine residues in the amino terminus of I κ B proteins. For example, I κ B α , which interacts with p65/p50 heterodimers, is phosphorylated by IKK at Ser32 and Ser36. Phosphorylated I κ B α is then recognized by specific enzymes that initially attach one ubiquitin peptide at nearby lysine residues within I κ B α . Attachment of the first ubiquitin leads to ubiquitin–ubiquitin conjugation by other enzymes to form a ubiquitin polymer (Fig. 2). Polyubiquitin-marked I κ B α is then recognized and degraded by the 26S proteasome (Fig. 2). Although most stimuli that activate NF κ B make use of this general pathway, hypoxia and ultraviolet irradiation appear to activate NF- κ B by distinct mechanisms.

NF- κ B Translocates to the Nucleus, Binds DNA, and Acts as a Transcription Factor

The phosphorylation, ubiquitination, and degradation of I κ B releases NF- κ B from its tonic state of inhibition and exposes its nuclear localization signal. Nuclear localization signals are generally composed of a single cluster of five to seven basic amino acids, often including lysine (K) and arginine (R). For example, the core nuclear localization signal is KRKR in p65, KRQ(glutamine)K in p50, and KKQK in c-Rel. Specific transporter proteins called karyopherins recognize these nuclear localization signals, act as molecular chaperones, and direct the movement of NF- κ B into the nucleus (Fig. 2). Mutations of the DNA sequence coding for these amino acids prevent nuclear import and block NF- κ B transcriptional activity, thus demonstrating that these residues are critical for the function of NF- κ B. Once in the nucleus, NF- κ B binds κ B responsive elements in the promoter of various genes (Fig. 2). Although NF- κ B regulates many different genes at the transcriptional level, most are key modulators of inflammatory and immune responses. Among this general class of genes are cytokines and chemokines such as interleukin-1 (IL-1), IL-2, IL-6, IL-8, tumor necrosis factor- α

(TNF- α), β -interferon, and γ -interferon. Other NF- κ B-induced genes important for inflammation and immunity are certain cell adhesion molecules, complement factors, antiapoptotic genes, and immune cell receptors.

Upon binding a consensus κ B responsive element (i.e., 5'-GGGRNYYCC-3'), NF- κ B stimulates transcription of such genes by interacting with other transcription factors or with proteins called coactivators. Although an increasing number of transcription factors and coactivators can act as a bridge between NF- κ B and the basal transcription machinery to enhance transcription, some of these proteins can also repress NF- κ B transactivation in a context-specific manner. For instance, CCAAT-enhancer binding protein- β can repress NF- κ B at the promoter of the angiotensinogen gene or synergize with NF- κ B at the promoter of the IL-6 and IL-8 genes. The cyclic AMP-response element binding protein (CBP/p300) acts in concert with NF- κ B to stimulate gene transcription. CBP/p300 is particularly important because it serves to mediate mutually antagonistic interactions between NF- κ B and the glucocorticoid receptor, which mediates the anti-inflammatory and immunosuppressive effects of glucocorticoids. Interestingly, AP-1 (Fos-Jun) is another transcription factor that displays positive interactions with NF- κ B but negative interactions with the glucocorticoid receptor.

FACTORS AND RECEPTORS THAT ACTIVATE NF- κ B

Having outlined the common pathway for NF- κ B activation, it is now fruitful to examine some of the diverse signaling cascades that converge on the IKK/I κ B/NF- κ B system. NF- κ B activation can occur in response to general cellular stress or in response to specific signaling molecules. For example, oxidative stress and DNA damage, which are produced by many agents, lead to NF- κ B activation. In contrast, more specific receptors transduce endogenous signals from cytokines such as TNF- α and IL-1 into an intracellular cascade that activates NF- κ B. A wide range of pathogens, including bacteria and viruses, also activate NF- κ B, either via specific membrane-bound receptors or by coopting intracellular components of signaling pathways. There is also significant crosstalk or interaction between NF- κ B and other transcription factors such as the steroid receptors. One of the most prominent is the glucocorticoid receptor, which antagonizes the activated form of

NF- κ B, thereby blocking inflammatory and immune responses. A brief overview of some of the receptors and the signaling mechanisms involved in NF- κ B activation and inhibition is provided in the following sections.

TNF- α and TNFR1

The TNF family of ligands, including TNF- α , lymphotoxin- α (LT- α), LT- β , and LIGHT, are generally transmembrane proteins that act in a juxtacrine fashion to influence the function of adjacent cells. The sole exception is LT- α , which is normally a secreted factor. Despite being active in its membrane-bound form, TNF- α can also be released by proteolytic cleavage to form an active, soluble ligand. The TNF family of ligands is trimeric and usually composed of one type of protein. Lymphotoxin- β , however, forms biologically active heterotrimers with LT- α . Although each ligand has its own membrane-bound receptor, TNF- α and its cognate receptor, TNFR1, are the best characterized pair with regard to the intracellular signaling pathways that activate NF- κ B.

The TNF- α and TNFR1 signaling pathway is of particular interest because it can either induce or inhibit programmed cell death (apoptosis). In fact, NF- κ B plays a pivotal role in determining whether an apoptotic program is initiated or whether a survival program is activated. TNF- α triggers apoptosis in NF- κ B-deficient cells or when NF- κ B-induced gene expression is blocked. In contrast, TNF- α -induced activation of NF- κ B results in the synthesis of survival factors that block apoptosis. The earliest events in the latter signaling pathway include binding of trimeric TNF- α to at least two TNFR1 molecules and the juxtaposition of the intracellular domains of TNFR1. Association of two or more intracellular domains leads to the recruitment of TNFR1-associated death domain, which in turn recruits receptor-interacting protein 1, TNF receptor-associated factor 2 (TRAF2), and TRAF1. The events downstream from this step are still unclear but appear to involve activation of kinase cascades that ultimately phosphorylate and activate the IKK complex. Although TNF- α undoubtedly activates NF- κ B, a great deal of work remains to be done to provide a clear picture of the entire cascade leading up to the common NF- κ B activation pathway.

IL-1 and IL-1R1

Interleukins are a family of 10 cytokines that exert inflammatory effects on diverse tissues. The first interleukins discovered were IL-1 α and IL-1 β .

Considering that these two molecules are regulated independently, it is somewhat surprising that they exhibit essentially the same biological effects by interacting with the same membrane-bound receptors. Interleukin-1 receptor 1 (IL-1R1) is a functional receptor that can be activated by both IL-1 α and IL-1 β . In contrast, IL-1R2 is nonfunctional and appears to act as a "decoy receptor" that can competitively inhibit IL-1 signaling via IL-1R1. This functional difference is not due to any difference in the extracellular domain of the receptors, which are highly homologous in primary structure and contain three immunoglobulin-like domains. Rather, IL-1R1 and IL-1R2 differ in their intracellular domain: IL-1R1 contains a domain that is truncated in IL-1R2. Indeed, fusion of the intracellular domain from IL-1R1 to the extracellular domain of IL-1R2 makes the latter receptor functionally active and responsive to IL-1 α and IL-1 β .

The intracellular domain of IL-1R1 therefore plays a critical role in transducing the extracellular signal into an inflammatory cellular response. Specifically, IL-1 binds to IL-1R1, resulting in a conformational change in the receptor. The ligand-receptor complex then recruits IL-1R1 accessory protein. This ternary complex is required for intracellular signaling events that include recruitment of the adapter and effector protein MyD88. MyD88 activates interleukin receptor associated kinase (IRAK) and TRAF6. In turn, TRAF6 activates a downstream kinase cascade, including TGF- β -activated kinase 1 and NF- κ B-inducing kinase (NIK). Ultimately, NIK appears to phosphorylate and activate IKK. Although the last step in this cascade has not been definitively established, it is clear that the proinflammatory effects of IL-1 are mediated by activation of the IKK/I κ B/NF- κ B system.

Microbial Pathogens and Toll-like Receptors

Toll was initially discovered in *Drosophila* as a protein involved in the development of the dorsal-ventral axis, but it was subsequently found to be a key protein in triggering innate immune responses. Twelve mammalian homologs of Toll, called toll-like receptors (TLRs), have been found and more may well be discovered. Although TLRs have a distinct extracellular domain, they have an intracellular domain very much like that of interleukin receptors. Consequently, TLRs signal through an intracellular mechanism very much like that of IL-1R1. The unique extracellular domain, however, varies among different TLRs and appears to

play a role in recognition of specific groups of pathogens, such as gram-negative bacteria, gram-positive bacteria, mycobacteria, and yeasts. The specificity of particular TLRs for certain components of each class of pathogens may be important in triggering tailored immune responses. For example, TLR4 recognizes components of the bacterial cell wall such as lipopolysaccharide and does so in conjunction with CD14. Lipopolysaccharide is a well-known and widely used activator of NF- κ B. Deletion of either TLR4 or CD14 leads to an extremely blunted inflammatory response to lipopolysaccharide. After the external domain binds lipopolysaccharide, the internal domain of TLR4 undergoes a conformational change and physically interacts with MyD88. This protein then engages IRAK, TRAF6, as well as other downstream components typical of the IL-1 signaling cascade. Although TLR4 activates the IKK/I κ B/NF- κ B system, additional work needs to be done on other TLRs to determine if their effects are also mediated by NF- κ B and to explore more rigorously the hypothesis that different TLRs produce tailored responses to particular pathogens.

Viral Infection and Viral Proteins

A broad range of viruses are capable of activating the IKK/I κ B/NF- κ B signaling pathway: NF- κ B is activated by human immunodeficiency virus (HIV-1), human T cell leukemia virus type I (HTLV-1), hepatitis B virus, hepatitis C virus, influenza virus, and others. To be more accurate, viral products are the proximate factors that lead to NF- κ B activation. Nevertheless, these factors do not appear to trigger NF- κ B by activating specific pattern-recognition receptors analogous to TLRs, as do bacterial pathogens. Instead, viral proteins interact at various points in different NF- κ B signaling pathways. Because of the large number of viruses that activate NF- κ B and the diverse mechanisms involved, it is beyond the scope of this article to review more than a few well-characterized and medically important pathways.

HTLV-1 and a protein called Tax that it encodes are a major cause of adult T cell leukemia. The Tax protein is required and sufficient on its own to cause transformation of primary human lymphocytes into cancer cells. Although this protein interacts with a number of transcription factors to alter patterns of gene expression, we are primarily interested in how this protein takes over NF- κ B signaling. The mechanism appears to be fairly simple in that Tax directly interacts with the IKK- γ subunit of IKK, leading

to persistent activation of IKK- α and IKK- β , continuous degradation of I κ B, and sustained activation of NF- κ B. Given that Tax-mediated activation of NF- κ B plays a key role in the expression of downstream genes involved in malignant transformation by HTLV-1, it is important to note that disruption of NF- κ B signaling may be involved in a number of other cancers.

Multiple mechanisms activate NF- κ B during HIV-1 infection. For example, double-stranded (ds) RNA-activated kinase PKR senses the intermediate retroviral dsRNA, is thereby activated, and phosphorylates NIK and IKK. This pathway of NF- κ B activation is presumably common to most, if not all, retroviruses, including HTLV-1. Binding of HIV-1 to CD4 also appears to activate NF- κ B by way of two additional pathways that have not been discussed and are not as clearly defined. In one, HIV-1 interacts with CD4 and crosslinks the receptor. Crosslinked CD4 stimulates Ras, Raf, and mitogen-activated protein kinase pathways that appear to phosphorylate IKK. In the other pathway, HIV-1 binding to CD4 results in phosphorylation of phosphatidylinositol 3-kinase, the subsequent activation of Akt serine-threonine kinase, and the ultimate phosphorylation and activation of IKK. Overall, viral activation of NF- κ B is prolonged relative to the normal pattern of activation in response to endogenous signals. This occurs because viruses circumvent regulatory mechanisms that would normally inactivate the NF- κ B signaling pathway.

ANTAGONISTIC INTERACTIONS BETWEEN NF- κ B AND GLUCOCORTICOIDS

Glucocorticoids are a class of lipophilic, steroidal hormones produced by the adrenal cortex. These hormones are synthesized and secreted in response to physical, physiological, and social stressors, including pain, starvation, and agonistic interactions with other individuals of the same species. Much like the other well-known adrenal hormone adrenaline, glucocorticoids play a central role in the fight or flight response. Glucocorticoids do so by binding to specific glucocorticoid receptors and profoundly influencing the physiology and function of numerous tissues in vertebrates. For instance, glucocorticoids have well-characterized effects on the brain and behavior. In addition, they mobilize energy stores by promoting gluconeogenesis in the liver, degradation of proteins to free amino acids in muscle, and lipolysis in adipose tissues. This class of hormones also has medically

important immunosuppressive and anti-inflammatory effects that are, in part, mediated by antagonistic interactions with the NF- κ B signaling pathway. In the following sections, we discuss how glucocorticoids and the glucocorticoid receptor block NF- κ B signaling and vice versa.

General Mechanism of Glucocorticoid Action

Before we discuss the influence of glucocorticoids on NF- κ B signaling, we briefly describe the classical mode of action of these hormones. In general, glucocorticoids have their effect by entering cells and interacting with the intracellular, cytoplasmic glucocorticoid receptor (GR α). Upon binding ligand with a high affinity, the monomeric GR α undergoes a conformational change, dissociates from regulatory heat shock proteins, and is phosphorylated. The glucocorticoid-GR α complex then forms homodimers and translocates to the nucleus, where it binds to specific DNA sequences called glucocorticoid responsive elements (GREs). In this way, the glucocorticoid-GR α complex usually stimulates gene transcription by interacting with coactivators and the basal transcription machinery (Fig. 3).

Glucocorticoid Induction of I κ B

Glucocorticoids can inhibit NF- κ B signaling by inducing the expression of new protein. In particular, the glucocorticoid-GR α complex binds to GREs within the promoter of the I κ B gene and stimulates its transcription (Fig. 4A). This messenger RNA is translated into the inhibitory I κ B protein, which then sequesters activated, nuclear NF- κ B and directs its movement out of the nucleus. Synthesis of new I κ B protein is a general mechanism for terminating NF- κ B activity and is observed both *in vivo* in whole animals and *in vitro* in cell culture. However, an important caveat is that glucocorticoid-induced expression of I κ B has not been observed in all studies and may be cell-type specific. Moreover, this effect is relatively slow and may be more important for resetting the system to its basal homeostatic state rather than inhibiting the initial transcriptional activity of NF- κ B.

Direct Interactions between NF- κ B and GR α

Interestingly, GR α can inhibit the transcriptional activity of NF- κ B more directly by physically

Figure 3 General mechanism of action for glucocorticoid receptors as described in the text.

interacting with the NF- κ B protein. Given that this interaction does not require new protein synthesis, it is perhaps the most important mechanism whereby glucocorticoids immediately antagonize NF- κ B signaling. There is evidence that such protein-protein interactions induce conformational changes that prevent NF- κ B from binding κ B responsive elements (Fig. 4B). In other cases, however, the interaction with GR α does not block DNA binding by NF- κ B. In these instances, GR α actually associates with the transactivation domain of the p65 subunit of NF- κ B while it sits on κ B responsive elements (Fig. 4C). The glucocorticoid-GR α complex thereby disrupts NF- κ B interactions with the basal transcription machinery that are mediated by coactivators. Another hypothesis that has less support is that GR α competes for a limited number of coactivators that are required to form a bridge between NF- κ B and the basal transcription machinery. Finally, it is possible that GR α binds to DNA sequences called negative GREs within the promoter of NF- κ B responsive genes. Negative GREs of this sort are known to mask binding sites for other transcription factors as well as the basal transcription machinery. Additional studies are required to clarify the

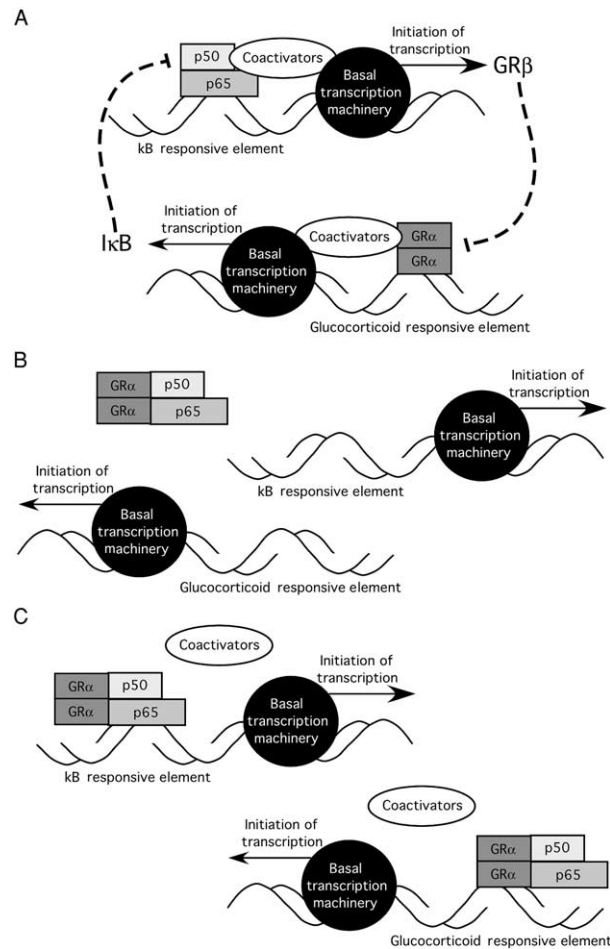

Figure 4 (A) Induction of inhibitory proteins I κ B and GR β . (B) GR-NF- κ B interactions that block DNA binding. (C) Disrupted interactions with transcriptional machinery.

relative importance of these mechanisms and whether they contribute to cell- or tissue-specific patterns of glucocorticoid antagonism of NF- κ B signaling.

NF- κ B Induction of Dominant Negative GR β

There is reciprocal antagonism of glucocorticoid signaling by activated NF- κ B. The mechanisms responsible for this effect are essentially the converse of those previously described, including interference at the level of DNA binding (Fig. 4B) and obstruction of interactions with the basal transcription machinery (Fig. 4C). However, studies indicate that activation of NF- κ B by IL-1 or TNF- α may also cause glucocorticoid insensitivity in a manner analogous to the induction of I κ B. In particular, IL-1 and TNF- α stimulate the preferential accumulation of a dominant

negative form of the glucocorticoid receptor called GR β . This alternatively spliced isoform of GR is only found in humans, is constitutively nuclear, and blocks the transcriptional activity of GR α when it is more abundant than the normal isoform. Although the physiological importance of GR β has been debated, it has been reported that levels of GR β are elevated in disease states refractory to treatment with glucocorticoids. Thus, stimuli that activate NF- κ B may block the anti-inflammatory effects of glucocorticoids by inducing GR β and glucocorticoid resistance (Fig. 4A).

CONCLUSION

NF- κ B is a ubiquitously expressed transcription factor that regulates the expression of numerous genes involved in stress and inflammatory responses. Although one form of NF- κ B is constitutively nuclear and transcriptionally active in B cells, forms of NF- κ B in other cell types are retained in the cytoplasm in association with inhibitory proteins called I κ Bs. Inactive cytoplasmic NF- κ B, however, is an inducible transcription factor. Activation of NF- κ B in these cells depends on the phosphorylation, ubiquitination, and degradation of the I κ B protein, which exposes a nuclear localization signal on NF- κ B. Subsequent translocation of NF- κ B to the nucleus results in binding of this transcription factor to specific DNA sequences called κ B responsive elements within the promoters of inducible genes, including important cytokines and chemokines. A number of receptors transduce endogenous signals such as TNF- α and IL-1 into intracellular signaling cascades that activate NF- κ B. A wide range of exogenous stimuli, including viral and bacterial pathogens, DNA-damaging agents, and oxidative stress, will also trigger the core IKK/I κ B/NF- κ B signaling pathway. In summary, NF- κ B is an extremely important transcription factor that has pleiotropic effects and integrates endogenous and exogenous signals. Because it plays such a pivotal role in normal physiology, misregulation of NF- κ B can lead to various disease states, including asthma, arthritis, autoimmune disease, and certain cancers.

Glucocorticoids have an important influence on NF- κ B activity by opposing its action at a number of levels. Glucocorticoids bind to the GR, which then dissociates from regulatory heat shock proteins. The GR subsequently undergoes phosphorylation and translocates to the nucleus, where it binds to specific DNA sequences called glucocorticoid responsive elements within the promoters of inducible genes such as I κ B. Newly synthesized I κ B then interacts

with the activated, nuclear form of NF- κ B and escorts it out of the nucleus. Importantly, the activated GR can also physically interact with NF- κ B and directly block its transcriptional activity. Antagonistic interactions between GR and NF- κ B signaling pathways explain an important part of the anti-inflammatory and immunosuppressive effects of glucocorticoids, which are widely prescribed for the treatment of disease states related to NF- κ B misregulation.

CLINICAL FEATURES OF PATIENTS WITH PAGET'S DISEASE

As noted above, the majority of patients with Paget's disease are asymptomatic and bone pain is the most common symptom. Skeletal deformities are usually seen in the skull, face, or lower extremities, with the lumbar spine, femur, and pelvis being the most commonly affected bones. Deformities of bone, such as an increase in head size, bowing of a limb, or curvature of the spine, may occur in advanced cases. Pagetic bone is susceptible to fracture with moderate stress. Bone pain associated with Paget's disease is usually due to degenerative arthritis in joints contiguous to bones affected with Paget's disease. Severe headaches or deafness from nerve entrapment can develop from skull involvement with Paget's disease. Dental problems due to temporomandibular involvement can also occur. Involvement of the spine can result in compression fractures, spinal stenosis, and neurological impairment, as well as degenerative arthritis. Because of the increased vascularity of pagetic lesions, the lesions can feel warm to the touch and elderly patients can develop high-output cardiac failure. In addition, patients with Paget's disease can develop hypercalciuria and hypercalcemia, due to accelerated bone resorption induced by immobilization.

Bone radiographs and isotopic bone scans are abnormal in patients with Paget's disease. Bone scans show marked accumulation of the radiolabeled bisphosphonates in the region where the bone formation is markedly increased and can outline early lesions that are not detectable by radiographic techniques. Bone scans are the most sensitive method of detecting pagetic lesions and can be used to follow the activity of the disease in these patients. In the skull, the patients can develop discrete round or oval lesions in the frontal occipital bones, called "osteoporosis circumscripta." In the long bones, the lesions usually begin in the subchondral region of either epiphysis and advance proximally or distally at a rate of approximately 1 cm per year in untreated patients. Initial lesions appear osteolytic, followed by a chaotic sclerotic appearance, and finally become osteosclerotic. Considerable thickening of the sclerotic bone results in bone deformity. Paget's disease usually does not cross the joint space to affect an adjacent bone and, as noted above, it is extremely rare for new lesions to develop in previously uninvolved bones in patients with Paget's disease over the course of their disease.

BIOCHEMICAL MARKERS AND HISTOLOGIC ABNORMALITIES

The biochemical markers provide an integrated assessment of the cellular events occurring throughout the skeleton of patients with Paget's disease. The earliest index of bone matrix resorption was measurement of urinary hydroxyproline excretion while ingesting a low-gelatin diet. This index is well correlated with the extent of the disease despite the fact that hydroxyproline is a prominent component of extraskelatal connective tissue as well as skeletal collagen. Newer markers, such as collagen cross-links and associated peptides used, reflect the primary lesion in Paget's disease, the increase in bone resorption. Urinary N-telopeptide, pyridinoline, and deoxypyridinoline have all been reported to be more specific indices of skeletal matrix resorption and are not influenced by dietary gelatin. Serum tartrate-resistant acid phosphatase, presumably released by osteoclasts, appears to be another index of bone resorption in Paget's disease but is not routinely used. The most useful markers for the increased osteoblast activity in Paget's disease are the total alkaline phosphatase and bone-specific alkaline phosphatase activity levels in serum. Patients also showed significantly higher endothelin-1 circulating levels than controls, with a positive correlation with serum alkaline phosphatase, but not with urinary hydroxyproline. However, serum calcium levels are typically normal in Paget's disease and serum osteocalcin levels appear to be a poor index of the progression of the disease.

Histologic examination of bone biopsy revealed abundant structurally abnormal osteoclasts. Osteoclasts are increased in number and size and contain as many as 100 nuclei per multinucleated cell compared to 3 to 5 nuclei for a normal osteoclast. These osteoclasts have characteristic ultrastructural abnormalities including microfilaments, paracrystalline arrays located in the nucleus and sometimes in the cytoplasm, which are absent in nonpagetic bone or bone marrow cells. These inclusions closely resemble nucleocapsids of viruses of the *Paramyxoviridae* family. Osteoblasts are also increased in lesions in patients with Paget's disease and they appear to be morphologically normal. Osteoblasts contain abundant rough endoplasmic reticulum and mitochondria in a well-developed Golgi zone, consistent with the increased bone formation activity that occurs in the active lesions. In advanced lesions in patients with Paget's disease, the marrow is also abnormal. Normal

hematopoietic elements are usually absent and replaced by mononuclear cells intermixed with highly vascular connective tissue. The bone matrix in Paget's disease is highly abnormal in structure due to disordered bone remodeling. The bone matrix consists of erratic patterns of "cement lines" and demonstrates a "mosaic" pattern. The matrix is interspersed with numerous foci of woven bone, reflecting the increased rates of bone deposition.

TREATMENT OF PAGET'S DISEASE

Bisphosphonates are the most common treatment for patients with Paget's disease. These inorganic phosphate compounds inhibit osteoclast-mediated bone resorption and induce osteoclast apoptosis. These compounds have been shown to inhibit osteoclast formation and osteoclastic bone resorption through their effects on the cholesterol biosynthesis pathway. Etidronate was the original bisphosphonate used in patients with Paget's disease. It is an orally active bisphosphonate that lowers bone turnover, urinary hydroxyproline, and serum alkaline phosphatase levels by approximately 50% in patients with Paget's disease. Since that time, more potent bisphosphonates have been used in patients with Paget's disease. Pamidronate, an intravenous bisphosphonate, induces long-term remissions in patients with Paget's disease at doses of 60 or 90 mg given by single infusions. Additional courses of treatment can be given to patients to achieve normal or near-normal serum alkaline phosphatase levels for long periods of time. Other more potent bisphosphonates, including tiludronate, alendronate, and residronate, have been used in patients with Paget's disease. Residronate is 1000 times more potent than etidronate in its capacity to inhibit bone resorption and given orally over 2 to 3 months can normalize serum alkaline phosphatase levels in 50–70% of patients. All oral bisphosphonates induce mild upper gastrointestinal symptoms and rarely cause iritis. Clodronate treatment has also been shown to reduce serum levels of interleukin-6 (IL-6) soluble receptor in patients with Paget's disease. Zoledronate is the most potent bisphosphonate under investigation to treat Paget's disease. Patients also have been treated with salmon calcitonin or human calcitonin, which induced remissions and lowered bone turnover, urinary hydroxyproline, and serum alkaline phosphatase levels by approximately 50%. However, resistance to calcitonin frequently developed in the majority of patients. Mithramycin, a cytotoxic chemotherapeutic agent, has been used

to treat patients with Paget's disease who are unresponsive to calcitonin or the bisphosphonates. This agent has the potential for severe toxic side effects and is used only in patients who are refractory to other therapies.

GENETICS OF PAGET'S DISEASE

Familial incidence is common in Paget's disease and 15–40% of patients with the disease have an affected first-degree relative. Therefore, genetic factors play an important role in the pathogenesis of Paget's disease of bone. The disease often is inherited in an autosomal-dominant manner, manifesting genetic heterogeneity and incomplete penetrance. Familial Paget's disease has an equal incidence in males and females. A genetic locus for Paget's disease has been identified on chromosome 18q in a region near the familial expansile osteolysis (FEO) locus in several large families with Paget's disease. FEO is a disease related to Paget's disease but occurs in patients at a much younger age and is a much more severe disease. FEO is an extremely rare disease, affecting only a very limited number of kindreds in the world; it is also mapped to chromosome 18q and is linked to activating mutations in the TNFRSF11A gene, which encodes receptor activator of nuclear factor κ B (NF- κ B) (gene symbol RANK). In patients with juvenile Paget's disease, a homozygous deletion of the gene on chromosome 8q24.2 that encodes osteoprotegerin, a member of the superfamily of tumor necrosis factor receptors, has been reported. However, linkage studies, coupled with mutation screening, have excluded involvement of RANK and also osteoprotegerin in the majority of patients with Paget's disease of bone. Studies also indicated that patients with Paget's disease have an increased incidence of osteosarcoma, with approximately 1% of patients with Paget's disease developing osteosarcoma in an affected bone. This incidence of osteosarcoma is 1000 times higher than that in the general population for this age group. Genetic studies have demonstrated linkage in 7 of 7 patients with osteosarcoma to loss of heterozygosity in a region of 18q that is adjacent to or within a locus for Paget's disease on 18q.

A genome-wide search of familial Paget's disease of bone further indicated genetic heterogeneity of the disease, with candidate loci on chromosomes 2q, 10q, and 5q. In the gene encoding sequestosome 1 (SQSTM1/p62), mapped within the critical region on chromosome 5q35–qter, a proline-leucine amino acid change at codon 392 (P392L) was identified in French

Canadian patients with Paget's disease of bone. The frequency of mutation was 16 and 46% for sporadic and familial cases tested, respectively. Further studies also identified different mutations affecting the highly conserved ubiquitin-binding domain of SQSTM1/p62 protein in patients with familial and sporadic Paget's disease. It is well known that SQSTM1/p62 mediates IL-1 and tumor necrosis factor α cytokine signaling to activate NF- κ B. However, the precise role that SQSTM1/p62 may play in the pathogenesis of Paget's disease of bone remains to be elucidated.

VIRAL ETIOLOGY

Since the early 1970s, a variety of studies have implicated paramyxoviruses in Paget's disease. A viral etiology has been proposed for Paget's disease, with an initial description of nucleocapsid-like structures in the nuclei and cytoplasm of pagetic osteoclasts by electron microscopy. Immunocytochemical studies further confirmed that these nuclear inclusions cross-reacted with antibodies that recognized measles virus or respiratory syncytial virus nucleocapsid antigens. *In situ* hybridization techniques also identified the presence of measles virus mRNA sequences in up to 90% of osteoclasts and other mononuclear cells in pagetic bone specimens. Similarly, canine distemper virus nucleocapsid antigens were also detected in osteoclasts from patients with Paget's disease. These paramyxoviral-like nuclear inclusions are not unique to Paget's disease and were reported in patients with FEO and rarely in patients with osteopetrosis, pycnodysostosis, otosclerosis, or oxalosis. This has raised the possibility that the virus is a nonetiologic agent in a cell altered by a genetic defect.

To further explore the viral etiology, using reverse transcription-polymerase chain reaction (RT-PCR) analysis, the measles virus nucleocapsid transcripts from freshly isolated bone marrow cells from patients with Paget's disease were amplified. These measles virus nucleocapsid transcripts contain mutations clustered at the C-terminal end of the messenger RNA. All these mutations were sense mutations and resulted in amino acid substitutions in the nucleocapsid gene product. The mutations occurred at a rate of 1% in the total measles virus nucleocapsid gene isolated from a patient with Paget's disease. It was further demonstrated that osteoclast precursors, the granulocyte/macrophage colony-forming units (GM-CFU), as well as mature osteoclasts from patients with Paget's disease, expressed measles virus nucleocapsid transcripts. Since GM-CFU circulate and also give rise to

monocytes and granulocytes in the peripheral blood, peripheral blood mononuclear cells from patients with Paget's disease and normals were then examined for expression of measles virus nucleocapsid transcripts. RT-PCR analysis demonstrated that peripheral blood samples from 9 of 10 patients with Paget's disease contained measles virus nucleocapsid transcripts, whereas none of the 10 normals tested expressed measles virus nucleocapsid transcripts. The authors have been unable to find canine distemper virus or respiratory syncytial virus nucleocapsid transcripts in patients. In contrast, canine distemper virus nucleocapsid transcripts were detected in affected bones from 100% of patients tested using *in situ* RT-PCR techniques. Furthermore, it has also been demonstrated that infecting canine bone marrow cells with canine distemper virus results in the development of multinucleated cells that share some of the phenotypic characteristics of pagetic osteoclasts. However, other workers have been unable to detect paramyxoviral nucleocapsid transcripts in samples obtained from patients with Paget's disease.

The presence of measles virus or canine distemper virus transcripts in osteoclasts and osteoclast precursors from patients with Paget's disease does not indicate a pathophysiologic role for these genes in the development of the pagetic lesions. It is possible that these paramyxoviral transcripts and paramyxoviral-like inclusions are simply markers for the disease and have no pathophysiologic significance. Studies found that normal osteoclast precursors (GM-CFU) transduced with retroviral vectors expressing the measles virus nucleocapsid gene formed large osteoclasts more rapidly and with increased numbers of nuclei, were hypersensitive to 1,25-dihydroxyvitamin D₃ [1,25-(OH)₂D₃], and had increased bone-resorbing capacity compared to normal osteoclasts. In contrast, normal osteoclast precursors transduced with the measles virus matrix gene did not express an abnormal phenotype. In further studies, we have targeted CD46, human measles virus receptor to cells of the osteoclast lineage in transgenic mice, and demonstrated that measles virus infection of osteoclast precursors from CD46 transgenic mice form osteoclasts, which express a pagetic phenotype *in vitro*. Taken together, these data suggest a potential pathophysiologic role for the paramyxoviral nucleocapsid gene that is expressed in patients with Paget's disease.

However, measles virus infection has a similar incidence worldwide and occurs in very young patients, whereas Paget's disease is a disease of the elderly. These observations suggest that if paramyxoviruses have an etiologic role in Paget's disease, these viral infections must persist for long periods of time. To

further investigate a potential site for the initial infection of osteoclast precursors with Paget's disease, the hypothesis that very early pluripotent hematopoietic stem cells, which can persist for long periods of time in a quiescent phase, may be the initial target for the paramyxoviral infection in patients with Paget's disease was tested. It was found that other hematopoietic lineages from patients with Paget's disease in addition to the osteoclast lineage, including the erythroid and the erythroid precursors (burst-forming unit-erythroid, or BFU-E) and multipotent myeloid precursors (colony-forming unit granulocyte, erythrocyte, megakaryocyte, macrophage, or CFUGEMM), which give rise to megakaryocytes, monocytes, erythroid cells, and granulocytes, also contain paramyxoviral nucleocapsid transcripts. Thus, if the initial site of infection occurs in a small number of primitive pluripotent hematopoietic stem cells that predominantly remain in G₀, this might explain the chronicity of the infection. Furthermore, there may be a genetic predisposition for chronic paramyxoviral infections of hematopoietic precursors in patients with Paget's disease. However, a cause-and-effect relationship of paramyxoviruses in Paget's disease remains to be proven as no infectious virus has been isolated from pagetic cells and, in addition, it is not clear how the initial lesion occurs in Paget's disease.

PAGETIC OSTEOCLASTS AND OSTEOCLAST PRECURSORS

Bone marrow culture techniques identified several abnormalities in osteoclast formation and osteoclast precursors from patients with Paget's disease. These studies provided new insights into the potential pathogenesis of Paget's disease. Osteoclast-like multinucleated cells formed more rapidly with increased numbers (10- to 100-fold) and with more nuclei per osteoclast and they expressed high levels of tartrate-resistant acid phosphatase in marrow cultures from patients with Paget's disease compared to normals. In addition, osteoclast formation in pagetic bone marrow cultures was induced at 1,25-(OH)₂D₃ concentrations that were 10 to 100 times lower than those required in normal marrow cultures. Structural examination of the osteoclast-like cells that formed in these cultures showed that they had many of the features of pagetic osteoclasts but lacked the characteristic nuclear and cytoplasmic inclusions. Immunocytochemical studies confirmed that measles virus and respiratory syncytial virus nucleocapsid antigens were expressed in osteoclasts formed *in vitro* in these cultures.

Osteoclasts from patients with Paget's disease also appear to produce increased levels of IL-6 and express high levels of IL-6 receptors compared to normal osteoclasts. *In situ* hybridization studies have further identified increased levels of IL-6, c-fos proto-oncogene, and Bcl-2 anti-apoptotic gene mRNA expression in pagetic osteoclasts. IL-6 receptor and nuclear factor-IL-6 mRNA levels were also increased in osteoclasts from bone samples from patients with Paget's disease compared to those with osteoarthritis. These data suggest that IL-6, which stimulates human osteoclast formation, may act as an autocrine/paracrine factor to enhance osteoclast formation in patients with Paget's disease and increase the osteoclast precursor pool. IL-6 levels were also shown to increase in bone marrow plasma and peripheral blood of patients with Paget's disease. In addition, the increased levels of IL-6 in the peripheral blood of patients with Paget's disease may in part explain the increased bone remodeling seen in bones not clinically involved with Paget's disease.

To further investigate the potential abnormalities in osteoclast precursors in patients with Paget's disease, studies were conducted to assess the number of osteoclast precursors in marrow aspirates from involved bones from patients with Paget's disease and compared these to normals. It has been found that the number of early osteoclast precursors (GM-CFU) was increased significantly in marrow aspirates from patients with Paget's disease compared to normals. Interestingly, when the osteoclast precursors were separated from the marrow microenvironmental elements present in the marrow aspirates, similar numbers of osteoclast precursors were detected in these aspirates. These data suggested that the marrow microenvironment enhanced osteoclast precursor growth compared to the normal marrow microenvironment.

To determine the potential role of the marrow microenvironment and enhanced osteoclast formation in patients with Paget's disease, reconstitution experiments were conducted using highly purified populations of osteoclast precursors from patients with Paget's disease or normals and marrow stromal cells from patients with Paget's disease and normals. Coculture of normal osteoclast precursors with marrow stromal cells from patients with Paget's disease resulted in enhanced growth of the osteoclast precursors from normals. Interestingly, when osteoclast precursors from patients with Paget's disease were cocultured with marrow stromal cells from normals, they also showed increased growth. These data suggest that both the marrow microenvironment and the

osteoclast precursors are abnormal in patients with Paget's disease.

These studies also confirmed that the osteoclast precursors were hypersensitive to $1,25\text{-(OH)}_2\text{D}_3$ compared to normals. The increased sensitivity to $1,25\text{-(OH)}_2\text{D}_3$ of osteoclast precursors from Paget's patients is mediated through the vitamin D receptor. This was confirmed by up-regulation of 24-hydroxylase mRNA expression in pagetic osteoclast precursors at concentrations of $1,25\text{-(OH)}_2\text{D}_3$ that are 1 log less than that required for normal osteoclast precursors. The increased sensitivity to $1,25\text{-(OH)}_2\text{D}_3$ was not due to increased numbers of vitamin D receptors in pagetic osteoclast precursors compared to normals, but appeared to be due to enhanced affinity of the vitamin D receptor in pagetic cells for its ligand compared to normals. The basis for the increased affinity of $1,25\text{-(OH)}_2\text{D}_3$ for the vitamin D receptor is unknown. Potentially it could be due to enhanced expression of coactivators that interact with the vitamin D receptor and $1,25\text{-(OH)}_2\text{D}_3$ to induce gene expression or could result from decreased levels of suppression of corepressors that interact with $1,25\text{-(OH)}_2\text{D}_3$ and the vitamin D receptor.

The osteoclast precursors from patients with Paget's disease also appear to be hyperresponsive to RANK ligand and marrow stromal cells from pagetic lesions have increased RANK ligand expression. RANK ligand is a critical osteoclast differentiation factor that is expressed on marrow stromal and osteoblast cells in response to several osteotropic factors. The increased sensitivity of osteoclast precursors from Paget's patients to RANK ligand appears to be due to interactions of these precursors with IL-6. The addition of neutralizing antibodies to IL-6 decreased the sensitivity to RANK ligand in the osteoclast precursors from patients with Paget's disease to normal levels. Similarly, the addition of IL-6 to cultures of normal osteoclast precursors enhanced the responsiveness of these precursors to RANK ligand to the levels seen with pagetic osteoclast precursors. The enhanced expression of RANK ligand and IL-6 in pagetic lesions could contribute to the abnormal osteoclast development and highly localized nature of Paget's disease (Fig. 1). It has been shown that SHIP mice, inositol 5' phosphatase-deficient mice, are severely osteoporotic with increased numbers of osteoclast precursors and hyperactive osteoclasts. In addition, serum levels of IL-6 are markedly increased in these mice as in Paget's disease. However, the basis for these abnormalities in both osteoclasts and osteoclast precursors from patients with Paget's disease is still unknown.

Figure 1 Abnormal osteoclast formation in Paget's bone micro-environment. The osteoclast precursors contain measles virus transcripts (MV) and are hyperresponsive to RANK ligand (RANK L). The osteoclasts overexpress IL-6 and the marrow stromal/osteoblast cells overexpress RANK ligand.

SUMMARY

Paget's disease of bone is a chronic focal skeletal disorder that affects up to 2 to 3% of the population over the age of 60 years. The disease is an autosomal-dominant trait with genetic heterogeneity. Recurrent mutations in the ubiquitin-associated domain of sequestosome 1 have been identified in patients with Paget's disease. Osteoclasts and osteoclast precursors from patients with Paget's disease are abnormal; they appear to be hyperresponsive to $1,25\text{-(OH)}_2\text{D}_3$ and RANK ligand and contain paramyxoviral transcripts. The basis for these abnormalities and the role that the paramyxoviruses may play in this disease are still unclear.

90%. Spiral computed axial tomography (CT), which is up to 98% sensitive, most commonly demonstrates a mass in the head of the pancreas. Pancreatic adenocarcinoma appears as a hypodense mass compared to the surrounding pancreatic parenchyma with bolus injection of intravenous contrast material. Furthermore, the relationship to the mesenteric arterial blood supply and superior mesenteric vein and portal vein confluence is well visualized on CT and hepatic metastasis can also be demonstrated. A mass in the head of the pancreas or a dilated pancreatic and biliary duct without a mass in a jaundiced patient suggests the diagnosis of pancreatic cancer. Endoscopic retrograde cholangiopancreatography (ERCP) is the best test to visualize the pancreatic duct and biliary system and it is warranted in patients with duct dilation without a mass on CT or in whom the diagnosis is otherwise unclear. Sampling the pancreatic duct by brush or biopsy is reported to diagnose pancreatic cancer with a sensitivity as high as 92% and a specificity as high as 96%. The diagnosis may be more difficult in patients with chronic pancreatitis who have ductal abnormalities due to chronic inflammation. In addition to diagnosing pancreatic cancer, biliary ductal obstruction can be relieved with a stent placed during ERCP for patients who are unresectable. In patients who are candidates for surgery, the placement of a biliary stent has been demonstrated to increase postoperative infectious complications and placement is not warranted. Other modalities such as magnetic resonance imaging (MRI), endoscopic ultrasound combined with fine-needle aspiration, and positron emission tomography play a limited role in the diagnosis of pancreatic cancer, but they are promising modalities that may be of future benefit. MRI is useful in patients with an allergy to CT contrast or those with renal dysfunction.

SURGICAL THERAPY

Surgical resection of the head of the pancreas (pancreaticoduodenectomy) was first successfully performed by the German surgeon Walter Kausch in 1912. Allen O. Whipple reported the first successful cases in the United States in 1935 and he popularized the operation. During the last 30 years of the 20th century, the mortality of pancreaticoduodenectomy for pancreatic cancer decreased from 30–35% to less than 5%, making this procedure the standard of care for patients with a resectable cancer in the head of the gland. A standard pancreaticoduodenectomy includes the removal of the gallbladder, common bile duct, duodenum, head of the pancreas, and the antrum

of the stomach. Reconnecting the stomach, pancreas (mucosal-to-mucosal anastomosis), and bile duct (end-to-side anastomosis) to the jejunum to reestablish intestinal continuity completes the operation. The most common alternative to the standard operation is the pylorus-preserving pancreaticoduodenectomy, which was repopularized by Traverso and Longmire in the late 1970s. There appears to be little difference to removing or preserving the pylorus in terms of blood loss, operative time, morbidity, mortality, recurrence rates, or long-term survival. The morbidity rate following pancreaticoduodenectomy is fairly high (35–40%). The common complications of the pancreaticoduodenectomy include pancreatic fistula, hemorrhage, intra-abdominal abscess, and delayed gastric emptying.

Adenocarcinoma of the body and tail of the pancreas is less likely to be amenable to surgical resection because of a later presentation, resulting in larger tumors and an increased likelihood of metastatic disease. A distal pancreatectomy and splenectomy should be performed in patients who are deemed resectable by CT scan. Survival rates for patients with adenocarcinoma of the body and tail are the same stage-for-stage with patients with cancer of the head of the gland.

In patients who are explored for a possible resection and are found to be unresectable, a choledocho- or cholecystojejunostomy should be performed if the patient has preoperative jaundice and does not have a biliary stent. Additionally, a gastrojejunostomy should be performed at the time of exploration if the patient has preoperative signs and symptoms of a gastric outlet obstruction.

RADIATION AND CHEMOTHERAPY

Despite some success with complete pancreatic resection, local recurrence rates of 50–86% and liver metastasis of 60–90% have been reported following surgery. This has led to the use of pre- and postoperative radiation and chemotherapy in an attempt to reduce the local failure and regional metastasis that are so common in this disease. Additionally, radiation and chemotherapy are the only treatments for the 80% of patients who present with locally advanced disease or metastasis.

Resectable Pancreatic Cancer

Adjuvant chemoradiation for pancreatic cancer was originally reported in 1985 by the Gastrointestinal Tumor Study Group (GITSG)-9173, which randomized patients to external beam radiation therapy

(40 Gy) and 5-fluorouracil (5-FU) (500 mg/m²) given in bolus fashion during the radiation and once a week for 2 years or no therapy. Median survival was improved from 10.9 to 21 months with the therapy and 2-year overall survival was increased from 18 to 43% in favor of the adjuvant therapy. This study included only 18 patients, who were accrued over 8 years. Similar studies from Johns Hopkins University and the Mayo Clinic also reported increased median and 2-year survival with adjuvant chemoradiation. In all of these studies, the patients with recurrent disease eventually failed in the same pattern as those that did not receive any therapy: local disease, liver metastasis, and carcinomatosis with malignant ascites.

Improvements in radiation and chemotherapy administration have occurred, resulting in the treatment of many patients with external beam radiation and continuous 5-FU-based chemotherapy after resection. Although routinely used for the past 10–15 years, studies such as the EORTC Gastrointestinal Tract Cancer Cooperative Group and the European Study Group for Pancreatic Cancer Trial 1 (ESPAC-1) have reported no benefit with adjuvant chemoradiation in patients with pancreatic cancer. Further randomized, prospective studies are needed to clarify this issue and evaluate other drugs, such as gemcitabine, in the adjuvant setting.

Because adjuvant chemoradiation is delayed in up to 25% of patients following pancreatic resection, neoadjuvant chemoradiation has been examined in several centers. This form of therapy ensures that all patients receive multimodality therapy and patients who have disseminated disease on restaging studies are not subjected to laparotomy. A typical protocol consists of rapid-fractionation external beam radiation (30 Gy in 2 weeks) combined with systemic 5-FU or gemcitabine. The patient undergoes restaging by spiral CT and a resection if this appears to be technically feasible. Overall long-term survival appears to be approximately the same as with traditional adjuvant therapy.

Unresectable Pancreatic Cancer

Patients with unresectable pancreatic cancer have undergone trials similar to those for patients undergoing resection. The first trial sponsored by the GITSG was reported in the early 1970s. Patients with unresectable locally advanced pancreatic cancer (no distant metastasis) received split-dose radiation (60 Gy) and bolus 5-FU. Median survival increased from 22 to 39 weeks and this study is the original basis for offering chemoradiation in patients with unresectable disease.

Several other GITSG trials have examined other agents such as doxorubicin, streptozocin, or mitomycin C in combinations with 5-FU. None of these have been reported to be superior to 5-FU alone and most result in a significant increase in hematologic toxicity. Gemcitabine, a deoxycytidine analogue capable of inhibiting DNA replication and repair, has been shown to provide a survival advantage over 5-FU in patients with locally advanced disease and has become the drug of choice in these patients.

PALLIATIVE THERAPY

Tumor-associated pain due to invasion of the celiac and mesenteric nerve plexuses is almost universal in patients with pancreatic adenocarcinoma. Narcotic analgesia is effective in only approximately 50% of patients. Neurolytic celiac plexus block with 50–100% alcohol can be performed percutaneously or intraoperatively. This results in immediate pain relief in 90% of patients and 23–70% of patients experience long-term pain relief. Video-assisted thoracoscopic bilateral splanchnectomy relieves pain in over 95% of patients, with 50% experiencing long-term relief. This technique should be considered in patients who fail narcotic analgesia and chemical nerve blocks.

There are several options for the palliation of obstructive jaundice. Endoscopic retrograde cholangiopancreatography and placement of a biliary stent is the first line of therapy and has a success rate of over 95%. If this fails, a percutaneous transhepatic internal–external biliary catheter can be placed radiographically and this catheter can subsequently be internalized. Biliary stents are complicated by obstruction, recurrent jaundice, and cholangitis, but they can be exchanged, thus avoiding an operation. If the endoscopic and percutaneous techniques fail, a surgical cholecysto- or choledochojunostomy should be performed. Surgery is successful 98% of the time; however, the morbidity in the unresectable pancreatic cancer patient approaches 30% and the mortality can be as high as 10%.

Gastric outlet obstruction (GOO) occurs in 3 to 19% of patients with unresectable or metastatic pancreatic cancer. In patients undergoing a staging laparotomy who are deemed unresectable or have evidence of metastasis, a gastrojejunostomy should be performed if the patient had preoperative or intraoperative evidence of a GOO. The decision to bypass a patient with unresectable or metastatic disease who presents with a GOO is more difficult. The development of GOO has been demonstrated to occur as a

near terminal event in most series. Moreover, the mortality of a gastrojejunostomy in these patients ranges from 19 to 80%. Endoscopic stent placement and radiographic stent placement in patients with GOO due to pancreatic cancer have been successful and these techniques should be attempted prior to surgical bypass.

Pancreatic Endocrine Tumors (PET)

see Gastrointestinal Neuroendocrine Tumor Syndromes

Table 1 Main Endocrine Syndromes Caused by Pancreatic Islet Cell Tumors

| Type | Incidence | Male:female ratio | Clinical features | Histology | Comment |
|----------------------------|---------------------|---------------------------------------|---|---|---|
| Insulinoma | 1–4 per million | 40:60 for benign; 50:50 for malignant | Episodic fasting and/or reactive hypoglycemia with inappropriately raised plasma insulin, C-peptide, and proinsulin levels | 90% are solitary benign tumors composed mainly of insulin-containing B cells; 10% are metastatic | 1–5% of insulinomas are MEN1; insulinoma is the third commonest tumor in families with MEN1 |
| Zollinger-Ellison syndrome | 0.5–1 per million | 60:40 | Intractable abdominal pain, diarrhea, gastrointestinal bleeding, epigastric tenderness; high gastric acidity with inappropriate and nonsuppressible gastrinemia | 60% of tumors are metastatic, 20% are benign, and 20% are diffuse; tumor is usually <2 cm in diameter | 33% of gastrinomas occur in families with MEN1 |
| Verner Morrison syndrome | 0.2–0.4 per million | 25:75 | Profuse watery diarrhea, hypokalemia, low gastric acidity, flushing of skin, hyperglycemia, and greatly elevated plasma VIP levels | Tumor is usually >8 cm in diameter and composed predominantly of VIP-containing cells | Not associated with MEN1 |
| Glucagonoma | 0.1–0.2 per million | 20:80 | Characteristic skin rash, mild diabetes, anemia, depression and often an enlarged liver; plasma glucagon grossly elevated | Over 60% have metastasized by the time of diagnosis; cells predominantly glucagon-containing | Not associated with MEN1 |
| Somatostatinoma | <0.1 per million | 1:2 | Abdominal pain, steatorrhea, cholelithiasis, hyperglycemia (or hypoglycemia); high plasma somatostatin | Generally large (>8 cm) metastasizing tumors containing many different cell types | Often associated with other “endocrine” syndromes due to simultaneous hormone secretion |

Note. MEN1, multiple endocrine neoplasia type 1; VIP, vasoactive intestinal polypeptide.

TREATMENT

Surgical ablation is the treatment of choice, especially—though not necessarily only—when the tumor is confined to the pancreas. When surgery is impracticable or unsafe, palliative treatment with specific inhibitors of hormone secretion, e.g., diazoxide and octreotide, or of hormone action, e.g., omeprazole, is indicated. Radiotherapy and nonspecific anticancer chemotherapy are rarely of value but metastases—because of their usually slow growth and small number in the liver—may be destroyed with benefit by cryotherapy or arterial embolization.

PROGNOSIS

Prognosis following removal of a benign islet cell tumor is excellent with no reduction in life expectancy. For a patient with metastases, prognosis depends largely on the ability to control the endocrine syndrome by pharmacological means. It

must, however, always be guarded, as tumor growth is inexorable.

PP is a member of the “PP family” of regulatory peptide hormones. Other structurally related peptides include peptide YY (PYY) and neuropeptide Y (NPY). As their names suggest, the peptide members share considerable amino acid sequence homology, but are found in widely disparate locations, including the pancreas (PP), the distal gut (PYY), and the central nervous system (NPY). The circulating levels of PP have been found to vary with a number of normal and pathologic conditions in human (Table I). The

Table I Alterations in PP Levels

| | |
|----------------------|--|
| Elevated levels in: | Normal aging |
| | Obesity (accompanied by glucose intolerance) |
| | Early type 1 diabetes |
| | Neuroendocrine (islet cell) tumors |
| Deficient levels in: | Chronic pancreatitis |
| | (Proximal or total) pancreatic resection |
| | Diabetic autonomic neuropathy |
| | Vagal denervation |

presence of G protein-coupled receptors specific for PP and its related peptides has been confirmed and the population of hepatic PP receptors has been shown to vary inversely with the circulating levels of PP.

PHARMACOKINETICS AND METABOLISM

The half-life of exogenously administered PP in the peripheral venous system is approximately 5 to 7 min. The metabolic clearance rate and volume of distribution do not change significantly when blood concentrations of the peptide are increased. Sustained elevations of PP after a meal cannot be accounted for by a low metabolic clearance rate. Therefore, the peptide must be continuously released in the postprandial period to maintain the high level.

PP levels are elevated in patients with chronic renal failure. A close correlation exists between the glomerular filtration rate and serum PP levels, which suggests that the kidney may play a dominant role in the clearance of PP from the circulation.

REGULATION OF SECRETION

PP is released into the blood following a meal. The response to food is generally biphasic, with plasma concentrations rising four- to sixfold above basal levels within 5 min after food ingestion. The initial release lasts 30 to 60 min and is followed by a secondary response lasting more than 5 h. Protein is the most potent enteral stimulator of PP release, closely followed by fat, whereas glucose has a lesser effect.

Vagal mechanisms are not only the most powerful stimulators of PP secretion, but also are required for nearly all other stimuli of the PP cell. Central vagal activity can be increased either by sham-feeding, a rather specific but mild stimulation, or by hypoglycemia, a less specific but stronger stimulus. PP

secretion is stimulated by “chew-and-spit” sham-feeding. The response is eliminated by vagotomy and can be abolished by atropine, even at very small doses.

Hypoglycemia, whether induced by insulin or not, strongly stimulates PP secretion. Hypoglycemia also elicits parasympathetic and sympathetic adrenal activation, as well as a series of secondary endocrine responses. The PP response, however, is mediated through efferent vagal activity, as indicated by its abolition after vagotomy and inhibition by atropine. The adrenal medulla does not appear to play any major role in PP secretion, as the response is unchanged after adrenalectomy.

The magnitude of the PP response is proportional to the degree of hypoglycemia. PP secretion is surprisingly sensitive to a small decrease in blood glucose. It is even stimulated by rebound hypoglycemia occurring late after an oral glucose tolerance test, despite a nadir in blood glucose of only 55 mg/dl.

A surprisingly long-lasting response is seen when PP secretion is stimulated by activation of endogenous vagal activity. After sham-feeding, PP concentrations remain elevated for hours, even though the stimulus may last for only 15 min. It is quite likely that the prolonged elevation of PP concentrations in plasma in these circumstances is due to continued secretion. Cessation of electrical vagal stimulation is followed by a rapid decline of plasma PP concentrations with a half-life of 5.5 min, similar to the half-life of exogenously administered PP. Thus, hypoglycemia or sham-feeding causes prolonged activation of the “vagal center” responsible for PP secretion. This phenomenon may be an important aspect of the prolonged PP secretion detected after a meal.

The isolated perfused human pancreas model has been used to investigate the neural regulatory mechanism of the endocrine pancreas. In this model, human pancreata are procured from heart-beating organ donors. Following organ procurement, the pancreas is perfused via the splenic artery and the effluent is collected from the splenic vein. Electrical stimulation of the neural plexus along the splenic artery can be performed in the presence or absence of selective neural blockers and hormonal responses in the venous effluent can be examined. In this model, cholinergic stimulation with combined perfusion of phentolamine and propranolol (α - and β -adrenergic antagonists) during splanchnic nerve stimulation causes a marked stimulation of PP release, consistent with the vagal dependency of *in vivo* PP release. Activation of α -adrenergic fibers causes strong suppression of PP secretion and activation of β -adrenergic fibers causes mild stimulation.

PP release is also mediated by enteric hormonal agents such as cholecystokinin (CCK), secretin, bombesin, and gastric inhibitory polypeptide. Intravenous infusion of cerulein, an analogue of CCK, stimulates an increase in plasma PP levels in humans and infusions of 20% pure CCK in humans achieve similar results. The most potent stimulus for PP release on a molar basis in dogs is pure CCK, followed by octapeptide of CCK and synthetic human gastrin. Phenylalanine and tryptophan, instilled into the duodenum, cause a significant increase in PP levels. Duodenal acidification also releases PP, but the response is significantly less than that obtained by infusion of the two amino acids. The mechanism of PP release by phenylalanine and tryptophan appears likely to involve the intermediate release of CCK, which in turn stimulates the release of PP. Oleate and liver extract, both strong releasers of CCK, also stimulate the release of significant amounts of PP when infused into the intestine of dogs. These findings suggest that endogenously released CCK plays an important role in the prolonged or so-called intestinal phase of PP release (Fig. 2).

Gastro-entero-hepatic Actions of PP

Basal pancreatic secretion of fluid and protein is inhibited by physiologic doses of PP in dogs and in humans. At physiologic doses, PP inhibits secretin- and cerulein-stimulated pancreatic protein and bicarbonate secretion in dogs. Secretin- and CCK-stimulated pancreatic secretion of trypsin was markedly inhibited and bicarbonate output was less markedly, but significantly, inhibited by PP. In humans, PP inhibited secretin-stimulated pancreatic secretion in volume, enzyme activity, and total concentration. However, PP appeared to have no effect on pancreatic fluid bicarbonate concentration in humans.

PP infusion does not affect gastric acid or pepsin secretion or the plasma levels of insulin, glucagon, secretin, gastrin, glucose, or lipids. Additionally, there are no signs or symptoms of cardiovascular or gastrointestinal alterations in healthy persons. In dogs, pharmacologic doses of PP had no effect on steady-state bile flow but did cause choledochal resistance and relaxation of the gallbladder. Basal and stimulated output of bilirubin is inhibited significantly by PP infusion at physiologic levels.

Satiety, Obesity, and Hyperphagia

A number of studies suggest that PP may play a role in feeding and obesity and, therefore, in glucose

Figure 2 Pancreatic polypeptide is a 36-amino-acid peptide that is secreted by the F cells of the islet. There is significant homology across species.

metabolism. R. L. Gingerich and co-workers observed that the amount of PP in the pancreas is elevated in hyperglycemic, obese mice. Subsequently, R. J. Gates and N. R. Lazarus reported reversal of hyperphagia, obesity, and glucose intolerance after administration of PP in obese, hyperphagic mice and concluded that the abnormalities seen were due to a deficiency of PP release.

B. Glaser and colleagues studied the relationship of PP levels with both obesity and glucose intolerance in humans. Obese subjects with normal oral glucose intolerance demonstrated low basal and low stimulated levels of PP compared to age-matched controls. Obese subjects with abnormal oral glucose tolerance demonstrated elevated basal levels of PP, however, and an exaggerated PP response to stimulation. W. B. Zipf and colleagues observed that obese children with Prader-Willi syndrome were PP-deficient and that their hyperphagia was reduced by PP administration. PP administration to normal dogs has also been shown to induce weight loss. A 14-day continuous subcutaneous infusion of PP resulted in a 3.5% loss of body weight in 20 kg dogs allowed normal access to food. The weight loss was reversed within 4 weeks after cessation of the PP infusions. A satiety effect of NPY has also been observed by several investigators and laboratory and clinical studies continue to explore the possible role of PP and NPY as satiety-inducing agents. The role of PP is also being investigated in patients undergoing successful bariatric surgery.

REGULATION OF INSULIN ACTION

The liver occupies a central role in the regulation of glucose metabolism. The ability of the liver to produce glucose during times of fasting or stress, and to

take up glucose after feeding, is essential for metabolic homeostasis and PP appears to play an important role in the hepatic response to insulin. A study by Y. S. Sun and colleagues examined pancreatogenic diabetes in a canine model of chronic pancreatitis created by pancreatic duct ligation. The hyperinsulinemic–euglycemic glucose clamp technique and radioisotopic methods were used to quantify hepatic and nonhepatic insulin-stimulated glucose turnover. Hepatic glucose production in normal animals was suppressed by insulin, but dogs with chronic pancreatitis demonstrated far less insulin-induced suppression of hepatic glucose production. This insulin resistance could be demonstrated only in the liver and not in nonhepatic tissue. Furthermore, it occurred only in animals with impaired meal-stimulated PP secretory activity. Thus, PP deficiency was uniformly associated with profound hepatic insulin resistance.

In subsequent experiments, the same animals were restudied at varying time points during continuous subcutaneous infusion of bovine PP. The hepatic insulin resistance previously observed in PP-deficient animals was corrected after PP administration (Fig. 3). Serial glucose tolerance tests, performed over 28 weeks after the PP infusion period, demonstrated that glucose tolerance was significantly improved posttreatment, as compared to pretreatment values.

N. E. Seymour and colleagues studied hepatocyte insulin-binding characteristics to determine whether insulin receptor function or expression is altered by PP. Maximal insulin-binding capacity was significantly lower in tissue from animals with chronic pancreatitis than from control, sham-operated animals (Fig. 4). This loss of high-affinity binding sites was observed in the liver but not in skeletal muscle. PP administration in animals with chronic pancreatitis resulted in significantly greater hepatic insulin-binding capacity

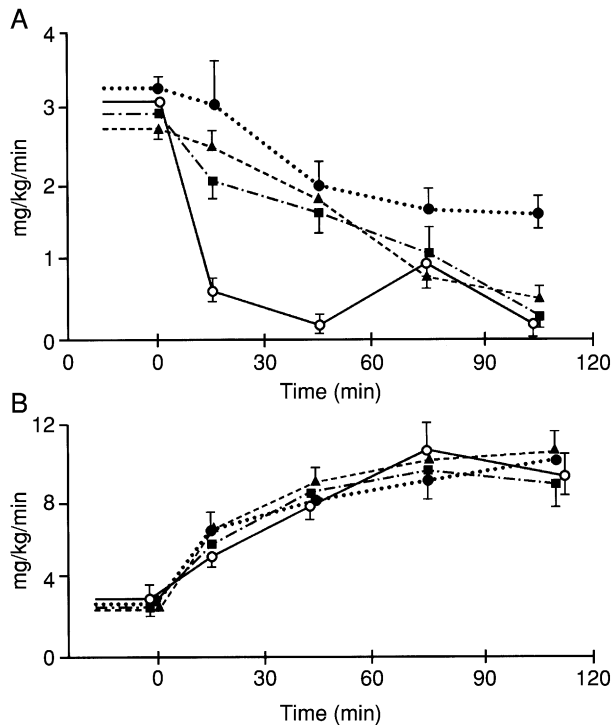

Figure 3 (A) Hepatic glucose production rates. The responses of dogs with chronic pancreatitis at days 6 and 11 of continuous subcutaneous PP infusion were significantly lower than the pre-treatment response by paired analysis ($P < 0.05$). (B) The overall glucose disposal rates achieved by insulin infusion in these studies. Reprinted from Sun *et al.* (1986), with permission.

than was observed after vehicle administration alone (Fig. 4) and approximated that of the control (non-pancreatic) group. During glucose tolerance tests performed immediately prior to the procurement of tissues, the magnitude and duration of the serum glucose elevation following an intraduodenal dextrose challenge were reduced by PP administration in animals with pancreatitis.

Serum immunoreactive insulin levels were not altered by PP administration, but the restoration of high-affinity insulin-binding sites produced by exogenously administered PP suggested alterations in the expression of hepatic insulin receptors. Subsequent studies by this group showed that diminished hepatic insulin receptor gene expression seen in PP-deficient animals is reversed by exogenous PP administration.

The glucoregulatory effect of PP therefore appears to reside in its role in the expression of the hepatic insulin receptor protein. Diminished PP levels are associated with a loss of high-affinity insulin receptor sites on hepatocytes, which creates a state of hepatic insulin resistance. Although other factors may play a

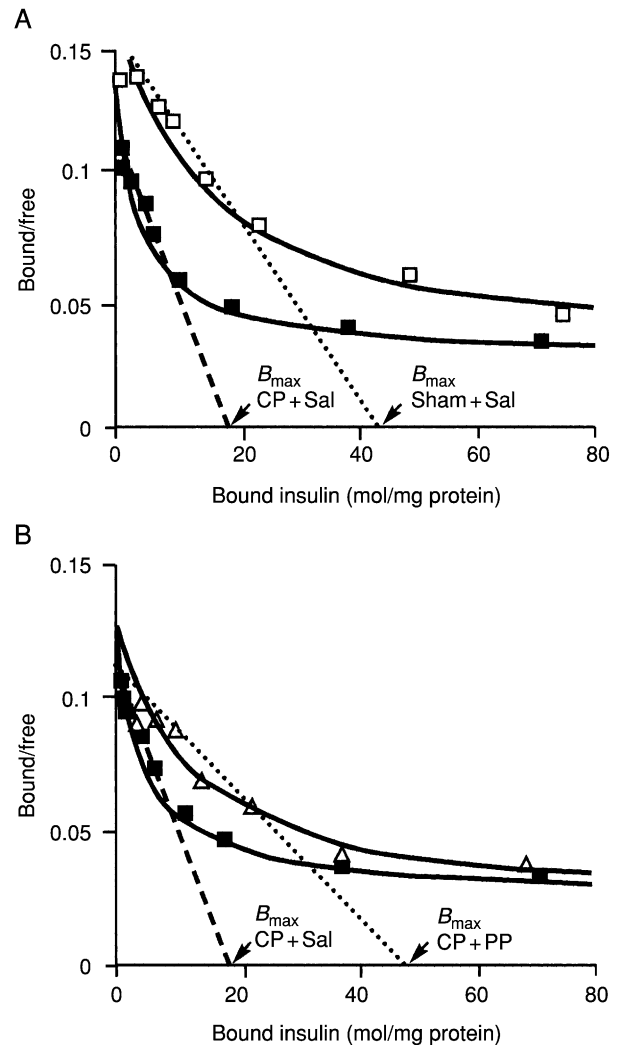

Figure 4 (A) Effect of chronic pancreatitis on hepatic insulin binding: Scatchard plot of insulin binding in solubilized hepatic membranes from saline-administered, sham-operated rats (sham, open squares) and saline-administered, chronic pancreatic rats (CP, filled squares). (B) Effects of PP administration (PP, 200 $\mu\text{g}/\text{kg}$ per day) on hepatic insulin binding in chronic pancreatitis: Scatchard plot of insulin binding in solubilized hepatic membranes from saline-administered chronic pancreatic rats (CP+Sal, filled squares) and PP-treated rats (CP+PP, open triangles). role in the hepatic insulin resistance that characterizes pancreatogenic diabetes, a loss of insulin-binding sites due to the reduced expression of hepatic insulin receptor protein appears to be the primary mechanism of PP's glucoregulatory role. Replacement of PP by exogenous administration reverses the hepatic insulin resistance and at least partially corrects the abnormal hepatic glucose production.

The Role of PP in Pancreatogenic Diabetes

Patients with severe chronic pancreatitis also have a profound meal-stimulated PP secretory deficiency compared to normal subjects (Fig. 5). During an initial, baseline hyperinsulinemic–euglycemic clamp study, a pattern of profound hepatic insulin resistance similar to that seen in the canine studies was found to occur in these PP-deficient patients (Fig. 6). Glucose clamp studies were repeated 1 to 2 months later during the final 2 hours of an 8 h intravenous infusion of bovine PP, which replicated physiologic serum concentrations of postcibal immunoreactive PP (750–1000 pg/ml). Hepatic responses to insulin in PP-deficient patients were restored to normal by PP (Fig. 6). However, insulin-stimulated glucose disposal in normal control subjects was not altered by the PP infusion. There was no PP-induced alteration in serum insulin or glucagon concentrations in either of the experimental groups. These data indicate that PP replacement was successful in reestablishing the normal hepatic response to insulin. A third set of glucose clamp studies was performed 1 to 2 months after the PP administration. Hepatic glucose output in response to insulin in PP-deficient patients had returned to near-baseline values, which confirmed the etiologic role of PP deficiency in the hepatic resistance to insulin (Fig. 6).

N. E. Seymour and colleagues examined glucose turnover in patients with a remote history of pancreatectomy. In these subjects, proximal pancreatectomy

and distal pancreatectomy were distinguished from one another, since only the former was associated with a loss of PP secretory activity and low circulating PP levels (Fig. 7). Three hyperinsulinemic–euglycemic clamp studies were performed in each subject, separated by at least 1 month. An 8 h intravenous PP infusion

Figure 7 Immunoreactive PP (IR-PP) response to a test meal for eight control subjects (open circles), four non-PP-deficient resection patients (filled triangles), and six PP-deficient resection patients (filled squares). Reprinted from Seymour *et al.* (1998), with permission.

was administered before the second study. PP-deficient, proximal pancreatectomy subjects demonstrated an impairment in hepatic insulin responses in the first study and required significantly smaller glucose infusions than normal control subjects to maintain euglycemia during insulin infusion (Fig. 8). This insulin resistance was completely reversed by PP administration during the second clamp study, but was evident again during the final infusion study in the absence of PP. No alteration in peripheral glucose disposal was observed with either pancreatectomy or PP administration. These studies provide strong evidence for a selective hepatic metabolic effect of PP.

Clinical Implications of Alterations in PP Secretion

Diabetes Mellitus

Mean basal concentrations of plasma PP are elevated in normal aging and in type 1 and type 2 diabetes mellitus. PP levels are particularly elevated in type 2 (adult onset, non-insulin-dependent) diabetic patients, which may represent a compensatory response to a loss of insulin synthesis or action. Early type 1 diabetic patients may also exhibit high levels of PP before they experience a complete loss of islet tissue due to the progression of disease.

Destruction of the pancreas by pancreatitis or surgical removal of the pancreas is associated with a form of glucose intolerance termed "pancreatogenic diabetes"

Figure 8 Glucose infusion rate (mg/kg/min) during the final hours of a 2 h insulin infusion in normal control (open squares), non-PP-deficient resection (filled circles), and PP-deficient resection (filled squares) subjects. The glucose infusion requirement for PP-deficient subjects was significantly greater during the PP infusion study than during the control study ($P < 0.03$). Reprinted from Seymour *et al.* (1998), with permission.

(or type 3 diabetes), which differs from both type 1 and type 2 diabetes in several respects (Table II). Diabetes in these conditions rarely, if ever, results in ketoacidosis, but can be associated with labile blood glucose levels and frequent episodes of iatrogenic hypoglycemia. This specific pattern of abnormal glucose homeostasis is likely caused by the simultaneous deficiencies in insulin, glucagon, and PP secretion.

Chronic Pancreatitis

Chronic pancreatitis is a complex pathologic state consisting of lifelong exocrine and endocrine derangement. Endocrine dysfunction manifests itself as diabetes mellitus, but multiple hormone deficiencies have been demonstrated. Basal and meal-stimulated levels of circulating immunoreactive PP are especially affected by chronic pancreatitis, so much so that measurement of PP levels has been suggested as a screening procedure for the diagnosis of chronic pancreatitis. In PP-deficient states such as chronic pancreatitis, there is demonstrable hepatic resistance to insulin, which can be reversed by the administration of PP (Fig. 9).

Pancreatic Surgery

A PP-deficient state frequently arises after surgical resection of the proximal pancreas because the hormone is synthesized predominantly in the head of the gland. K. Inoue and colleagues confirmed the abolishment of PP responses to ingested nutrients in patients after pancreaticoduodenectomy. In the study by N. E. Seymour and colleagues, healthy, young (age less than 30 years) male patients who had undergone pancreatic resection and who had a deficient PP response as a consequence of their pancreatic resection had a measurable impairment of hepatic insulin sensitivity. This effect was not associated with impaired glucose tolerance, however, when insulin and glucagon secretory function was present.

The risk of pancreatogenic diabetes is increased when proximal pancreatectomy is performed in older patients, however, or when near-total or total pancreatectomy is performed. The development of duodenum-preserving pancreatic resection techniques by H. G. Beger and colleagues, and by C. F. Frey, has been shown to be associated with improved glucose tolerance postoperatively. The preservation of glucose tolerance with operative techniques that spare part or all of the PP-rich region of the pancreas further supports the role of PP in glucose homeostasis.

Artificial Endocrine Pancreas

The artificial endocrine pancreas, used clinically, is simple in its concept. A sensor electrode measures

Table II Types of Diabetes Mellitus

| Parameter | Type 1 IDDM juvenile onset | Type 2 NIDDM adult onset | Type 3 pancreatogenic postoperative onset |
|--------------------------------|-------------------------------|-----------------------------|--|
| Ketoacidosis | Common | Rare | Rare |
| Hyperglycemia | Severe | Usually mild | Mild |
| Hypoglycemia | Common | Rare | Common |
| Peripheral insulin sensitivity | Normal or increased | Decreased | Increased |
| Hepatic insulin sensitivity | Normal | Normal or decreased | Decreased |
| Insulin levels | Low | High | Low |
| Glucagon levels | Normal or high | Normal or high | Low |
| PP levels | High | High | Low |
| Typical age of onset | Childhood or adolescence | Adulthood | Any |

Figure 9 Mean plasma glucose concentration during 180 min after 40 g/m² oral glucose tolerance test (OGTT) in chronic pancreatitis patients ($n = 10$) and controls ($n = 6$). Open circles indicate impaired or diabetic status during the initial OGTT. Filled circles indicate normal or nondiagnostic status during the initial OGTT. OGTT 2 was performed 18 h after an 8 h infusion of bovine PP (2 pmol/kg min). OGTT 3 was performed 1 month later. Eighteen hours after PP infusion, every patient with impaired diabetic OGTT showed a lower mean plasma glucose response. Reprinted from Andersen (1990). The role of pancreatic polypeptide in glucose metabolism. In "Gastrointestinal Endocrinology: Receptor and Post-receptor Mechanisms," (J. C. Thompson, ed.), pp. 333–357. Academic Press, San Diego, CA, with permission.

the level of blood glucose. This information is fed into a small computer that energizes an infusion pump, and from a small reservoir, controlled amounts of insulin enter the patient's circulation. K. Hanazaki and colleagues developed a new artificial pancreas with a multiple-chamber injection pump to facilitate infusion of not only insulin, but also PP. The addition of PP decreased insulin requirements in pancreatctomized dogs during a 72 h trial period. This observation suggests that PP, or a PP-like agonist, may become a useful adjunct in the treatment of diabetes.

SUMMARY

PP release is both hormonally and neurally mediated and both exaggerated or diminished PP responses are valuable indicators of the integrity of the neuro-entero-pancreatic system. Although subtle effects on pancreatic exocrine function and choleresis are associated with PP, its major role appears to be that of a glucoregulatory hormone. PP may play a role in food ingestion as a satiety mediator, but its most consistent function appears to be that of a regulator of hepatic insulin action, through its mediation of hepatic insulin receptor protein synthesis. Therapeutic opportunities, such as replacement of PP in states where the hormone is deficient, are being explored clinically. In the future, PP analogues, as well as PP-receptor agonists or antagonists, may become useful clinical tools.

parathyroidectomy on the basis of local invasion ($n = 5$), tumor pathology ($n = 4$), or distant metastases ($n = 2$). Hypercalcemia was less severe than usually observed in patients with parathyroid carcinoma and parathyroid hormone (PTH) levels were not unusually high for patients on maintenance hemodialysis. Only one patient died of hypercalcemia. The authors concluded that no preoperative features distinguished hemodialysis patients with parathyroid carcinoma from those with parathyroid hyperplasia and that the clinical course may be more benign because of the tendency for renal insufficiency to lower serum calcium levels.

Familial Hyperparathyroidism

Parathyroid cancer has been reported in patients with familial hyperparathyroidism, particularly those with autosomal dominant isolated hyperparathyroidism that is not part of the multiple endocrine neoplasia type 1 (MEN1) syndrome. In one such family, there was no evidence of antecedent hyperplasia in unaffected glands and chromosomal abnormalities commonly observed in other solid tumors were identified (a reciprocal translocation between chromosomes 3 and 4, trisomy 7, and a pericentric inversion in chromosome 9). Analyses of tumor DNA from one family member with parathyroid carcinoma showed no evidence of *ras* gene mutations, PTH gene arrangement, or allelic loss from chromosome 11q13, the locus of the gene for MEN1. The risk of parathyroid carcinoma is also greatly increased in patients with the hyperparathyroidism–jaw tumor syndrome, which has been localized to chromosome 1q21–q31.

MOLECULAR PATHOGENESIS

Oncogenes and tumor suppressor genes have been implicated in the development of parathyroid tumors. Cyclin D1 or PRAD1 (parathyroid adenoma 1) is an oncogene located on chromosome 11q13; its protein product is a cell cycle regulator. Rearrangement of the cyclin D1 gene with the regulatory region of the PTH gene has been reported in 5% of parathyroid adenomas and the cyclin D1 oncoprotein is overexpressed in 18–40% of parathyroid adenomas. In one study, overexpression of cyclin D1 protein was found in 90% of parathyroid cancers. However, it is uncertain whether overexpression of cyclin D1 protein is a causative or an associative phenomenon.

There is also strong evidence that inactivation of the tumor suppressor gene RB (retinoblastoma) on

chromosome 13 may contribute to the development of parathyroid carcinoma. Together with cyclin D1, RB is important in cell cycle control. In one study, 11 parathyroid cancers lacked a RB allele and most had a complete absence of nuclear staining for the RB protein. In contrast, only one parathyroid adenoma lacked the allele and none had abnormal staining for the RB protein. Several other investigators have also reported that allelic deletions on chromosome 13 are more common in parathyroid cancer than in benign primary hyperparathyroidism. These data strongly support the presence of a tumor suppressor gene on the long arm of chromosome 13, critical for the development of parathyroid carcinoma. However, as the deleted portion of chromosome 13 is large, it remains to be determined whether RB or a different gene on 13q will prove to be the primary causative tumor suppressor. Another important cell cycle regulator, the p53 tumor suppressor gene, does not appear to be a major contributor to the pathogenesis of parathyroid carcinoma.

Several new locations have been identified for potentially important oncogenes or tumor suppressor genes that seem to be preferentially or exclusively found in parathyroid carcinomas as compared with adenomas. Tumor-specific gains or losses of chromosomal material suggest that oncogenes on chromosomes 1q, 5q, 9q, 16p, 19p, and Xq and tumor suppressor genes on chromosomes 1p, 3q, 4q, 13q, and 21q may be involved in the pathogenesis of parathyroid carcinoma. Moreover, since a number of the regions commonly lost in adenomas (including 11q, the site of the MEN1 gene) were never or rarely lost in carcinomas, these results also support the hypothesis that parathyroid carcinomas tend to arise *de novo* rather than from preexisting adenomas. Clarification of the molecular pathogenesis of parathyroid carcinoma will aid in the diagnosis of difficult cases and may provide important clues or biological targets for future development of new and more effective therapies.

CLINICAL FEATURES

General Considerations

The clinical features of parathyroid cancer are due primarily to the effects of excessive secretion of PTH rather than to infiltration of vital organs by the tumor. Thus, signs and symptoms of hypercalcemia often dominate the clinical picture in addition to symptoms of hyperparathyroid bone disease and renal involvement (renal insufficiency, nephrolithiasis, or nephrocalcinosis). It is critical that parathyroid cancer be

considered in the differential diagnosis of parathyroid hormone-dependent hypercalcemia. All too often the diagnosis of parathyroid carcinoma is made in retrospect when hypercalcemia recurs due to local spread or distant metastasis of the tumor. The best outcomes for patients with parathyroid cancer occur when there has been complete resection of the tumor at the time of the first surgery. Several features of the patient with primary hyperparathyroidism should suggest a malignant rather than a benign disease (Table I).

Demographic Features

Benign primary hyperparathyroidism is considerably more common in women than in men (3–4:1). In contrast, there is no association of gender with parathyroid carcinoma and the ratio of affected women to men is 1:1 in most reported series. Patients with primary hyperparathyroidism typically present in their fifties or sixties, whereas the average patient with parathyroid carcinoma is in his or her forties, approximately 10 years younger. However, two reviews (the Mayo Clinic experience and the National Cancer Data Base) found that the average age of their patients was in the middle fifties. Thus, although it is reasonable to consider the possibility of parathyroid cancer when primary hyperparathyroidism is diagnosed in a man and or a younger individual, gender and age are of limited assistance in the setting of the individual patient.

Symptoms and Biochemical Characteristics

Benign primary hyperparathyroidism usually presents with mild hypercalcemia (within 1 mg/dl above the

upper limit of normal) that is often asymptomatic and usually discovered incidentally. In contrast, the serum calcium level in parathyroid cancer is much higher, generally above 14 mg/dl or 3–4 mg/dl above the upper limit of normal. Typical signs and symptoms of hypercalcemia, including fatigue, weakness, weight loss, anorexia, nausea, vomiting, polyuria, and polydipsia, are almost always present. Bone pain, fractures, and renal colic are much more common when primary hyperparathyroidism is due to a parathyroid cancer than an adenoma. Extremely high levels of parathyroid hormone are unusual in benign primary hyperparathyroidism, where circulating concentrations are commonly less than twice the upper limit of normal. In contrast, parathyroid hormone levels in patients with parathyroid cancer are generally much higher, ranging from 3 to 10 times above the upper limit of normal. Serum alkaline phosphatase activity is often frankly elevated in patients with parathyroid carcinoma, whereas levels are usually in the normal or upper-normal range in patients with benign primary hyperparathyroidism. Finally, patients with parathyroid carcinoma may have elevated levels of α - and β -subunits of human chorionic gonadotropin, whereas patients with primary hyperparathyroidism do not.

Physical Findings

A palpable neck mass has been reported in 30–76% of patients with parathyroid carcinoma, yet is distinctly unusual in benign primary hyperparathyroidism. This important clinical finding constitutes another striking difference between benign and malignant parathyroid disease. In addition, recurrent laryngeal nerve palsy in a patient with primary hyperparathyroidism who has not had previous neck surgery suggests local spread of

Table I Parathyroid Carcinoma and Benign Primary Hyperparathyroidism: Typical Features

| | Parathyroid carcinoma | Primary hyperparathyroidism |
|--|-----------------------|--------------------------------------|
| Female:Male ratio | 1:1 | 3.5:1 |
| Average age (years) | 48 | 55 |
| Asymptomatic | <5% | >80% |
| Serum calcium | >14 mg/dl | ≤1 mg/dl above upper limit of normal |
| Parathyroid hormone | Markedly elevated | Mildly elevated |
| Palpable neck mass | Common | Rare |
| Renal involvement ^a | 32–80% | 4–18% |
| Skeletal involvement ^b | 34–91% | <5% |
| Concomitant renal and skeletal disease | Common | Rare |

^aIncludes nephrolithiasis, nephrocalcinosis, and impaired renal function in the absence of any other etiology.

^bIncludes osteitis fibrosa, subperiosteal resorption, “salt and pepper” skull, and diffuse osteopenia on plain radiographs.

the tumor and is also very suggestive of parathyroid cancer.

Target Organ Involvement

The classical target organs of parathyroid hormone—namely, the kidney and the skeleton—are affected with greater frequency and severity in parathyroid carcinoma than is typically observed in benign primary hyperparathyroidism. The prevalence of renal involvement in benign primary hyperparathyroidism, including nephrolithiasis, nephrocalcinosis, and impaired glomerular filtration, is less than 20%. In contrast, renal colic is a frequent presenting complaint of parathyroid carcinoma. The prevalence of nephrolithiasis was 56% and the prevalence of renal insufficiency was 84% in the Mayo Clinic series, somewhat higher than in previous reports in which the prevalence of renal involvement has ranged from 32 to 60%.

Bone pain and pathologic fractures are also common features of parathyroid cancer. Patients with benign primary hyperparathyroidism rarely have skeletal complaints and specific radiologic signs are found in less than 5% of patients. In contrast, specific radiologic signs of hyperparathyroid skeletal disease are commonly seen in parathyroid carcinoma, with osteitis fibrosa cystica, subperiosteal bone resorption, “salt and pepper” skull, absent lamina dura, and diffuse osteopenia reported in 44 to 91% of cases. Another distinguishing feature is the development of concomitant bone and stone disease in parathyroid cancer, whereas simultaneous and symptomatic involvement of the kidneys and skeleton is distinctly unusual in primary hyperparathyroidism.

Recurrent severe pancreatitis, peptic ulcer disease, and anemia occur with greater frequency in patients with malignant disease than in those with benign primary hyperparathyroidism.

Acute Primary Hyperparathyroidism

Parathyroid cancer is more difficult to distinguish from acute primary hyperparathyroidism, also known as parathyroid crisis, with which it shares many clinical features. As parathyroid crisis is also characterized by marked elevations of serum calcium and parathyroid hormone, the diagnosis of parathyroid cancer should always be considered. Whereas a preoperative distinction between these two entities is not possible, it is important to bear the potential for cancer in mind since the surgical approaches differ.

Summary

Features that should lead a physician to suspect that a patient with hypercalcemia and elevated parathyroid hormone levels has parathyroid cancer are shown in [Table I](#). However, some patients with parathyroid cancer may present with signs and symptoms that are quite mild. Whether this is because the disease is diagnosed at an earlier stage is unclear. Conversely, some patients with benign primary hyperparathyroidism may present with more severe disease than is commonly seen. In such patients, the distinction between benign and malignant disease on clinical grounds may be difficult or impossible, since profound hypercalcemia, renal disease, and osteitis fibrosa or diffuse osteoporosis may occur and even concomitant kidney and bone disease may be present. In either situation, it is preferable to have a high index of suspicion for parathyroid carcinoma than to miss the opportunity for surgical cure by failing to consider it in the differential diagnosis.

PATHOLOGY

Gross Pathology

Certain operative findings are helpful in distinguishing between benign parathyroid adenomas and parathyroid carcinoma. Parathyroid adenomas are usually soft, round or oval in shape, and reddish-brown in color. In contrast, parathyroid carcinomas are usually lobulated and firm to stony-hard in consistency. Approximately half are surrounded by a dense, fibrous, grayish-white capsule that adheres tenaciously to adjacent tissues and makes the tumor difficult to separate from contiguous structures. If there is gross infiltration of adjacent thyroid, nerve, muscle, or esophagus, or if there are cervical node metastases, the diagnosis of carcinoma is a simple matter. Unfortunately, any one or all of these operative findings may be absent.

Histology

As is the case with many endocrine neoplasms, the histopathologic distinction between benign and malignant parathyroid tumors is difficult to make. In 1973, Shantz and Castleman, based on an analysis of 70 cases of parathyroid carcinoma, established a set of criteria for the pathologic diagnosis of this malignancy. These histologic features are as follows: (1) uniform sheets of (usually chief but occasionally oxyphil) cells arranged in a lobular pattern and separated by dense fibrous trabeculae; (2) mitotic figures within

tumor parenchymal cells that must be distinguished from endothelial cell mitoses; and (3) capsular or vascular invasion. Unfortunately, neither of the first two features is pathognomonic of parathyroid carcinoma, both having been reported in parathyroid adenomas. However, capsular invasion and vascular invasion correlate well with subsequent tumor recurrence and their presence greatly increases the likelihood that the tumor is malignant. Finally, the overall histologic pattern is probably more useful than any single feature in differentiating parathyroid carcinoma from adenoma. Cellular atypia, including nuclear pleomorphism and enlargement and macronucleoli, has been associated with a greater likelihood of malignancy. The presence of more than one of the above-mentioned characteristics in a lesion should alert the pathologist.

Other Histologic Markers

Although several histologic techniques have been used to improve the diagnosis of parathyroid carcinoma, none have proved consistently helpful. Electron microscopy of parathyroid cancer reveals nuclear and mitochondrial alterations and evidence of increased secretory activity but is not useful in distinguishing benign from malignant tumors. Nuclear diameter is larger in parathyroid carcinomas than in adenomas, but is not very useful in the individual case. Measurement of nuclear DNA content by flow cytometry is of limited value both in establishing the diagnosis of parathyroid carcinoma and in predicting the invasive potential of the tumor. Although mean nuclear DNA content is greater and an aneuploid DNA pattern is more common in parathyroid carcinoma than in adenomas, aneuploidy occurs too frequently in parathyroid adenomas to be useful in differentiating benign from malignant parathyroid tumors.

Immunohistochemical staining of RB protein with polyclonal antibodies is usually absent in parathyroid carcinomas and almost always present in parathyroid adenomas. However, staining for RB protein with monoclonal antibodies was not useful in distinguishing between benign and malignant parathyroid tumors. Similarly, immunostaining for the cell cycle-associated antigen Ki-67, a marker of proliferative activity, is not consistently useful for distinguishing carcinomas from adenomas.

Invasive growth of various neoplasms may be facilitated by tumoral secretion of proteolytic enzymes, such as gelatinase A. Farnebo *et al.* have reported that gelatinase A mRNA was detected in 14 of 18 unequivocal and 4 of 13 equivocal parathyroid cancers. The

strongest signal was detected in the fibroblasts and macrophages at the tumor border, rather than in the tumor cells. This new technique may prove useful for the diagnosis of malignancy.

NATURAL HISTORY

Parathyroid carcinoma is an indolent, albeit tenacious, tumor with rather low malignant potential. It tends to recur locally at the operative site and spread to contiguous structures in the neck. Metastases occur late in the course of the disease with spread via both lymphatic and hematogenous routes. Cervical nodes (30%) and lung (40%) are involved most commonly, followed by liver (10%). Occasional involvement of bone, pleura, pericardium, and pancreas has been reported.

MANAGEMENT

Initial Surgery

The most effective therapy for parathyroid carcinoma is complete resection of the primary lesion at the time of the initial operation when extensive local invasion and distant metastases are less likely. Therefore, both preoperative suspicion and intraoperative recognition are of paramount importance in the management of this cancer. This is particularly important in the era of minimally invasive parathyroidectomy, when full neck exploration with identification of all four parathyroid glands is less common than it used to be. Those patients in whom the clinical presentation is suggestive of parathyroid carcinoma warrant thorough exploration of all four parathyroid glands, since parathyroid carcinoma has been reported to coexist with benign adenomas or hyperplasia.

When the gross pathologic findings suggest malignancy, the following steps should be taken:

- The lesion should be removed *en bloc* together with the ipsilateral thyroid lobe and isthmus.
- The trachea should be skeletonized.
- Any contiguous tissues to which the tumor adheres should be resected.
- Great care should be taken to avoid rupture of the capsule of the gland, which increases the likelihood of local seeding of the tumor.
- If the recurrent laryngeal nerve is involved in the tumor, it must be resected.
- Tracheoesophageal, paratracheal, and upper mediastinal lymph nodes should be excised.
- Extensive lateral neck dissection is indicated only when there is spread to the anterior cervical nodes.

The situation is more complex when the diagnosis is made in the early postoperative period on the basis of pathology, particularly in view of the controversy surrounding the histopathology of parathyroid carcinoma. However, a second neck exploration is indicated under the following conditions:

- The gross characteristics of the lesion are typical of a parathyroid cancer.
- The histology appears to be aggressive with extensive vascular or capsular invasion.
- The patient remains hypercalcemic.

If any of these conditions apply, the structures adjacent to the tumor site should be resected in the manner described above. If none of these features are present and the diagnosis was made solely on the basis of the microscopic characteristics, immediate reoperation may not be necessary since a simple complete resection of the tumor may be curative. However, careful observation of the patient is essential and frequent measurement of parathyroid hormone and serum calcium levels is necessary.

Medical Management of the Postoperative Patient with Parathyroid Cancer

The postoperative management of a patient with parathyroid cancer must include careful attention to the serum calcium level. Prolonged severe elevation of parathyroid hormone is usually associated with increased bone resorption and formation. The amount of unmineralized bone matrix (osteoid) may be greatly increased. Sudden withdrawal of excess parathyroid hormone will permit rapid deposition of calcium and phosphorus into the excess unmineralized osteoid. This process may be associated with severe and symptomatic hypocalcemia ("hungry bone syndrome"). Although hungry bone syndrome should be regarded as a sign that the surgery has been successful, it can be dangerous and must be managed aggressively. The hypocalcemia may be severe and protracted, requiring large doses of intravenous calcium. If hyperparathyroidism was severe and there was evidence of skeletal involvement (elevated alkaline phosphatase, radiographic lesions of hyperparathyroidism), the patient should remain in the hospital until it is clear that hypocalcemia can be managed with oral calcium supplements. Sufficient supplemental calcium and calcitriol should be prescribed to maintain the serum calcium at the low end of the normal range. As the bones heal and the remaining parathyroid glands recover, the requirement for calcium will decrease,

permitting gradual reduction of the doses of calcium and withdrawal of calcitriol. After this point, serum calcium and parathyroid hormone levels should be monitored every 3 months.

Surgical Management of Recurrent or Metastatic Disease

The management of recurrent or metastatic parathyroid carcinoma reflects the rather indolent biology of this cancer and, in contrast to many other tumors, is primarily surgical. Recurrent carcinoma in the neck should be treated with wide excision of the involved area, including the regional lymph nodes and other involved structures. Since even very small tumor deposits may produce sufficient parathyroid hormone to cause severe hypercalcemia, resection of accessible distant metastases in lymph nodes, lungs, or liver should be performed. Resection, even if incomplete, may provide significant palliation, resulting in periods of normocalcemia that range from months to years. In addition, surgical debulking of tumor deposits may make it easier to control the hypercalcemia medically.

Preoperative Localization of Recurrent Parathyroid Cancer

In patients with recurrent hypercalcemia, preoperative localization studies should be performed. However, careful palpation of the neck should not be neglected, since recurrence occurs earliest and most often at the original site and such tumors are frequently palpable. Thallium-201–technetium-99m scanning is useful in locating tumors in the neck and upper mediastinum. Technetium-99m–sestamibi used concurrently with a handheld, gamma-detecting probe may also be useful for the intraoperative localization of abnormal parathyroid tissue. Thallium-201 is also helpful for situations in which the thyroid has been partially or completely resected or when pulmonary metastases are suspected. Computerized tomography and magnetic resonance imaging are useful adjuncts to ultrasonography in evaluation of the neck and are superior for detection of distant metastases in the chest or abdomen. Positron emission tomography with a positron-emitting analogue of 2-deoxyglucose (^{18}F fluorodeoxyglucose) has also been reported to successfully localize parathyroid cancer deposits. If noninvasive testing does not yield results, arteriography or selective venous catheterization may be useful. Fine-needle aspiration biopsy should be avoided in order to avoid seeding deposits of malignant tissue.

Radiation Therapy

Parathyroid carcinoma is not a radiosensitive tumor. The use of radiation therapy to control tumor growth and decrease hormone production has been ineffective in the majority of cases in which it has been attempted. In the occasional situation, radiation to the neck after surgery for recurrence may be helpful in preventing tumor regrowth.

Chemotherapy

Attempts to control tumor burden with chemotherapy have been disappointing. Because of the rarity of parathyroid carcinoma, experience with various chemotherapeutic regimens is limited to scattered case reports. Several regimens (nitrogen mustard; vincristine, cyclophosphamide, and actinomycin D; adriamycin, cyclophosphamide, and 5-fluorouracil; and adriamycin alone) have been ineffective. Two patients have been treated with synthetic estrogens with some success. A single patient with pulmonary metastases responded to treatment with dacarbazine, 5-fluorouracil, and cyclophosphamide with a decrease in PTH and normalization of serum calcium for 13 months. Another patient responded to dacarbazine alone with a brief but significant decline in her serum calcium level. An 18-month remission with regression of a mediastinal mass and pleural effusion was induced in a patient with a nonfunctioning parathyroid carcinoma by a regimen consisting of methotrexate, doxorubicin, cyclophosphamide, and lomustine. Such approaches are probably worth trying if surgical measures fail.

Management of Hypercalcemia

When parathyroid carcinoma has become widely disseminated and surgical resection is no longer effective, cure is impossible. However, even at this juncture, relatively prolonged survival can be achieved with adequate control of hypercalcemia, although the extremely elevated PTH levels and the intensity of the associated bone resorption often make this goal difficult to realize.

Acute hypercalcemia associated with parathyroid carcinoma is treated in the same way as hypercalcemia due to any other cause. Management includes infusion of saline to restore fluid volume and enhance urinary calcium excretion. After this has been accomplished, loop diuretics are added to further increase calciuresis. Agents that inhibit osteoclast-mediated bone resorption are virtually always necessary.

Bisphosphonates

The bisphosphonates are a group of drugs that inhibit osteoclast-mediated bone resorption. Several of these drugs have shown some promise in the therapy of parathyroid carcinoma.

Clodronate (Cl_2MDP) lowers serum calcium in parathyroid carcinoma when administered intravenously. It is widely available in Europe and the United Kingdom, but it is not available in the United States. Pamidronate, when infused for periods ranging from 2 to 24 h and at doses ranging from 45 to 90 mg per day, has been at least transiently effective in lowering serum calcium levels in several patients with parathyroid cancer. A more potent bisphosphonate, zoledronate, has been approved in the United States for the treatment of hypercalcemia. Zoledronate, at doses of 4 and 8 mg, has been shown to be superior to pamidronate (90 mg) in the treatment of hypercalcemia of malignancy, in terms of both the response rate and the duration of response. Though zoledronate has not been specifically evaluated in parathyroid cancer, it is a reasonable approach to controlling hypercalcemia in these patients.

Plicamycin

Plicamycin (mithramycin), another specific inhibitor of bone resorption, lowers serum calcium levels in parathyroid carcinoma. It is administered intravenously at a dose of 25 $\mu\text{g}/\text{kg}$ over 4 to 8 h and may be repeated at daily intervals for up to 7 days until the serum calcium falls into an acceptable range. Unfortunately, plicamycin has toxic effects on the liver, kidneys, and bone marrow that increase with the number of exposures. Intravenous bisphosphonates have largely supplanted plicamycin in the therapy of hypercalcemia.

Calcimimetics

In normal circumstances, parathyroid hormone secretion is mediated by a cell surface calcium-sensing receptor and this regulatory response is generally retained in benign parathyroid tumors. An allosteric modulator of the calcium receptor with calcimimetic properties has been shown to lower serum parathyroid hormone and calcium concentrations in patients with primary hyperparathyroidism. This same agent was used to treat a patient with parathyroid carcinoma. Serum calcium was controlled for 2 years without adverse effects. Newer calcimimetic agents are under investigation in parathyroid cancer and may show promise in its management.

Calcitonin

Although calcitonin inhibits osteoclast-mediated bone resorption, increases urinary calcium excretion, and has been reported to lower serum calcium in two patients with parathyroid cancer, it is not very effective in most cases.

Immunization

A patient with parathyroid carcinoma metastatic to lungs and pleura had severe hypercalcemia that was resistant to oral clodronate, intravenous pamidronate, octreotide, 5-fluorouracil, and streptozotocin. She was immunized with human and bovine PTH peptides, followed with booster doses at 4 and 11 weeks. Antibodies against PTH were detected at 4 weeks. Before therapy, serum calcium varied between 3.5 and 4.2 mmol/liter. Serum calcium levels remained significantly lower (2.5 to 3.0 mmol/liter) throughout the 6 months of observation. There was rapid improvement in her clinical condition and no significant adverse effects were observed. If confirmed, this would seem to be a novel and relatively simple approach to the control of hypercalcemia in patients resistant to other measures.

PROGNOSIS

The prognosis of parathyroid carcinoma is quite variable. No single characteristic correlates predictably with outcome. Early recognition and complete resection at the time of the initial surgery offer the best prognosis. The average time between surgery and the first recurrence is approximately 3 years although intervals of up to 20 years have been reported. Once the tumor has recurred, complete cure is unlikely although prolonged survival is still common in these circumstances with palliative surgery. Five-year survival rates vary from 40 to 86%. The National Cancer Database survey reported 10-year survival to be approximately 49%.

parenchymal cells, fat cells, and fibrovascular stroma. The parenchymal cells are usually arranged in nests and cords, nourished by a rich capillary network. The functional cells of the parathyroid are mainly of the chief-cell type although other populations of cells (oxyphil cells, clear cells, and transitional oxyphil cells) are found. Most authorities believe that the different parenchymal cell types reflect variabilities in the morphologic expression of chief cells. Chief cells are polygonal in shape and contain a slightly eosinophilic cytoplasm and small round nucleus. The oxyphil cells show dense eosinophilic cytoplasm and small nuclei. Clear cells are a form of chief cells with abundant cytoplasmic glycogen; these are usually seen in the parathyroids of embryos and fetuses and their numbers significantly decline with age. Cells with cytologic features intermediate between chief cells and oxyphil cells are termed transitional oxyphil cells. The number of oxyphil and transitional oxyphil cells is small at birth; however, it increases with age and in certain pathological conditions.

The stromal fat content of a parathyroid gland is significantly lower than 50%. In an adult normal parathyroid, approximately 17 to 75% of the cells are adipocytes and their number varies with the nutritional status and weight of the individual.

PATHOLOGY

The clinical syndrome of hypercalcemia, especially if it is asymptomatic or associated with mild symptoms, is due to pathological lesions of the parathyroids. Up to 90% or more of hypercalcemia cases are due to primary hyperparathyroidism.

Hyperparathyroidism

Hyperparathyroidism can be divided into primary and secondary types. Primary hyperparathyroidism is characterized by inappropriate secretion of parathyroid hormone (PTH) from enlarged parathyroid glands in the absence of a known stimulus for PTH, leading to hypercalcemia. Secondary hyperparathyroidism is an increase in parathyroid hormone most commonly in response to hypocalcemia or hyperphosphatemia associated with renal failure. Tertiary hyperparathyroidism refers to autonomous parathyroid hyperfunction in patients with secondary hyperparathyroidism.

Primary Hyperparathyroidism

Primary hyperparathyroidism (PHP) is a common disorder of the parathyroid gland and can occur in

all age groups, although it is rare in children. The cause of PHP is unknown; suggested causes include head and neck irradiation, mutations of the multiple endocrine neoplasia type 1 (MEN1) gene, and abnormalities in the genes involving the 11q13 locus and in the retinoblastoma (RB) gene.

The pathologic lesions responsible for primary hyperparathyroidism include hyperplasia, adenoma, and, rarely, carcinoma.

Parathyroid Hyperplasia

Primary parathyroid hyperplasia is defined as the proliferation of the parenchymal cells, leading to an increase in gland weight in multiple parathyroid glands in the absence of a known stimulus for parathyroid hormone secretion.

Two types of parathyroid hyperplasia are seen: the more common chief cell hyperplasia and the rare water cell or clear cell hyperplasia.

Chief cell hyperplasia. It can be estimated from the literature that 15% of hyperparathyroidism cases are caused by parathyroid hyperplasia; however, some reports have indicated that approximately half of the cases of primary hyperparathyroidism are produced by hyperplasia. The stimulus for this disorder is unknown; however, a role for a possible circulating factor that can initiate proliferation of parathyroid cells in culture has been suggested. Familial hyperparathyroidism or MEN syndrome is seen in approximately 30% of patients with chief cell hyperplasia. It has been shown that hyperplasias are monoclonal proliferations. Parathyroid hyperplasia associated with MEN1 involves allelic deletions on chromosome 11 and such lesions are larger than those without deletions. Similar deletions have also been encountered in sporadic parathyroid adenomas. This suggests that the monoclonal proliferations may develop after a phase of polyclonal hyperplasia.

On gross examination, all four glands are enlarged and the combined weight can range from 150 mg to over 20 g, but usually is in the range of 1 to 3 g. Chief cells constitute the dominant cell type; however, one may also observe intermixed oxyphil cells and transitional oxyphil cells. The cells are usually arranged in a solid, trabecular, or nodular pattern (Fig. 1). Nodule formation can also be seen leading to asymmetrical gland enlargement.

The cytoplasmic fat in chief cells is either reduced or absent. The nodular areas are usually devoid of fat, whereas those between the nodules may contain fat. Nuclear pleomorphism and mitoses are rarely found in primary hyperplasia.

Figure 1 A whole-mount section of a case of nodular hyperplasia of the parathyroid, showing a thinly encapsulated parathyroid nodule surrounded by hypercellular parathyroid.

Water/clear cell hyperplasia. This rare condition is characterized by the proliferation of vacuolated water/clear cells in multiple parathyroid glands. It is more common in females and causes pronounced hypercalcemia and severe clinical disease. This is the only parathyroid disorder in which the superior glands are larger than the lower pair of glands. The affected glands tend to be larger and irregular in shape and the proliferating cells may infiltrate into the surrounding tissue of the neck.

Parathyroid Adenoma

Parathyroid adenoma is the single most common cause of PHP. The incidence of parathyroid adenoma is reported to be between 30 and 90%; this variation is due to a lack of application of standardized diagnostic pathologic criteria and differences in the patient populations that were studied. Adenomas are more common in females than in males, with a ratio of approximately 3 to 1.

Parathyroid adenoma can originate in any of the four parathyroid glands; however, it is more common in the lower glands than in the upper glands. Approximately 10% of the adenomas are found at ectopic sites, including the mediastinum, thyroid, and esophagus and within the retroesophageal tissue.

Grossly, adenomas are oval or kidney-shaped, reddish-brown in color, and soft in consistency. They usually replace the entire parathyroid gland or a grossly visible yellowish-brown rim of residual parathyroid may be identified. In some cases, the adenomas are multilobated, which may account for their incomplete excision. Some pathologists believe that the remaining normal parathyroid rim is a reliable criterion for the

Figure 2 Parathyroid adenoma with a thin fibrous capsule and a rim of compressed normal parathyroid containing fat cells.

diagnosis of adenoma; however, it is seen in only 50 to 60% of cases and its absence does not exclude the presence of a parathyroid adenoma. Parathyroid adenomas can markedly vary in size and weight; the size can range from <1 to >3 cm; similarly, the weight can range from 300 mg to several grams.

As viewed by light microscopy, adenomas are usually encapsulated and can show a rim of compressed normal parathyroid (Fig. 2). The tumor cells are usually arranged in nests and cords surrounded by a rich capillary network. Chief cells are the dominant cell type in the majority of parathyroid adenomas; oxyphil cells and transitional oxyphil cells can also be seen in varying proportions scattered within the collections of chief cells. Some adenomas are composed exclusively of oxyphil cells, the so-called “oxyphil adenomas.” These tumors tend to be larger than the chief cell adenomas and the serum calcium tends to be minimally elevated.

The chief cells in adenomas can exhibit nuclear pleomorphism and giant cell formation. Some authors have indicated that the presence of random nuclear atypia is reassuring that a parathyroid tumor is benign. Mitotic figures are uncommon in adenomas; however, they have been encountered in a few cases. It has been suggested that the presence of mitoses is indicative of malignancy in parathyroid adenoma; however, this observation needs further examination in large cohorts of cases.

Parathyroid adenomas can show prominent cystic degeneration. Other degenerative changes are more commonly seen in large tumors and include fibrosis, hemorrhage, cholesterol clefts, hemosiderin, and calcification.

Adenomas are virtually devoid of adipocytes, which are observed only in the normal rim of the compressed parathyroid. Rarely, some cases of adenomas can show collections of adipocytes, which can be mistaken for normal parathyroid. Parathyroid adenoma is considered a single-gland disease; however, double adenomas have been reported. The proposed criteria for this diagnosis include the presence of two enlarged hypercellular glands and the identification of two other normal-sized parathyroids. Long-term follow-up after excision of double adenomas must demonstrate a lack of recurrence of hypercalcemia to accept this diagnosis; unfortunately, some patients with double adenomas represent metachronous quadruple-gland disease; i.e., hyperplasia and the true nature of the cause of hyperparathyroidism in these cases may become apparent only on prolonged follow-up.

Lipoadenoma—The So-Called “Hamartoma of the Parathyroid”

These are rare parathyroid neoplasms, which were initially described as parathyroid “hamartoma.” They usually occur in the cervical region; however, cases in the superior and posterior mediastinum have been reported. Most of these are functional tumors and are associated with hyperparathyroidism. Grossly, lipoadenomas are circumscribed, rarely encapsulated, and yellowish-tan in color and they show a lobulated cut surface. As viewed by light microscopy, lipoadenomas consist of mature adipose tissue or myxoid stroma and nests of parathyroid parenchyma. In some cases, other mesenchymal elements, including metaplastic bone, can be seen. The parenchymal component of the lipoadenomas includes chief cells and some oncocytic cells, which are usually arranged in thin cords, tubules, and abortive acini.

Parathyroid Carcinoma

Parathyroid carcinoma is seen in 0.5 to 2% of cases of PHP. There appears to be an equal sex distribution, whereas adenomas are most commonly seen in females. Patients with parathyroid carcinoma are younger than those with adenoma and usually present with pronounced hypercalcemia and/or with systemic manifestations related to hypercalcemia, e.g., nephrolithiasis, renal failure, and bone disease. Parathyroid carcinoma is rarely associated with familial endocrine disorders or secondary parathyroid hyperplasia. The initial clinical presentation of parathyroid carcinoma may be that of a palpable neck mass, which can be mistaken for a tumor originating in thyroid.

On gross examination, parathyroid carcinomas are large tumors with adherence to and invasion of

the surrounding structures, such as the thyroid and the soft tissues of the neck and peri-esophageal region. This infiltration into the neighboring neck structures serves as an important surgical finding and may initiate an *en bloc* resection of the tumor mass with surrounding adherent structures. However, some tumors may be totally encapsulated, lack gross invasion, and resemble parathyroid adenomas. Parathyroid carcinoma involves only one gland and rarely has been reported to arise in ectopic locations.

As viewed by light microscopy, the entire gland is traversed by broad fibrous bands, which seem to originate from the capsule and extend into the substance of tumor, leading to a lobulated appearance (Fig. 3). Parathyroid carcinomas are usually composed of chief cells; however, oxyphil cells and transitional cells can also be seen. In some cases, the entire tumor is composed of oxyphil cells. The cells can exhibit a bland cytology or show marked anaplasia.

Mitotic figures are observed in most cases; some pathologists have suggested this feature to be of great importance in diagnosing parathyroid carcinoma. However, mitoses can also be seen in parathyroid adenoma and hyperplasia and their absence does not rule out a diagnosis of carcinoma. The authors believe that, although not definite indicators of malignancy, mitoses in parathyroid lesion should be of concern since the follow-up in reported benign cases of parathyroid tumor with mitoses is limited. Marked mitotic activity and abnormal mitotic figures in unequivocal carcinomas are indicators of poor prognosis.

The only reliable indicator of malignancy in parathyroid carcinoma is invasion of the surrounding structures and metastases. Parathyroid carcinomas infiltrate into the surrounding neck structures and

Figure 3 Parathyroid carcinoma showing broad fibrous bands intersecting the tumor.

soft tissues in the form of “tongue-like” protrusions. However, this should be distinguished from “pseudo-invasion,” which is seen in large adenomas caused by degeneration and subsequent fibrosis and “trapping” of tumor cells. Vascular invasion is seen in 10 to 15% of parathyroid carcinomas and is usually regarded as a reliable indicator of malignancy; however, some authors have observed this feature in large adenomas.

Other microscopic features, such as desmoplastic reaction, mitotic activity, nuclear atypia, and necrosis, are more common in carcinoma than in benign lesions; none of these is diagnostic of malignancy.

Nonfunctioning parathyroid carcinomas are rare. These lesions tend to be large and consist primarily of clear or oxyphil cells. These tumors can be confused with primary thyroid cancers, such as Hürthle cell lesions or medullary carcinoma. The parathyroid origin can be confirmed by positive immunohistochemical staining for parathyroid hormone and a negative reaction for thyroglobulin and calcitonin.

Parathyroid carcinoma usually behaves in an indolent fashion. Metastases can occur in up to one-third of patients and are found in regional lymph nodes, bone, lung, and liver. Multiple recurrences are common and can occur over a 15- to 20-year period. Fatal outcome in patients with parathyroid carcinoma is due mainly to the effects of excessive parathyroid hormone secretion and uncontrolled hypercalcemia rather than to a tumor mass effect. Therefore, surgical excision of recurrences or metastases can provide excellent palliation by lessening the tumor burden and concomitant hormone production.

Atypical Adenoma

This is a relatively new entity in parathyroid pathology. Some authors have suggested that if some features of malignancy, including mitoses and necrosis, are present without an infiltrative growth pattern or metastases, those cases should be designated as “atypical adenoma.” The few available follow-up studies have shown that these tumors will behave in a clinically benign fashion.

Familial Hyperparathyroidism

Primary hyperparathyroidism can present as a manifestation of MEN1 and MEN2 or as a familial disease without involvement of other endocrine organs.

Multiple Endocrine Neoplasia Syndromes

Parathyroids can display pathologic changes in most patients with MEN1 (Wermer’s syndrome). This syndrome is characterized by lesions of the pituitary, parathyroid, and endocrine pancreas, foregut carcinoid

tumors, and adrenocortical tumors. The parathyroid involvement is perceived as the earliest and most prevalent manifestation and is usually detectable at the age of 20 to 30 years in 90% of affected patients. The pathologic changes in the parathyroid are similar to those seen in nodular chief cell hyperplasia. Molecular analysis has shown that MEN1 lesions represent monoclonal proliferations possibly originating in the background of polyclonal hyperplasia.

Primary hyperparathyroidism is seen in 10–20% of patients with MEN2. The other features of this syndrome include medullary thyroid carcinoma (often bilateral), C cell hyperplasia, unilateral or bilateral pheochromocytoma, and adrenal medullary hyperplasia. Usually all four parathyroids are involved but in some cases one gland is affected, suggesting an “adenoma.” The degree of hypercalcemia in MEN2 patients is usually less severe than in those with MEN1; in MEN2, serum calcium and parathyroid hormone levels may be normal despite gland enlargement. Genetic studies have demonstrated the MEN2 locus to be on chromosome 10q11.2, the region of the ret proto-oncogene. Point mutations within the cysteine-rich extracellular region of the ret proto-oncogene have been detected in MEN2 and familial MTC and specific mutations have been revealed in families with parathyroid involvement.

Familial Isolated Primary Hyperparathyroidism

This condition is an autosomal-dominant inherited disease; however, a few families show autosomal-recessive inheritance. Parathyroid glands often show chief cell hyperplasia; some families may show adenomas, an increased risk for parathyroid carcinoma, and other nonendocrine tumors. The autosomal-dominant form has been found to be related to the MEN1 locus; however, other studies have disputed these findings.

Unusual Lesions of the Parathyroid

Parathyroid Cysts

Parathyroid cysts are rare, commonly occur in the neck, and usually involve the lower parathyroids; however, some have been reported in the mediastinum. Parathyroid cysts are more common in females; these lesions are usually large, ranging in size from 1 to 6 cm. Mediastinal parathyroid cysts can be mistaken for superior/anterior mediastinum tumors. These cysts may also contain fragments of thymic tissue and are sometimes referred to as third pharyngeal pouch cysts.

Grossly, these cysts are unilocular, are smooth-walled, and contain watery clear fluid, which is high

Figure 4 Light microscopy of a parathyroid cyst, showing a single cyst within the parathyroid lined by a single layer of epithelium.

in parathyroid hormone content. As viewed by light microscopy, the cyst wall is lined by a single layer of glycogenated epithelium and can show nests of normal parathyroid (Fig. 4). Some authors have suggested that these cysts originate due to fusion of the smaller microcysts often seen in normal parathyroids, whereas others believe that these cysts may represent embryologic remnants of pharyngeal pouches, which undergo cystic degeneration with entrapped parathyroid tissue. However, the majority of authors believe that parathyroid cysts represent degenerating adenomas and in fact some of these cases present with or are associated with hyperparathyroidism.

Parathyroid cysts can be encountered on fine-needle aspiration (FNA) and it can be difficult to distinguish them from a cystic thyroid nodule. The aspiration sample almost always consists of clear watery fluid, which can be assayed for parathyroid hormone to confirm the cytologic impression.

Parathyromatosis

In primary and secondary hyperplasia of the parathyroid, small collections of parathyroid cells, mainly chief cells, rarely are encountered embedded within the surrounding soft tissue of the neck and mediastinum outside the confines of the parathyroid gland capsule. Normally, these lesions are not detectable; however, in cases of diffuse hyperplasia of the parathyroids, all functional tissue may become hyperplastic and appear as separate tissue fragments on histologic examination.

Parathyromatosis can occur for two main reasons: seeding of hypercellular parathyroid tissue during

surgical excision of abnormal parathyroid tissue (usually hyperplasia) and overgrowth of embryologic parathyroid rests. Both forms of parathyromatosis can lead to recurrent hyperparathyroidism following excision of abnormal parathyroid glands. These fragments can be confused with local invasion by parathyroid carcinoma. An examination of the parathyroids along with the clinical history always proves to be helpful in arriving at the correct diagnosis.

INTRAOPERATIVE ASSESSMENT

The intraoperative assessment of the parathyroid gland during parathyroidectomy is usually limited to identification of the tissue. This procedure usually involves correct labeling, gross examination measurement, and weighing of the specimen. The representative sample is frozen and stained with hemotoxylin and eosin stains (15–16, 147). Usually, the identification of parathyroid tissue is not difficult (the accuracy rate of correct identification of tissue as parathyroid ranges up to 99%); however, in some cases, it may be difficult to distinguish from other neck tissues including lymph node, thyroid, and ectopic thymus. Some authors have also advocated the use of intraoperative cytology preparations in conjunction with frozen section to increase the efficacy of identification of parathyroid tissue.

A frozen section error and failure to localize the abnormal parathyroid gland can lead to failed parathyroidectomy. A rapid parathyroid hormone assay in conjunction with frozen section can be helpful in indicating the successful excision of abnormal parathyroid gland(s). The samples for parathyroid hormone assay are obtained before excision of the parathyroids from the thyroid veins. Follow-up samples are procured again after the removal of the suspected abnormal parathyroid gland(s); a rapid fall in parathyroid hormone (by at least 50%) is indicative of successful removal of abnormal parathyroid.

In normal parathyroid glands, 80% of the cells are nonsecretory and contain intracytoplasmic fat, whereas hyperfunctioning chief cells contain much less or are devoid of intracytoplasmic fat. Therefore, the pathologist can use fat stains (Sudan IV or oil red O) or metachromatic stains (e.g., toluidine blue) to differentiate between adenoma and hyperplasia. However, fat stain is helpful in only 80% of cases and should be interpreted in conjunction with gross findings, gland weight, and size.

Density gradient measurements can also be employed to assess the ratio of parenchymal to fat cells. This rapid technique provides an objective

evaluation of the parenchymal mass. It involves procuring a sample from the abnormal (preferably center) and normal rim of a grossly enlarged gland and determining their densities in a 25% mannitol solution. Abnormal parathyroid tissue will sink due to decreased fat content and high parenchymal mass. The surgeon can perform this test in the operating room to distinguish between normal and abnormal parathyroid glands.

In addition to the above-mentioned techniques of intraoperative assessment of parathyroid pathology, a close communication between the surgeon and the pathologist during surgery is prudent.

In short, the recommended procedure for intraoperative and histologic assessment of the parathyroid gland is as follows: the largest gland, resected first, should be weighed, measured, and examined histologically. In the case of diffuse proliferation of chief cells, presence of normal rim, lack of intracellular lipid, and presence of second normal gland, a diagnosis of adenoma can be rendered. However, another parathyroid gland should always be sampled to distinguish between single-gland and multigland disease, since some hyperplastic glands may resemble adenomas and only up to 70% of adenomas will show a rim of normal tissue.

SPECIAL STUDIES

Cytology

A majority of parathyroid lesions are not palpable; therefore, it is unlikely that FNA will be performed on a parathyroid tumor. However, image-guided FNA is helpful in patients undergoing repeat surgical excisions for recurrent/persistent hypercalcemia where the anatomy is distorted. In addition, as mentioned, some parathyroid adenomas, especially those located in the capsule of the thyroid, can be mistaken for thyroid nodules and hence will undergo FNA. The parathyroid FNA samples usually show a monotonous population of small round cells with chromatin arranged in an organoid or a trabecular arrangement. Some cases may also show the presence of vascular cores. Immunostaining for parathyroid hormone may help in distinguishing these lesions from primary thyroid tumors.

Proliferative Markers

It has been shown that cell proliferation markers (MIB1/Ki67) can be helpful in distinguishing between parathyroid adenomas and hyperplasia. However, other studies have shown similar proliferative indices

for adenomas and hyperplasias. Some authors have reported higher numbers of labeled nuclei for proliferating cell nuclear antigen in parathyroid adenomas than in hyperplasias.

Cyclin-dependent kinase inhibitor p27 helps regulate the transition from the G₁ to the S phase of the cell cycle. Normal tissues show higher levels of this protein than their neoplastic counterparts. It has been reported by performing *in situ* hybridization for p27 mRNA that normal parathyroids express higher levels of p27 than hyperplasia, adenomas, and carcinomas.

Flow Cytometry

Both image and flow cytometry techniques have been used to assess the nuclear DNA content of normal and abnormal parathyroid glands. Normal parathyroid gland usually shows diploid patterns; however, tetraploidy has been observed associated with adenomas in some normal glands, indicating multiglandular abnormality. Both diploid and tetraploid DNA patterns are observed in adenomas as well as hyperplastic glands. Aneuploidy has been reported in up to 25% of adenomas and in a considerably higher percentage of parathyroid carcinomas. In parathyroid carcinoma, aneuploidy has been shown to be associated with poor prognosis; however, hyperplastic glands can also show aneuploid DNA content. Therefore, the finding of aneuploidy in parathyroid lesions does not indicate a diagnosis of malignancy.

Genetics

It has been shown that the overexpression of PRAD1 (for parathyroid adenoma)/cyclin D1 induced by a DNA rearrangement of the PTH gene can be seen in parathyroid adenomas. This rearrangement is created by a break in the vicinity of the parathyroid gene on the short arm of chromosome 11 (band 11p15), a second break in the long arm (band 11q13), rotation of the central fragment around the axis of the centromere, and rejoining. However, in addition to adenomas this gene has been found to be overexpressed in nodular hyperplasia as compared to diffuse hyperplasia of parathyroid.

The retinoblastoma gene (Rb) is a tumor suppressor gene. Allelic deletion of the Rb gene on chromosome 13 has been reported in parathyroid tumors. It has been shown that a majority of parathyroid carcinomas show abnormal expression of Rb protein, with a complete or predominant absence of nuclear staining for protein, whereas parathyroid adenoma shows positive nuclear staining for Rb protein. Thus, this differential staining

for Rb protein can assist in the distinction between parathyroid adenomas and carcinomas. However, one must be careful in interpreting these results since some parathyroid carcinomas do not show loss of Rb protein and a few adenomas do.

Figure 1 Primary structure of bovine PTH. Shown is the complete 84-amino-acid sequence of the mature, secreted form of bovine PTH.

tissues, including the skeleton. The (1-34) region of PTHrP exhibits significant amino acid sequence homology to the (1-34) region of PTH (~35% identity; Fig. 2); like PTH, PTHrP mediates many of its biological actions via the PTH-1 receptor, which is consequently also called the PTH/PTHrP receptor.

Though the calcium homeostatic actions of PTH can be explained by activation of the PTH-1R in bone and kidney, PTH also binds to an as yet uncloned receptor that binds both PTH(1-84) and carboxy-terminal fragments that do not bind to the PTH-1R. These fragments can block the bone-resorbing actions of PTH(1-34) and other stimuli of resorption by mechanisms being explored.

PTH SYNTHESIS AND SECRETION

In mammals, PTH is synthesized as a 115-amino-acid preprohormone. The 25-amino-acid presequence is removed by signal peptidase during translocation of the nascent polypeptide chain across the endoplasmic reticulum and the 6-amino-acid prosequence is removed during subsequent processing of the peptide through the *trans*-Golgi network. The mature 84-amino-acid hormone is then packaged into storage granules, where it remains until it is secreted or degraded by proteases found in the secretory granules. These proteases include various cathepsins (-B, -D, and -H) and their activities result in the secretion of PTH fragments of various lengths, with most containing carboxy-terminal immunoreactive epitopes. Since the studies mentioned earlier demonstrate activities of carboxy-terminal PTH fragments, intracellular processing of PTH in the parathyroid gland may have great functional significance.

Ambient Ca_o^{2+} concentrations regulate the rates at which PTH is synthesized, secreted, and degraded via a negative feedback loop. A calcium-sensing receptor (CSR), which is expressed on the parathyroid cell surface, detects the level of extracellular Ca^{2+} . The CSR is a GPCR that contains a large (~600 amino acid) amino-terminal extracellular domain in which resides multiple binding sites for Ca^{2+} . The binding of Ca^{2+} to the CSR is highly cooperative (Hill coefficient ~5) and this cooperativity results in the capacity to detect extremely small variations in Ca_o^{2+} . As Ca_o^{2+} binds to the CSR, PTH secretion is repressed immediately and, on a longer time scale, PTH synthesis and parathyroid cell proliferation are repressed. PTH degradation continues when Ca_o^{2+} is elevated, so most of the immunoreactive PTH secreted under these conditions consists of carboxy-terminal fragments. All of these activities are reversed in the presence of low concentrations of Ca_o^{2+} . Thus, the parathyroid glands adapt to both the immediate (seconds to minutes) and the longer term (days to weeks) changes in

PHYSIOLOGICAL ACTIONS OF PTH IN BONE AND KIDNEY

Bone Resorption and Calcium Release

The calcium-homeostatic response of bone to PTH is complex but is known to involve two principal cell types: osteoblasts and osteoclasts. Osteoblasts are the bone-building cells of marrow stromal cell origin that express PTH-1 receptors on their cell surface, whereas osteoclasts are multinucleated and mobile bone-resorbing cells of the macrophage lineage that do not express PTH-1 receptors on their cell surface. The osteoclastic cells respond to PTH through indirect mechanisms: PTH stimulates the production of RANK (receptor activator of nuclear factor- κ B) ligand by osteoblasts. RANK ligand is a member of the tumor necrosis factor family. As a membrane-spanning protein on the surface of osteoblasts, RANK ligand binds to its receptor, RANK, on osteoclasts and osteoclast precursors to stimulate production of osteoclasts and the activity and survival of mature osteoclasts. PTH can have both acute and long-term effects on release of calcium from bone. Whereas the acute homeostatic release of calcium from bone in response to PTH may require osteoclast activity, the precise cellular and molecular mechanisms are not well understood. The longer term resorptive effects are associated with dramatic increases in osteoclast number and activity and can result in severe reductions in bone mineral density, trabecular number, and bone strength.

Bone Formation and the Bone Anabolic Response

When PTH binds to the PTH-1 receptor, it not only triggers bone resorption through the RANK ligand pathway, but also increases bone formation by osteoblasts. The exact mechanisms for this activation are still poorly understood and likely to be multifactorial. PTH administration increases the number of osteoprogenitor cells, assessed with cell culture assays. PTH also decreases the apoptotic death of cells of the osteoblast lineage and may recruit renewed osteoblast activity from dormant bone-lining cells. Osteoblasts secrete insulin-like growth factor-I and transforming growth factor- β in response to PTH and PTH-mediated bone resorption releases a number of growth

factors from bone matrix. Through these and other mechanisms, PTH increases both the number and activity of osteoblasts.

Multiple variables determine whether the bone formation response to PTH or the bone resorption response to PTH will dominate. These variables include the dose and timing of PTH administration and the location of target osteoblasts in trabecular or cortical bone. Whereas continuous overexposure of bone to PTH results in dramatic and severe reductions in bone mineral density (BMD) and structural integrity of the trabecular network, F. Albright and co-workers showed as long ago as 1929 that intermittent exposure of bone to PTH, as achieved through daily subcutaneous injections, produces significant increases in bone mass. Since this discovery, the net anabolic effect of intermittently administered PTH on bone, particularly in the trabecular compartments of long bones and vertebral bodies, has been well documented (Fig. 3). The cellular and molecular mechanisms that underlie this anabolic effect of intermittent PTH on bone are not completely understood, but it is clear that the effect involves an increase in the rate of overall bone turnover, with a net increase in osteoblast-mediated bone formation, relative to osteoclast-mediated bone resorption. The findings have suggested that PTH or a PTH analogue could be used to treat osteoporosis and several clinical trials have been conducted to evaluate this possibility. The largest trial, conducted by Neer and co-workers in 2001, was a double-blind randomized trial involving 1637 postmenopausal osteoporotic women that directly tested the effects of PTH(1-34), administered once daily by subcutaneous injections at doses of 20 or 40 μg , on bone strength. The results showed that relative to the placebo-treated controls, PTH significantly increased BMD (by 9.7% at the lumbar spine) and significantly reduced the risk of vertebral and nonvertebral fractures (by 65 and 53%, respectively) during the 21-month study. PTH(1-34) thus may be more effective than any of the other agents used to treat osteoporosis (calcitonin, bisphosphonates, and estrogen). There is considerable interest in developing other, potentially orally active, PTH-based therapies for the treatment of this common skeletal disease.

Effects in the Kidney

PTH acts on cells of the distal and proximal portions of the convoluted renal tubules. In response to PTH distal tubular cells mediate the retrieval of calcium from the glomerular filtrate, whereas actions on

Figure 3 Anabolic effect of PTH in bone. Shown are proximal tibia from adult rats that were ovariectomized to induce an osteoporotic state and treated for 90 days with either (A) vehicle or (B) PTH(1-34). In the PTH-treated tibia, the mineralized surface (stained darkly) and trabecular connectivity are increased, compared to the vehicle-treated control. Reprinted from Stewart *et al.* (2000), with permission.

proximal tubular cells decrease the reabsorption of phosphate from the urine. An important longer term effect of PTH in the kidney is the stimulation of the synthesis of the vitamin D 1- α -hydroxylase in proximal tubule cells. This enzyme catalyzes the synthesis of 1,25-dihydroxyvitamin D₃ [1,25(OH)₂D₃], which, in turn, promotes the intestinal absorption of dietary calcium and the release of calcium from bone.

STRUCTURE–ACTIVITY RELATIONSHIPS IN PTH

Determinants of Receptor-Binding Affinity

PTH(1-34) contains all the structural information required for biological activity at the PTH-1 receptor;

thus, the peptide binds to this receptor with nanomolar affinity ($K_d \sim 3$ nM) and stimulates cAMP formation in cells expressing the PTH-1 receptor with nanomolar potency ($EC_{50} \sim 2$ nM). Structure–activity relationship studies of PTH have revealed that the principal receptor-binding and receptor-activation functions of PTH(1-34) reside largely in the C-terminal (15-34) and N-terminal (1-14) regions of the peptide, respectively. One of the shortest fragments that retains detectable receptor-binding capacity is PTH(15-34) ($K_d \sim 10$ μ M). Within the (15-34) segment, residues Trp²³, Leu²⁴, Leu²⁸, and Val³¹ have been identified by substitution analysis as key determinants of receptor-binding affinity. These residues are thought to form the hydrophobic face of an amphiphilic α -helix, with Arg²⁵, Lys²⁶, Lys²⁷, and Asp³⁰ constituting the opposite hydrophilic face (Fig. 2). The hydrophobic face of this helix could play an important role in receptor binding by directly contacting a complementary hydrophobic surface in the receptor. An alternative mechanism, however, is that the hydrophobic surface of this helix mediates interaction with the lipid phase of the cell membrane surrounding the receptor and thereby indirectly facilitates the receptor-binding process. Since the specific mechanism by which PTH binds to its receptor is not known, either mechanism remains plausible and the two, particularly if occurring sequentially, are not mutually exclusive. Whereas the amino acid sequences of the (15-34) regions of PTH and PTHrP molecules from different species are not highly conserved, amphiphilic character is well preserved in this region of each ligand. Though the amino-terminal region of PTH cannot bind to the receptor independently, contacts between this amino-terminal region and the extracellular receptor loops and transmembrane regions of the receptor contribute importantly to the overall binding affinity of PTH to the PTH-1R.

Determinants of cAMP Signaling

Consistent with their functional importance in activating the AC/cAMP/protein kinase A (PKA) signaling pathway, the N-terminal residues of PTH and PTHrP are highly conserved, with only two positions in the (1-14) regions differing between human and chicken PTH (Fig. 2). Deletion of the first few amino acids from PTH(1-34) results in peptides, such as PTH(3-34) and PTH(7-34), that bind to the receptor with adequate affinities ($K_d \sim 10$ to 100 nM) but elicit little or no cAMP response. Thus, N-terminally truncated

peptides, such as PTH(3-34) and PTH(7-34), can function as competitive PTH-1 receptor antagonists. One of the most effective and widely used PTH receptor antagonists, [Leu¹¹, D-Trp¹²]PTHrP(7-34)NH₂, also functions as an inverse agonist against constitutively active PTH receptors that have been identified in patients with Jansen's chondrodysplasia. Val² is particularly important for receptor activation, as PTH(1-34) analogues having this residue substituted by bulkier amino acids, such as arginine and tryptophan, exhibit severely diminished cAMP-signaling potencies with near normal binding affinities and these analogues also function as PTH-1 receptor antagonists.

N-terminal PTH peptides shorter than PTH(1-28) exhibit little or no biological activity, at least in cells that express the endogenous PTH-1 receptor. In cells that overexpress the cloned PTH-1 receptor via stable or transient DNA transfection, peptides as short as PTH(1-14) exhibit at least some cAMP agonist activity, albeit with potencies that are ~10,000-fold weaker than that of PTH(1-34) ($EC_{50} = \sim 200 \mu M$ and $\sim 2 nM$, respectively). Such weak potency can be attributed to the absence of the principal receptor-binding determinants in the PTH(15-34) domain. Subsequent work on the PTH(1-14) scaffold peptide has resulted in analogues, such as [α -aminoisobutyric acid (Aib)^{1,3}, Gln¹⁰, Har¹¹, Ala¹², Trp¹⁴]PTH(1-14)NH₂, that are as potent as PTH(1-34) in cells overexpressing the cloned PTH-1 receptor and only ~10-fold weaker than PTH(1-34) in cells expressing lower levels of the endogenous receptor. The modifications in these analogues are thought to improve affinity and potency by either providing new side chain contacts with the receptor, as for the Leu¹¹ → homoarginine substitution, constraining the peptide in the preferred (bioactive) conformation, as for the Ala^{1,3} → Aib substitutions, which stabilize α -helical structure, or both, but the specific mechanisms have not been elucidated. Nevertheless, such minimized PTH analogues could provide clues for the design of novel low-molecular-weight PTH-1 receptor agonists (peptidic or nonpeptidic) that can be used to treat osteoporosis or other diseases of bone and mineral metabolism.

Determinants of Non-cAMP Signaling Responses

Although in most cell-based PTH assay systems the AC/cAMP/PKA response to PTH predominates, in

certain settings and to varying extents, PTH stimulation of other intracellular signaling cascades is readily observed (Fig. 4). In many cell types, including COS-7 cells transiently transfected with the PTH-1 receptor, PTH stimulates the PLC/IP₃/diacylglycerol pathway, leading to the mobilization of intracellular calcium and the activation of PKC. In certain cells, such as renal distal tubule cells, PTH stimulates the PLD/phosphatidic acid signaling response, and in renal proximal tubule cells, PTH stimulates the PLA₂/arachidonic acid signaling response. The residues in PTH(1-34) that are involved in activating the various non-cAMP-mediated signaling cascades are not well defined, although residues 1 and 2 have been shown to be important for stimulating the PLC/IP₃ response in transfected cells, and, interestingly, residues 29-32 have been implicated as PKC activation determinants in rat osteosarcoma cells. This PKC response may involve the activation of PLA₂ or PLD rather than PLC. Little is also known regarding the means by which the various intracellular signaling pathways that are activated determine a given target cell's ultimate response to PTH, but this is an area that clearly warrants intense investigation.

Three-Dimensional Structure of PTH

The three-dimensional structure of PTH(1-34) has been analyzed by solution-phase nuclear magnetic resonance (NMR) spectroscopy, as well as by X-ray crystallography. The NMR studies, performed in a variety of solvents, including aqueous buffers, buffers containing the helix-promoting solvent, trifluoroethanol, and phospholipid micelles, have generally indicated the presence of two α -helical segments: a short N-terminal helix extending approximately from Ser³ to Leu¹¹ and a longer C-terminal helix extending approximately from residues Asn¹⁶ to Asp³⁰. A flexible hinge or turn region generally separates the two helices. It has been proposed based on functional studies and theoretical considerations that PTH(1-34) forms a U-shaped structure with the N- and C-terminal domains interacting. Hydrophobic interactions between Leu¹⁵ and Trp²⁵ have been observed by NMR methods, but otherwise intramolecular contacts between the N-terminal and C-terminal domains of PTH(1-34) are generally not seen. The crystal structure of PTH(1-34) was reported in 2001 by researchers at Eli Lilly and this study revealed a single linear α -helix that extended nearly from one end of the molecule to the other (Val² to His³²) and contained only a slight (15°) bend

Figure 4 The PTH/PTH receptor/G protein complex. The interaction of PTH with the PTH-1 receptor involves binding interactions between residues in the (15–34) region of the ligand (small, stippled oval) and the receptor's amino-terminal extracellular domain (large, stippled oval) and signaling interactions between residues in the (1–14) domain of PTH (small, solid oval) and the portion of the receptor containing the three extracellular loops and seven transmembrane helices (cylinders). The ligand-activated PTH-1 receptor couples to multiple signaling pathways, depending on the cell type and the presence or absence of ancillary cytoplasmic proteins, such as the Na^+/H^+ exchanger regulatory factors (NHERFs), as shown by M. Mahon and colleagues. In most cells, the PTH-1 receptor couples strongly (as indicated by the heavy arrow) to the AC/cAMP/PKC pathway via G_{α_s} . It also couples to the PLC/IP₃/Ca²⁺/PKC pathway via $G_{\alpha_q/11}$, the PLD/phosphatidic acid/PKC pathway, and the PLA₂/arachidonic acid/PKC signaling pathway, the latter two pathways involving as yet unidentified G proteins. In certain cells and in the presence of NHERE, the PTH-1 receptor couples to the inhibitory G protein (G_{α_i}), which results in diminished AC/cAMP signaling, as well as increased PLC/IP₃ signaling, an effect possibly mediated by the β/γ -subunits that dissociate from the activated G protein heterotrimer. Positive effects are indicated by a plus sign and solid arrows; a negative effect is indicated by a minus sign and a dashed arrow.

at the midsection. This finding raises the somewhat unexpected possibility that the biologically relevant structure of PTH(1-34) is a continuous α -helix. The increased potencies seen in PTH analogues containing helix-stabilizing substitutions, such as the Aib substitutions at positions 1 and 3 in PTH(1-14), and side-chain to side-chain lactam bridges between certain pairs of $i, i+4$ residues (e.g., Lys¹³-Asp¹⁷, Lys¹⁸-Asp²², Glu²²-Lys²⁶, and Lys²⁶-Asp³⁰) in PTH(1-31) or PTH(1-34) analogues, support the notion that the N-terminal and C-terminal domains of PTH are α -helical when the ligand is bound to the receptor. Such studies, however, do not elucidate the tertiary structure of the bound ligand. The question of whether PTH adopts a linear or folded conformation when

binding to the receptor, therefore, remains a matter of uncertainty and debate in the literature.

PTH-PTH RECEPTOR INTERACTIONS

Molecular Properties of the PTH-1 Receptor

The primary structure of the PTH-1 receptor was first determined by Jüppner, Abu-Samra, Segre, and colleagues at Massachusetts General Hospital, who isolated cDNA clones encoding the receptor from both kidney and bone cell lines. The human PTH-1 receptor is 593 amino acids in length. Its specific three-dimensional structure is largely unknown, although it

is presumed to follow the general seven-transmembrane domain architecture common to all GPCRs. The amino-terminal extracellular (N) domain of the PTH-1 receptor is approximately 170 amino acids in length and contains four N-linked glycosylation sites and six disulfide-linked cysteine residues. The PTH-1 receptor shares amino acid sequence homology to the receptors for a number of other peptide hormones that are similar in size to PTH(1-34), including calcitonin, secretin, glucagon, vasoactive intestinal polypeptide, growth hormone-releasing hormone, corticotropin-releasing hormone, and several others. These structurally related receptors form the class B subgroup of GPCRs. The PTH-1 receptor mediates the biological actions of both PTH and PTHrP and couples strongly to heterotrimeric G proteins containing the stimulatory variant of α -subunit (G_{α_s}) to induce adenylyl cyclase-mediated cAMP signaling and it can also couple to $G_{\alpha_q/11}$ -containing G proteins to induce IP_3/Ca_i^{2+} signaling, as well as to G_{α_i} -containing G proteins to inhibit adenylyl cyclase activity (Fig. 4).

TIP39 and the PTH-2 Receptor

Usdin and colleagues at the National Institutes of Health screened a human brain cDNA library for family B-type GPCRs by hybridization methods and thereby isolated a receptor that is 51% identical, at the amino acid level, to the PTH-1 receptor. This PTH-2 receptor responds to PTH but not to PTHrP. The intended ligand for the PTH-2 receptor, however, is most likely not PTH, because the rat PTH-2 receptor responds to neither PTH nor PTHrP. Instead, the intended ligand is likely to be tuberoinfundibular peptide of 39 amino acids (TIP39). This previously unknown peptide was isolated from bovine hypothalamus by Usdin and colleagues and shown to potently activate the PTH-2 receptor (rat or human) but not the PTH-1 receptor. TIP39 bears faint homology to PTH(1-34) (Fig. 2). Although the biological role of this ligand/receptor pair is unknown, Usdin and colleagues have presented evidence suggesting that it plays a role in pain nociception.

Mode of PTH Binding to the PTH-1 Receptor

The molecular mechanism by which PTH binds to and activates the PTH-1 receptor has been deduced largely from receptor mutagenesis and photochemical cross-linking studies. These data suggest that the interaction is complex and involves multiple points

of contact, with two principal components, as postulated by the "two-domain hypothesis." This involves (1) an interaction between the carboxy-terminal domain of PTH(1-34) and the N domain of the receptor, which provides the majority of binding energy to the complex, and (2) an interaction between the amino-terminal domain of the ligand and the juxta-membrane region of the receptor containing the extracellular loops and seven-transmembrane helices (TMs), which provides the specific contacts required for receptor activation (Fig. 4). Presumably, binding of the ligand to the receptor results in a change in the arrangement of the intracellular loops and helices that results in activation of G proteins and interaction with other intracellular constituents.

DISEASES OF PTH METABOLISM AND ACTION

Increased secretion of PTH may be an appropriate response to hypocalcemia (secondary hyperparathyroidism) or due to primary abnormalities of the parathyroid glands, which lead to hypercalcemia (primary hyperparathyroidism). Primary hyperparathyroidism is caused by hyperplasia or adenoma affecting one or more of the four parathyroid glands. Most commonly, mutations in parathyroid chief cells lead to clonal expansion of parathyroid cells that do not suppress PTH secretion in response to hypercalcemia as well as normal cells. Inactivating mutations of the CSR cause mild parathyroid hyperplasia when present in one of the gene's alleles. The hypercalcemia in this disorder (familial hypocalciuric hypercalcemia) is caused both by the mild increase in PTH secretion and by the PTH-independent actions of the CSR to increase reabsorption of calcium from the urine. Secondary hyperparathyroidism is caused by renal failure, malabsorption of calcium from the intestine, or other causes of hypocalcemia.

Reduced PTH secretion resulting in hypocalcemia reflects impaired parathyroid function and may be caused by destruction of parathyroid tissue by autoimmune or other processes, by complex congenital disorders, such as the DiGeorge syndrome, or by disorders of PTH secretion caused by hypomagnesemia or activating mutations of the CSR.

Pseudo-hypoparathyroidism (PHP) results from defects not in PTH production but in PTH responsiveness and is of two principal types: PHP1a, which is accompanied by Albright's hereditary osteodystrophy (AHO) and other endocrine system defects, and PHP1b, which is not associated with AHO or other

endocrine defects. PHPIa is caused by inactivating mutations in $G_{\alpha s}$; the gene for PHPIb also maps to the $G_{\alpha s}$ locus, but specific mutations have not yet been identified.

Genetic abnormalities of the PTH1-R cause diseases that reflect the dual function of the PTH1-R as both a PTH receptor and a PTHrP receptor. Jansen's metaphyseal chondrodysplasia is a rare autosomal dominant disease characterized by dwarfism (reflecting PTHrP-like actions at the growth plates of bones) and hypercalcemia (reflecting PTH-like actions on bone and kidney) and is caused by activating point mutations in the PTH1-R that increase the rate of basal cAMP signaling. Four such mutations have been identified, each of which occurs at the intracellular end of a predicted transmembrane domain segment: His²²³ → Arg in TM2; Thr⁴¹⁰ → Pro or Arg in TM6 and Ile⁴⁵⁸ → Arg in TM7. The antagonist analogue [Leu¹¹, D-Trp¹²]PTHrP(7-34)NH₂ has been shown by *in vitro* studies to function as an inverse agonist against these constitutively active PTH-1 receptors and to thus reduce their basal rate of cAMP signaling. Blomstrand's chondrodysplasia is a rare embryonic lethal condition caused by inactivating mutations in the PTH-1 receptor. The mutations result in a severely overcalcified fetal skeleton with extremely short limbs—a phenotype that closely resembles that seen in “knockout” mice having homozygous deletions of the PTH-1 receptor gene. Three mutations have been identified: a single nucleotide change that results in an 11-amino-acid deletion in TM5 due to an mRNA splicing error, a frameshift mutation in extracellular loop 2, and a missense mutation that changes Pro¹³² in the receptor's N domain to leucine.

CONCLUSIONS

The critical role that PTH plays in regulating the concentrations of extracellular calcium involve direct but complex effects on bone and kidney target cells. These effects are mediated through the PTH-1 receptor, a G protein-coupled receptor, that also regulates the developmental actions of PTHrP. PTH holds promise for the treatment of osteoporosis, since it increases bone mass and strength when administered intermittently. PTH interacts with its receptor through a two-site mechanism that involves interactions between the (15-34)-binding domain of the

ligand and the amino-terminal extracellular domain of the receptor and between the amino-terminal (1-14) signaling portion of the ligand and the juxta-membrane portion of the receptor. Understanding this molecular mechanism further should provide a better appreciation of how alterations in PTH physiology can be interpreted and manipulated in the clinical setting.

Unfortunately, both men succumbed to their disease and the consequences of its treatment. Solomon Berson and Rosalyn Yalow won the Nobel Prize in 1963 for developing an immunoassay for the measurement of parathyroid hormone (PTH). Adolf Hanson, a medical student in Minnesota, and James Collip, a Canadian biochemist, separately developed parathyroid extract to treat tetany, the symptoms of hypoparathyroidism and osteoporosis.

The introduction of the serum channel autoanalyzer in the mid-1960s issued in a new era of parathyroid surgery in that it facilitated making the diagnosis of primary hyperparathyroidism. There was a precipitous increase in the incidence of the disease and asymptomatic patients became the rule, rather than the exception. Additional technical advances have included the following: improved preoperative localization with sestamibi [\pm single photon emission computed tomography (SPECT)], intraoperative localization with the gamma probe, the rapid intraoperative parathyroid hormone (intraop PTH) assay, and the use of minimally invasive parathyroidectomy with unilateral neck exploration employing a small incision and regional anesthesia in the ambulatory setting.

PRIMARY HYPERPARATHYROIDISM

Anatomy and Pathology

Most humans have four parathyroid glands, which lie on the posterior surface of the thyroid. The average weight of a parathyroid is 35 to 40 mg and in adults their color turns to yellow as the fat content increases. The inferior parathyroids originate from the third branchial pouch, whereas the superior parathyroid glands descend from the fourth branchial pouch. Both the superior and inferior parathyroid glands receive their blood supply from the inferior thyroid artery. They are made up of chief and oxyphil cells, as

well as fibrovascular stroma and adipose tissue. Primary hyperparathyroidism (HPTH) can be produced by three different pathologic lesions (Fig. 1). A parathyroid adenoma is a benign encapsulated neoplasm that is responsible for 80–90% of hyperparathyroidism cases (Fig. 2). It usually affects a single gland, but 2–5% of patients with primary HPTH have adenomas in two glands (“double adenoma”). Hyperplasia is a proliferation of parenchymal cells that affects all of the parathyroid glands, and it accounts for approximately 10% of cases of primary HPTH. It also is associated with multiple endocrine neoplasia (MEN) 1 (primary HPTH combined with lesions of the pancreas and pituitary) and 2A (primary HPTH, medullary thyroid cancer, and pheochromocytoma) syndromes. Surgical treatment for parathyroid hyperplasia is with either subtotal parathyroidectomy or total parathyroidectomy with autotransplantation. Thymectomy also should be performed for patients with the MEN syndromes. Parathyroid carcinoma is a slow-growing neoplasm of the parenchymal cells that is responsible for 0.5–2% of cases of primary HPTH. Unlike adenomas, carcinoma is invasive.

Diagnosis and Presentation

Primary HPTH is the third most common endocrinologic disorder, after diabetes mellitus and thyroid disease. It is characterized by hypersecretion of PTH from one or more parathyroid glands, leading to hypercalcemia. The diagnosis is made by demonstrating an elevated serum calcium, elevated intact PTH (iPTH) level, and normal or increased urinary calcium concentration. The 24 h urine collection can help to exclude the diagnosis of benign familial hypocalciuric hypercalcemia (BFHH), which results in increased blood calcium and iPTH levels but *low* urinary calcium.

Prior to the advent of the automated serum channel autoanalyzer, patients typically presented with the

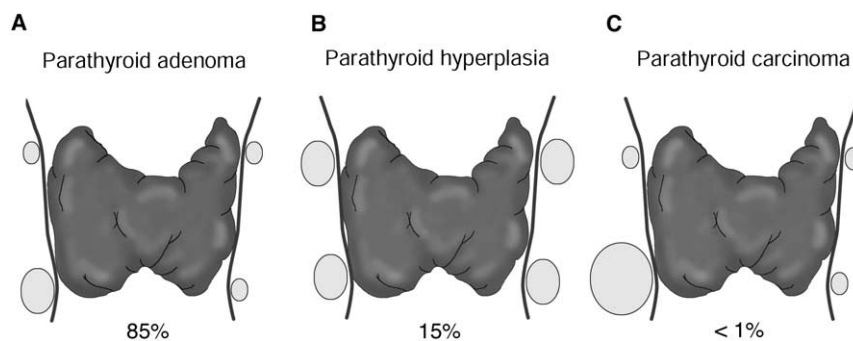

Figure 1 Causes of primary HPTH and their prevalence.

Figure 2 Parathyroid adenoma. A rim of normocellular parathyroid tissue with adipose surrounds a proliferation of chief and oncocytic cells below.

clinical manifestations of hypercalcemia, which included the classic pentad of painful bones, kidney stones, abdominal groans, psychic moans, and fatigue overtones. Since the autoanalyzer has become available, however, the biochemical diagnosis is usually made prior to the appearance of symptoms, and many patients are asymptomatic or at most minimally symptomatic. Although there was a National Institutes of Health consensus conference in 1990 and another workshop in 2002 about the management of asymptomatic primary HPTH, there is still no consensus among endocrinologists and endocrine surgeons about whether to survey these patients with nonoperative medical therapy or to refer them for early surgery. The value of parathyroidectomy in asymptomatic patients with mild to moderate hypercalcemia has been debated, because the natural history of primary HPTH is still not well understood and rapid increases in the serum calcium level and progression of symptoms or complications are uncommon in patients with borderline hypercalcemia.

Localization Procedures

Preoperative

There is a consensus that preoperative localization is useful prior to primary exploration, since it can allow for unilateral exploration in the setting of a localizing scan. Localization is absolutely essential prior to reoperation. A number of noninvasive preoperative methods exist, including sestamibi technetium (Tc)-99 m scintigraphy, ultrasonography, computed tomography (CT), magnetic resonance imaging (MRI), and thallium (Tl)-201–Tc-99 m pertechnetate scanning. There is general consensus that the single best

study is sestamibi (especially when combined with SPECT), which works by virtue of the fact that mitochondria take up Tc-99 m, and parathyroid cells have a large number of mitochondria (Fig. 3). The sensitivity reported for adenomas is in the 85–95% range, with a specificity of approximately 90%. Its sensitivity is limited in multiglandular disease. SPECT is particularly helpful in detecting smaller lesions and adenomas located behind the thyroid gland.

Ultrasound is easy to perform, well-tolerated, and can be done quickly and inexpensively. However, its accuracy depends on the skill and experience of the ultrasonographer, with sensitivity varying from 22 to 82%. CT is less sensitive than MRI, is relatively expensive, and exposes the patient to radiation. MRI is preferable in that it does not require the administration of contrast, but it is expensive; its sensitivity ranges from 50 to 80%. Tl–Tc uses subtraction imaging dependent on the uptake of thallium by parathyroid tissue. Parathyroids weighing less than 500 mg are usually not detected, and sensitivity ranges dramatically from center to center, with rates as low as 27% reported.

Invasive preoperative localization procedures include parathyroid arteriography, selective venous sampling, and fine-needle aspiration (FNA); these techniques are usually reserved for the reoperative neck. Arteriography, which has a sensitivity of 60%, includes examination of the thyrocervical trunks, the internal mammary arteries, and the carotids to look for parathyroid adenomas, which appear as highly vascularized, oval blushes. Venous sampling lateralizes approximately 80% of tumors by obtaining a blood sample for the PTH assay from the smallest possible

Figure 3 Sestamibi scan localizing a left-sided, inferior parathyroid adenoma (arrow) in the neck of a patient who subsequently underwent a MIP. Note the physiologic tracer uptake in the heart.

branches of the cervical and mediastinal veins. A gradient between the PTH concentration in peripheral blood and that in the selective venous sample establishes the site of venous drainage of the tumor. FNA is usually combined with ultrasound and can confirm that a cervical mass is indeed a parathyroid gland.

Intraoperative

The rapid intraoperative PTH (quick PTH) assay can be used to confirm the removal of hypersecreting parathyroid glands and predict a curative procedure. Its use is associated with reduced operating time. The first reported use of the assay was in 1988, but it has been refined significantly since then, largely due to the work of George Irvin. A peripheral blood specimen should be obtained prior to surgery. The equipment and technician to run the assay can be stationed inside or just outside the operating room. Repeated blood specimens from a peripheral line (better) or ipsilateral internal jugular vein should be drawn intraoperatively prior to resection of the gland (in order to capture a spike from the preoperative baseline due to manipulation of the gland during exploration) and then approximately 5 and 10 min after the excision. A 50% reduction in the PTH value from the baseline level is used often as an indication that the exploration has been successful. Operative failure rates for initial and reoperative parathyroidectomy have decreased significantly with this adjunct.

Radio-guided parathyroidectomy employs additional intraoperative localization of the adenoma following intravenous injection of sestamibi technetium-99m 2 to 4 h prior to surgery and a quantitative gamma counter with a 9 to 14 mm probe in the operating room. Gamma counts are obtained at the start of surgery in all four quadrants of the neck, through the skin and after incision under the muscles, with care taken not to interpret radioactivity emitted by the heart. Exploration where counts are highest focuses surgery and reduces operative time. The activity of the removed parathyroid gland is checked with the gamma probe to confirm cure. The excised adenoma emits radioactivity that is at least 20%, and usually higher than 50%, of postexcision background. In addition, the postexcision radioactivity in all four quadrants of the neck should equalize.

Surgery

Bilateral Neck Exploration

The standard operative approach to the treatment of hyperparathyroidism is to explore both sides of the

neck and to identify all parathyroid tissue. This is usually performed under general anesthesia, although it can be performed under regional block. Bilateral neck exploration allows accurate intraoperative diagnosis of the pathology causing the patient's disease and individualized treatment based on the number of enlarged glands. Mediastinotomy should not be performed at the primary exploration, but rather should be reserved if necessary for reexploration after further localization studies have been performed.

Parathyroidectomy offers definitive treatment for primary HPTH and the cure rate (defined as normocalcemia 6 months postoperatively) after bilateral neck exploration performed by an experienced surgeon is greater than 95%. There is clear evidence that clinical outcomes are associated with the experience of the surgeon performing the parathyroidectomy, such that high-volume endocrine surgeons have higher cure rates and lower complication rates. The rate of persistent hyperparathyroidism can be as high as 30% in less experienced hands. Perioperative complications include injury to the recurrent laryngeal nerve(s), leading to hoarseness or frank airway compromise if both nerves are damaged (reported rates of <1% to as high as 10%), hypoparathyroidism (2–3%), hematoma, and wound infection. The risks of these are theoretically less when exploration is confined to one side of the neck.

Minimally Invasive Parathyroidectomy

Eighty-five percent of primary HPTH results from a single adenoma, and it is cured by excision of that one gland. Therefore, with better preoperative localization, targeted surgery using unilateral neck exploration under regional or local anesthesia is becoming standard care. MIP involves preoperative localization (by, for example, sestamibi with SPECT) followed by limited exploration with cervical block anesthesia, using the intraoperative PTH assay to confirm the adequacy of resection. Patients with known multigland hyperplasia are not offered MIP. However, if such a patient is encountered during a MIP, bilateral exploration can be accomplished with the technique or the procedure can be converted to general anesthesia.

The skin incision is typically limited to 1 to 4 cm. A superficial cervical block is administered on the ipsilateral side of the sestamibi-localized adenoma. In most patients, approximately 20 cc of 1% lidocaine containing 1:100,000 epinephrine is used and supplemented during surgery as required. It is delivered deep to the posterior border of the sternal head of the sternocleidomastoid muscle on the ipsilateral side

of the adenoma, with care taken not to deliver the anesthetic intravascularly. Propofol is discontinued at least 5 min before PTH sampling because it can interfere with the PTH assay. Sedation is used to minimize patient anxiety while maintaining an awake, conscious patient who can phonate. A focused exploration then is performed based on the preoperative localization study, and the intraoperative PTH assay is used to confirm adequacy of parathyroid gland excision in the operating room as described above. The success of MIP has been confirmed by evidence of cure and complication rates that are at least as good as those achieved by conventional bilateral exploration. Specifically, in a series of 656 parathyroidectomies (of which 401 were performed in the standard fashion and 255 were performed with MIP), there were no significant differences in complication (3.0 and 1.2%, respectively) or cure rates (97 and 99%, respectively).

The first endoscopic parathyroidectomy was reported by Michel Gagner in 1996. Since then, MIP has been modified in a number of ways. In addition to radio-guided parathyroidectomy (described above), endoscopic and video-assisted parathyroidectomy are other variations on the minimally invasive approach. In endoscopic parathyroidectomy, access is obtained at the sternal notch for the endoscope and (generally) two lateral port sites are created for dissecting instruments. Carbon dioxide is insufflated at low pressure (<8 mm Hg) for visualization, but there can be problems when it diffuses in the neck and mediastinum, when operative space is lost during suction, and because there is no tactile assessment during surgery.

Video-assisted parathyroidectomy, pioneered by Paolo Miccoli, does not require steady gas flow but rather a brief insufflation of carbon dioxide to establish the operative space. It requires a 15 mm skin incision 1 cm above the sternal notch, which accommodates tactile assessment, suction-irrigation, dissection, and retraction equipment. A separate 10 mm trochar site is made vertically in the midline to accommodate the insufflator at the start of the case and then a 30° 5 mm endoscope. The largest series showed that mean operative time was less than 1 h. Video-assisted parathyroidectomy has been modified by Brunt, such that it can be performed as a gasless procedure.

Reexploration

Up to 10% of surgical failures may be attributed to an incorrect diagnosis at the time of primary exploration. Whereas multiple-gland disease accounts for 5–15% of patients undergoing initial exploration, up to 37% of patients who go to reexploration have multiple

gland disease rather than a single adenoma. Still, inexperience on the part of the surgeon is a major cause of surgical failure because of the lack of knowledge of the usual and unusual “hiding places” of the parathyroids.

Once the diagnosis of persistent or recurrent primary HPTH has been confirmed, previous operative notes and pathology reports should be obtained and reviewed. There are clear-cut indications for preoperative localizing studies before secondary exploration. Reexploration generally returns the surgeon to the neck, unless there is compelling evidence in the localization workup that the missing gland is located in the mediastinum, because the neck remains by far the most common site of “missed” glands. Furthermore, the majority of ectopic mediastinal parathyroid glands can be extirpated by a cervical approach. The lateral approach should be considered, as it avoids midline scar tissue. If the cervical approach to the mediastinum is inadequate, a partial or complete sternal split can be employed. Intraoperative localization in the form of intraoperative PTH and/or ultrasound is helpful during reoperation.

In the largest series, cure of hypercalcemia at reoperation ranges from 85 to 95%, and it is associated with the experience of the endocrine surgeon. Risks include failure, permanent hypoparathyroidism (10–15%), and recurrent laryngeal nerve injury.

Medical Alternatives

The optimal clinical management of patients with asymptomatic disease has not yet been established. The principal debate is whether patients should be managed with early operation or whether surveillance or medical therapy can be employed safely until the development of clinical sequelae.

Recommendations for referral to surgery were reported at the Workshop on Asymptomatic Primary Hyperparathyroidism: A Perspective for the 21st Century, held at the National Institutes of Health on April 8–9, 2002. They include the following:

- Patients with serum calcium levels greater than 1 mg/dl above the upper limits of normal should be referred for surgery.
- Patients with 24 h urinary calcium greater than 400 mg should be referred for surgery.
- Patients with a creatinine clearance reduced by more than 30% compared with age-matched subjects should be referred for surgery.
- Patients with a bone density measurement at the lumbar spine, hip, or distal radius that is more than

2 standard deviations below peak bone mass (T score < -2.5) should be referred for surgery.

- All individuals with primary HPTH under the age of 50 should be referred for surgery.
- Patients for whom medical surveillance was either undesirable or impossible should be referred for surgery.

There are still no medical therapies for which there are convincing data regarding either their efficacy or their safety. As specific therapy for the hypercalcemia of primary HPTH, estrogen might reduce the serum calcium somewhat, but is not generally effective until levels of estrogen are reached that are higher than most women or their physicians would consider acceptable. Three new classes of agents—raloxifene, bisphosphonates, and calcimimetics—have shown preliminary efficacy on surrogate markers of severity of disease, including serum calcium and bone density, but these effects have not been verified based on clinical outcomes. There is no rationale for diets that are restricted in calcium; vitamin D sufficiency should be maintained.

SECONDARY AND TERTIARY HYPERPARATHYROIDISM

Pathology and Clinical Presentation

Secondary HPTH occurs when there are external factors, such as chronic renal failure, that stimulate the parathyroid glands to increase the production of PTH, leading to hyperplastic overgrowth. Renal failure leads to hyperphosphatemia and decreased renal conversion of 25-hydroxycholecalciferol to 1,25-dihydroxycholecalciferol, resulting in diminished intestinal calcium absorption. Both of these effects lead to hypocalcemia, which stimulates PTH secretion and parathyroid gland hyperplasia. Approximately 90% of patients with chronic renal failure have evidence of secondary HPTH.

With prolonged stimulation of the parathyroids, tertiary HPTH may develop. This occurs in patients with longstanding renal insufficiency, when the parathyroids develop autonomous hyperfunction and no longer respond to calcium feedback inhibition, resulting in hypercalcemia. It also occurs in patients with longstanding secondary HPTH following renal transplantation.

Clinical manifestations include persistent or worsening of skeletal symptoms (including the classic osteitis fibrosa cystica), pruritis, extraskelatal calcifications, and calciphylaxis. In most patients, the condition

is managed by reducing phosphate in the diet, administering phosphate binders, dialysis, or treatment with 1,25-dihydroxyvitamin D₃. Kidney transplantation remains the best option for correction of the metabolic abnormalities.

Subtotal Versus Total Parathyroidectomy

Parathyroidectomy is indicated when medical therapy fails to control progressive secondary HPTH. The two accepted operations for the management of secondary HPTH are subtotal parathyroidectomy and total parathyroidectomy with heterotopic parathyroid autotransplantation. In subtotal parathyroidectomy, “three and a half” glands are removed and a 40 to 60 mg remnant of the most normal-appearing gland is left in place and marked with a clip. Its theoretical advantage is that it induces less postoperative hypocalcemia because the parathyroid remnant left *in situ* continues to function. This can be particularly important in non-compliant patients who may not take calcium supplementation. The main disadvantage is that remedial cervical operations for recurrent disease are tedious and carry an increased risk of recurrent laryngeal nerve injury. According to the largest series, 10–16% of patients had postoperative hypercalcemia, 8% required reoperation because of remnant growth, and 4–25% had hypocalcemia lasting longer than 1 year.

In total parathyroidectomy with autotransplantation, at least four glands are resected, and the most suitable gland is selected to obtain the autograft. A 40 to 60 mg portion of this gland is sliced into small fragments, and 10 to 15 fragments are placed into separate intramuscular pockets in the forearm (away from present or planned arteriovenous fistula/graft sites). The advantage is that if hyperparathyroidism recurs in the transplanted parathyroid tissue, the graft can be partially resected under local anesthesia. Published series show a 5–38% rate of postoperative hypercalcemia, a 2–6% chance of recurrence requiring graft resection, and a 5–30% chance of hypocalcemia lasting greater than 1 year. Cryotherapy of parathyroid tissue is an important adjunct when autotransplantation is used in the case of parathyroid transplant failure.

PARATHYROID CANCER

Parathyroid carcinoma accounts for approximately 1% of primary HPTH. Preoperative findings suggestive of the diagnosis include very high calcium and iPTH levels, a large cervical mass, and intraoperatively a

hard grayish-white parathyroid gland that is adherent to surrounding tissue. Still, it may be very difficult to make this diagnosis intraoperatively; in 20% of primary operations in one series, the diagnosis of carcinoma was not expected either preoperatively or during the procedure.

The largest published series included 286 patients collected over a 10-year period and showed a 5-year survival rate of 85.5% with a 10-year survival rate of 49.1%. Like most endocrine tumors, parathyroid carcinoma is slow-growing, and distant metastases occur late in the progression of the disease. To avoid local recurrence, initial *en bloc* resection of parathyroid carcinoma (including any locally invaded tissue such as a contiguous ipsilateral thyroid lobe) is recommended when the diagnosis is suspected at the time of parathyroidectomy. Capsular rupture must be avoided. An aggressive approach to recurrent disease is often beneficial, and surgical excision of metastases is the single most effective treatment in palliating the accompanying hypercalcemia.

material varies from 36 to 90%. The pattern of adrenal gland involvement—with the medulla being the site of primary involvement and with areas of focal and generalized hemorrhage affecting both medulla and cortex—initially described in 1983 by Reichert has been repeatedly reported ever since. The adrenal gland is the most common extrapulmonary site of CMV infection.

In 1985, Glasgow and associates found CMV adrenalitis in 21 of 41 patients examined and widespread lipid depletion in most cases (a nonspecific finding on autopsies of critically ill patients). The adrenal cortical involvement was limited to 10% of the cortex in most and was less than 70% of all cases. In an attempt to establish clinicopathologic correlation, 32 patients were also analyzed for clinical signs and symptoms as well as laboratory evidence of adrenal insufficiency. Common findings were hyponatremia (75%), hypotension (34%), hypokalemia (19%), hyperkalemia (16%), vomiting, diarrhea, and fever (percentage not specified). No patient had hyperpigmentation. Morning levels of serum cortisol were normal or elevated in 5 of 5 patients. One of 2 patients tested had a subnormal increase in cortisol after adrenocorticotropic hormone (ACTH) infusion. Despite significant pathologic adrenal abnormalities, no clinical adrenal insufficiency was documented. The degree of adrenal cortical damage seen was considered less than that usually associated with adrenal insufficiency.

In 1990, Pulakhandman and Dincsoy found CMV infections in half of 74 autopsied cases of AIDS. In 37 cases, the adrenal gland was the most commonly affected organ; the lungs were affected in 55% of cases. CMV inclusions were found in endothelial, cortical, and medullary cells. The CMV adrenalitis was diffuse in 10 cases and focal in 20. Analysis of the clinical data from 30 subjects revealed no findings related to the adrenal pathology, with the possible exception of a serum sodium:potassium ratio of less than 30 in those with more severe adrenal pathology.

Clinical Studies

Adrenal function is among the most commonly reported endocrine parameters in patients with HIV/AIDS. Many of the signs and symptoms characteristic of adrenal insufficiency are frequently seen in severely ill patients with HIV infection. However, definite adrenal insufficiency is rare in patients with AIDS. The results of adrenal function studies in patients with AIDS vary depending on the patients studied, the severity of the disease, the concomitant intercurrent

illnesses and medications to which they are exposed, and the methods of adrenal testing (baseline or stimulated levels of glucocorticoids and/or ACTH).

Studies in Adults

Most studies of adrenal function have been performed on adults with HIV infection. Early reports documented both normal and diminished cortisol responses to ACTH in patients with AIDS. Membreno *et al.* studied 74 randomly selected hospitalized patients with AIDS and 19 patients with AIDS-related complex (ARC). Based on subnormal cortisol responses to ACTH stimulation, 4 patients with AIDS were diagnosed as having adrenal insufficiency. Mean basal cortisol levels were higher in patients with AIDS than in healthy individuals, but ACTH-stimulated cortisol responses were not different from normal. However, stimulated levels of 17-deoxysteroid levels [corticosterone and 18-OH-deoxycorticosterone (18-OHDOC)] were lower than normal. Patients with ARC responded in a similar manner as those with AIDS. Based on these findings, the researchers suggested that impaired 17-deoxysteroid levels, especially 18-OHDOC, might be a harbinger of progressive adrenal disorder. Plasma ACTH levels were normal, not elevated, as would be anticipated, in patients with adrenal insufficiency, suggesting a possible pituitary defect in these patients. Administration of the hypothalamic factor corticotropin-releasing hormone (CRH) resulted in subnormal 18-OHDOC responses in 2 patients. The researchers advanced the hypothesis that HIV pituitary infection could lead to selective hypopituitarism and hypoadrenalism, with subsequent HIV adrenal infection leading to complete adrenal insufficiency.

Dobs and associates reported normal cortisol responses to ACTH in 36 of 39 ambulatory patients with AIDS. Although no clinical evidence of endocrine disorder was found, Merenich reported lower baseline cortisol and aldosterone and ACTH-stimulated cortisol levels in 40 asymptomatic HIV-infected men compared with 27 HIV-infected age-matched control subjects; 1 patient had low cortisol and also low ACTH-stimulated aldosterone levels.

HIV-infected patients have been reported to have lower responses in cortisol and/or ACTH to cold stress or tetanus toxoid administration. Several investigators, however, have reported elevated baseline levels or 24-h secretion of cortisol and/or ACTH.

In 1992 and 1993, Catania compared proopiomelanocortin-derived peptides and cytokines in 80 patients with AIDS and in 80 normal subjects. Average plasma α -melanocyte-stimulating hormone levels were higher

in the AIDS patients, but mean levels of cortisol, ACTH, β -endorphins, interleukin-1 (IL-1), IL-6, and tumor necrosis factor were not different between the two groups.

In a prospective study of 98 HIV-infected patients, Raffi *et al.* found only 4 patients with low baseline and 7 with low ACTH-stimulated cortisol levels. Only 2 patients were believed to have adrenal insufficiency.

In 2001, Eledrisi and Verghese described three patients with AIDS who had clinical features suggestive of adrenal insufficiency but normal ACTH stimulation tests. Following repeat testing, the diagnosis of adrenal insufficiency was made in one patient. The other two patients required overnight metyrapone test to confirm the diagnosis. All three patients had improvement in their clinical condition following glucocorticoid therapy.

To further explain the effect of HIV infection on the HPA axis, Azar and Melby administered ovine CRH (oCRH) to 25 non-AIDS ambulatory HIV-infected patients and 10 normal volunteers: 6 patients had diminished cortisol and ACTH responses to CRH, 6 had low cortisol and normal ACTH responses, and 13 had normal cortisol and ACTH responses. They suggested enhanced hypothalamic CRH production in HIV infections as a possible explanation for their results. Complex interactions between the immune and HPA axis, mediated by cytokines and perhaps lymphocyte-produced ACTH, have been postulated to explain the mechanisms by which HIV infections may affect adrenal function.

Hyponatremia has been reported in 30% to more than 50% of hospitalized patients with AIDS. In most patients, however, hyponatremia is thought to be caused by renal and/or gastrointestinal losses and/or the syndrome of inappropriate secretion of antidiuretic hormone. Hyporeninemic hypoaldosteronism and mineralocorticoid deficiency have been reported in a few patients with AIDS. However, the adrenal mineralocorticoid pathway is normal in both the baseline and ACTH-stimulated states in most HIV-infected patients.

Serum levels of dehydroepiandrosterone have been reported to be decreased in HIV-infected patients, to correlate with CD4 levels, and to be a predictor of the progression of HIV infection to AIDS. Norbiato reported nine patients with AIDS and characteristic clinical features of adrenal insufficiency with elevated cortisol levels, suggesting resistance to glucocorticoids by abnormal glucocorticoid receptors on lymphocytes.

The bulk of the data suggest that adrenal insufficiency can be a complication of HIV infection, and

health care professionals should have a high index of suspicion of subtle adrenal dysfunction.

Studies in Children

In a study of children with symptomatic HIV infections ($N=28$), Rapaport *et al.* measured morning serum cortisol levels and found that the lowest levels occurred in those with the lowest CD4 levels. ACTH tests performed on 2 children with the lowest cortisol levels were normal, suggesting normal adrenal glucocorticoid function. In several ill children with AIDS who were suspected of having adrenal insufficiency, normal baseline cortisol levels were found in all. In 4 subjects, ACTH-stimulated cortisol responses were normal, excluding the diagnosis of adrenal insufficiency.

Oberfield and associates found normal or slightly elevated baseline and ACTH-stimulated cortisol levels, with mildly diminished stimulated serum deoxycorticosterone and corticosterone levels, in 12 HIV-infected children, 2 of whom were receiving ketoconazole, a drug known to inhibit adrenal function. Laue *et al.* reported normal cortisol response to ACTH in 8 of 9 children with AIDS; the 1 patient with a subnormal response was receiving treatment with ketoconazole. Schwartz *et al.* found normal cortisol responses to glucagon stimulation in 12 of 12 HIV-infected children.

HPA AXIS AND HIV TREATMENT

Treatment of HIV infection has undergone substantial changes during the past two decades. However, several agents still used have been known to affect the HPA axis. Hypoadrenalism may result from ketoconazole or rifampin treatment. Symptoms of adrenal insufficiency have been reported following cessation of megestrol acetate therapy.

Symptoms that may represent HPA axis dysfunction have also been reported. Hypoglycemia has been demonstrated in patients with AIDS treated with pentamidine and trimethoprim sulfamethoxazole. Hyponatremia has been associated with pentamidine and vidarabine therapy.

Yanovski's group postulated that the increase in abdominal adipose tissue found in HIV-infected patients treated with protease inhibitors (PIs) could be due to abnormalities in adrenal function. Patients on a PI regimen had normal diurnal cortisol secretion, cortisol secretory dynamics after oCRH, cortisol-binding globulin levels, and glucocorticoid number and affinity. The following abnormalities were noted: increased basal and CRH-stimulated plasma

ACTH and 24-h urinary 17-OHCS excretion and decreased urinary free cortisol. The study did not include any HIV-infected patients who were not on PI treatment; therefore, the changes observed, although coinciding with PI treatment, can not be solely ascribed to the use of PIs. They concluded that the changes observed seem to represent a distinct but undefined form of hypercortisolism that could not be related directly to the HPA axis.

CONCLUSION

There have been numerous advances in the areas of epidemiology, management, prevention, and prophylaxis of HIV disease globally. Much effort is currently focused on prevention strategies, with vaccines playing a potential pivotal role. Some phase 3 trials of vaccines are already under way.

Endocrine effects of HIV infection are not easily recognized by clinical signs and/or symptoms, baseline hormonal evaluation, or even stimulation tests. Although a single consistent HIV-related HPA axis dysfunction has not been documented, persistent and careful investigation of the HPA axis may disclose potential abnormalities. Recognition and treatment of these disorders should improve the quality of life of the patients. The evaluation and treatment of endocrine alterations in patients with HIV infection is an increasingly important clinical and investigational area of pediatric endocrinology.

Figure 1 Signaling from RTKs and GPCRs. Insulin and EGF bind to their respective receptors (IRK and EGFR), leading to the activation of the intrinsic kinase activity and autophosphorylation of the receptor on tyrosine residues. This promotes the tyrosine phosphorylation and the activation of downstream effectors, which in turn bind to SH2-containing proteins and thus entrain downstream signaling steps. The binding of agonist to GPCRs facilitates the association between receptor and trimeric G proteins. This association promotes the dissociation of GDP and association of GTP with the G_{α} -subunit of the trimeric complex. G_{α} -GTP is then released from the trimeric complex and interacts with cell surface enzymes (E), leading to the activation of downstream signaling. PY proteins, phosphotyrosine proteins.

domain of the β -subunit, in which circumstance it manifested augmented tyrosine kinase activity against exogenous substrates. Studies using scanning electron microscopy and computer modeling have established that one molecule of insulin binds within a pocket formed by the two α -chains of the IR and that there is a subsequent conformational change that approximates the β -subunits, thus facilitating autophosphorylation on contralateral tyrosine residues (i.e., transphosphorylation).

An analogous process is observed with the EGFR and other receptor tyrosine kinases (RTKs) in that one ligand effects dimerization by bifacially binding separate RTK subunits, in effect promoting their association and facilitating their autophosphorylation on tyrosine residues (Fig. 1). Of significance was the recognition that autophosphorylation effected RTK

activation and hence the tyrosine phosphorylation of other cellular substrates—a key step in the signaling mechanism for this family of receptors. Rather uniquely, it was found that the level of tyrosine kinase activity of the IRK was sustained in the absence of insulin binding to the α -subunit as long as the β -subunit remained tyrosine-phosphorylated (Table I). Of importance was the recognition that the tyrosine kinase activity of the IRK and EGFR as well as other RTKs is necessary for the realization of hormone action. Thus, mutating the ATP-binding site of the IRK completely inactivated kinase activity and abolished the insulin response without impairing insulin binding. Interestingly, it was soon apparent that IRK activation was also sufficient for the insulin response in that activating the IRK in the absence of insulin entrained the full insulin response.

Postreceptor Cascade

The activation of RTKs effects signaling in two general ways. One is to provide specific phosphotyrosine motifs in the cytosolic domain of the receptor itself, the motifs of which bind downstream signaling molecules via their intrinsic SH2 domains. This signaling pattern is well exemplified by the platelet-derived growth factor (PDGF) receptor. Alternatively, the RTK promotes the tyrosine phosphorylation of downstream docking proteins, which in turn bind SH2-containing molecules, and thus entrains downstream signaling steps. This is exemplified by the IRK and its insulin receptor substrate (IRS) substrates. Depending on the nature of the SH2-containing molecule, there is an activation of an inherent enzyme activity [e.g., phosphatidylinositol 3-kinase (PI3K)] or the facilitation of its association with other molecules (e.g., Grb2, Shc), eventually effecting the activation of distal kinase(s) and/or phosphatases.

The serpentine receptors contain no intrinsic enzymatic activity. The binding of hormone in this receptor family appears to alter the conformation of its intracellular loop(s) to facilitate the association of the hormone-bound receptor with trimeric G proteins (Fig. 1). This association promotes the dissociation of GDP and the correlative association of GTP with the

G_{α} -subunit of the trimeric G protein. Subsequently, G_{α} -GTP is released from the trimeric complex to interact with and alter the activity of various cell surface enzymes [viz. adenylate cyclase, phospholipase C (PLC)]. This alteration may be either an augmentation or a restraint of the production of intracellular second messengers (viz. cyclic AMP, diacylglycerol) (Fig. 1).

INTERNALIZATION AND SIGNALING

The Insulin Receptor Kinase (IRK)

Following the demonstration that receptors could be identified in non-plasmalemma-containing cell fractions, it was quickly found that ^{125}I -labeled peptide hormones (viz. insulin and lactogens) were rapidly internalized into nonlysosomal vesicular elements in rat liver. Of particular interest was the appreciation that these internalized ligands retained their integrity. These observations led to the proposal that the internalized hormones were acting to effect signaling from these intracellular structures, which were originally appreciated as "unique vesicles" and subsequently named endosomes (ENs). The demonstration that activated IRKs and EGFRs were internalized into endosomes strengthened the view that signal

transduction was not limited to the cell surface but occurred within the endosomal system as well (Fig. 2).

With respect to the IRK, activated receptor has been shown to accumulate in ENs from liver, adipocytes, and skeletal muscle. The discovery and use of

the powerful insulin mimetic peroxovanadium (pV) compounds has contributed to the understanding of the significance of internalized IRKs. In particular, Bevan *et al.* showed that *in vivo* administration of pV compounds selectively activated the endosomal IRK

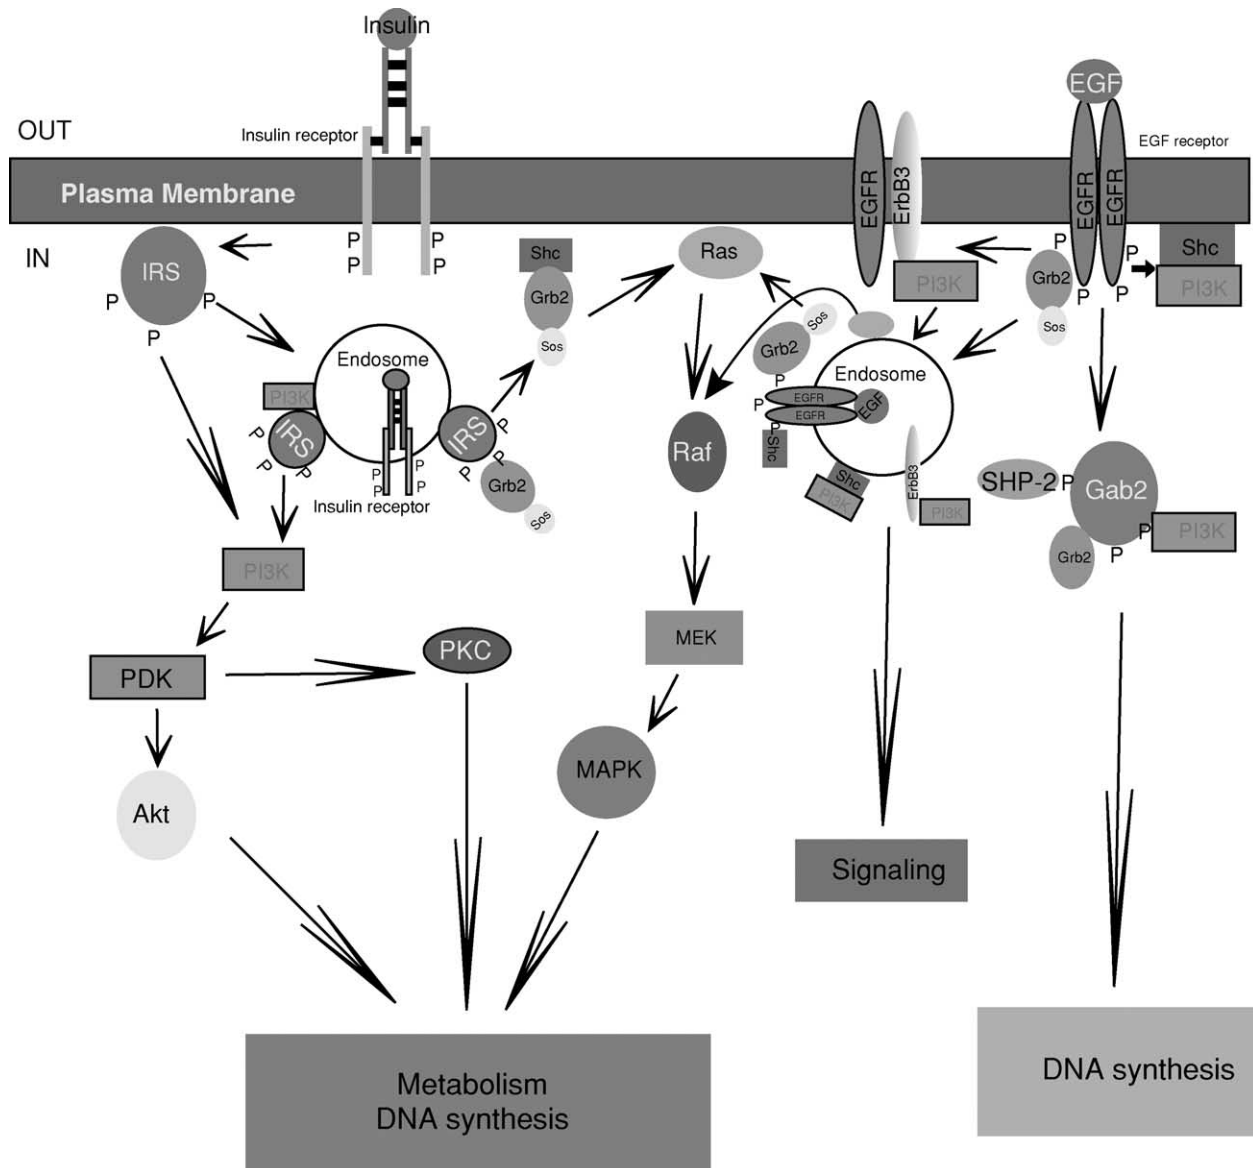

Figure 2 Signaling from endocytosed receptors. Insulin binding leads to autophosphorylation of IRK β subunits, increased IRK exogenous kinase activity, and rapid internalization of the activated hormone–receptor complex into ENs. Tyrosine phosphorylation of downstream adapter proteins (such as IRS1) by PM and endosomal IRK leads to the recruitment of SH2-containing proteins (such as PI3K and Grb2). Recruitment of PI3K to IRS1 effects the activation of its kinase activity entraining downstream events, leading to metabolic changes and DNA synthesis. Recruitment of Grb2 to IRS1 leads to activation of the Ras–Raf–MEK–MAPK cascade. EGF binding to its PM receptor leads to receptor homo- or heterodimerization, autophosphorylation, and activation. This is followed by a rapid internalization of the receptor. EGFR or ErbB3 phosphorylation enables recruitment of proteins via their SH2 domain (Shc, Grb2, PI3K) or phosphotyrosine binding (PTB) domain (Shc) at both the PM and ENs, leading to the activation of Raf-1 and the MAPK cascade. In liver, activated EGFR leads to the accumulation of cytosolic tyrosine-phosphorylated Gab2, which recruits and activates PI3K, as part of a multimeric complex, leading to DNA synthesis. PKC, protein kinase C; PDK, phosphoinositide dependent kinase.

and that IRS1 tyrosine phosphorylation ensued as a consequence.

There has also been a growing appreciation that compartmentalization of downstream signaling molecules may play a significant role in cell signaling. Thus, insulin was found to induce a decrease in hepatic plasma membrane (PM) content of IRS1 and IRS2 with a corresponding increase in their concentration in ENs. In 3T3-L1 adipocytes, substantial quantities of IRS1 and IRS2 were found in internal membranes. Similar findings were made in low-density membranes (LDM) from adipocytes, a fraction representing endosomal elements in this cell type. Furthermore, insulin administration effected the phosphorylation of IRS1 in LDM followed by its dissociation into the cytosol. These events in adipocytes appear to exclude interactions at the PM, which appears to differ from observations in rat liver. It has also been observed that insulin induces a rapid increase in the levels of p85 in ENs, in association with IRS1 and IRS2, with IRS1 accounting for the bulk of the recruitment. The kinetics of association are consistent with the formation of these complexes at the cell surface and their internalization into ENs. These findings compare to those in other insulin target tissues, such as 3T3-L1 adipocytes, where insulin induced the association of PI3K mainly with LDM or microsomes. In contrast, PDGF stimulated the recruitment and activation of PI3K exclusively in PM but unlike insulin PDGF did not induce GLUT4 translocation from the LDM to the PM. Interestingly, it was found that, in 3T3-L1 adipocytes, impaired insulin-stimulated GLUT4 translocation induced by oxidative stress is associated with the inhibition of redistribution of both IRS1 and activated PI3K between LDM and cytosol, whereas the activity of this enzyme in total lysates was not affected. Taken together, these data support the concept that insulin-induced compartmentalization of key signaling molecules is important for transducing at least some aspects of the insulin response. These studies and related observations are summarized in [Table I](#).

The Epidermal Growth Factor Receptor Kinase (EGFRK)

Ligand binding to the EGFR initiates dimerization, receptor autophosphorylation, and activation of signal transduction pathways as well as trafficking events that relocalize the receptor from the cell surface to intracellular compartments. There are data indicating the involvement of specialized membrane domains in the initial steps leading to EGFR internalization. These

include caveolae and clathrin-coated pits but probably involve noncoated domains as well. The initial endocytic vesicles fuse to endosomes that deliver the receptor and their ligands to various intracellular destinations.

EGF-induced receptor endocytosis plays at least two functions. It was first demonstrated as a mechanism for attenuating the signal generated at the cell surface. Indeed, various studies have shown that an increase in mitogenic responses induced by EGF binding to the receptor correlates with the decrease of receptor internalization. In contrast, in rat liver, reports have described the presence of activated receptors in endosomes and the increasing association over time of Shc, Grb2, and mSos with the internalized receptor whose tyrosine phosphorylation state correspondingly increased. There has been increasing evidence indicating a role for internalized activated EGFR in influencing downstream signaling molecules. Of particular interest are the well-characterized data linking endocytosis of EGFR with ERK1/2 activation. In fibroblasts, internalized EGFRs participate in the activation of p21/Ras and in normal rat kidney (NRK) cells intact actin cytoskeleton has been reported to be necessary for EGF-mediated transport of caveolin from the cell surface into early endosomes as well as activation of the MAPK pathway. Other evidence has been provided by the work of Viera and colleagues in HeLa cells overexpressing dominant-negative (K44A) dynamin. In such cells, which are specifically defective in receptor-mediated endocytosis, a decrease in EGFR tyrosine phosphorylation was found, consistent with earlier observations showing the hyperphosphorylation of endosomal EGFR versus PM EGFR. Furthermore, in these cells a decrease in MAPK phosphorylation and activation was seen along with augmented phosphorylation of PLC- γ and Shc. Other evidence showing the importance of receptor internalization in aspects of EGF signaling comes from two additional studies. Molecules involved in the mitogen-activated protein kinase (MAPK) cascade were localized in highly purified endosomes from rat liver. Using the same purified fraction, the authors also showed that administration of EGF led to the redistribution of Raf-1 from the plasma membrane into endosomes. Finally, using combined imaging microscopy and fluorescence resonance energy transfer, Sorkin elegantly demonstrated that activated EGFR interacts with Shc and Grb2 in membrane ruffles and endosomes. These studies, which provide evidence that EGFR endocytic trafficking is required to trigger MAPK signaling pathways, and others implicating endosomal EGFR in cell signaling are summarized in [Table II](#).

Work from the authors' laboratory has shown that the activation of PI3K is a necessary step in EGF-induced mitogenesis of primary rat hepatocytes in culture. Following EGFR activation, three different molecules become tyrosine-phosphorylated and recruit PI3K to phosphotyrosine motifs. These three molecules were shown to be ErbB3, Shc, and Gab2. The last molecule was cloned and shown to be the essential docking molecule involved in EGF-induced PI3K-dependent mitogenesis in rat liver. In addition, it has been shown that, whereas ErbB3 and Shc are tyrosine-phosphorylated and internalized into endosomes, tyrosine-phosphorylated Gab2 is largely a cytosolic entity. These relations are also noted in Fig. 2.

G Protein-Coupled Receptors

In addition to their classical responses (Fig. 1), many G protein-coupled receptors (GPCRs) activate MAPK cascades. As with the EGFR, internalization seems to be crucial for ERK1/2 activation. Following ligand binding, the activation of GPCRs leads to the recruitment of β -arrestin to the activated receptor. This step often terminates or attenuates signaling by blocking the interaction of G proteins with the receptor (desensitization). However, various studies have shown that β -arrestins also target the receptors to clathrin-coated vesicles for subsequent internalization and act as scaffold proteins, which contribute to the modulation of responses under the control of GPCRs. β -Arrestins form complexes with signaling molecules

such as Src. The association of β -arrestins and Src modulates GPCR endocytosis, leading to MAPK activation. The downstream mechanism of ERK1/2 activation by GPCRs appears to involve the same intermediates as those activated by RTKs. It is thought that $G_{\beta\gamma}$ -subunits stimulate the tyrosine phosphorylation of the adapter protein Shc and the recruitment to the plasma membrane of the Ras guanine exchange factors such as Grb2-mSos complex. Recruitment of mSos facilitates Ras GDP/GTP exchange, leading to the recruitment of Raf into the complex with activated Ras. Subsequent signal transduction involves the sequential phosphorylation of MEK (MAPK kinase) and MAPK. Studies using various inhibitors of endocytosis are consistent with the view that GPCR-mediated ERK1/2 activation is endocytosis dependent and that different inhibitors of internalization specifically block Raf-mediated activation of MEK. The endocytosis of GPCRs is also required for CXCR2-mediated chemotaxis and somatostatin-mediated inhibition of growth hormone expression. These and related observations are summarized in Table III.

In contrast, the classical β 2-AR (adrenergic receptor) signaling pathway, mediated by G proteins and leading to the activation of adenylate cyclase and phospholipase C, is unaffected by dominant-negative (K44A) dynamin, which significantly inhibits endocytic vesicular trafficking. This demonstrates that in contrast to ERK1/2 activation, these signaling events occur entirely at the plasma membrane as depicted in Fig. 1.

In some systems, GPCRs also stimulate tyrosine kinase signaling cascades by inducing transactivation of RTKs. An example is the agonist activation of the β 2-AR in COS-7 cells inducing the formation of a multireceptor complex containing both β 2-AR and EGFR in which the EGFR becomes activated along with the activation of ERK1/2. These transactivations are also sensitive to inhibitors of endocytosis, consistent with a key role for the endocytic process in activation of the ERK cascade by GPCRs via this mechanism.

Other Receptor Systems

Table IV summarizes observations about other receptors that indicate that there is internalization of activated receptors in aspects of cell signaling. With time it has become increasingly clear that peptide hormones effect signal transduction both at the cell surface and within the endosomal system as well. A number of observations supporting this model of signaling are summarized in Tables I to IV. In Fig. 2, signal transduction is depicted as deriving from both the cell surface and the earlier components of the endosomal system. Though Fig. 2 deals with insulin and EGF, comparable patterns clearly apply to other hormones and growth factors. In ENs, in addition to insulin- and EGF-induced concentration of activated IRKs and EGFRs, respectively, there was a concentration of

key signaling molecules involved in the propagation of insulin and EGF signaling.

SUMMARY

Different patterns of cell signaling have been distinguished. In one instance, a signal initiated at the cell surface might be continued within endosomes and hence be augmented in both intensity and duration. This would appear to be the case for IRK activation and tyrosine phosphorylation of IRS1 and the molecular events that derive from the activation of this docking protein. Alternatively, certain signaling events might be restricted to one or another of the cellular compartments traversed by ligand-receptor complexes. Thus, the activation of the MAPK pathway by EGFR exemplifies the requirement for ligand-receptor internalization.

The availability of new techniques for manipulating molecular structure and for visualizing molecular localization has accelerated the elucidation of cell signaling. Ever more has been learned about the complexity of the signaling process with respect to the number of molecules involved in mediating and modulating the signal cascade and with respect to the requirement that there be a redistribution of activated receptors and signal transducing molecules into different cellular compartments for signaling to be fully realized. In the next few years, it is anticipated

insertion occur while the growing peptide chain is still attached to the ribosome. After the peptide chain is completely inserted into the ER, the signal sequence is removed by the signal cleavage enzyme (signalase) located on the inner surface of the ER. With the assistance of chaperones, the prohormone is correctly folded and disulfide bonds are formed. Some prohormones are modified by N-linked glycosylation in which sugar residues are added to asparagines and glutamines.

The prohormones are transported by specific vesicles to the Golgi apparatus, where they are further modified in different Golgi compartments. Additional carbohydrates are added to serine and threonine residues (O-linked glycosylation). Existing carbohydrate residues are further modified. In the *trans*-Golgi network (TGN), some tyrosine residues are sulfated on their hydroxyl group. This enzymatic reaction is performed by protein tyrosine sulfotransferase. The tyrosines that are sulfated have multiple adjacent acidic residues that constitute the consensus sequence for sulfation. This modification may be important for the biological activity of the peptide.

In the TGN, prohormones are sorted into regulated secretory granules with other proteins destined for secretion, including the enzymes responsible for their processing. The nature of the molecular recognition of prohormones as material for these granules is still a mystery. Whether there are specific sorting receptors that recognize prohormone or whether some structural feature is recognized is unknown. It

is not known whether prohormones are cleaved entirely within secretory granules or whether the cleavage starts earlier in the ER or Golgi. This may differ for different prohormones. Inside the secretory granule, there is a concentration step, wherein the internal calcium concentration increases while the pH drops. Drugs that disrupt the Golgi (Brefeldin) or prevent the acidification of secretory granules (chloroquine and ammonium chloride) greatly decrease the processing of prohormones. A typical example of the modifications that occur during the production of several neuropeptides from one prohormone is shown in Fig. 1.

Prohormones for peptide hormone and peptides undergo limited and specific endoproteolysis during their passage through the regulated secretory pathway. The biologically active elements in the prohormone are flanked by single or double basic residues. Not all such residues are sites for cleavage; somehow the endoproteases detect which sites are to be cleaved and ignore the others. This probably involves the three-dimensional structure of these sites and how it relates to the active site of the enzyme.

The enzyme(s) responsible for the endoproteolytic cleavages during processing has not been completely established, although considerable progress has been made in this area. The most likely candidates are members of a family of enzymes called the prohormone convertases (PCs). They are calcium-dependent serine proteases that operate at acidic pH and are

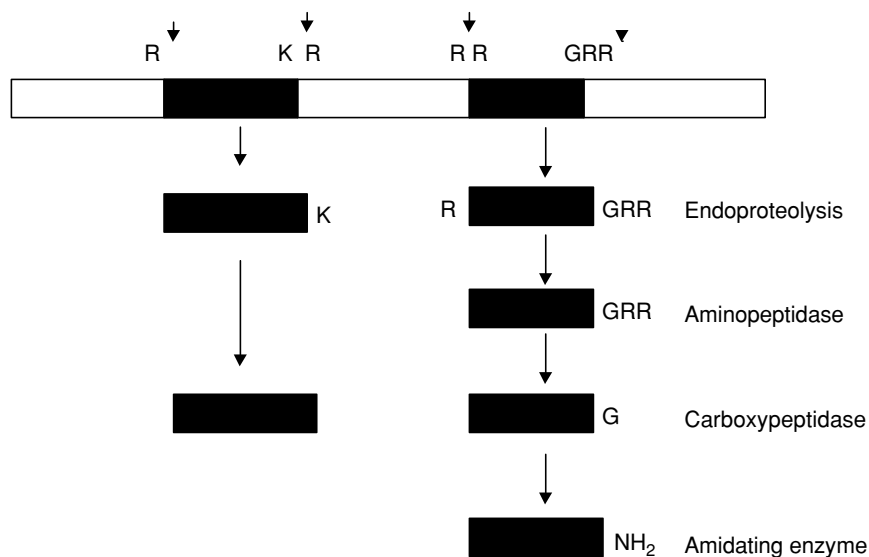

Figure 1 Schematic diagram of the sequential modifications required to produce an amidated peptide (on the right) and a non-amidated peptide (on the left). The active peptide is indicated by the black boxes. The cleavage sites are indicated by the down arrows. R, arginine; K, lysine; G, glycine.

related to the enzyme subtilisin from the bacteria *Bacillus subtilis*. A large body of experimental evidence suggests that three members of this family are the most important for endoproteolysis in endocrine and neuronal cells that possess the regulated secretory pathway PC1, PC2, and PC5. These enzymes are widely distributed in the brain and in endocrine tissues and are present in a number of endocrine and neuronal tumor cell lines. They appear to have the correct catalytic activity and inhibition or deletion of their expression has been shown to alter the processing of prohormones that they express.

After endoproteolysis, exoproteases, such as carboxypeptidases and aminopeptidases, remove basic amino acids that may have been left on the peptides that were excised by endoproteases (see Fig. 1). These residues are not needed for biological activity and in some cases need to be removed to expose a glycine residue, so that it can be converted to a carboxy-terminal amide by the amidating enzyme. A number of carboxypeptidase enzymes that have the correct activity have been identified; carboxypeptidase E appears to be responsible for the processing of many, but not all, peptides.

The amidation reaction is probably the last modification and it is performed by a copper- and ascorbate-requiring enzyme. This amidation modification is found in approximately one-half the biologically active peptides and, in these peptides, it is essential for biological activity. In all cases, the immediate

precursor of the amide is a glycine residue on the carboxyl terminus. This reaction is catalyzed by a multifunctional enzyme called peptidyl- α -amidating monooxygenase (PAM).

The vesicles containing the processed peptides are transported to the site of release and wait until an appropriate signal arrives, such as depolarization or increased external calcium, to cause them to fuse with the plasma membrane, releasing their contents outside the cell.

TWO EXAMPLES OF DIFFERENTIAL PROCESSING

Most peptide prohormones do not display differential processing; however, there are a number of them that do. Two examples are described.

The proopiomelanocortin precursor is one of the first examples of differential processing to be discovered. As shown in Fig. 2, POMC mRNA is expressed in the anterior and intermediate lobes of the pituitary and in the brain of the rodent. The products that are isolated from these tissues are quite different and that is a result of differential tissue-specific processing. The anterior lobe makes larger forms, whereas the intermediate lobe and the brain make smaller, more highly processed forms.

The other example is pro-cholecystokinin processing. The biosynthesis of cholecystokinin (CCK) is

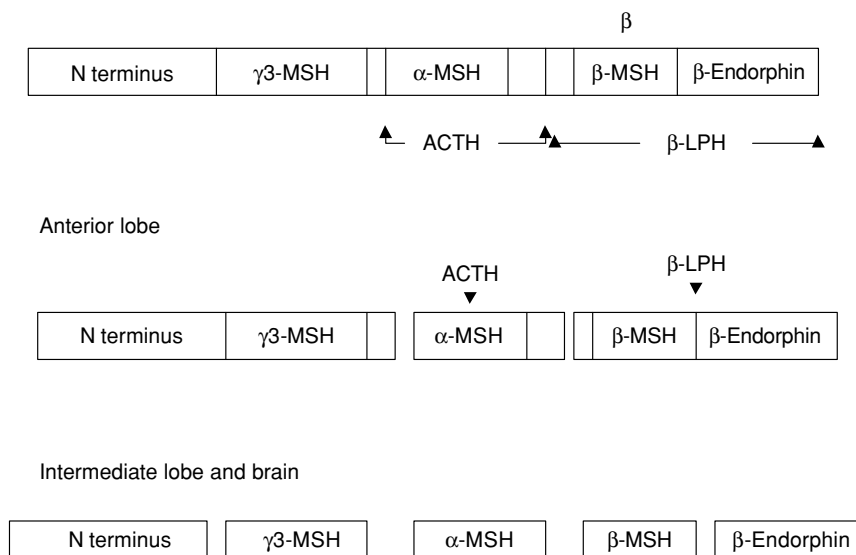

Figure 2 Schematic diagram of differential processing of POMC in the anterior, intermediate lobes of the pituitary and the rodent brain. Intact POMC is shown at the top of the figure. The major products found in the anterior lobe of the pituitary are shown in the middle and the major forms found in the intermediate lobe and brain are shown at the bottom. ACTH, adrenocorticotrophic hormone; β -LPH, β -lipotropic hormone; MSH, melanocyte-stimulating hormone.

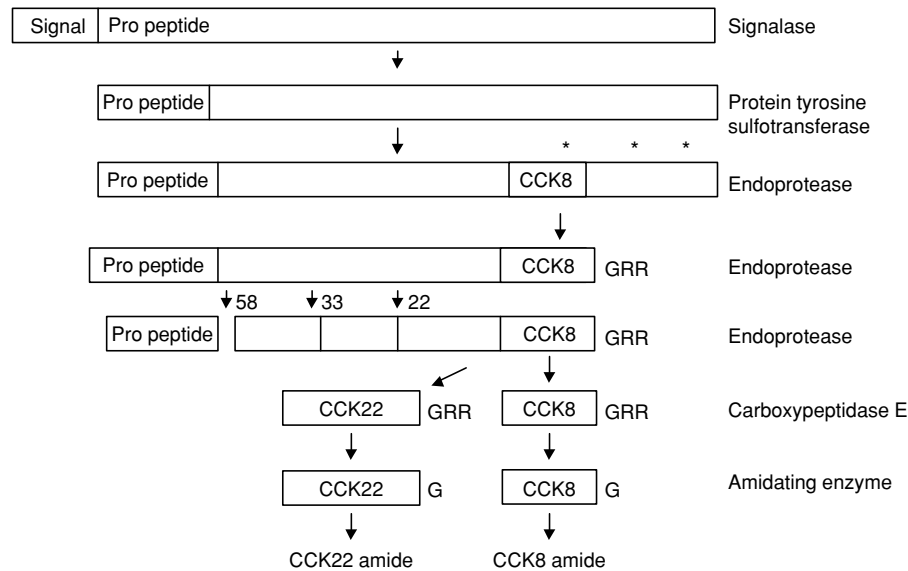

Figure 3 Schematic diagram of the temporal order and the enzymes involved in pro-CCK processing and how different forms of CCK are produced. This diagram shows the production of CCK22 and CCK8. Larger forms are cleaved at sites indicated by the down arrows.

shown in Fig. 3. This case is different and simpler than that for POMC. The forms of CCK that are found are different in size, but they share the same CCK8 amide moiety and have similar biological activity. CCK8 is the major form found in mammalian brain, whereas mammalian intestine makes mainly larger forms of CCK, such as CCK22, CCK33, and CCK58. All of the CCK found is tyrosine sulfated.

A related peptide, gastrin, which shares some homology with CCK, is found in both sulfated and unsulfated forms. Like CCK, it comes in different sizes (gastrin 14, 17, and 34) that have the same biological activity. The degree of sulfation varies with the age of the animal. This represents an additional aspect of differential processing.

THE MECHANISM OF DIFFERENTIAL PROCESSING

The mechanism of differential processing is not completely understood. The most likely explanation is tissue-specific differences in the distribution and activity of the endoproteases.

THE PHYSIOLOGICAL SIGNIFICANCE OF DIFFERENTIAL PROCESSING

Differential processing happens for a reason. The process of producing peptides is very energy-dependent

and represents a major commitment on the part of the cell producing the peptides. In both of the examples described, some of the final peptides have different physiological roles. One of the major products of POMC processing is adrenocorticotrophic hormone, the peptide responsible for stimulating corticosterone secretion from the rodent adrenal gland. It is made in the anterior pituitary, where it is destined for secretion into the circulation. It would not be useful to make it in the brain as it would reach the adrenal with difficulty. In contrast, other forms, such as the melanocyte-stimulating hormone peptides and β -endorphin, are made in the brain, where they serve neurotransmitter or neuromodulator roles.

In the case of CCK, a similar reasoning applies. CCK is a major gastrointestinal hormone that is released into the bloodstream from the intestine after a meal to regulate food intake, gallbladder contraction, and pancreatic enzyme secretion. The larger forms of CCK made and released by the intestine are more stable in circulation than the smaller forms, so they make better hormonal agents. CCK8, the major form found in brain, is a neurotransmitter or neuromodulator. It is released in small amounts at the synaptic cleft, excites its receptor, and is rapidly degraded.

Another interesting aspect of the differential processing of pro-CCK and gastrin involves the existence of glycine-extended peptides. Different tissues contain varying amounts of glycine-extended CCK and gastrin peptides. These peptides have not been converted to

amides by the amidating enzyme. Interestingly, these peptides are reported to have their own receptors and biological activity distinct from the receptors that bind amidated CCK and gastrin peptides. In this case, regulation of PAM activity may be controlling the production of these peptides to subserve specific physiological functions.

maintaining homeostasis, enabling the organism to develop, grow, and reproduce normally and to respond effectively to a wide range of environmental demands and stresses. By definition, they are released into the circulation and thereby reach distant targets, but many are also released locally where they influence neighboring cells via paracrine mechanisms or signal across synaptic junctions in the case of neurons in the central nervous system (CNS).

These important regulatory peptides or their precursors are all encoded in typical genes that are expressed via the conventional transcriptional and ribosomal mechanisms of protein biosynthesis. However, they are translated initially as presecretory proteins that are directed into the secretory pathway at the level of the endoplasmic reticulum (ER) via N-terminal signal peptides that interact with SRP (signal recognition particle) and SRP receptors. During or shortly after translocation, they fold and undergo signal peptide cleavage in the ER cisternae, are transported to the Golgi apparatus, and are then stored intracellularly in mature secretory vesicles (storage granules) awaiting secretory signals or, in some instances, are secreted constitutively in an unregulated manner (Fig. 1). In rare instances, proteins destined for secretion may lack a typical N-terminal signal peptide, achieving entry into the secretory pathway or direct exit from the cell by alternative intrinsic motifs acting via mechanisms that are not well understood. Important requirements for most peptide hormones and neuropeptides are that their sorting and retention within secretory granules are highly efficient and that they are discharged by exocytosis only in response to nutrients, metabolites, neurotransmitters, or other hormonal signals, i.e., that their secretion is tightly regulated. Achieving this requires that neuroendocrine cells express certain gene combinations, or modules, that encode components of a regulated secretory pathway to receive and store the secreted products, as well as mechanisms for directing the newly synthesized hormonal peptides, often as precursors, into this highly developed arm of the secretory pathway. This sorting mechanism must either actively or passively allow these products to gain access to secretory granules as these form in the *trans*-Golgi network (TGN). Once formed, secretory granules mature in the cytosol and become competent for secretion. They then are released in response to signals by exocytotic fusion of the granule membrane with the plasma membrane.

REGULATION OF PEPTIDE HORMONE BIOSYNTHESIS

The biosynthesis of most peptide hormones is regulated at multiple levels. The rate of transcription of the gene encoding the hormone is usually responsive to the level of demand for the hormone. The transcriptional complex is usually made up of combinations of various transcription factors, coactivators, repressors, and elements of the basal transcriptional machinery. Individual components may also be regulated by phosphorylation/dephosphorylation, proteolysis, or other rapidly acting modulatory signals. The stability of the mRNA is also regulated in many instances. However, these regulatory actions can act only at a relatively slow pace over periods of hours or even days to alter the levels of mRNA for the hormone, as it usually constitutes a very major proportion of the total mRNA of the endocrine cell. For example, insulin mRNA makes up approximately 10% of the total pancreatic beta cell mRNA population. Hence, it is difficult to rapidly modulate proinsulin synthesis on a minute-to-minute basis via this mechanism, whereas long-term adjustments to increased demand rely on this level of control.

The rate of translation of the particular mRNA encoding a hormone is also often closely controlled, independently of other cellular mRNAs, leading to rapid changes in the rate of hormone biosynthesis. This modulation occurs largely at the level of initiation of translation through mechanisms that vary the number of mRNA molecules being translated at any given time. The precise mechanism of regulation of translation remains unclear, but clearly involves signal transduction pathways that can act within seconds to minutes to modulate both initiation and elongation rates, but only the former is known to be specific for a particular (hormonal) product. As a result, the rate of synthesis can be greatly accelerated or shut down very rapidly in response to signals such as the glucose level in the pancreatic beta cell.

The result of the operation of the above-described mechanism regulating hormone biosynthesis is to maintain a relatively constant large pool of hormone in the secretory granules (for example, there are as many as 13,000 granules containing insulin, approximately 5×10^{-15} mol in each beta cell). Active bursts of secretion can lead to rapid fluctuations (5–20%) in the size of the granule pool, which is then replenished more slowly, by synthesis, usually over a period of several hours. Prolonged or excessive stimulation of secretion, however, can

Figure 1 Subcellular organization of the biosynthetic pathway of a protein/peptide hormone within a typical neuroendocrine cell—the pancreatic islet beta cell. The preprohormone is synthesized by ER-associated ribosomes (RER) and then is cotranslationally sequestered and cleaved to proinsulin within the lumen of the ER. The prohormone chain folds and forms the correct disulfide bonds of insulin within this compartment and then the fully structured proinsulin molecules are transferred to the *cis*-Golgi region in small coated vesicles. After traversing the Golgi, the prohormone is sorted from the *trans*-Golgi network (TGN) into secretory granules, processed by convertases to insulin, and ultimately released from the cell by exocytosis, as shown. Arrows indicate the direction of movement via subcellular compartments. The regulated secretory pathway is shown on the left and the unregulated, or constitutive, pathway is shown on the right. Timescales indicate intracompartamental residence times. Dashed arrows indicate alternative or minor pathways of (pro)hormone sorting as follows: (1) from the TGN to the lysosomes via the mannose-6-phosphate pathway for degradation; (2) from the early immature secretory granules via small clathrin-coated vesicles that link to the constitutive pathway, i.e., “constitutive-like” secretion; (3) from mature granules to lysosomes, a pathway of intracellular degradation of unused mature secretory granules via autophagy, and (4) a proposed endocytic pathway for recycling excess membrane from the cell surface after exocytosis, along with membrane-associated processing enzymes, such as furin, via endosomes (E), ultimately to the Golgi apparatus (see text for details). Modified from Steiner, D. F. (2001). Biosynthesis of insulin. In “Handbook of Physiology” (H. M. Goodman, ed.), Section 7, “The Endocrine System,” Vol. 11 (L. S. Jefferson and A. D. Cherrington, eds.), pp. 49–78. Oxford University Press, New York.

deplete the granule pool and may lead to abnormal states of glandular hyperplasia, associated with chronic increased production combined with diminished stores due to accelerated turnover of secretory granules.

POSTTRANSLATIONAL PROCESSING OF HORMONE PRECURSORS

Most small peptide hormones, growth factors, and neuropeptides are derived from larger precursor

proteins (proproteins), which are synthesized and transported, as outlined in Fig. 1. After reaching the TGN, these precursor forms begin to interact with specialized endoproteolytic enzymes, the prohormone or proprotein convertases, commonly referred to as PCs, which carry out the proteolytic excision of their product hormone or hormones. The convertases are serine proteases, related to bacterial subtilisin and the yeast convertase, kexin (Fig. 2). Some members of the nine-member convertase family (furin, PC6B, and PC7) are tethered by C-terminal transmembrane domains to the TGN membrane and cycle to the cell surface and endosomes in constitutive vesicles, whereas others, such as PC2, PC1/3, and PC5/6A, are efficiently sorted into newly forming secretory granules along with newly synthesized precursor proteins and carry out their proteolytic processing within this subcellular compartment. The processing of a much-studied typical peptide hormone precursor, proinsulin, is illustrated schematically in Fig. 3. The convertase PC1/3 acts first to cleave on the C-terminal side of the pair of arginine residues spanning the junction between the insulin B chain and C peptide (B–C junction), creating an intermediate form: 32,33 split proinsulin. A second enzyme, carboxypeptidase E (CPE), an exoprotease, then rapidly removes the basic residues that remain attached to the C terminus of the B chain. PC2 then preferentially recognizes this intermediate and cleaves at the basic pair linking the C peptide to the A chain (C–A) junction, followed by removal of the basic residues from the C peptide by CPE. This sequence of four reactions gives rise to mature insulin and C peptide, the two major secreted products of the beta cell. These products remain stored in mature secretory granules pending their release by exocytosis in response to glucose or other signals or until their ultimate intracellular turnover if they remain unused.

Proinsulin conversion provides a paradigm for the proteolytic processing of most, but not all, of the many other neuroendocrine precursor proteins. Intragranular processing is also an appropriate mechanism for the processing of neuropeptide precursors. These are sorted into small, dense-core vesicles in the neuronal cell body and undergo maturation as the vesicles migrate along microtubular networks within axons to distal synaptic junctions, where they are stored and secreted. Proteolytic processing thus typically begins 15–30 min after biosynthesis of the precursor, as it initially must traverse the secretory pathway from the ER via the Golgi apparatus and into the granules, and it then continues over a period of several hours. The overall time-course exhibits

pseudo-first-order kinetics with half-times for precursor to product disposition of 30 min to 1 h in warm-blooded species. This relatively slow time-course of maturation of secretory products is thus well adapted to the kinetics of axonal transport, but also is well suited to most endocrine cells, which usually contain large granule stores that are only partially depleted by normal secretory demands.

SPECIFIC EXAMPLES OF PROHORMONE PROCESSING

Islet Hormones

Whereas both PC2 and PC1/3 are expressed at high levels in the insulin-producing pancreatic beta cells, the islet alpha, delta, and gamma cells that produce glucagon, somatostatin-14 (SS-14), and pancreatic polypeptide, respectively, express only PC2 and this convertase acts alone to cleave these hormones from their precursors. PC2 null mice have been produced and are essentially completely blocked for glucagon production, exhibiting a chronic mild hypoglycemia and alpha cell hyperplasia that can be corrected by chronic glucagon administration. The processing of proglucagon is more complex, however, as this multifunctional precursor also contains the additional biologically active peptides, glucagon-like peptide-1 (GLP-1) and GLP-2. These peptides are excised from proglucagon when it is expressed in intestinal L cells that contain only, or mainly, PC1/3. This convertase processes proglucagon at several distinct sites to release GLP-1 (7–37) and GLP-2, whereas glucagon remains in an inactive form as part of larger N-terminal fragments (glycentin and/or oxyntomodulin), as illustrated in Fig. 4. Note that in pancreatic alpha cells, GLP-1 and GLP-2 are released only as inactive components of the larger, unprocessed C-terminal fragment called the “major proglucagon fragment.” Prosomatostatin processing to SS-14 in the islet cells, as noted above, requires PC2 and this is also the case in brain. In PC2 null mice, SS-28 accumulates instead of SS-14 through the action of an as yet unidentified convertase (Fig. 4).

In the beta cells, PC2 ablation leads to significant (30–35%) accumulations of proinsulin, including elevated levels of des-31,32 proinsulin intermediate (normal value less than 5%), whereas PC1/3 ablation causes a more severe proinsulin processing defect, associated with high levels of intact proinsulin and elevated des-64,65 proinsulin intermediate (85–90% of total insulin-related material). Thus, PC1/3 appears to be more important than PC2 for proinsulin processing

Figure 2 Structural organization of the eukaryotic prohormone convertase family. All members have a preregion (Pre) and a proregion (Pro) followed by a subtilisin-like catalytic domain (Cat) having conserved Asp (D), His (H), Asn (N), and Ser (S) residues that form the catalytic triad (D, H, S) and the transition state-stabilizing oxyanion residue (N). Note that the latter is (D) rather than (N) in all PC2s examined in both vertebrates and invertebrates. The catalytic domain is followed by the conserved and essential P domain, which is necessary for the folding and stability of the enzymes. The variable C-terminal region determines the subcellular localization and sorting of the convertases. Those with transmembrane (TM) and/or cysteine-rich (CR) regions (e.g., furin, PC5/6B, PC7) are usually found in the distal Golgi or TGN, where they become active at the slightly acidic pH of this compartment and function mainly in the constitutive pathway. The convertases usually undergo autocatalytic propeptide cleavage as they exit the ER, but do not release the propeptide or become active on substrates until they reach their Golgi/TGN destination. Pro-PC2 is again exceptional in that propeptide cleavage occurs in a later compartment (TGN/secretory granules) and activation follows this cleavage only if pro-PC2 has interacted with NE protein 7B2 during intracellular transit to the Golgi. (See text for more details.) All the convertases and the yeast furin homologue kexin require micro- to millimolar calcium concentrations for activity. Kexin has a serine/threonine-rich region following the P domain (S/TR). The convertases lacking TM domains, especially PC2, PC1/3, PC4, and PC5/6A (A), are not retained in the Golgi, but instead enter the regulated secretory granules where their more acidic enzyme optimum (pH 5–6) enhances their processing. Most remain intact, except for PC1/3, which loses its C-terminal 137-residue tail via cleavage at an intrinsic dibasic site either by its own action or by that of other convertases within the secretory granules. This truncated form has enhanced processing activity on some PC1/3 substrates. Shown below kexin are two novel convertases, SKI-1/SPI and NARC-1. These more distantly related forms are also expressed in the secretory pathway and process a variety of precursors, but have significantly altered substrate specificity. Whereas most convertases generally cleave only at sites containing K/R-R↓, R-X-K/R-R↓, or R-X-X-R↓, the novel convertases prefer sites having a hydrophobic residue in both the P1 and P2 positions, e.g., R-X-V-L↓ or Y-V-L-L↓. They also lack other features, having either a highly modified P-like domain (NARC-1) or an unrelated sequence (SKI-1) (A = PC5/6A; B = PC5/6B). AH, amphipathic helix.

and, though either convertase alone is capable of producing some fully processed insulin in the absence of the other (Fig. 4), both are required for normal highly

efficient processing. In contrast, the precursor of islet amyloid polypeptide (amylin), a peptide related to calcitonin/calcitonin gene-related peptide (CGRP), which

Figure 3 Processing of proinsulin by PC1/3, PC2, and CPE in the pancreatic β cell. Although both convertases PC1/3 and PC2 are able to process either of the two sites that must be cleaved to remove the C peptide, PC1/3 prefers the B/C junction and PC2 prefers the C/A site. Moreover, cleavage of the B/C site generates a preferred substrate for PC2, the des-31,32 proinsulin intermediate. Consequently, the pathway shown on the right-hand side is predominant and the pathway on the left probably occurs only to a limited extent. In mice lacking PC2, some insulin is generated (approximately 65% of total insulin-like material) along with elevated levels of des-31,32 proinsulin and intact proinsulin. However, as predicted from this formulation, PC1/3 null mice have a much more severe block in proinsulin processing (less than 10–15% of insulin is generated) associated with a small buildup of des-64,65 proinsulin with large amounts of intact proinsulin. CPE acts after each convertase to remove the two C-terminal basic residues in a stepwise fashion from the split products generated by the initial PC1/3 or PC2 cleavages, giving rise to the two naturally occurring major stored products in beta cells, insulin and C peptide (bottom structure). The fate of the basic residues released in precursor processing is not known.

is also expressed mainly in the islet beta cells, is more dependent on PC2 than PC1/3 for its processing. In PC2 nulls, only N-terminally extended pro-islet amyloid polypeptide (pro-IAPP) intermediate material is produced, whereas PC1/3 nulls exhibit only a modest accumulation of unprocessed material (see Fig. 4).

Gastrointestinal Hormones

Whereas PC1/3 clearly plays an essential role in proglucagon processing in the intestinal L cells to generate GLP-1 and GLP-2, as mentioned above, it is also

necessary for cholecystokinin (CCK) maturation in intestinal I cells, as well as a major portion of gastrin maturation in antral G cells. However, neural processing of CCK in PC1/3 null mice is unaffected, indicating the likely involvement of other convertases in the CNS processing of CCK precursors. The effects of PC2 deficiency on gastrin processing are also partial, indicating that other convertases expressed in the antral gastrin-producing G cells (e.g., PC1/3 and PC5/6) may also be capable of cleaving at specific K-K sites to generate mature gastrin. Such sites, which have a P1 (first upstream position) lysine (K) rather than an arginine (R) residue, are frequently substrates for PC2.

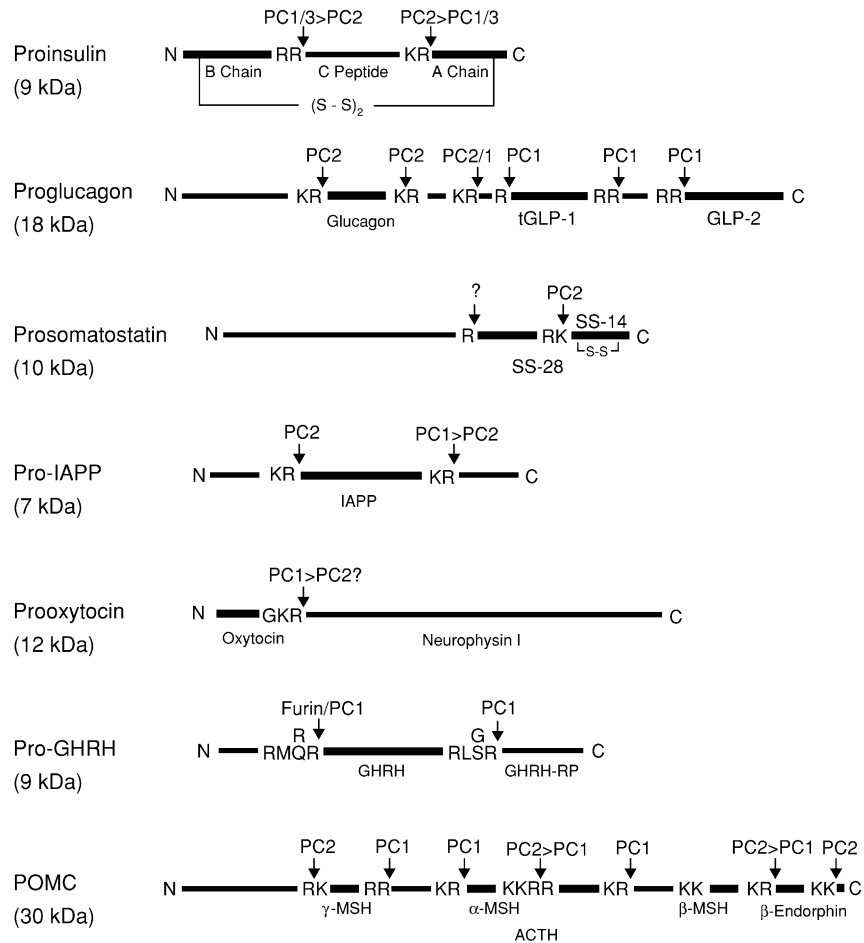

Figure 4 Selected examples of peptide prohormone precursor structure illustrate the diversity in size and structural organization of this subset of the many kinds of proproteins that are processed in the secretory pathway by the PC family of convertases. The N-terminal signal peptides are not shown here, as these are usually cleaved off by signal peptidases in the ER before synthesis of the entire peptide chain is completed (i.e., within the first 1–2 min postinitiation of translation *in vivo*). The active regions in these precursors are all represented by thicker lines and the surrounding inactive prosequences are represented by thin lines. The lysine (K) and/or arginine (R) residues at cleavage sites are indicated and usually occur as pairs. However, in some precursors, upstream basic residues are sometimes present, as indicated in the GHRH sequence. Above each site is indicated the convertase or convertases that cleave at that site in order of their processing efficiency at that site, as shown by *in vivo* or *in vitro* studies, as discussed in the text. Superscripts R and G above the pro-GHRH sequence denote substitutions found in the human vs mouse proteins.

Other gut hormones, such as motilin, ghrelin, secretin, peptide YY, vasoactive intestinal polypeptide, and glucose-dependent insulinotropic peptide/gastric inhibitory peptide, are also derived from precursors, but little is known about their processing requirements.

Hypothalamic and Pituitary Hormones

Adrenocorticotrophic hormone (ACTH) is the only major anterior pituitary hormone that is derived from a proprotein precursor. Its precursor, proopiomelanocortin (POMC), is perhaps the most remarkable

example of a large multifunctional precursor (Fig. 4). POMC contains within its ~30 kDa sequence a large N-terminal proregion that is believed to be involved in its sorting into the regulated secretory pathway followed by a melanocyte-stimulating hormone (MSH)-like sequence, γ -MSH, that has been found to play a role in blood pressure regulation via the melanocortin 3 receptor (MCR3). A joining peptide is then followed by the 39-residue ACTH sequence, the first 13 amino acids of which also can be cleaved out, acetylated, and amidated to produce α -MSH (melanocortin), another important MSH-like sequence that acts via MCR4 to regulate

food intake and through MCR1 to influence pigmentation. The ACTH sequence is followed by that of β -lipoprotein, a large C-terminal peptide that contains another MSH-like sequence (β -MSH) and ends in β -endorphin, an opioid peptide family member that contains the 5-residue Met enkephalin sequence at its N terminus.

The processing of POMC differs significantly between the anterior and intermediate lobes of the pituitary. Anterior pituitary corticotrophs express mainly PC1/3 and this convertase is responsible for selected cleavages in POMC that produce mainly ACTH and smaller amounts of β -endorphin (Fig. 4). These peptides are secreted in response to stressful stimuli under the influence of hypothalamic corticotropin-releasing hormone/factor (CRH/CRF) transported to the pituitary directly via the hypothalamic–hypophyseal portal vein system. Humans or mice lacking PC1/3 are unable to produce mature ACTH, but exhibit only a mild degree of adrenocortical insufficiency. In the neurointermediate pituitary lobe (more prominent in rodents, absent in human), both PC1/3 and PC2 are expressed and the added PC2 acts mainly to increase the production of the MSH-like peptides (α , β , and γ) from POMC (Fig. 4). CPE or its homologues, N-acetylases and the bifunctional peptidyl amidating monooxygenase (PAM), also act on many of these products to acetylate N termini and/or remove C-terminal basic residues to expose C-terminal glycine residues that are then converted to carboxamides by the action of PAM.

The posterior pituitary hormones oxytocin and vasopressin are derived from homologous precursors that also contain their corresponding neurophysins or binding proteins (Fig. 4). The nonapeptide hormones lie at the amino terminus in their precursors and thus only a single cleavage is required for their maturation (after signal peptide excision). It appears that either PC1/3 or PC2 or both of these convertases may be involved in the processing of provasopressin and prooxytocin in their cells of origin—the magnocellular neurons of the supraoptic nuclei at the base of the hypothalamus.

The hypothalamus is also the source of several releasing factors that control the secretion of anterior pituitary hormones, as well as various other peptide hormones/neuropeptides that regulate appetite, food intake, and energy balance. The four major hypothalamic releasing factors are CRH, gonadotropin-releasing hormone (GnRH), growth hormone-releasing hormone (GHRH), and thyrotropin-releasing hormone (TRH). The first three are derived from linear proproteins having an AB (CRH), a BC (GnRH), or

an ABC structure (GHRH), where B represents the active sequence and A and C are propeptides. Processing on the N-terminal side of GHRH can be accomplished *in vitro* by furin, PC1/3, and PC5A, whereas the C-terminal site is cleaved preferentially by PC1/3 (Fig. 4). In mice lacking PC1/3, GHRH is not processed normally, leading to the accumulation of higher molecular weight forms that lack activity. As a consequence, the mice exhibit postnatal growth retardation accompanied by low levels of growth hormone and insulin-like growth factor-I. The mode of processing of the other releasing factor precursors has not yet been investigated in detail. However, GnRH function is relatively normal in both PC1/3 and PC2 null mice, whereas TRH production appears to be reduced in PC1/3 nulls. *In vitro* studies of TRH processing indicate that both PC1/3 and PC2 are required for efficient processing of its multicopy precursor, which contains at least five copies of the sequence Lys-Arg-Gln-His-Pro-Gly-Lys-Arg. After PC cleavage, CPE and PAM then process it to give rise to Gln-His-Pro-NH₂, which is then cyclized at position 1 to pyroGlu-His-Pro-NH₂, the mature releasing hormone.

Peptides involved in hypothalamic regulation of food intake include leptin, agouti-related protein (AGRP), α -MSH, neuropeptide Y (NPY), GLP-1, cocaine and amphetamine related transcript (CART), orexin-A, and orexin-B. As noted earlier, α -MSH processing requires PC2 and PC1/3, whereas GLP-1 processing requires only PC1/3. The CART precursor, pro-CART, also requires both PC1/3 and PC2 to produce the two major active isoforms CART I (55–102) and CART II (62–102). However, PC2 is the major convertase producing CART II. The CART precursor exists in two isoforms differing in length in the N-terminal propeptide region due to alternative splicing of the mRNA. Both PC2 and PC1/3 have been reported to be able to process pro-NPY, but *in vivo* PC2 may predominate in sympathetic neurons. The requirements for processing pro-NPY are not well defined. Leptin, AGRP, and the orexins are not processed by convertases.

The opioid peptides arise mainly from three major precursors; proenkephalin, prodynorphin, and POMC. Both PC1/3 and PC2 appear to be involved in the full maturation of these multicassette precursors, as noted earlier in the case of POMC. The PC2 null mice, however, exhibit major deficits in enkephalins and dynorphins, suggesting that this convertase plays a major role in processing *in vivo*. A dual role for both convertases has been found in processing the proorphalin/nociceptin precursor and also the promelanin-concentrating hormone precursor. The neurotensin/

neuromedin precursor is processed by PC2 together with PC1/3 or PC5/6A.

Parathyroid Hormone and Calcitonin

The biosynthesis of parathyroid hormone (PTH) differs significantly from that of most of the others discussed above because of its unusual structure, mode of processing, and secretory regulation. Pro-PTH bears only a hexapeptide extension at its N terminus, analogous to that in proalbumin (Fig. 4). Proalbumin is processed by furin and is secreted constitutively from hepatocytes. However, PTH secretion is regulated primarily by circulating calcium levels. The PTH prohormone is also processed by furin and/or PC7 and is then either secreted or degraded intracellularly by lysosomal cathepsins, dependent on the ambient calcium concentrations, rather than being stored. This unique mechanism seems to represent a special adaptation to regulation via calcium sensing. Less is known regarding the biosynthesis and processing of procalcitonin (Fig. 4), aside from the derivation of its mRNA via alternative splicing of a single gene that encodes both calcitonin and the homologous CGRP on separate interchangeable exons. CGRP is expressed mainly in the brain and autonomic systems, whereas calcitonin is secreted mainly from the thyroid medullary C cells. Both PC1/3 and PC2 have been identified in calcitonin/CGRP-producing cells. IAPP is also a member of this family (Fig. 4).

ADDITIONAL POSTTRANSLATIONAL MODIFICATIONS

Glycosylation

Both N-glycosylation and Ser/Thr glycosylation occur in the secretory pathway. N-Glycosylation involves the addition of preformed mannose-rich immature polysaccharides to asparagine residues. It usually occurs early in the secretory pathway in the ER, where it assists in peptide folding and ER quality control. The glycoprotein hormones thyroid-stimulating hormone (TSH), follicle-stimulating hormone (FSH), and luteinizing hormone (LH) are the most prominent examples in this category, but prohormones, such as POMC, also are N-glycosylated. In some instances, correct N-glycosylation influences biological activity, e.g., TSH glycosylation is regulated by TRH. Rarely, O-glycosylation of serine or threonine residues takes place during later stages of transit from the ER to the Golgi or in the *cis* or medial Golgi cisternae after peptides have exited the ER. This type of modification has been described in POMC and is also

postulated to occur in proglucagon, but its role remains obscure.

Other Modifications

C Terminus

Many neuropeptides are modified by amidation to enhance their stability and/or receptor-binding potency. This modification usually results whenever a C-terminal glycine is present or is exposed by the actions of a carboxypeptidase E-like activity during the maturation of a precursor. The glycine then becomes a substrate for the dual-activity PAM complex, a single polypeptide having two enzymatic activities. Many examples of such modifications exist, including GLP-1 (7–37)-amide, vasopressin, oxytocin, and α -MSH.

N Terminus

Peptide hormones are sometimes modified by N-acetylation, as in the case of α -MSH. This modification results from the transfer of an acetyl group from acetyl coenzyme A to the N-terminal amino group. Other N-terminal modifications result from cyclization of N-terminal glutamine to pyroglutamic acid. Such modifications enhance stability by preventing the action of aminopeptidases. In very rare instances, amino mono- or dipeptidases act on precursor proteins following their maturation to remove interfering N-terminal residues. Examples are the activation of the yeast α mating factor and honey bee promellitin by an aminodipeptidase, which removes several successive Glu-Ala dipeptides as secondary cleavages during the maturation of these biologically active peptides.

Sulfation/Phosphorylation

Phosphorylation of serine or threonine residues occasionally occurs, e.g., in POMC. However, the role, if any, of this modification is not apparent. Sulfation of tyrosine residues, however, is found in gastrin and some other peptide hormones, where it often enhances biological activity.

Lipid Modifications

A number of lipid modifications of proteins are well known, including prenylation, palmitoylation, and cholesterol addition; these modifications have not yet been described in peptide hormones. However, it has been shown that ghrelin, a hormone produced in the stomach that regulates appetite and also stimulates growth hormone release, is octanoylated at position 3,

a serine. This modification is necessary for biological activity and also might be expected to influence the behavior of the peptide in the circulation due to its added lipophilicity. The mechanism of addition of octanoate is not known.

DEFECTS IN PEPTIDE HORMONE BIOSYNTHESIS

Inherited Defects

Hormone deficiencies can arise from defects at many levels in the processes that underlie the production and/or action of hormones. Genetic defects play a prominent role by affecting the structure, synthesis, folding, intracellular transport, processing, and release of hormonal peptides. A number of inherited defects in proinsulin structure that influence the folding, sorting, processing, and/or biological activity of insulin have been described. The Akita mouse is diabetic due to a point mutation that changes the A7 cysteine to arginine in proinsulin II, resulting in misfolding of proinsulin, severe ER stress, and ultimately beta cell failure and cell death, leading to hyperglycemia. Another point mutation at position B10 (His → Asp) in human proinsulin causes selective mis-sorting of some of the mutant proinsulin into the constitutive secretory pathway, causing elevated circulating proinsulin levels. Other insulin gene mutations have less dramatic phenotypes, but are often associated with mild familial MODY (maturity-onset diabetes of the young)-like diabetes (autosomally dominant forms of diabetes). Some of these single point mutations affect proinsulin cleavage sites, especially at the C peptide–A chain junction, and lead to elevated circulating levels of partially cleaved proinsulin intermediates, whereas those of another group affect insulin structure, lowering its biological activity by factors of up to 1000-fold. Defects of a similar nature that influence the biosynthesis, translocation, folding, processing, or receptor binding and activity have also been described in a number of other protein hormones or their precursors, including growth hormone, leptin, POMC, PTH, TSH, LH, FSH, and vasopressin in both human and experimental animals (e.g., vasopressin in the Brattleboro rat and leptin in the ob/ob mouse). Such mutations cover the gamut of possibilities, including disordered splicing, frame-shifts, deletions, and point mutations. Gene disruptions of a number of hormones or their precursors, including growth hormone, prosomatostatin, proenkephalin, POMC, pro-TRH, and pro-NPY, have also been carried out in the laboratory.

Inherited defects in transcription factors that can influence hormone gene expression and secretion have also been described, in addition to the large numbers of such mutations that have already been described in the membrane and nuclear receptor families that influence hormone action. Mutations in PDX-1, a beta cell-specific transcription factor that influences both proinsulin and prohormone convertase gene transcription, lead to diminished insulin production, giving rise to the MODY4 syndrome. Other forms of MODY are caused by mutations of the beta cell glucose-sensor protein, glucokinase (MODY2), or in several hepatic nuclear factor genes, including HNF4 α (MODY1), HNF1 α (MODY3), and HNF1 β (MODY5), that regulate beta cell glucose metabolism and insulin secretory responses to glycemic stimuli.

Processing Enzyme Defects

It is clear that defects in the prohormone convertases can produce multifaceted endocrine/metabolic disorders in human subjects, as well as in knockout mouse models. Some of the consequences of gene disruption of PC1/3 and PC2 have already been described above. PC2 null mice are surprisingly vigorous despite the lack of glucagon, SS-14, α -MSH, and γ -MSH and relatively severe deficits of opioid and several other neuropeptides. Interestingly, many of the features of PC2 ablation are reproduced in the 7B2 null mouse. The multifunctional 28 kDa neuroendocrine protein 7B2 contains a potent PC2 inhibitory region at its C terminus, but also contains another domain that plays an essential role in pro-PC2 activation. Thus, 7B2 null mice have no active PC2 and share many aspects of the PC2 null phenotype, but unlike PC2 nulls they tend to oversecrete ACTH, which accumulates in the pituitary intermediate lobe in the absence of PC2, and this leads to the development of fulminating Cushing's-like syndrome early in life, leading to death at 5–6 weeks. Altered dopaminergic regulation of interleukin secretory activity seems to underlie this phenomenon, but strain differences in mice with this mutation also appear to contribute to its severity.

Mice lacking PC1/3, as noted earlier, exhibit abnormalities in growth, due to a lack of mature GHRH, but also have a complex polyendocrinopathy resulting in part from disordered hypothalamic/pituitary processing of POMC, as well as of gastrointestinal (GI) processing of proglucagon to GLP-1 and GLP-2, and the production of other GI peptide hormones, as well. These animals exhibit a mild chronic diarrhea with bulky, soft stools, without evident GI mucosal

pathology, suggestive of a motility disorder. In human, PC1/3 deficiency has been described in a 43-year-old woman of normal stature, but with severe obesity that began as early as age 4. This patient also exhibited mild hypogonadism and ACTH deficiency with elevated circulating POMC-like material. Like the PC1/3 null mice, this patient also had a very high proportion of circulating intact proinsulin associated with increased levels of des-64,65 proinsulin intermediate. Two very young subjects lacking PC1/3 have also been studied in the laboratory of Stephen O'Rahilly and associates at Addenbrooke Hospital (Cambridge, UK). Interestingly, these patients suffered from diarrhea and in this respect resembled the PC1/3 null mice.

Another convertase null, the PC4^{-/-} mouse, exhibits defects only in reproductive functions, as this convertase is expressed mainly in testis and ovary.

A spontaneous mutation causing obesity in a mouse strain first identified at The Jackson Laboratory in the 1970s and initially called the "fat" mouse has been shown to be due to an inactivating point mutation in the CPE gene (CPE^{fat}). These animals develop obesity and hyperglycemia, which in males progresses to diabetes. The processing of a large number of prohormones, including proinsulin, is disrupted by a lack of CPE in many parts of the neuroendocrine system. A surprising consequence is the powerful product inhibition of the endoproteolytic activity of the prohormone convertases by the buildup within secretory granules of C-terminally extended intermediates generated by their action. These animals exhibit a polyendocrinopathy with obesity as a major consequence, suggesting that CPE plays an important role in the processing of many key hypothalamic peptides involved in food intake and energy balance, acting in concert with the PCs. Interestingly, neither the PC1/3 or PC2 null mice exhibit obesity, for reasons that are not yet clear.

Conclusions

It is clear that defects are possible at many levels in the biosynthesis and processing of peptide hormones, ranging from their structural genes, their regulatory elements, the specialized transcription factors that regulate the differentiation of their cells of origin or the expression of their genes per se, the regulation of their translation, folding, posttranslational processing, sorting, and retention in secretory granules, and the regulation of the signal transduction pathways and

ion channels leading to secretory granule release. Increased knowledge of such defects can contribute in major ways to the understanding of many common endocrine disorders, including diabetes, obesity, and other disturbances of growth, reproduction, food intake, energy metabolism, stress responses, and aging.

nuclei, lysosomes, and peroxisomes. Proteins that are destined to be secreted, such as (precursors for) peptide hormones, contain a signal peptide at their amino terminus and are translocated to the lumen of the rough ER after cleavage of the signal sequence. Once a secretory protein has reached the lumen of the ER, it does not have to cross an intracellular membrane any longer and moves toward the Golgi complex (Fig. 1). This complex consists of three functionally distinct compartments (*cis*, medial, and *trans*) that correspond to sequential cisternae (rigid lamellae) in its stack. Secretory proteins enter the Golgi on the *cis* side and exit it from the *trans* side to reach the *trans*-Golgi network (TGN) of the secretory pathway. In the TGN, regulated secretory proteins are sorted away from the constitutively secreted proteins, packaged, and concentrated into electron-dense, granular storage vesicles called secretory granules. The number of secretory granules may vary considerably within a cell depending on its functional state. The granules that bud off the TGN are immature and gradually develop to mature secretory granules that are stored in the cytoplasm until the proper and specific stimulus triggers the cell to release the regulated product by the process of exocytosis (fusion of the membrane of the secretory granule with the plasma membrane).

PROCESSING STEPS IN THE ER

Initially, the folding and assembly of newly synthesized proteins into their proper tertiary and quaternary structures were thought to be a spontaneous process. However, it is clear that protein folding in the cell needs to be controlled by helper proteins, termed molecular chaperones, which reduce the probability of formation of incorrect structures. Molecular chaperones are structurally unrelated proteins (e.g., heat shock proteins of the hsp90, hsp70, and hsp60 families) that are part of the cell's protein folding and degradation machinery and that mediate correct protein folding/assembly (without being themselves components of the final structures) or prevent aggregation reactions and premature folding in a number of compartments in a variety of cell types. Their expression is specifically induced by temperature shifts or other cellular stress conditions, but most chaperones are also expressed under normal growth conditions. Examples of ER molecular chaperones include the hsp70 family member immunoglobulin-binding protein (BiP, also known as GRP78), the calcium-binding, integral type I single-spanning membrane protein calnexin, the luminal calnexin-homologue calreticulin, and the soluble acidic protein disulfide isomerase

Figure 1 The secretory pathway in an endocrine cell. Biologically inactive peptide hormone precursor proteins (prohormones) are transported through the various subcompartments of the regulated secretory pathway and undergo a number of processing steps, eventually leading to the regulated secretion of bioactive peptide hormones.

(PDI) that catalyzes thiol:protein-disulfide interchange reactions. Proteins that fold properly in the ER are efficiently transported through the secretory pathway. The export of proteins that fail to fold is prevented by a stringent process of conformation-based ER quality control. These unfolded proteins are rapidly degraded in a pre-Golgi degradation compartment, presumably often involving their reverse translocation back to the cytosol and degradation by a cytosolic proteolytic machinery (the ubiquitin–proteasome system). Accumulation of misfolded proteins in the ER may induce the so-called unfolded protein response, a mechanism protecting the cell against damage caused by improperly folded proteins. In addition to folding, most secretory proteins undergo a number of post-translational modifications in the ER, including disulfide bond formation (facilitated by PDI), glycosylation (proceeding to the TGN), phosphorylation, and oligomerization.

TRANSPORT FROM ER TO GOLGI AND THROUGH THE GOLGI COMPLEX

Once secretory proteins are properly folded and modified in the ER, they move to specialized regions, the ER export sites, and are packaged in coated, irregularly shaped transport vesicles. Following uncoating, the transport vesicles form vesicular–tubular clusters [VTCs; also called the ER–Golgi intermediate compartment (ERGIC)] that move along microtubules to the Golgi. ER-resident proteins (such as the folding enzymes) contain retention and retrieval signals to hold them in this compartment. For example, lumenal ER proteins contain the tetrapeptide retrieval sequence Lys-Asp-Glu-Leu, in single-letter code KDEL, at their carboxyl terminus and these proteins are retrieved by the KDEL receptor. Although it is not clear whether a signal is needed for secretory proteins to leave the ER, receptors have been proposed to be involved in their exit from the ER. One example concerns ERGIC-53, a recycling type I transmembrane protein with an ER retention motif that functions as a mannose-binding lectin to extract secretory glycoproteins from the ER. Furthermore, soluble secretory proteins may be transported via the p24 family of type I transmembrane putative cargo receptors that are major constituents of the transport vesicles and continuously recycle between the ER and Golgi with their short, carboxy-terminal cytoplasmic domains acting as ER export or retrieval signals by binding cytoplasmic coat protein

complexes (COP-I and -II). Each of the transport steps connecting the ER and the Golgi, and connecting the Golgi compartments to one another, is unidirectional and energy- and GTP-dependent. Small GTP-binding proteins (20–30 kDa, e.g., the Rab proteins) are distributed throughout the secretory pathway with distinctive subcellular locations and regulate vesicular trafficking between the subcompartments. In addition, the traffic is regulated by integral membrane proteins [vesicular soluble *N*-ethylmaleimide-sensitive attachment protein receptors (v-SNAREs) and target (t)-SNAREs] for docking the vesicle to the membrane of the acceptor compartment and soluble proteins (NSF and SNAPs) to initiate vesicle fusion. In this vesicular model of protein transport, all anterograde (forward) and retrograde (backward) intra-Golgi steps involve transport only via vesicles. Alternatively, a nonvesicular transport mechanism may be present in which Golgi cisternae form at the *cis*-face of the stack, probably by VTC fusion, and then progressively mature into *trans*-cisternae (cisternal maturation model). In this model, cisternae (or intermittent tubular continuities) carry secretory cargo through the stack in the anterograde direction, and vesicles transport Golgi enzymes in the retrograde direction, allowing cisternal maturation to occur by progressive uptake of material from older stacks. At the TGN, the cisternae ultimately disintegrate and evolve into a collection of secretory vesicles, including immature secretory granules.

SORTING IN THE TGN

If a protein does not possess any sorting signal other than the signal peptide sequence, this protein will be vectorially transported from the ER to the Golgi to the cell surface. Such proteins follow the constitutive pathway, a default route of nonselective bulk flow. The constitutive pathway is a basic feature of all secretory cells and is also responsible for the delivery of integral membrane components (e.g., receptors) to the cell surface. Signal-dependent protein sorting is thought to occur in the TGN. Proteins en route to lysosomes (e.g., lysosomal hydrolases) are modified by the addition of high-mannose chains (mannose-6-phosphate) to their attached N-linked oligosaccharides and this modification allows the lysosomal proteins to bind to mannose-6-phosphate receptors in the Golgi complex (lysosomal pathway). In addition to the constitutive pathway, specialized eukaryotic secretory cells (exocrine, endocrine, and neuronal cells) possess a regulated pathway for the delivery of regulated secretory

products, such as prohormones and prohormone processing enzymes, to the extracellular space; the regulated exocrine pathway is, however, clearly distinct from the (neuro)endocrine route. Sorting signals are likely present to direct (neuro)endocrine proteins to secretory granules and to separate them from constitutively secreted proteins. It is not clear whether such a sorting signal (1) would be recognized by a membrane-bound receptor (with carboxypeptidase E being a proposed but hotly debated receptor candidate); (2) is responsible for the observed spontaneous aggregation of (neuro)endocrine proteins in the mildly acidic, high- Ca^{2+} milieu of the TGN; or (3) is necessary to retain the regulated proteins in the immature granule, away from the budding constitutive vesicle (sorting by retention). Also, lipid microdomains (rafts) in the TGN may be involved in the sorting process by interacting with regulated proteins. Furthermore, members of the granin family of acidic neuroendocrine-specific proteins (chromogranin A, chromogranin B/secretogranin I, secretogranins II and III, and the neuroendocrine polypeptide 7B2) may play a role in the sorting event by acting as an aggregation vehicle for other regulated proteins; granins are major matrix constituents of secretory granules and thus markers for these granules. Finally, when subsets of soluble proteins are packaged into different ER-derived vesicles that, according to the cisternal maturation model, lead to distinct VTCs and Golgi cisternae, presorting of secretory proteins at the level of the ER would occur, thus increasing the efficiency of the final sorting step in the TGN.

BIOGENESIS OF SECRETORY GRANULES

At the TGN, secretory proteins are packaged in immature secretory granules (ISGs), the formation of which may involve lipid rafts, similar to the situation for apical targeting in epithelial cells. ISGs undergo homotypic (ISG–ISG) fusion and gradually develop to a mature secretory granule (MSG) with a change in the size, membrane composition, and content of the granule, and an increased concentration (as much as 200-fold) of the regulated secretory proteins. Furthermore, maturation involves progressive acidification and loss of the clathrin coat because small regions of the maturing granules pinch off as clathrin-coated vesicles that remove soluble proteins for constitutive-like secretion, transport to endosomes, or retrieval to the TGN. The MSGs thus contain only regulated proteins as any constitutive protein is

removed from the ISG by its packaging in the constitutive transport vesicles that readily fuse with the plasma membrane.

POSTTRANSLATIONAL MODIFICATIONS OF PROHORMONES

In addition to glycosylation and phosphorylation in the early stages of the secretory pathway, a secretory protein can undergo sulfation at carbohydrate side chains or tyrosine residues in the late pathway (by carbohydrate and tyrosylprotein sulfotransferases, respectively). The first step in proprotein proteolytic processing is usually an endoproteolytic cleavage in the TGN or ISG on the carboxy-terminal side of a recognition site, often a pair of basic amino acids and mostly Lys-Arg or Arg-Arg. The proprotein processing enzymes are calcium- and pH-dependent serine endoproteases related to the bacterial proteolytic enzyme subtilisin and are called proprotein convertases (PCs). These enzymes are structurally related (most strongly at their active sites) and form a gene family consisting of at least seven members, including furin (also called paired basic amino acid residue cleaving enzyme), the prohormone convertases PC1/PC3 and PC2, and (in yeast) KEX2. Furin and KEX2 are active in constitutively secreting cells. The neuroendocrine-specific enzymes PC1/PC3 and PC2 cleave prohormones and are selectively present in cells equipped with the regulated secretory pathway. Differential expression of PC1/PC3 and PC2 may result in a different secretory output from endocrine and neuronal cells. Furthermore, a single prohormone may give rise to multiple peptide hormones with a variety of bioactivities. For example, processing of proopiomelanocortin (POMC) can result in α -, β -, and γ -melanocyte-stimulating hormones (MSHs), the stress hormone adrenocorticotropin (ACTH), and the endorphins, peptides with endogenous opiate-like activity. POMC cleavage by the PC1/PC3 enzyme generates ACTH, whereas PC2 produces the MSHs and endorphins. PCs become active by autocatalytic cleavage of an amino-terminal propeptide that may act as an intramolecular chaperone for proenzyme folding. The 7B2 protein has been found to act as a chaperone specific for PC2 by transiently interacting with the proenzyme form, facilitating pro-PC2 transport and activation. The pro-SAAS protein, with a structural organization similar to that of 7B2, appears to have PC1/PC3 as its major intracellular binding target. The proper acidic environment in the subcompartments of the secretory pathway, essential for optimal PC cleavage activity, is

supplied by a H⁺-pumping vacuolar-type ATPase. Following cleavage by PCs, exoproteolytic removal of the exposed carboxy-terminal basic residues occurs by the enzyme carboxypeptidase E (or KEX1 in yeast). Finally, the generated peptide may undergo one or two modifications that are crucial for its biological activity, namely, acetylation at the amino terminus and amidation at the carboxy terminus if the peptide ends in glycine (by the enzyme peptidyl-glycine- α -amidating monooxygenase).

ENDOCRINE DISEASES LINKED TO THE SECRETORY PATHWAY

A detailed understanding of the processes by which peptide hormones are produced and released is desirable, as a growing number of endocrine disorders have been linked to malfunctioning transport, sorting, and processing mechanisms in the secretory pathway. For instance, mutations in the thyroid prohormone thyroglobulin may lead to defective prohormone folding and assembly, reduced ER export, and an ER storage disease (hypothyroidism). In patients with familial hyperproinsulinemia, a mutation in the B-chain of proinsulin probably causes improper prohormone folding and sorting with diversion of the mutant molecule from the regulated to the constitutive pathway. Alternatively, in such patients an altered prohormone processing site in proinsulin may occur, resulting in partially cleaved proinsulin intermediates. Familial neurohypophyseal diabetes insipidus may be caused by mutations in the vasopressin–neurophysin II prohormone gene, leading to inefficient signal peptide cleavage, impaired ER export, or improper prohormone folding and resulting in reduced vasopressin production. Familial hypoparathyroidism is due to a mutation in the gene region encoding the signal peptide of preproparathyroid hormone. A mutated exon–intron splice junction gives rise to exon skipping during growth hormone gene expression, resulting in

misfolding of the mutant growth hormone that causes Golgi fragmentation, disrupted ER-to-Golgi traffic, and familial growth hormone deficiency. Another growth disorder (Laron-type dwarfism) can be caused by a mutation in the growth hormone receptor gene, leading to defective membrane expression of the receptor. A form of diabetes mellitus appears to be due to a mutant insulin receptor, leading to disrupted receptor folding and transport. Finally, PC1/PC3-inactivating gene mutations lead to multiple endocrine deficits resulting from defective prohormone processing (obesity, hyperproinsulinemia, and hypogonadism).

proteins identified as being necessary for secretion in yeast would be related to those necessary for neurotransmitter release. Combining these genetic techniques with biochemical techniques, reconstitution assays, and effects on morphology has led to the identification of proteins involved in vesicle-mediated transport from the endoplasmic reticulum to the Golgi complex, for sorting vacuolar proteins from secretory proteins and for transporting proteins from the Golgi complex to the plasma membrane. Many of the proteins identified in yeast turned out to be identical to those involved in vesicle transport in mammalian cells and in neurotransmitter release from synaptic vesicles. In addition, the same proteins were found in neuroendocrine cells and hormone release had the same sensitivity to cleavage of the toxin-sensitive proteins as neurotransmitter release had. These results demonstrated that there are many membrane fusion events in cells with the same underlying mechanisms.

PROTEINS INVOLVED IN SECRETORY GRANULE EXOCYTOSIS AND THEIR POSTULATED FUNCTIONS

The following classes are families of proteins for which there is good evidence that they are involved in membrane fusion.

Soluble *N*-Ethylmaleimide-Sensitive Factor Receptor Proteins

The soluble *N*-ethylmaleimide-sensitive factor receptor (SNARE) proteins came from the original assay for these proteins, which was the ability to bind NSF (*N*-ethylmaleimide-sensitive factor). The best characterized SNAREs are those that were identified as being important for membrane fusion in neurons, based on their sensitivity to toxins: synaptobrevin 2 (or VAMP), syntaxin Ia, and SNAP-25. All SNAREs are membrane-bound and are weakly homologous to one another in sequences of approximately 60 amino acids called the SNARE motif. The SNARE motifs are functionally important for membrane fusion as these sequences mediate the formation of a core complex that initiates the start of membrane fusion (Fig. 1). The core complex has been well described for the three SNAREs mentioned above and consists of a stable complex of synaptobrevin 2, syntaxin Ia, and SNAP-25, composed of four α -helices of SNARE motifs, one each from the C- and N-terminal ends of SNAP-25, one from synaptobrevin, and one from syntaxin. Formation of this complex is necessary for

Figure 1 Steps in exocytosis. (A) A secretory granule is transported to the plasma membrane and is attached to specific sites in ways that are not yet identified. This step is often called docking and may involve munc18a. (B) A second step, sometimes called priming, may involve the start of the formation of the core complex by SNARE proteins. (C) Partial fusion causes merging of one layer of each membrane. (D) Fusion, caused by complete formation of a fusion pore that subsequently fully opens, is driven by complete formation of the core complex of SNARE proteins.

the fusion process to occur and may begin fusion by forcing the two membranes into close proximity (Fig. 1). The SNARE motifs are unstructured when not assembled in the core complex. An exocytotic

fusion complex made from yeast SNARE proteins has similar properties, indicating that vesicle fusion occurs by similar mechanisms in yeast and human. Mutations that cause single amino acid substitutions in SNARE proteins that occur at residues in the core of the α -helix bundle result in severe impairment of the SNARE function of membrane fusion, providing further proof of the importance of these proteins in the process.

Core complex formation among SNAREs is a property with little specificity, so that many SNAREs will bind to one another to make the complex. Therefore, formation of this complex is important for membrane fusion, but does not confer the specificity necessary to ensure that vesicles fuse in the correct locations.

SNAREs are widely distributed in all cells and each SNARE has a characteristic subcellular distribution, although they may be present in more than one intracellular location. Neuroendocrine cells have SNAREs mediating secretory granule exocytosis that are the same as those mediating synaptic vesicle exocytosis, including syntaxin 1A, syntaxin 1B, and SNAP-25, found primarily in the plasma membrane, and synaptobrevin 2 (or VAMP 2), found in the secretory granule membrane.

NSF

The function of this protein is to dissociate the core complex formed by SNAREs. NSF was originally isolated because it is necessary for membrane fusion in reconstituted systems, where it acts with SNAPs (soluble NSF attachment proteins; no relation to SNAP-25) and ATP to allow the core complex of SNAREs to dissociate so that they may recycle to cause more fusion. ATP is hydrolyzed in the process, which makes the action of NSF similar to that of chaperones in the cells that facilitate folding. NSF does not participate in the membrane fusion process directly and appears not to be necessary except to put SNAREs into a state from which they can form a complex.

Sec1/Munc18 Proteins

Sec1/Munc18 proteins (or SM proteins) were originally discovered by genetic screens for secretion in yeast and *Caenorhabditis elegans* and were identified biochemically in mammalian cells as proteins present in nerve endings associated with synaptic vesicles. Investigations with mice lacking munc18a have also shown that the protein is necessary for exocytosis in

mammals. Munc18a binds the SNARE protein syntaxin 1 and it appears that most SM proteins interact with members of the syntaxin family with some degree of specificity. When munc18a is bound to syntaxin, syntaxin is unable to form the core complex with other SNAREs, which suggested a role as a negative regulator for exocytosis, but such a role is not consistent with the data indicating that it is essential for membrane fusion. In mouse adrenal chromaffin cells lacking Munc18a (or Munc18-1), exocytosis of large dense-core vesicles containing catecholamines was reduced 10-fold and the number of vesicles found next to the plasma membrane was reduced 10-fold, but overexpressing munc18a increased the number of releasable vesicles from adrenal chromaffin cells. These results have been interpreted to indicate that SM proteins function in the initial attachment of vesicles to membranes, before the actual process of membrane fusion begins.

Rab Proteins

The Rab family members are relatively small proteins that bind and hydrolyze GTP, initially identified in yeast as being necessary for secretion by genetic screening. There are over 10 Rab genes in yeast and over 60 in mammals; each gene is associated with specific subcellular organelles. Rab3a is one of the best investigated proteins and it is present in large amounts in presynaptic nerve endings. When GTP is bound, Rab3a is associated with synaptic vesicles, and when the GTP is hydrolyzed to GDP, Rab3a dissociates. Dissociation of GDP and rebinding of GTP allow Rab3a to rebind to synaptic vesicles. Rab3a and a similar member, Rab3b, are also present in neuroendocrine cells associated with secretory granule membranes.

Although Rab proteins are implicated in secretion, the exact role has been difficult to define, possibly because each Rab may have more than one role or because Rab proteins from one set of subcellular organelles may be able to substitute when needed for Rab proteins with other distributions. There is evidence that Rab proteins both facilitate and inhibit Ca^{2+} -stimulated exocytosis.

GTPases represent a superfamily of proteins whose mode of action in general is to bind to and activate effector proteins when they themselves have GTP bound, but this property is lost after GTP hydrolysis. Characterization of Rab3 effectors appears to be a way to learn more of the function of Rab3. Several such proteins have been identified; these include rabphilin, a peripheral membrane protein associated with

secretory vesicles, Rim (Rab-interacting molecule), identified in a yeast 2 hybrid screen, and calmodulin, a protein that changes conformation when it binds Ca^{2+} , which allows it to activate many proteins after increases in cytosolic Ca^{2+} .

Synaptotagmins

Both exocytosis from synaptic vesicles and exocytosis from secretory granules occur in response to increases in cytosolic Ca^{2+} and in this respect differ from most fusion of other vesicles involved in intracellular transport. Synaptotagmins are a family of proteins; synaptotagmin I is associated with synaptic vesicles and secretory granules and has been proposed to be the molecule that mediates the Ca^{2+} responsiveness. *C. elegans*, *Drosophila melanogaster*; and mice that lack synaptotagmin have been produced and in all these organisms, neurotransmitter release evoked by Ca^{2+} was reduced. The exact way in which synaptotagmin mediates Ca^{2+} responsiveness is not known; the amino acid residues identified as binding Ca^{2+} in solution using the isolated protein are not necessary for Ca^{2+} responsiveness in neurons. It seems logical that synaptotagmin would exert an inhibitory effect on fusion processes until Ca^{2+} concentrations increase, but a specific mechanism has not yet been elucidated.

STEPS IN FUSION

Although exocytosis from synaptic vesicles and that from secretory granules appear very similar at the final stages, the initial mechanisms for locating the vesicle near the membrane are quite different. Synaptic vesicles form by invaginations from the plasma membrane and so are near the plasma membrane from the start. They fill by pumping neurotransmitters into the vesicle, using membrane transport proteins. Secretory granules, however, form around aggregates of protein hormones in the *trans*-Golgi lumen and then must be transported from that region to the plasma membrane, a process that includes penetrating a network of actin filaments near the plasma membrane in neuroendocrine cells. Two proteins with homology to receptor-type protein tyrosine phosphatases are enriched in neuroendocrine cells and associated with secretory granules. These membrane proteins, known as ICA512 (or IA2) and phogrin, are not associated with synaptic vesicles. Their preferential location on secretory granules indicates that they have a specific function and evidence is consistent with these proteins playing a role in the transport of secretory granules to the plasma membrane.

Once at the plasma membrane, both synaptic vesicles and secretory granules attach to the membrane, a process that is sometimes referred to as docking. Attaching to the membrane is not the same as initiating fusion and the process appears to involve munc18a in mammalian cells. It is possible that Rab3s may play a role in this step. Docking occurs at specific sites on the plasma membrane and the specificity of different Rabs for intracellular organelles makes them attractive candidates for providing specificity, but if they do provide such specificity, the mechanisms by which they do so are unknown.

After docking, there is an additional step before fusion, which has in some cases been called priming, which occurs both to synaptic vesicles and to secretory granules. A candidate for this step may be partial assembly of the SNARE core complex and may also involve partial fusion of the membranes by fusion of one layer of the bilayer of each membrane (Fig. 1). The fusion reaction itself involves opening of a fusion pore. Opening the pore is reversible; it may flicker open and close so quickly that vesicle contents are not released. Once the fusion pore widens, however, the process goes to completion, the contents are released, and exocytosis has occurred. This step is mediated by complete formation of the core complex of SNARE proteins. It has not yet been completely demonstrated how formation of the core complex causes fusion nor whether there are other as yet unidentified proteins that are actively involved after the core complex forms.

For secretory granules and synaptic vesicles in neuroendocrine cells and neurons, the increase in cytosolic Ca^{2+} , caused by entry through Ca^{2+} channels, triggers exocytosis of vesicles that have docked at the plasma membrane and that have undergone a subsequent step, possibly partial fusion. The exact mechanisms by which Ca^{2+} triggers opening of the fusion pore remain to be identified.

GENE EXPRESSION

A gene has two parts: (1) the section of DNA on a chromosome that contains a region that is transcribed into an RNA chain, which in turn is translated into the protein encoded thereon, and (2) a DNA region that is involved in controlling or regulating the expression (transcription) of the gene. The regulatory region is often called the promoter region and is located adjacent to and just before (usually referred to as being upstream or 5' of) the transcribed region. The other end of the gene is called the 3'-end.

The DNA sequence is numbered starting at +1, corresponding to the first nucleotide of the region of the gene that is transcribed into RNA. The nucleotide located immediately 5' of the start of transcription is numbered -1 and the nucleotide positions in the DNA sequence of the promoter region of the gene are described by increasing negative numbers as one counts further upstream from -1. A specific DNA sequence "element" known as the TATA-box is located at approximately -20 in the promoter region of most mammalian protein-encoding genes (see Fig. 1). Certain nuclear proteins bind specifically to this TATA-box and are involved in the positioning of the RNA polymerase enzyme at the correct starting point of transcription. Other regulatory DNA sequence elements are usually located 5' to the TATA-box. These other elements are sites where proteins called

transcription factors can specifically bind and cause an increase, or sometimes a decrease, in the amount of expression observed for the gene being controlled (Fig. 1). Most promoters have several different elements where transcription factors can bind. It is these transcription factors that are involved in the regulation of the expression of the gene. In some situations, a transcription factor can bind to an element and have a negative influence on the effect of another (different) protein binding to a second element, but in a different situation that factor may have a positive influence on the second factor and result in an even higher level of gene expression.

An example of such a DNA element capable of specifically binding to certain transcription factors is the cyclic AMP (cAMP) regulatory element (CRE). This site has a consensus DNA sequence consisting of eight nucleotides; TGACGTCA. The CRE binds to a transcription factor called CREB (for CRE-binding protein) and also to other factors, such as activating transcription factor 1 and AP-1 (activating protein 1). A protein that can bind to a given DNA sequence element may require different nucleotides within the element for specific binding compared to those nucleotides required by another protein that can bind to the same DNA sequence. For example, when binding to the CRE, the CREB and AP-1 proteins both touch some, but not all, of the nucleotides within the DNA

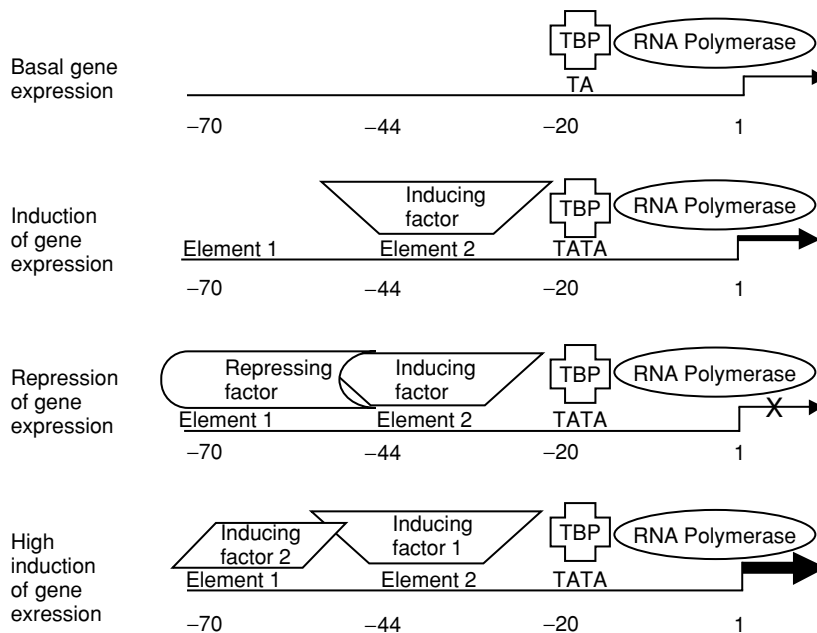

Figure 1 Examples of general molecular mechanisms of gene expression regulation showing the relative positions of some regulatory DNA elements and their associated transcription factor proteins aligned along a gene's promoter region.

sequence of the element, but the actual nucleotides that each of these proteins interacts directly with are not the same.

CREB activity is regulated by phosphorylation at specific amino acids within its protein sequence. Phosphorylation of transcription factors is performed by a variety of protein kinases that are intermediaries in many of the signaling pathways that transmit signals (such as growth- or differentiation-related signals) from the cell surface membrane to the nucleus. Protein kinase A (PKA) is involved in phosphorylating CREB to stimulate its binding to the CRE, whereas another enzyme, protein kinase C, is involved in activating AP-1. Other enzymes, such as calcium-calmodulin-dependent protein kinases (CaM kinases) I, II, and IV, can also phosphorylate CREB to activate it, as can enzymes in the Ras-mitogen-activated protein kinase (MAPK) pathway.

Nuclear hormones represent another major pathway through which growth and differentiation signals are transmitted from the cell surface to the nucleus, where they affect gene expression. Nuclear hormones function by binding to a family of transcription factors known as the nuclear hormone receptors. These include receptors for sex steroids such as the estrogen receptor (ER) and those for corticosteroids such as the glucocorticoid receptor (GR) and they also include receptors for vitamins, such as the retinoids [retinoic acid receptor (RAR) and retinoid X receptor (RXR)], and for lipid metabolites, which are the ligands for a group of proteins called the peroxisome proliferator receptors (PPAR). Each member of the nuclear hormone receptor family exists in several subtypes usually indicated by the Greek letters α , β , and γ . The nuclear hormone receptor family of proteins can regulate the expression of genes by binding to specific DNA elements in the promoter of the gene being controlled or by interacting with other transcription factors through protein-protein interactions.

The following sections provide several detailed examples of the molecular mechanisms regulating peptide hormone gene expression.

CORTICOTROPIN-RELEASING HORMONE

CRH is a hypothalamically derived hormone that orchestrates the stress response. Stressor-induced activation of the hypothalamus-pituitary-adrenal axis results in a series of neural and endocrine adaptations known as the "stress response." The stress response

is responsible for allowing the body to make the physiological and metabolic changes necessary to cope with the demands of a homeostatic challenge. The challenge to homeostasis by any stressor initiates the release of CRH from the hypothalamus, which in turn results in the release of adrenocorticotrophic hormone (ACTH) from the pituitary into the general circulation. ACTH then acts on the adrenal cortex, resulting in the release of steroid hormones, glucocorticoids, into the blood. Glucocorticoids act in a negative feedback fashion to terminate the release of CRH from the hypothalamus. CRH has also been identified in many tissues outside the hypothalamus, in particular, in the human placenta during pregnancy. Placental CRH becomes detectable in maternal plasma at approximately 16–20 weeks gestation and the plasma CRH concentration increases exponentially throughout pregnancy and peaks during labor. Placental production of CRH has been linked to the length of gestation in humans and several groups have reported that increased concentrations in maternal blood are associated with preterm delivery.

The promoter region of the human CRH (hCRH) gene contains consensus DNA sequences for several known transcription factors (see Fig. 2). There is complete conservation among four species (human, ovine, mouse, and rat) of several of these consensus regulatory elements, including a CRE, estrogen regulatory element half-sites (1/2ERE), an ecdysone regulatory element (EcRE), two TATA-boxes (TBP), and a CDXA regulatory element, suggesting the importance of these sites in hCRH gene expression.

There is a consensus CRE located at position –221 to –228 in the hCRH promoter, and activators of the PKA signaling pathway, such as cAMP, increase the expression of CRH both in the placenta and in the hypothalamus. Stress can rapidly lead to phosphorylation of CREB and to induction of CRH in the hypothalamus. CaM kinases are involved in the regulation of CRH in the hypothalamus, but this has not been explored in the placenta. The Ras-MAPK pathway is also present in the placenta but it has not been shown to be involved in the regulation of placental CRH production.

Different proteins bind to the CRE in placental versus hypothalamic cell models. The CREB protein is present in both the hypothalamus and the placenta. However, component proteins of the AP-1 transcription factor (Jun and Fos) differ between these two tissues. The Jun protein is present in the nucleus of placental cells and binds to the CRE, whereas the nuclear protein from a mouse pituitary cell line (AtT20) shows the presence of the Fos protein. The transcription factor AP-2 (activating protein 2) has

Figure 2 The DNA sequence of the proximal section of the hCRH gene promoter. The regulatory elements discussed in the text are indicated.

also been reported to interact with transcription factors binding to the CRE and to regulate CRH gene expression in placenta.

Deletion or mutation of the CRE in the hCRH promoter results in markedly reduced hCRH gene expression in placental cells in response to cAMP but does not completely abolish it. Further analysis in human choriocarcinoma (JEG) cells and rat choriocarcinoma cells has identified another region, located between nucleotides -128 and -109 , that is responsive to cAMP. This region contains a consensus element for the homeobox transcription factor CDXA

(see Fig. 2). Mutation of this CDXA-response element (CDXRE) also reduces but does not eliminate induction of the hCRH promoter by cAMP in AtT20 cells. Therefore, cAMP-mediated signaling pathways use both the CRE and the CDXRE to stimulate hCRH gene expression in placenta and hypothalamic cells.

Glucocorticoids mediate inhibition of hCRH gene expression in the hypothalamus, whereas these steroid hormones stimulate the expression of hCRH in the placenta. The hCRH promoter does not contain a consensus glucocorticoid-response element (GRE) although there is a half-site at -600 to -593 (Fig. 2).

Assays *in vitro* identified three regions of the promoter that can bind GR (Fig. 2, heavily overlined sequence). These sites are not involved in the glucocorticoid-mediated stimulation of hCRH gene expression in the placenta and glucocorticoids stimulate hCRH gene expression in the placenta through the CRE, presumably through protein-protein interactions with proteins that bind at the CRE. In other cells, the hormone-activated GR negatively or positively modulates the expression of AP-1-dependent genes, depending on which subunit of the AP-1 dimeric protein complex is present. For example, homodimers of Jun can interact with GRs to stimulate promoter activity, whereas heterodimers between Jun and Fos interact with GRs to repress promoter activity.

A region of the hCRH promoter, between nucleotide positions -278 and -246, has been identified as being responsible for negative regulation by glucocorticoids in cAMP-stimulated AtT20 cells. This negative GRE (nGRE) corresponds to one of the DNA regions mentioned above that can bind the GR *in vitro*. Surprisingly, in the absence of this nGRE, the hCRH promoter is stimulated by glucocorticoids in AtT20 cells in a manner similar to that seen in placenta cells. The nGRE colocalizes to a consensus EcRE (see Fig. 2). Mutation of this EcRE in the hCRH promoter results in a doubling of hCRH gene expression in primary placental cell cultures. This mutation of the EcRE did not cause any change in hCRH expression in AtT20 cells. Therefore, this region of the promoter appears to act as a general inhibitor in placental cells and as a nGRE in pituitary cells. Ecdysone is an insect steroid hormone that has a role in insect molting and metamorphosis. Mammals do not have ecdysone receptors and ecdysone as such has no known role in mammalian gene regulation. Ecdysone and its receptor (EcR) do not tend to form homodimers but tend to associate with other members of the nuclear receptor superfamily. RAR and RXR can form functional dimers with EcR in mammalian cells and it is possible that PPAR may have a role in regulating hCRH through the

EcRE since it often forms heterodimers with RXR and RAR.

In placenta, hCRH gene expression is repressed by estrogen, whereas the estrogen antagonist ICI 182780 stimulates hCRH gene expression. Although the hCRH promoter contains five 1/2 EREs, no binding of estrogen receptor to the 1/2 EREs has been observed. In endometrial cells, estrogen has also been found to inhibit hCRH gene expression. The placental estrogen effect involves ER- α and apparently occurs through protein-protein interactions with other transcription factors or cofactors.

CHORIONIC GONADOTROPIN

The human reproductive hormone chorionic gonadotropin (hCG) is a key messenger in embryonal/fetal to maternal communication during embryonic development and plays an important role in the establishment and maintenance of pregnancy. hCG is a member of the heterodimeric glycoprotein hormone family. The members of this hormone family share a common α -subunit and have unique β -subunit peptides. The α -subunit gene is regulated in three different cell types and two tissue types: the trophoblasts of the placenta and the gonadotropes and thyrotropes of the anterior pituitary. In addition, the α -subunit gene needs to be coordinated with the expression of a specific β -subunit gene. The hCG- β gene has a TATA-less promoter and is expressed almost exclusively in the placenta.

A summary of the regulatory sites identified in the hCG- α and hCG- β genes is shown in Fig. 3. In addition to these, there is a pituitary-specific region located between nucleotide positions -500 and -200. Within that region, two smaller regions have been identified as being specific for expression in cells of gonadotrope lineage and another region is specific for expression in thyrotropes. The junction regulatory element (JRE) of the hCG- α gene appears to bind a trophoblast-specific protein. Cellular signaling

Figure 3 A schematic representation of the hCG- α and hCG- β gene promoters showing the regulatory elements discussed in the text.

pathways utilizing cAMP are able to activate hCG- α and hCG- β genes through two tandem CREs in the hCG- α promoter and through the several sites that constitute a composite regulatory element in the hCG- β promoter, as shown in Fig. 3. In hCG- β , the three AP-2 sites and the Jun-binding site are all involved in activation through cAMP pathways. The two adjacent CREs in the hCG- α promoter and the Jun site of hCG- β bind the Jun protein in addition to the CREB protein.

AP-2 is involved in regulating both the α - and β -subunit genes, the hCG- α gene through a region also referred to as the upstream regulatory element (URE) and the hCG- β gene through three AP-2-binding sites. AP-2 and Sp1 (selective promoter factor 1) work through complex cooperative mechanisms to control basal as well as cAMP-mediated gene regulation. AP-2 is regulated by retinoic acid and this may be a mechanism whereby retinoic acid stimulates hCG secretion from JEG3 cells. However, RXR α and PPAR γ are able to bind directly to specific sites within the hCG- β promoter and stimulate gene expression, and ligands for these two receptors have an additive effect on hCG synthesis. Thus, retinoic acid may have a direct (RXR/PPAR) or an indirect (through AP-2) effect on hCG production.

PLACENTAL LACTOGEN

The hPL/growth hormone (hGH) gene locus consists of five structurally related genes clustered on human chromosome 17. hGH-N is a pituitary-specific growth hormone, hGH-V is a placental-specific growth hormone variant, hPL-A and hPL-B are identical proteins found in the fetal and maternal circulations, and hPL-L was long thought to be a pseudo-gene (nonfunctional gene) until the discovery of novel peptides encoded by it. Although the promoter regions of the hGH/hPL gene family share 91–99% sequence identity over the proximal 500 bp region (–500 to –1), it is evident that the factors that regulate hPL gene expression are largely different from those that regulate the hGH gene. These conserved 500 bp sequences located immediately 5' to the coding regions in this gene family are sufficient to permit pituitary-specific gene

expression. Expression in placental trophoblast cells requires a Sp1 site for basal expression and two AP-2 sites for maximal expression (see Fig. 4). Trophoblast-specific expression also requires the placental-specific enhancer region [or chorionic somatomammotropin enhancer (CSE)] located ~2.2 kb 3' of the gene cluster. There is also a pair of pituitary-specific silencers (PSF) located ~2 kb 5' of each placentally expressed gene. Thus, tissue-specific regulation of the hPL gene is controlled by a combination of enhancer and silencer elements.

There are also two composite sites identified that are important for activation of hPL gene expression by nuclear hormone receptors (NHR) (see Fig. 4). Site A is transactivated by RAR α , whereas site B is transactivated by RAR α , by T₃R β (thyroid hormone receptor), and by vitamin D receptor. The RAR- and T₃R-stimulated expression is repressed by the orphan receptor ARP-1, which also binds to the composite NHR. As was the case for hCG, it has been shown that ligands for RXR and for PPAR are able to stimulate hPL synthesis. Although not yet thoroughly defined, it is clear that several different nuclear hormone receptors may function to control hPL gene expression in the placenta.

The hPL-B promoter has two potential binding sites for the transcription factor NF-IL-6 [nuclear factor–interleukin-6; also known as CCAAT/enhancer-binding protein (C/EBP)]. Interleukin-1 acts on cell surface receptors, which activate the Ras-dependent MAPK cascade, and this, in turn, phosphorylates NF-IL-6. As mentioned earlier, this pathway is functional in placental cells and so it is interesting to note that a NF-IL-6 regulatory element is also present in the CRH promoter (see Fig. 2).

LEPTIN

Leptin is a hormone most commonly thought of in terms of its role in regulating body weight. Leptin performs this function through feedback control of energy balance to increase metabolism and depress appetite. Secreted by adipose cells, its concentration in the circulation correlates with body adiposity. Investigators have found that leptin is also expressed

Figure 4 A schematic representation of the hPL gene promoter showing the regulatory elements discussed in the text.

Figure 5 A schematic representation of the LEP gene promoter showing the regulatory elements discussed in the text.

in other tissues, including the brain, pituitary, and placenta. A correlation has been reported between umbilical cord leptin and conceptus size, indicating that leptin may also be involved in regulating conceptus growth or placental function.

A number of differences have already been recognized for leptin gene regulation in these different tissues. Expression of the leptin gene in adipocytes requires only the proximal 200 bp of the 5'-flanking DNA sequence. This region of the leptin promoter contains a TATA-box, a C/EBP site (or a NF-IL-6 site), an AP-2 site, and three Sp1-binding sites (Fig. 5). Placenta-specific leptin gene expression is enhanced by an upstream region of the promoter between positions -1951 and -1546. This upstream placenta-specific enhancer (PSE) requires the proximal region of the promoter to function as it has no promoter activity on its own. The transcription factor Sp1 can bind to sites within the PSE, although how these Sp1 sites might function as a tissue-specific enhancer in placentally derived cell lines has not yet been determined.

The leptin gene promoter is stimulated by estrogen and inhibited by anti-estrogens through ER- α , but in cells transfected with ER- β the leptin gene is stimulated by anti-estrogens. The molecular mechanism of this estrogen-mediated regulation has not as yet been clearly identified. Tissue-specific differences in leptin gene regulation are further evident from studies that show that cAMP inhibits leptin expression and secretion in adipocytes, whereas it stimulates leptin expression and secretion in placental trophoblast and trophoblast-derived cells and in rat C6 glioma and GH3 pituitary tumor cells.

hCG and hPL are stimulated by PPAR γ ligands and this is also true for leptin gene expression in placental cells. In adipocytes, however, PPAR γ ligands inhibit leptin gene expression. This inhibition occurs through the C/EBP site but does not involve binding of the PPAR γ to the DNA directly.

DIGEST

Although the peptide hormones discussed here represent proteins with a variety of distinctly different

physiological functions, they are all similar in that they are expressed in brain, placenta, and several other tissues. The promoter regions of each of the genes encoding these peptide hormones are also organized in ways distinctly different from the others. Nevertheless, it can be seen that there are also some striking similarities that warrant mention. cAMP-based signaling systems play significant roles in regulating these genes, often through complex interactions involving several transcription factors including CREB, AP-1, and AP-2. Nuclear hormone receptors regulate these genes through similarly complex molecular mechanisms involving the interaction of receptors such as GR, ER, RXR, and PPAR with transcription factors such as CREB, AP-1, AP-2, and C/EBP.

An implication of aggregation occurring before secretory granules form is that protein aggregation may both concentrate and segregate secretory granule proteins. Aggregation of secretory granule proteins in the *trans*-Golgi layer results in sorting because the small vesicles that bud off carry away soluble proteins, leaving behind the hormone aggregates, which are too large to be removed and which therefore stay as the core of the granule (Fig. 1). The ultimate proof that aggregation is sufficient for segregation will come with mutants that show a correspondence between aggregation in cells and storage in secretory granules.

There are proteins in secretory granules that do not form large aggregates and may remain soluble, such as galanin. It is not known whether these proteins are in fact efficiently stored in granules; the bulk of the newly synthesized protein may be constitutively secreted or degraded and small amounts of soluble proteins may end up in granules because they are incompletely taken away by the budding small vesicles. If they remain soluble and are efficiently segregated to granules, there must be an additional sorting mechanism besides aggregation.

Prolactin is a relatively simple hormone that is not processed beyond cleavage of the signal sequence responsible for its transport into the endoplasmic reticulum during synthesis. It is not yet known whether aggregates of prohormones exist in such an early stage as those of prolactin, because three-dimensional views of granules forming are available only for prolactin, but dense masses of proinsulin and proopiomelanocorticotropin have been detected by electron microscopy in the *trans*-Golgi lumen of the cells that produce each hormone, consistent with an early aggregation step.

Figure 1 The *trans*-layer of the Golgi complex in cells producing secretory granules. Protein hormones aggregate (large black shape) in the lumen of the *trans*-layer. The excess membrane and soluble proteins are removed by budding of small vesicles, until only membrane-enclosed aggregates are left. In order for this membrane-enclosed aggregate to function properly, the appropriate membrane proteins (shown as small black shapes in the membrane around the aggregates) must accumulate in the secretory granule membrane and not be removed by budding vesicles.

SEGREGATION OF SECRETORY GRANULE MEMBRANE PROTEINS

Formation of an aggregate is not sufficient for the formation of a normally functioning secretory granule. For example, Von Willebrand factor, a secretory protein that forms aggregates, forms dense-core membrane-enclosed structures that look like secretory granules when expressed in neuroendocrine cells, but release of the factor cannot be regulated as release of endogenous secretory granule proteins is. After formation, secretory granule proteins are transported to the plasma membrane where they undergo regulated exocytosis. These functions are mediated by membrane proteins including synaptobrevin, synaptotagmin, ICA512, and phogrin. For secretory granules to function properly, proteins that mediate the functions must accumulate in appropriate amounts in the granule membranes as they form. Because they do not accumulate around all aggregates, there must be some form of recognition between the aggregates of secretory granule proteins and membrane proteins necessary for secretory granule function (Fig. 1). Recognition of surface motifs of the aggregates may occur through protein, lipid, or a combination of the two. The features that are recognized and what causes the recognition have not yet been elucidated.

function, at least in part, by preventing unfolded proteins from forming irreversible aggregates instead of folding. Some proteins are also covalently modified in the endoplasmic reticulum during and after folding by glycosylation. Proteins that normally exist as oligomers must assume the correct quaternary structure in order to be transported further along the secretory pathway. Proteins that do not fold properly are normally degraded. There are proteases, enzymes that cleave proteins, in the endoplasmic reticulum; in addition, proteins that do not fold properly may be transported back through the membrane of the endoplasmic reticulum, where they are usually degraded by complexes, known as proteasomes, made up of proteases and other proteins. Neuroendocrine cells that synthesize large amounts of protein tend to have large numbers of proteasomes.

After folding and assembling correctly, proteins are transported further along the secretory pathway; all transport of these proteins is carried out in vesicles (Fig. 1). Transfer from the endoplasmic reticulum occurs through irregularly shaped vesicles that emerge from specific areas of reticulum membrane. The means by which some proteins are carried forward and others left behind is an area of intense investigation; although all the details are not clear, it appears that some proteins are actively carried forward to the next stage and other proteins are actively retained or retrieved from later stages in the secretory pathway.

The next stage is near the *cis*-Golgi layer; the vesicles that have left the endoplasmic reticulum fuse in the *cis*-Golgi region. This region of actively fusing

vesicles or vesicular-tubular clusters has been called the pre-Golgi intermediate compartment or the endoplasmic reticulum-Golgi intermediate complex. Sorting goes on in this region as proteins that escaped surveillance and left the endoplasmic reticulum inappropriately are deposited into vesicles to be returned there. The remaining vesicles eventually fuse to form the *cis*-layer of the Golgi complex.

The endoplasmic reticulum has other functions in addition to folding proteins. One important function essential for all cells is that it serves as a storage reservoir for Ca^{2+} , which facilitates the use of changes in the concentrations of intracellular Ca^{2+} as a signaling mechanism. In neuroendocrine cells, the release of intracellular Ca^{2+} is part of the signaling that controls the release of secretory granules. The endoplasmic reticulum also produces most of the lipids needed by cells.

THE GOLGI COMPLEX

The Golgi complex is a stack of flattened membrane cisternae (Fig. 1) usually located near the nucleus of the cell. In three dimensions, it resembles a broad ribbon-like structure. In cells secreting large amounts of proteins, there may be more than one such stack. Proteins arrive at the Golgi complex on the *cis* side and process to the *trans* side. It had long been assumed that proteins were carried forward from one layer of the complex to the next by small vesicles, but it has become generally accepted that each of the layers of the Golgi complex progresses through the stack, so that the *cis*-layer eventually becomes the *trans*-layer. Each layer metamorphoses in turn from a *cis* to a medial to a *trans* cisterna as small vesicles transport the enzymes that characterize the different layers of the Golgi complex back to the layer behind. A *cis*-layer takes on the characteristics of later compartments sequentially as vesicles or possibly tubular structures derived from later compartments cycle back the appropriate enzymes. The enzymes in the different layers further covalently modify some of the proteins as they process through the Golgi complex; possible modifications include further glycosylation, as well as phosphorylation and sulfation. The concept that it is the layers that process through the stack provides the simplest explanation why some proteins process through the stack in forms that are too large to be included in the small vesicles seen around the stacks by electron microscopy. Atrial natriuretic peptide, for example, appears in a dense aggregated form too large to be carried in vesicles in all layers of the Golgi complex in atrial cardiomyocytes.

Figure 1 The subcellular structures involved in the secretory pathway of protein hormone-producing cells.

When a Golgi layer reaches the *trans* side of the Golgi complex, small vesicles still bud to return enzymes and other constituents to the more newly formed layers; in addition, clathrin-coated vesicles bud off to transport vesicles to the lysosome and other vesicles bud to take soluble proteins to the plasma membrane, so that the entire *trans*-layer of the Golgi complex is consumed by budding of small vesicles to be replaced by the layer that formed after it. Proteins clearly have been sorted when they leave the *trans*-Golgi region, but the sites of sorting of different proteins may vary, as suggested by the finding of Howell and colleagues, who examined the Golgi complex in three dimensions, that only one type of vesicle is seen budding from regions of the *trans*-Golgi layer.

LYSOSOMES

Lysosomes are subcellular organelles that are full of hydrolytic enzymes called acid hydrolyases, which are active at pH 5, the pH of the lysosomal lumen. The function of lysosomes is to degrade unwanted structures in the cell. Unlike proteasomes, which are complexes of proteins that degrade cytosolic proteins one at a time, lysosomes are much larger and may not only digest single proteins, but may engulf entire structures in the cells, such as mitochondria and, in neuroendocrine cells, secretory granules (Fig. 1), resulting ultimately in their destruction.

The sorting of soluble acid hydrolases is the best understood of the sorting that is required in the secretory pathway. Lysosomal hydrolases have mannose-6-phosphate groups attached to their carbohydrate moieties and these groups are recognized by a transmembrane protein in the *trans*-Golgi layer called the mannose-6-phosphate receptor. Lysosomal enzymes bind to this transmembrane protein in the lumen of the Golgi cisternae and a protein called adaptor protein 1 (AP-1) binds to this protein on the cytosolic side. Clathrin, a protein identified years ago as a component of a caged structure around certain small membrane vesicles, binds to AP-1 and the membrane in this area begins to invaginate and forms a vesicle that carries the enclosed enzymes to the endosomes, a compartment en route to lysosomes. The two processes, sorting and transport, are linked, because the mannose-6-phosphate receptor that binds the vesicular cargo of lysosomal enzymes on the lumen side also binds the proteins necessary to form the vesicle on the cytosolic side. It seems likely that this mode of

sorting linked to transport may be a model for sorting soluble proteins in transport systems in many parts of the cell and not just to lysosomes.

SECRETORY GRANULES

The hallmark of the cytoplasm of neuroendocrine cells is large dense-core secretory granules, 100 to 1000 nm in diameter, containing concentrated hormone. The protein is so concentrated that it stains darkly, giving the granules their characteristic dense cores. The process of concentrating protein hormones has been called condensation; in the case of prolactin and growth hormone, in which it has been investigated biochemically, condensation is the formation of a large aggregate of protein hormone that is insoluble under the conditions present in the secretory granule. The aggregate is different from that which forms from unfolded proteins in the endoplasmic reticulum in that the hormone aggregate in the granules will rapidly resolubilize, producing native folded protein, when released from the cell, whereas the aggregates of unfolded proteins that sometimes accumulate in the endoplasmic reticulum are very difficult to resolubilize.

These aggregates form in the *trans*-Golgi layer before secretory granules form; this has been seen clearly by electron microscopy for proteins such as prolactin and atrial natriuretic peptide and detected biochemically for prolactin and growth hormone. As the *trans*-Golgi layer is consumed by budding of small vesicles, the aggregates, too large to be removed, remain, so that the dense core is left with less and less excess membrane around it; at this stage it is termed an immature secretory granule (Fig. 1). Eventually all the excess membrane is completely removed, leaving the mature secretory granule. In cells that make more than one secretory granule protein, the granules may not contain all proteins. Gonadotrophs, for example, produce both luteinizing hormone and follicle-stimulating hormone, but the secretory granules of these cells contain primarily one or the other hormone. In bag cells of *Aplysia californica*, proegg-laying hormone is cleaved into two portions and secretory granules form containing primarily one or the other part of the prohormone. The mechanism that causes these separations appears to be primarily self-association of each protein separately in the Golgi complex.

After they form, secretory granules are transported through the cell to the plasma membrane, where they

are released by exocytosis, when cells are stimulated. These functions of transport and stimulated release are mediated by membrane proteins in the secretory granules, such as synaptobrevin and synaptotagmin, that are known to mediate exocytosis. In addition, there are proteins that are specifically located in dense-core vesicles, such as IA2 (islet antigen 2), also called ICA512, and phogrin. These proteins may play a role in the correct transport of the secretory granules. Therefore, a second step in forming granules is the correct localization of proteins necessary for their proper function.

Regulated secretion of polypeptide hormones occurs through secretory granules formed from the Golgi complex. There is also another type of vesicle causing regulated secretion in neuroendocrine cells, synaptic vesicle-like microvesicles, which are small vesicles, less than 100 nm in diameter, the release of which is also stimulated by the same signals that regulate exocytosis. These vesicles have some of the same proteins that mediate stimulated release, including synaptotagmin and synaptobrevin. They differ from secretory granules, however, in that they do not have dense cores containing protein hormones and are not derived from the Golgi complex. In some cases, their contents are known; the microvesicles in beta cells of pancreatic islets contain γ -aminobutyric acid and those in adrenal cells contain acetylcholine. These vesicles appear closely related to synaptic vesicles in neurons

and, as synaptic vesicles, are formed at the plasma membrane by a process resembling endocytosis.

by release of inhibitory neurotransmitters [vasoactive intestinal peptide (VIP) and nitric oxide (NO)] from noncholinergic neurons.

Motilin is the only hormonal or neural peptide whose main function is interdigestive. It is released in cycles that coincide with the start of the migrating myoelectric complex. Peaks of circulating motilin coincide with phase 3 of the cycle, a short period of intense motor activity that sweeps residual contents of the intestine caudad. Immunoneutralization of circulating motilin disrupts phase 3 activity; conversely, infusion of motilin in concentrations that mimic circulating levels triggers premature phase 3 activity. Neural activity can modulate motilin levels and motor activity, but the precise mechanisms are not known.

PEPTIDE NEUROTRANSMITTERS AND SMOOTH MUSCLE ACTIVITY

Neural Organization

Neurons of the enteric nervous system, especially neurons of the myenteric plexus, modulate the intrinsic electrical and mechanical properties of smooth muscle. They constitute the final relay to smooth muscle cells and interstitial cells of Cajal; the latter appear to be interposed between motor nerve terminals and smooth muscle cells in some regions of the gut. Extrinsic adrenergic and peptidergic neurons in pre- and paravertebral ganglia synapse with and modulate the activity of enteric neurons.

Neurons of the myenteric plexus located between the circular and longitudinal smooth muscle layers fall into two broad categories. Approximately 25% contain VIP and/or its homologue, pituitary adenylate cyclase activating peptide (PACAP), often found together with neuronal nitric oxide synthase (nNOS). More than 60% contain ACh, often found together with the tachykinins, substance P (SP) and neurokinin A (NKA); the latter are derived from the same precursor, β -protachykinin. VIP neurons also contain a homologous peptide derived from the same precursor designated PHI in animals or PHM in humans. There is little or no overlap between neurons of these two categories. Acetylcholine and the tachykinins are the major excitatory motor neurotransmitters, whereas VIP and its homologs and NO are the major inhibitory neurotransmitters. The term inhibitory refers to their ability to inhibit (i.e., relax) smooth muscle tone and rhythmic electrical and contractile activity.

Pharmacology of Neurotransmitters

VIP, PACAP, and PHI/PHM

Receptors for these peptides are present on both smooth muscle cells and neurons. VIP and PACAP interact with VPAC₂ receptors on smooth muscle cells, which are coupled via G_s to stimulation of cAMP formation and inhibition of muscle tone and rhythmic activity. Neural VIP/PACAP receptors are present in two locations: on nerve terminals, where they act as autoinhibitory receptors to suppress further neurotransmitter release, and on cholinergic/tachykinin motor neurons that innervate the longitudinal muscle layer. Activation of these receptors upon release of VIP and PACAP from a subpopulation of myenteric interneurons stimulates release of ACh and tachykinins and induces longitudinal muscle contraction.

Nitric Oxide

Two types of NOS are found in smooth muscle of the gut: nNOS in neurons and eNOS in smooth muscle cells. The release of VIP and its homologues from nNOS neurons is mediated by NO: Suppression of NO release inhibits VIP release but not vice versa, and addition of NO or NO donors to isolated ganglia or synaptosomes stimulates VIP release. NO released from nerve terminals diffuses to smooth muscle cells to participate in muscle relaxation. There is no molecular or biochemical evidence that VIP and PACAP act on nerve terminals to stimulate NO release.

A distinct interplay occurs between VIP/PACAP and NO in smooth muscle cells. VIP and PACAP interact not only with their cognate VPAC₂ receptors but also with a single-transmembrane receptor, the natriuretic peptide receptor C (NPR-C), which is widely expressed in smooth muscle cells of the gut and is coupled to G_{i1} and G_{i2}. Detailed cellular and molecular studies have shown that interaction of VIP or PACAP with NPR-C leads to G_{i1/2}-dependent activation of eNOS and stimulation of NO formation in smooth muscle cells. Cyclic GMP formed in smooth muscle cells derives from activation of soluble guanylyl cyclase by NO diffusing from nerve terminals and NO formed by eNOS in smooth muscle cells. Thus, NO regulates VIP/PACAP release in neurons; in turn, VIP and PACAP regulate NO formation in smooth muscle cells.

It is worth noting that smooth muscle cells of *Tenia coli* are unique in two respects. The cells do not express eNOS, but they express a VIP-specific receptor that does not recognize PACAP and a PACAP-specific receptor that does not recognize VIP. Only the

VIP-specific receptor is coupled to cAMP formation. The PACAP-specific receptor may be a splice variant of the PAC₁ receptor, which causes relaxation by activating apamin-sensitive K⁺ channels.

SP and NKA

SP and NKA interact preferentially with NK₁ and NK₂ receptors on smooth muscle cells and nerve terminals. NKB, the preferred ligand for NK₃ receptors, is the product of a precursor that is virtually absent from the gut. NK₁ and NK₂ receptors are coupled via G_q to IP₃-dependent Ca²⁺ release and contraction in circular muscle and to arachidonic acid-mediated Ca²⁺ influx and Ca²⁺-induced Ca²⁺ release in longitudinal muscle. The receptors stimulate ACh release from cholinergic neurons and induce a contraction that is superimposed on the direct contraction.

Enkephalin and Dynorphin

Opioid neurons of the myenteric plexus release a variety of peptides derived from two precursors: proenkephalin, which yields [Met]enkephalin and C-terminally extended derivatives, and prodynorphin, which yields α- and β-endorphin and dynorphin-17; the latter is processed to smaller dynorphin fragments and eventually to [Leu]enkephalin. [Met]enkephalin and its derivatives are much more abundant than dynorphin and its derivatives in the gut. Three opioid receptor types (μ, δ, and κ) are present on circular smooth muscle cells only where they mediate contraction. In addition, μ receptors on cholinergic neurons mediate inhibition of ACh release, and δ receptors on inhibitory neurons mediate inhibition of NO, VIP, and related peptides. The neural receptors are most relevant functionally, particularly δ receptors on inhibitory neurons. When opioids are injected *in vivo* or added to smooth muscle strips *in vitro*, they produce a transient increase in muscle tone by direct action on smooth muscle cells and a sustained increase in rhythmic, nonpropulsive contractile activity that reflects the suppression of a predominant inhibitory neural input.

Somatostatin

Somatostatin is present exclusively in a small population of myenteric interneurons, where it serves as a relay in the peristaltic reflex. Although somatostatin receptors that mediate contraction are present on circular muscle cells, they lack functional relevance in the absence of muscle innervation by somatostatin neurons.

CGRP

In the stomach, CGRP-containing nerve fibers are extrinsic primary afferent fibers, whereas in the intestine and colon they are both extrinsic and intrinsic; the latter mediate the peristaltic reflex induced by mucosal stimuli. CGRP is present in other neurons, but its function is unknown. CGRP receptors on muscle cells are reported to cause direct relaxation.

In summary, neurotransmitters of functional importance are the excitatory motor neurotransmitters, ACh and tachykinins; the inhibitory motor neurotransmitters, NO and VIP and its homologues; the modulatory neurotransmitters, opioids and somatostatin; and the sensory neurotransmitter, CGRP. Excitatory motor neurotransmitters depolarize and inhibitory motor neurotransmitters hyperpolarize membrane potential. The changes in potential are known as excitatory junction potentials and inhibitory junction potentials, respectively. At an appropriate threshold, depolarization opens voltage-sensitive Ca²⁺ channels, resulting in Ca²⁺ influx, an increase in tone, and increase in the amplitude or frequency of rhythmic contractions. Hyperpolarization affects mainly rhythmic activity, which is either decreased or suppressed.

THE PERISTALTIC REFLEX: INTERPLAY OF MOTOR, MODULATORY, AND SENSORY NEUROTRANSMITTERS

The functional role of peptide and nonpeptide neurotransmitters is best exemplified by their coordinated release during the intestinal peristaltic reflex (Fig. 1). The reflex can be evoked by mechanical or chemical stimulation of the mucosa (stroking or pH change) and by radial muscle stretch. The reflex consists of a descending phase, during which circular muscle relaxes and longitudinal muscle contracts caudad to the site of stimulation, and an ascending phase, during which circular muscle contracts and longitudinal muscle relaxes. Two types of *in vitro* preparations have been used to study the reflex that permit simultaneous measurement of mechanical response and neurotransmitter release. In one preparation, a hollow segment of intestine is stretched at the caudad or orad end, and mechanical response is measured as the medium is sampled for neurotransmitter release. In the other, the segment is opened and pinned as a flat sheet, separated into three compartments. The reflex is evoked by stimulation in the central compartment, while mechanical response and neurotransmitter release in each compartment is measured.

Neurotransmitter Release during the Ascending and Descending Phases of the Reflex

A precise pattern of neurotransmitter release occurs with each phase. During the descending phase, there is an increase in the release of VIP, PACAP, NO, and somatostatin and a decrease in the release of [Met]enkephalin. The pattern of release reflects the role of these neurotransmitters in mediating the descending phase. Thus, release of VIP, PACAP, and NO from the nerve terminals of motor neurons innervating circular muscle mediates descending relaxation of this

layer. Release of the same neurotransmitters from interneurons that synapse with and activate ACh/tachykinin motor neurons that innervate longitudinal muscle mediates reciprocal contraction of this layer. The increase in the activity of VIP/PACAP/NOS motor neurons and interneurons is caused by a decrease in the tonic inhibitory influence of opioid ([Met]enkephalin) interneurons, which in turn is caused by an increase in the activity of somatostatin interneurons. Thus, as the reflex is evoked sensory input is relayed to somatostatin interneurons coupled to opioid interneurons, which in turn are coupled to VIP/PACAP/NOS motor neurons and interneurons (Fig. 1).

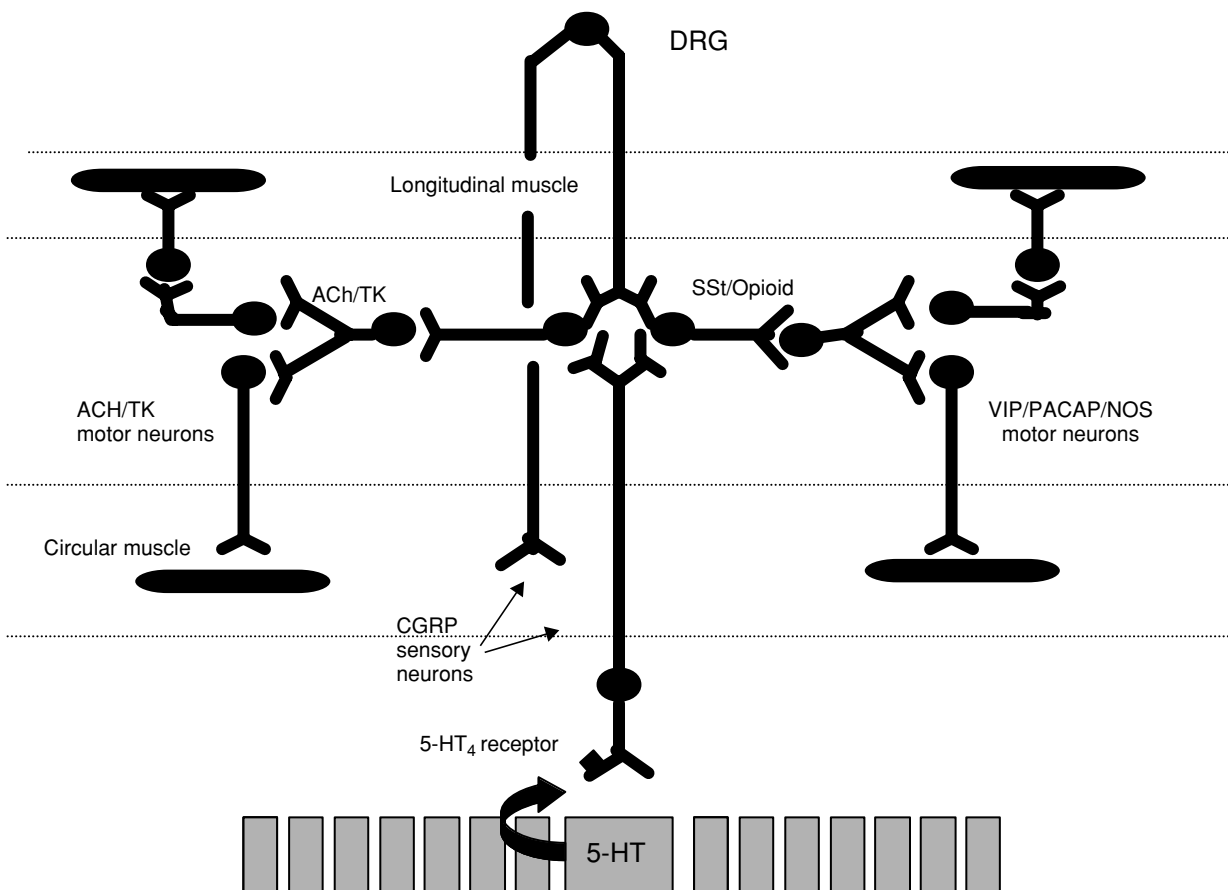

Figure 1 Model illustrating the regulation of intestinal peristaltic reflex. Mucosal stimulation causes the release of 5-HT, which acts on a 5-HT₄ receptor on intrinsic primary afferent CGRP neurons. Mechanical distension of the gut wall activates extrinsic primary afferent CGRP neurons with cell bodies located in the dorsal root ganglion (DRG). Both afferent neurons activate the same reflex pathway. The descending or caudal pathway is mediated by somatostatin (SSt) and opioid peptide interneurons coupled in series to (i) VIP/PACAP/NOS motor neurons, which innervate the circular muscle layer and cause descending relaxation of circular muscle, and (ii) VIP interneurons coupled to ACh/tachykinin (TK) motor neurons, which innervate the longitudinal muscle layer and cause descending contraction of longitudinal muscle during circular muscle relaxation. The ascending or oral pathway is less well defined but involves cholinergic interneurons and results in activation of ACh/TK motor neurons, which innervate the circular muscle layer and cause ascending contraction of circular muscle, and inhibition of ACh/TK motor neurons, which innervate the longitudinal muscle layer and cause ascending relaxation of longitudinal muscle during circular muscle contraction.

A reverse pattern of neurotransmitter release accompanied by an increase in SP and NKA release occurs during the ascending phase and determines the contraction of circular muscle and relaxation of longitudinal muscle. There is little direct inhibitory input to longitudinal muscle, at least in small animals. Contraction and relaxation of this muscle reflect, respectively, the increase and decrease in ACh and tachykinin release from motor neurons (Fig. 1).

The Sensory Limb of the Peristaltic Reflex

Two distinct populations of sensory neurons mediate the peristaltic reflex evoked by muscle stretch and mucosal stimulation. After nerve degeneration following surgical or chemical (using capsaicin) ganglionectomy, the reflex can be evoked by mucosal stimulation but not by muscle stretch. Conversely, after the mucosa is removed while maintaining intact extrinsic innervation, the reflex can still be evoked by muscle stretch. Thus, mucosal stimulation activates intrinsic sensory neurons with terminals in the mucosa and cell bodies in the myenteric plexus, whereas circular muscle stretch activates sensory neurons with nerve terminals in circular muscle and cell bodies in the dorsal root ganglia. The main sensory neurotransmitter in extrinsic and intrinsic neurons is CGRP, and its effect is relayed to the same circuits of interneurons and motor neurons that mediate the ascending and descending phases of the reflex.

The mechanism by which CGRP-containing intrinsic sensory neurons are activated is unique in that it involves release of 5-hydroxytryptamine (5-HT) from the mucosa. In both humans and experimental animals, mucosal stimulation releases 5-HT from enterochromaffin cells, one of two large stores of 5-HT in the body. 5-HT acts on 5-HT₄ receptors located on mucosal sensory nerve terminals, causing release of CGRP (Fig. 1). The addition of 5-HT or a selective 5-HT₄ agonist to the mucosal surface releases CGRP from capsaicin-sensitive sensory neurons and triggers the peristaltic reflex. Selective 5-HT₄ antagonists block CGRP release and the peristaltic reflex evoked by mucosal stimulation or by the addition of 5-HT to the mucosa. Both 5-HT₄ and CGRP antagonists suppress the ascending and descending phases of the reflex and the release of corresponding neurotransmitters. No release of 5-HT is seen when the peristaltic reflex is evoked by radial muscle stretch. Although the reflex has been traditionally viewed as a stereotypical response to intestinal distension (radial muscle stretch), it is unlikely that this represents the

normal physiological modality. The mere passage and chemical composition of digesta appear to be the main physiological triggers of the reflex and propulsion of intestinal contents.

Propagation of the Reflex

The caudad propagation of the reflex leads to propulsion of intestinal contents. The velocity of propulsion is readily measured *in vitro* using synthetic fecal pellets inserted into the oral end of the segment without distending the lumen. 5-HT₄ agonists added to the lumen of the segment accelerate the velocity of propulsion, whereas 5-HT₄ antagonists have the opposite effect. Elimination of the inhibitory influence of opioid neurons on VIP/PACAP/NOS neurons with opioid antagonists (particularly δ receptor antagonists) accelerates propulsion. The suppression of opioid activity greatly potentiates the ability of 5-HT to accelerate propulsion, such that a combination of near-threshold concentrations of a 5-HT₄ agonist and an opioid δ antagonist produces near-maximal stimulation of propulsion. The remarkable effect of this combination indicates its therapeutic potential, and highlights the importance of understanding the physiological interplay of peptide neurotransmitters and their regulators.

and a subtle change from full-length PYY stimulating both Y_1 and Y_2 receptors to a predominant PYY(3-36) activation of only Y_2 receptors occurs. This change in peptide pharmacology may be important in modulating feeding behavior and initiating satiety after eating a meal and as a result of postprandial increases in plasma PYY and its conversion to PYY(3-36).

DISTRIBUTION OF Y RECEPTORS ACTIVATED BY PYY OR PYY(3-36)

Each of the five different types of mammalian Y receptor known to exist (Y_1 , Y_2 , Y_4 , Y_5 , and y_6 ; the last type is written in lowercase because it is not expressed fully in human cells) is most commonly coupled to the inhibitory G protein, G_i . PYY and its C-terminal product PYY(3-36) exhibit high affinities for Y_1 and Y_2 receptors, respectively, and these receptor types are considered in detail in this article. The Y_4 receptor is not discussed in detail since this receptor exhibits a marked preference for PP and is relatively insensitive to PYY, PYY(3-36), and NPY. It should also be noted that the Y_3 receptor, which has not been cloned but exhibits an apparently unique pharmacology, is most probably an overtly NPY-preferring, Y_1 receptor.

Y_1 Receptors Activated by PYY

NPY and circulating PYY, but not physiological circulating levels of PYY(3-36) (or other C-terminal fragments of either peptide), will activate Y_1 receptors. Synthetic Pro³⁴-substituted analogues of NPY and PYY also have a high affinity for this receptor type. The Y_1 receptor is extensively expressed in the brain (e.g., cerebral cortex, dentate gyrus of the hippocampus, and certain thalamic and hypothalamic nuclei), the vascular system (where Y_1 receptors on vascular smooth muscle mediate increased tone), enteric neurons, and epithelia in mammalian intestine. In human and murine intestinal tissues, PYY (NPY and their Pro³⁴ analogues) activates epithelial Y_1 receptors to cause prolonged anti-secretory effects (a G_i protein-coupled mechanism). However, the Y_1 receptor is not the only Y receptor of importance in the gut. Both the Y_2 and Y_4 receptors also exhibit functional roles (and all three Y receptors will inhibit mucosal vectorial ion and fluid transport, i.e., anti-secretory effects). The different expression patterns of Y receptors have been described in rat intestine by Laburthe and co-workers and from these detailed studies likely functions may be postulated.

Y_2 Receptors Activated by PYY and PYY(3-36)

In the 1980s, Håkanson and colleagues presented the first pharmacological data indicating that a Y receptor type was preferentially activated by C-terminal fragments of either NPY or PYY [e.g., NPY(3-36), NPY(13-36) or PYY(3-36)] and that this receptor type was located prejunctionally at a number of sympathetic neuro-effector junctions. Activation of these receptors resulted in inhibition of noradrenaline (NA) and NPY release and the Y_2 receptor was therefore proposed to mediate neuronal feedback inhibition. This has subsequently been found to be the case in both the peripheral and central nervous systems in a wide range of mammalian tissues. Such a mechanism in the hypothalamus has also been suggested to underlie the anorexic effects of elevated postprandial PYY(3-36) in human subjects. But it would be wrong to presume that Y_2 receptors are exclusively prejunctional, as this receptor has been found frequently to mediate direct actions on postjunctional target cells, e.g., intestinal epithelia, where Y_2 receptors mediate anti-secretory ion transport effects.

Y_5 Receptors and Their Activation by PYY, PYY(3-36), NPY, and PP

PYY and PYY(3-36) can also stimulate Y_5 receptors and their localization in specific CNS regions outside the blood-brain barrier, known to be involved in appetite control, stimulated great research efforts aimed at discovering novel centrally active anti-obesity drugs. This receptor type is rarely expressed in peripheral tissues and thus circulating PYY and PYY(3-36) are predicted to have little if any peripheral Y_5 -mediated side effects. Initial hopes of a novel Y-related anti-obesity drug have faded as the complexity of multiple peptide pathways regulating appetite has been elucidated.

Other Y Receptor Types

At physiological concentrations, neither PYY nor PYY(3-36) has a significant effect on the PP-preferring Y_4 receptor. It is also debatable whether the Y_3 receptor actually exists. Subsequent to the sequencing of the human genome, it appears likely that this Y receptor type is probably a Y_1 receptor in tissues that are for some reason significantly less sensitive to PYY.

In conclusion, it can be presumed that elevated circulating levels of PYY will activate Y_1 and Y_2 receptors, whereas its metabolite will preferentially

stimulate Y_2 receptors. Neither peptide is predicted to cross the blood–brain barrier to any significant extent. Studies by Bloom and colleagues show that PYY(3–36) may be an important satiety factor acting on hypothalamic mechanisms in human.

REGULATION OF PYY SECRETION FROM INTESTINAL ENDOCRINE CELLS

Whereas NPY is an important neuropeptide that acts centrally to initiate feeding, PYY acts to ensure more efficient digestion of the ingested meal. Plasma PYY levels are raised within 30 min of ingestion of a meal, long before the luminal contents have reached the terminal intestine where there is a high density of PYY⁺ endocrine cells. PYY release is regulated by and also regulates the parasympathetic nervous system, specifically vagal nerve activity. Luminal nutritional factors, particularly fat and short-chain fatty acids (produced through fermentation of carbohydrates by colonic microflora), have also been found to stimulate PYY release and the peptide subsequently alters intestinal motility and electrolyte secretion/absorption. PYY may thus provide a negative feedback mechanism, inhibiting various mechanisms including neurally mediated pancreatic exocrine secretion after eating a meal.

FUNCTIONAL CONSEQUENCES OF PYY RELEASE

Ileal Brake and Epithelial Ion Transport

Two major effects of elevated postprandial PYY are reduced gastric emptying and delayed intestinal transit; both contribute to the ileal brake mechanism (together with reduced exocrine pancreatic secretion). PYY and PYY(3–36) exert long-lasting inhibition of ion and fluid transport, promoting a proabsorptive state in most mammalian intestines, including human isolated intestinal preparations and also in human subjects infused with PYY. These inhibitory effects can be mediated by Y_1 or Y_2 receptor or by a combination of the two together and (depending on the species under study) these effects may be either direct or indirect epithelial mechanisms.

Central Effects That Alter Intestinal Function

PYY, either when infused intravenously or when injected directly into the dorsovagal complex, inhibits

vagally stimulated gastric acid secretion and motility (a Y_2 receptor-mediated effect).

Pancreatic Exocrine Secretion

In human, PYY may be involved in stimulating the transition from the digestive to the interdigestive phase. Depending on the type of stimulant, PYY has inhibitory effects on exocrine pancreatic secretion in most species that have been tested. This is likely to be a Y_1 receptor-mediated, indirect effect, as few if any Y_1 receptors could be identified immunochemically on pancreatic duct cells. The mediator(s) of such indirect PYY effects is unknown. The Y_1/Y_2 agonist PYY can also inhibit postprandial cholecystokinin release. Duodenal fat-initiated release of secretin is also attenuated by PYY. Depending on the species of interest, endocrine pancreatic secretion, e.g., insulin and glucagon release, can be inhibited by PYY. Whether these inhibitory effects are direct or indirect also varies according to the prevailing stimulus. Evidence therefore indicates that PYY has the potential to inhibit pancreatic secretions at multiple sites and that the peptide is one of the major regulators that ultimately slow normal intestinal function.

Fatty Acid-Induced Differentiation

Aponte and colleagues have suggested that PYY and free fatty acids (FFA) may act in a concerted manner to change mucosal cell differentiation. Continuous replacement of mucosal cells by differentiating crypt stem cells is a process that is essential for maintaining normal intestinal function. The fact that FFA stimulate PYY release and that the peptide may then alter epithelial cell adhesion and differentiation provides another mechanism by which PYY could alter intestinal function over the longer term.

Growth Effects and Cancer

In vivo studies show that PYY infused to mimic postprandial levels has protective effects on gastric erosion stimulated by ethanol. This protective mechanism appears to be independent of vagal input and is likely to be Y_1 receptor-mediated. Colonic PYY has been shown to have local trophic effects in rat and mouse large bowel; thus, the peptide has a role in intestinal development and dietary adaptation. However, PYY expression is reduced in carcinomas compared with surrounding tissue areas. Specific adenocarcinoma cell lines constitutively express Y_1 and Y_4 receptors (and

would therefore be expected to be sensitive to circulating PYY and PP, respectively). Whether PYY has a role in the dysregulation of cell growth and the development and progression of adenocarcinoma is not clear. Its growth-promoting effects certainly require further investigation before stable analogues of PYY may be considered as novel therapies, e.g., to enhance the nutritional status of cancer patients, in combination with other agents.

PYY AND INTESTINAL DISORDERS

Elevated plasma levels of PYY have been reported in several diseases including steatorrhea, inflammatory bowel diseases, and acute infective diarrhea. More commonly, the changes in plasma PYY appear to be an adaptive response to alterations in the pathophysiology of gut function. However, in the condition of chronic idiopathic slow transit constipation, PYY appears to be a primary cause and may be one of the etiological factors of this particular syndrome. For these patients, who are insensitive to laxatives or bulking agents, only an enema will promote defecation. Although basal and peak circulating levels of PYY appear unchanged, the tissue levels of PYY are raised in these patients. Individuals show disruption of their neuroendocrine peptides and an increase in the number of PYY-containing endocrine cells in the ascending colon compared with controls. Increased PYY levels could therefore be responsible for the increased absorption, reduced secretion of water and electrolytes, and reduced motility (together with enhanced ileal brake), all of which would be proconstipatory.

Surgical removal of large intestine as a treatment for gastrointestinal disease, such as colorectal carcinoma or chronic slow transit constipation, also significantly removes the main source of PYY from the body. However, rapid adaptive changes appear to occur post-operatively so that these patients show either unaltered or elevated postprandial PYY levels and increased tissue PYY levels adjacent to the anastomosis site.

In conclusion, PYY exhibits multiple actions, many of them inhibitory and mediated by at least two of the five cloned Y receptors, depending on their discrete and differential expression. The PYY-synthesizing endocrine L cells of the large bowel play a pivotal role, not only in the regulation of digestive processes, but also in the adaptive responses to a range of luminal cues and changing dietary components.

Figure 1 The chemical structure of phentolamine.

doxazosine, is generally preferred in the prevention of hypertensive paroxysms or in the preoperative medical treatment of patients with pheochromocytoma.

Phentolamine is also used in the prevention or treatment of dermal necrosis and sloughing following intravenous administration or extravasation of norepinephrine.

Phentolamine has several other uses as well.

Phentolamine may be useful in relieving pseudo-obstruction of the bowel in patients with pheochromocytoma. This condition is dependent on the inhibitory effect of catecholamines on intestinal smooth muscle.

Phentolamine may be useful in the treatment of hypertensive crises caused by the abrupt withdrawal of clonidine or by the ingestion of tyramine-containing foods in patients treated with nonselective inhibitors of monoamine oxidase.

The use of phentolamine as a test for the diagnosis of pheochromocytoma is considered obsolete. In fact, the test, which is based on the degree of blood pressure decrease after intravenous phentolamine administration, is characterized by low sensitivity and specificity.

Figure 1 Action of PNMT.

PNMT mRNA is also analyzed by Northern blot analysis using a PNMT cDNA probe.

LOCALIZATION

In mammalian tissues, only the heart, adrenal medulla, brain, and brainstem have measurable amounts of PNMT.

PNMT is found mainly in the adrenal medulla and in a few neurons in the CNS. The enzyme is found in the cytoplasm of chromaffin cells.

PNMT activity exists in human lung, kidney, heart, liver, spleen, and pancreas. There is a significant correlation between tissue PNMT and epinephrine levels. PNMT in human lung and that in human bronchial epithelial cells were indistinguishable from adrenal PNMT. PNMT activity is present in red blood cells and cancer cell lines. Human kidney, lung, and pancreas show immunohistochemical staining with an antibody to adrenal PNMT.

Radiotracer studies indicate that nearly half of the epinephrine in urine may be made by the kidney.

PNMT GENE, mRNA, AND PROTEIN

The PNMT gene is located on chromosome 17. PNMT is encoded by a single gene that consists of three exons and two introns, spanning approximately 2100 bp.

The 5'-flanking regions of the gene contain possible transcription regulatory elements, such as the cyclic AMP-response element, glucocorticoid-response element, and Sp1-binding site.

In addition to the major human PNMT mRNA (type A, 1.0 kb), a minor mRNA (type B, 1.7 kb) was observed. The two types of mRNA are thought to be produced from a single gene through the use of alternative promoters.

Determination of the nucleotide sequence revealed that human PNMT consists of 282 amino acid residues with a predicted molecular weight of 30,853 kDa, including the initial methionine.

REGULATION OF PNMT

In embryonic adrenal gland, development of the enzyme activity is regulated by glucocorticoids and in cultured chromaffin cells and superior cervical ganglia, the activity is induced by nerve growth factor.

PNMT activity in a human bronchial epithelial cell line is dramatically increased by incubation with dexamethasone. Red blood cell PNMT activity is lower in males than in females, is increased in hyperthyroidism, and is decreased in hypothyroidism.

Pituitary adenylate cyclase-activating polypeptide, a member of the secretin/glucagon/vasoactive intestinal peptide family, induces the expression of PNMT mRNA. Egr-1 also increases the expression of the PNMT gene.

DISORDER IN DISEASES

Cushing's Syndrome

A possible contributing mechanism to the elevated cardiac output in Cushing's syndrome may be the increased epinephrine formation resulting from enhanced PNMT activity in the adrenal medulla and also in the myocardium.

Parkinson's Disease

Parkinson's disease primarily affects the dopaminergic nigrostriatal system; however, various cells in brain and adrenal medulla that express PNMT or exist in proximity to PNMT-expressing cells are also affected in the disease.

Multiple Sclerosis

PNMT is known to map to a region identified in two genome screens for multiple sclerosis (MS) and it directly regulates the amounts of norepinephrine and epinephrine, both of which play a significant role in the modulation of the innate immune response. The frequencies of two promoter polymorphisms of the

PNMT gene showed genetic association with MS in a case control study.

Pheochromocytoma

PNMT mRNA expression is greatly enhanced in epinephrine-secreting pheochromocytomas and gene expression may be enhanced by both cortisol and Egr-1.

corneal nerve fibers, and marfanoid habitus. The *RET* mutation affects exons 15 and 16, coding for the intracellular tyrosine kinase domain of RET protein.

Von Hippel–Lindau Syndrome

Von Hippel–Lindau (VHL) syndrome is another autosomal-dominantly inherited tumor syndrome associated with pheochromocytoma. Apart from pheochromocytoma, major tumors in VHL disease include renal cell carcinoma, hemangioblastoma, neuroendocrine pancreatic tumors, and endolymphatic sac tumors. Pheochromocytoma occurs in approximately 10–20% of VHL patients and is the presenting manifestation in approximately 5% of cases. In contrast to pheochromocytomas of patients with MEN2 (“adrenergic”), VHL-associated pheochromocytomas have a more “noradrenergic” phenotype, pointing to their different developmental stage; i.e., MEN2-related pheochromocytomas frequently possess all the enzymes to synthesize catecholamines from tyrosine to epinephrine, whereas less differentiated pheochromocytomas including those in VHL syndrome lack the enzymes involved in the final catecholamine biosynthesis pathway. Thus, symptoms and signs of patients with VHL-related pheochromocytoma are related to norepinephrine excess including, e.g., hypertension. The VHL tumor suppressor gene is located on chromosome 3p25–p26. A “second hit” is required in patients with *VHL* germ-line mutations to develop pheochromocytoma.

Neurofibromatosis Type 1

Neurofibromatosis type 1 (NF1) is the most common familial cancer syndrome predisposing to

pheochromocytoma and affects approximately 1 in 3000 individuals. The risk of pheochromocytoma in NF1, however, is small, approximately 1%. NF1 is inherited in an autosomal-dominant manner. Only 12% of NF1 patients are diagnosed with bilateral and multifocal pheochromocytomas and less than 5% of patients have metastatic pheochromocytoma. The NF1 gene is a tumor suppressor gene mapping to chromosome 17q11.2.

BENIGN VERSUS MALIGNANT PHEOCHROMOCYTOMA

Although mostly benign, approximately one-third of pheochromocytomas are malignant. Distinguishing benign from malignant pheochromocytoma is not possible based on histopathological features. Malignant pheochromocytoma is diagnosed based on the presence of metastatic lesions at sites where chromaffin cells are not usually present (e.g., liver, lungs, lymphatic nodes, and bones). Therefore, all pheochromocytomas, whether benign or not, must be considered to have the potential for malignancy. Whether benign or malignant, pheochromocytomas are potentially lethal tumors that require prompt diagnosis, localization, and treatment.

DIAGNOSIS

Biochemical evidence of excessive catecholamine production is crucial for the diagnosis of pheochromocytoma. Commonly used tests include 24h urinary outputs of catecholamines (norepinephrine and epinephrine), metanephrines (normetanephrine and metanephrine), and vanillylmandelic acid (VMA). Spectrometric assays of catecholamines, total metanephrines, and VMA have been superseded by high-performance liquid chromatography (HPLC) assays that allow diagnostically more sensitive measurements of fractionated norepinephrine and epinephrine or normetanephrine and metanephrine. HPLC assays have also been adapted for measurements of the much lower plasma concentrations of catecholamines and metanephrines. The latter can be measured in either the free or the much higher deconjugated forms (i.e., free plus sulfate-conjugated metanephrines). Urinary assays involve measurements of deconjugated metanephrines. Pheochromocytomas continuously produce free metanephrines by a process that is independent of catecholamine release. Measurements of free metanephrines in plasma are therefore proving to offer the most sensitive test for the diagnosis of pheochromocytoma. Since familial pheochromocytoma

has variable expression and age- and tumor-dependent penetrance, patients with familial predisposition to develop pheochromocytoma should be followed up on an annual basis, including the measurement of plasma metanephrines.

LOCALIZATION

Computed tomography (CT) and magnetic resonance imaging (MRI) are the most appropriate imaging modalities for initial localization of pheochromocytoma and both offer high sensitivity for detection of adrenal tumors. MRI is superior to CT for detecting extra-adrenal tumors. Both CT and MRI, however, have inadequate specificity to positively identify a mass as a pheochromocytoma. Metaiodobenzylguanidine (MIBG) scintigraphy provides an imaging modality that offers high specificity and is particularly useful for detecting extra-adrenal tumors and metastases. Sensitivity of MIBG scintigraphy is not as high as that of CT or MRI, but is higher for ^{123}I -labeled than for ^{131}I -labeled MIBG. Other promising methods for specific localization of pheochromocytoma include positron emission tomography coupled with agents such as [^{11}C]hydroxyephedrine or 6- ^{18}F fluorodopamine. In rare cases, where imaging studies are all negative, but where suspicion of a pheochromocytoma remains high, vena cava sampling may be useful for localizing the source of the high circulating levels of catecholamines or free metanephrines.

TREATMENT

Surgery provides the only effective curative treatment for pheochromocytoma. Because of the potentially fatal consequences of surgical anesthesia-induced release of catecholamines by a tumor, it is imperative that patients with pheochromocytoma be appropriately prepared for surgery. Maintenance of adequate blood pressure control using α -adrenergic blockers (e.g., phenoxybenzamine) or calcium channel blockers before surgery is important. Administration of α -methyl-*para*-tyrosine (metyrosine) to block synthesis of catecholamines may also be appropriate in patients with larger active tumors. There is no effective treatment for malignant pheochromocytoma. Chemotherapy with cyclophosphamide, vincristine, and dacarbazine may produce partial remission. Radiotherapies using ^{131}I -labeled MIBG or indium- or yttrium-labeled octreotide provide benefit in some patients with malignant pheochromocytoma, but again have not proven curative.

different types of cell-surface receptors that are activated by extracellular signaling molecules (agonists), including hormones, neurotransmitters, cytokines, growth factors, and antigens.

METABOLIC PATHWAYS FOR PHOSPHATIDYLINOSITOL TURNOVER AND ROLES OF INTERMEDIATES

These PLC products, DAG and Ins(1,4,5)P₃, are further metabolized by numerous enzymes and finally resynthesized to the PLC precursor PI(4,5)P₂ through many intermediate steps (Fig. 1). The entire receptor agonist-sensitive lipid pool (estimated at 80% of the total) is metabolized several times per minute. Thus, during receptor stimulation, PI(4,5)P₂ is continuously synthesized and supplied to PLC. This explains why the amount of Ins(1,4,5)P₃ produced often exceeds the decrease in the amount of PI(4,5)P₂ and, in some cases, the precursor lipid fails to decrease under receptor stimulation. This also explains why receptor stimulation resulted in an increase in ³²P incorporation

in phospholipids such as phosphatidylinositol (PI) and phosphatidic acid, which was reported in the early studies. Therefore, the PI response is also called PI turnover or PI cycle.

PI(4,5)P₂ is a substrate for not only PLC but also PI 3-kinase (PI3K), which catalyzes the phosphorylation of PI(4,5)P₂ to produce PI(3,4,5)P₃. There are several isoforms of PI3K and certain forms catalyze the conversion of PI to PI 3-phosphate [PI(3)P]. PI3K is also regulated by several extracellular stimuli through cell-surface receptors. The PI3K products PI(3,4,5)P₃ and PI(3)P as well as PI(4,5)P₂ serve as a membrane docking site for PLCs and other signaling molecules through their pleckstrin homology (PH) domains. PI(3,4,5)P₃ is also an important signaling molecule for cell survival through the activation of Akt/protein kinase B. The role of the cell-survival activity of PI(3,4,5)P₃ is supported by the observation that the loss of function mutation of the phosphatase and tensin homologue, which catalyzes the reverse reaction of PI3K, is found in certain cancer cells. PI(4,5)P₂ also plays critical roles as regulators for several enzymes such as protein kinase C, phospholipase

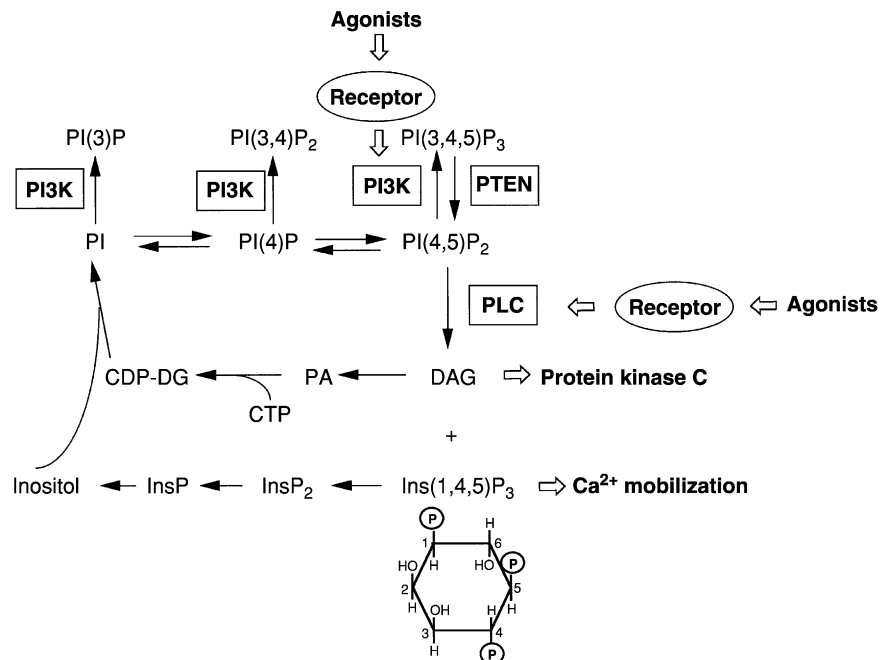

Figure 1 Metabolic pathway for inositol lipids and regulation by receptor stimulation. Receptor stimulation induces the activation of phosphoinositide-specific phospholipase C (PLC), which catalyzes the cleavage of phosphatidylinositol 4,5-bisphosphate [PI(4,5)P₂] into two intracellular second messengers: diacylglycerol (DAG), an activator for protein kinase C, and inositol 1,4,5-trisphosphate [Ins(1,4,5)P₃], a Ca²⁺ mobilizer from intracellular stores. The PLC substrate, PI(4,5)P₂, is also metabolized to phosphatidylinositol 3,4,5-trisphosphate [PI(3,4,5)P₃] by phosphatidylinositol 3-kinase (PI3K). The enzyme also produces phosphatidylinositol 3-phosphate [PI(3)P]. The enzyme activity is also regulated by receptors. These phosphoinositides play crucial roles in the recruitment of PLC from cytosol to membrane. PI, phosphatidylinositol; PI(4)P, phosphatidylinositol 4-phosphate; PA, phosphatidic acid; PTEN, phosphatase and tensin homologue.

D, and phospholipase A2. In addition, this phosphoinositide modulates the actin cytoskeleton through interaction with a variety of actin regulatory proteins.

FOUR TYPES OF PLC AND THEIR DOMAIN STRUCTURE

Eleven isoforms of PLC have been isolated and are divided into four types based on their structure: β ($\beta 1$, $\beta 2$, $\beta 3$, $\beta 4$); γ ($\gamma 1$, $\gamma 2$); δ ($\delta 1$, $\delta 2$, $\delta 3$, $\delta 4$); and ϵ (Table I). Among them, ϵ -type was identified in 1998 and its characteristics are being studied. In addition, it has been reported that numerous spliced variants are present in mammals. PLCs are also found in simple organisms such as yeasts, slime molds, filamentous fungi, and plants and these PLCs resemble mammalian δ , which is only ~ 85 kDa and is the smallest of the

PLCs. Thus, PLC- β , PLC- γ , and PLC- ϵ , which are present in higher eukaryotes, are thought to have arisen from an evolutionarily primitive PLC- δ .

The sequences of PLC contain a string of molecular domains (Fig. 2). All isoforms contain catalytic domains (X and Y) and regulatory domains that serve to recruit PLC to the vicinity of their substrate or activators through protein-protein or protein-lipid interactions. These regulatory domains include a PH domain, an EF-hand domain, and a C2 domain. The PH domains are composed of ~ 100 amino acid residues and have been identified in more than 100 other signaling proteins. These domains bind to polyphosphoinositides (or inositol phosphate) and $\beta\gamma$ -subunits of heterotrimeric G proteins ($G_{\beta\gamma}$) and appear to function as adapters or tethers, linking their host proteins to the membrane surface. A single PH

Table I Receptors and Regulators Linked to PLC Isoforms and Their Distribution

| Isoforms | Receptors | Regulators | Distribution | |
|-----------------|---|--|--|--|
| PLC- $\beta 1$ | GPCRs | $G_{\alpha q}$ | PI(3)P | Widely expressed, especially in cerebral cortex and hippocampus in brain |
| PLC- $\beta 2$ | GPCRs | $G_{\beta\gamma}$ | PI(3)P | Hematopoietic cells |
| PLC- $\beta 3$ | GPCRs | $G_{\alpha q}$, $G_{\beta\gamma}$ | PI(3)P | Widely expressed |
| PLC- $\beta 4$ | GPCRs | $G_{\alpha q}$ | PI(3)P | Retina and cerebellum |
| PLC- $\gamma 1$ | RTKs (PDGF, EGF, FGF, NGF, VEGF, HGF, etc.) Cytokines and immunoglobulin receptors (TCR, BCR, Fc ϵ RI, Fc γ Rs etc.) | NRTKs (Src, Syk, Tec, etc.) | PI (3,4,5) P ₃ | Widely expressed, especially in brain and lung |
| PLC- $\gamma 2$ | GPCRs (acetylcholine, angiotensin II, thrombin, PAF, ATP, etc.) | (Src/RTK) | PI(3,4,5)P ₃ | Hematopoietic cells |
| PLC- $\delta 1$ | $\alpha 1$ -Adrenergic, oxytocin, thromboxan A ₂ , bradykinin | G_{H} | Ca ²⁺ , PI(4,5)P ₂ | Most abundant among δ -types and widely expressed |
| PLC- $\delta 2$ | | | Ca ²⁺ , PI(4,5)P ₂ | Cerebral cortex and cerebellum Purkinje cells |
| PLC- $\delta 3$ | | | Ca ²⁺ , PI(4,5)P ₂ | Kidney, cardiac muscle, aorta, brain |
| PLC- $\delta 4$ | | | Ca ²⁺ , PI(4,5)P ₂ | Brain, skeletal muscle, testis, kidney |
| PLC- ϵ | EGF, β -adrenergic, prostaglandin E ₂ , muscarinic M ₃ -acetylcholine | Ras, G ₁₂ (G ₁₃), $G_{\beta\gamma}$ | | Widely expressed, especially in heart in human and liver in rat |

Note. The representative receptors and regulators involved in 11 isoforms of PLC and their distribution in tissues or cells in mammals are shown. GPCRs, G protein-coupled receptors; RTKs, receptor tyrosine kinases; NRTKs, nonreceptor tyrosine kinases; PDGF, platelet-derived growth factor; EGF, epidermal growth factor; FGF, fibroblast growth factor; NGF, nerve growth factor; VEGF, vascular endothelial growth factor; HGF, hepatocyte growth factor; TCR, T cell antigen receptor; BCR, B cell antigen receptor; Fc ϵ RI, high-affinity IgE receptor; Fc γ Rs, IgG receptors; PAF, platelet-activating factor.

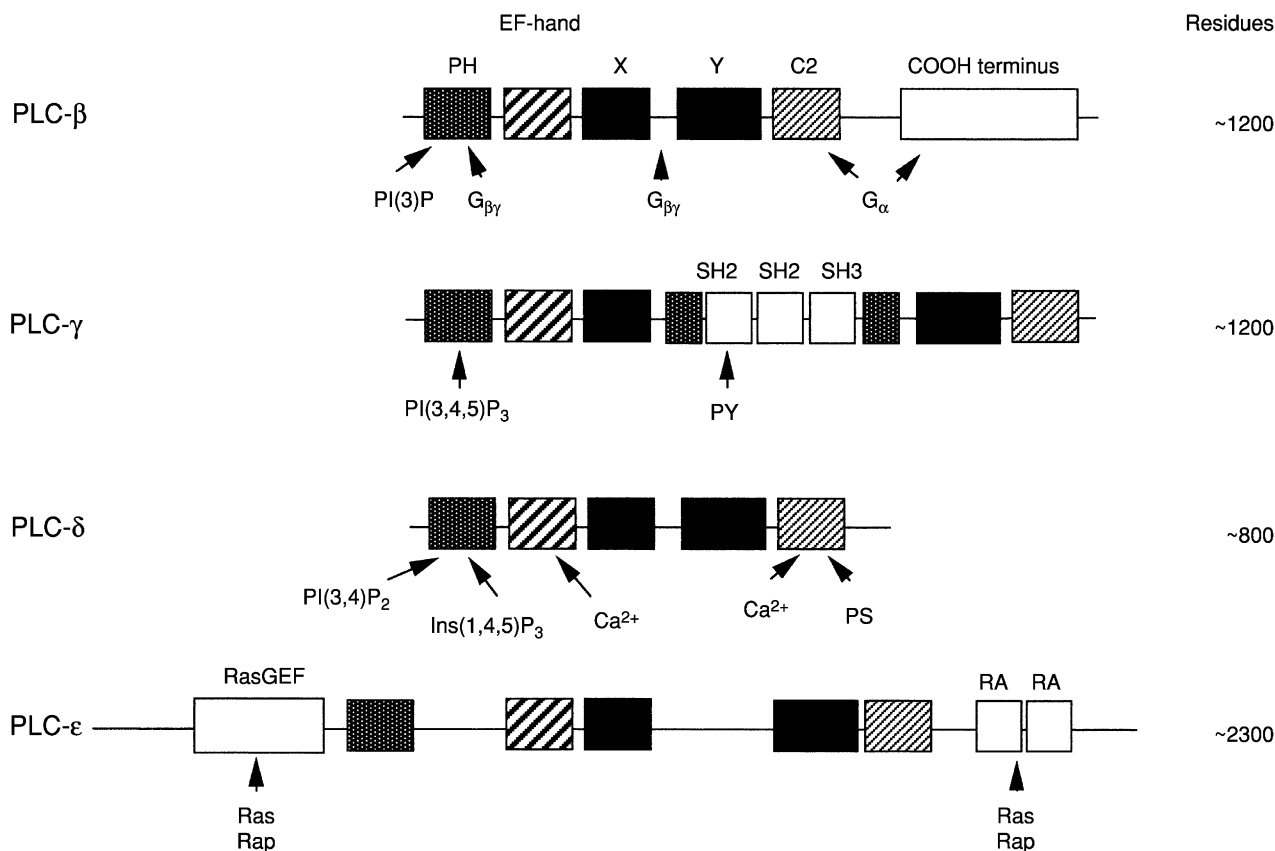

Figure 2 Domain structure of four types of PLC and their regulatory molecules. Structural domains present within four types of PLC are shown. PH, EF-hand, catalytic (X and Y), and C2 domains are present in all types of PLCs. In addition, a regulatory COOH terminus is present in PLC- β ; Src homology 2 (SH2) and Src homology 3 (SH3) domains are present within the second PH domain in PLC- γ ; and the Ras guanine nucleotide exchange factor (RasGEF)-like and Ras-associating (RA) domains are present in PLC- ϵ . Major regulatory molecules interacting with these domains are also shown. $G_{\beta\gamma}$, $\beta\gamma$ -subunits of heterotrimeric G proteins; G_{α} , α -subunits of heterotrimeric G proteins; PY, phosphotyrosine; and PS, phosphatidylserine.

domain appears to be present in all PLCs and an additional PH domain is split by two Src homology (SH) 2 (SH2) domains and one SH3 domain in PLC- γ . To the NH₂-terminal PH domains, PI(3)P and $G_{\beta\gamma}$ are bound in PLC- β , PI(3,4,5)P₃ is bound in PLC- γ , and PI(3,4)P₂ and Ins(1,4,5)P₃ are bound in PLC- δ . In the case of PLC- ϵ , the role of this domain has not been characterized. The roles of the EF-hand domain and C2 domain are unclear. These domains are known to bind Ca²⁺. The C2 domain of PLC- δ 1 has been estimated to contain three Ca²⁺-binding sites and their binding is thought to increase enzyme activity by forming a ternary complex with the enzyme and phosphatidylserine. In contrast, C2 domains of PLC- β and PLC- γ do not seem to bind Ca²⁺, but this domain of PLC- β 1 interacts with the α -subunit of G_q protein ($G_{\alpha q}$).

Additional regulatory domains or motifs are present in PLC- β , PLC- γ , and PLC- ϵ . PLC- β contains a

long COOH-terminal region; PLC- γ contains two SH2 domains and one SH3 domain, which bind phosphotyrosine-containing sequence and proline-rich sequences, respectively; and PLC- ϵ contains Ras-associating (RA) domains and a Ras guanine nucleotide exchange factor (RasGEF)-like domain. The different combinations of these regulatory domains in each PLC type determines their regulatory mechanism of enzyme activity.

REGULATION OF PLC ACTIVITY

PLC- β

PLC is usually present in cytosol. The PLC- β type interacts with PI(3)P, a PI3K product, through its PH domain, and this interaction is responsible for the recruitment of the enzyme from the cytosol to the membrane. All PLC- β isoforms are regulated by G

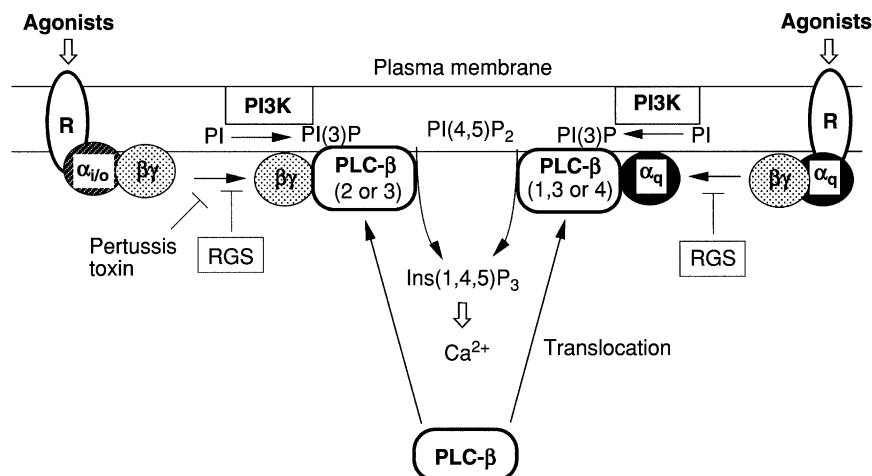

Figure 3 Regulation of PLC- β . PLC- β types are regulated by both G_q and G_i subfamilies. On stimulation of G_q -coupled receptors, $G_{\alpha q}$ subunits are dissociated from the complex and activate PLC- β_1 , PLC- β_3 , and PLC- β_4 by interacting with the C2 domain and regulatory COOH terminus. On the other hand, when G_i - or G_o -protein-coupled receptors are stimulated, $G_{\beta\gamma}$ subunits are dissociated and activate PLC- β_2 and PLC- β_3 by interacting with the PH domain. In both cases, PI(3)P produced by PI3K may play a role in the recruitment of the enzyme from cytosol to membrane. See text for further details.

protein-coupled receptors (GPCRs), such as muscarinic acetylcholine receptors and adrenergic receptors, through heterotrimeric G proteins that are composed of α -, β -, and γ -subunits (Table I and Fig. 3). The β - and γ -subunits are tightly associated under physiological conditions. The heterotrimeric G proteins are divided into four subfamilies based on their amino acid sequences and effector interactions of α -subunits: G_s , G_i , G_q , and G_{12} . Receptor stimulation induces an exchange of GDP to GTP on the α -subunits and thereby the dissociation of GTP-bound α -subunits and $\beta\gamma$ -subunits. All members (α_q , α_{11} , α_{14} , and α_{16}) of the α -subunits of the G_q subfamily can activate PLC- β_1 , - β_3 , and - β_4 through their C2 domains and the regulatory COOH terminus (~400 amino acid residues) sequences unique to PLC- β (Fig. 2). This terminus is also thought to be involved in membrane binding and nuclear localization. On the other hand, $G_{\beta\gamma}$ activates β_2 , β_3 , and, to a lesser extent, β_1 through their PH domains, although the concentrations of $G_{\beta\gamma}$ required for maximal enzyme activation are much higher than those of $G_{\alpha q}$. Pertussis toxin-sensitive G proteins, G_i or G_o proteins, are usually expressed at a higher level in the cells than other heterotrimeric G proteins. Thus, $G_{\beta\gamma}$, which activates PLC- β , may be derived from the toxin-sensitive G proteins. The activation of PLC is turned off by the intrinsic GTPase of $G_{\alpha q}$. The hydrolysis of GTP to GDP on $G_{\alpha q}$ leads to the reassociation of $G_{\alpha q}$ with $G_{\beta\gamma}$. The GTPase activity of $G_{\alpha q}$ is stimulated by PLC itself and also by a group of regulatory

proteins called regulators of G protein signaling (RGS). Approximately 20 species of RGS have been identified and have been shown to stimulate the GTPase activity of α -subunits of the G_i and G_q subfamilies.

PLC- γ

Except for the differences in their distribution and hence the receptor species coupled, there seems to be no fundamental difference in the regulatory mechanisms between two isoforms of the enzyme (PLC- γ_1 and - γ_2). This type of PLC contains two important domains, the PH domain and the SH2 domain, which serve to recruit the enzymes to membranes and activate them (Fig. 2). Representative receptors and important regulators involved in the regulation of PLC- γ are summarized in Table I. Tyrosine kinase, regardless of whether the receptors themselves possess intrinsic activity, is very important for the activation of PLC- γ . Receptors coupled to this type of PLC can be divided into three groups: receptor tyrosine kinases, which contain intrinsic tyrosine kinase activity; cytokine and immunoglobulin receptors; and GPCRs. In the latter two cases, receptors have no intrinsic tyrosine kinase activity and must activate nonreceptor tyrosine kinases such as Src and Syk.

The regulatory mechanisms of PLC- γ by receptor tyrosine kinases (RTKs) such as platelet-derived growth factor (PDGF) receptor and epidermal growth factor (EGF) receptor are illustrated in Fig. 4. These

Figure 4 Regulation of PLC- γ . The mechanisms of PLC- γ activation by receptor tyrosine kinases (RTKs), such as platelet-derived growth factor (PDGF) receptor, are shown. See text for further details.

receptors generally dimerize after the binding of these growth factors (first stage to second stage) and thereby autophosphorylate tyrosine residues (second stage). These phosphotyrosines provide docking sites for signaling molecules including PLC- γ and PI3K through their SH2 domains (third stage). The docking of PLC- γ results in the phosphorylation of the tyrosine residue (Tyr-783) of the enzyme that is required for enzyme activation. In concert with these events, PI3K is also activated through the binding of the SH2 domain of PI3K to another phosphotyrosine site of receptors, which in turn supplies PI(3,4,5)P₃. This phosphoinositide serves to anchor the enzyme through the PH domain of PLC- γ and the enzyme is then activated to cleave PI(4,5)P₂ (fourth stage). Thus, tyrosine kinase activation and subsequent protein-protein and lipid-protein interactions play pivotal roles in the activation of PLC- γ .

PLC- γ activation by immunoglobulin receptors, which have no intrinsic tyrosine kinase activity, requires the involvement of nonreceptor tyrosine kinases (NRTKs) (Table I). In the case of T cell antigen receptor (TCR), ligation of the TCR triggers the activation of Src-related NRTKs Lck and Fyn, which in turn results in phosphorylations of tyrosine residues in one chain of the receptor complex and ZAP-70 (a member of the Syk family of NRTK). The activated ZAP-70 then phosphorylates the downstream substrates and finally leads to the activation of PLC- γ . The activation of GPCRs sometimes induces tyrosine phosphorylation of RTKs such as PDGF receptor and EGF receptor. As a result, PLC- γ is activated as shown in Fig. 4. The phosphorylation of RTKs appears to be mediated by Src. Both G $_{\beta\gamma}$ subunits and G $_{\alpha}$ subunits including G $_{\alpha i}$ and G $_{\alpha s}$ have been suggested to be involved in the activation of Src.

PLC- δ

Four isoforms of PLC- δ have been identified in mammals. This type of PLC exhibits much higher sensitivity to Ca²⁺ than PLC- β and PLC- γ . This high Ca²⁺ sensitivity is attributable to the C2 domain specific to PLC- δ . It is therefore suggested that the enzyme activity of PLC- δ may be regulated by an intracellular Ca²⁺ increase that was attained by the activation of other PLC types. The PH domain of PLC- δ binds PI(4,5)P₂ and serves to anchor the enzyme on the membrane. The binding of PI(4,5)P₂ to the PH domain is promoted by Ca²⁺ binding to the EF-hand of the enzyme. Thus, intracellular Ca²⁺ is crucial for the regulation of the enzyme activity of PLC- δ . Although the physiological role is unclear, certain GPCRs are shown to couple to PLC- δ 1 through an atypical G protein, G_h (molecular weight of 74–80 kDa) (Table I). G_h also possesses transglutaminase activity. Unlike α -subunits of heterotrimeric G proteins, the GDP form of G_h tightly binds to PLC and GTP promotes their dissociation. Thus, G_h might be a negative regulator of PLC- δ 1. It is not known whether PLC- δ isoforms other than δ 1 are regulated by receptor stimulation.

PLC- ϵ

This type of PLC was discovered in 1998 and its regulatory mechanism has not been well characterized as yet. It is the largest (230–260 kDa) of the PLCs, and PLC- ϵ contains extra domains called RasGEF and RA domains specific to this type in addition to the catalytic (X and Y) domain and the regulatory C2 domain common to other types of PLC. The RasGEF domain is thought to function as a GDP-GTP exchange factor for Ras and Ras-related proteins. GTP-bound forms of

Ras and Rap bind to the RA domain and activate PLC- ϵ . EGF-induced Ras activation may be linked to the activation of PLC- ϵ by this mechanism. Cyclic AMP sometimes up-regulates PLC activity. This appears to be mediated by the nucleotide-dependent activation of Epac1 (GEF for Rap) and the subsequent activation of Rap2B, which may interact with the RA domain of the enzyme. This mechanism may partly explain cyclic AMP-dependent β -adrenergic and PGE1-receptor-mediated PLC activation. Thus, PLC- ϵ seems to function not only as a regulator of Ras and Ras-related proteins through the RasGEF domain but also as a regulator of their targets through the RA domain. In addition to the mechanisms related to Ras, PLC- ϵ is shown to be activated by $G_{\alpha 12}$ and $G_{\beta\gamma}$.

DISTRIBUTION AND PHYSIOLOGICAL ROLES OF PLC ISOFORMS

The major distribution sites of PLC isoforms are shown in Table I. PLC- β 1 and PLC- β 3 are widely expressed, especially in specific regions of the brain such as the cerebral cortex and hippocampus for PLC- β 1 and in the brain and liver for PLC- β 3, whereas PLC- β 2 is expressed abundantly in hematopoietic cells such as leukocytes and PLC- β 4 is expressed in the retina and cerebellum. As for PLC- γ types, PLC- γ 1 is widely expressed in several types of cells, whereas PLC- γ 2 expression is high in hematopoietic cells. Among PLC- δ types, δ 1 is most abundant and widely expressed. PLC- δ 2 is detected especially in the brain, whereas PLC- δ 3 and - δ 4 seem to be widely distributed. The expression of PLC- δ 4 in testis is noteworthy.

The pattern of the expression of PLC- γ types is reflected in their isoform-specific functions, which have been confirmed from studies of knockout mice. Mice lacking PLC- β 1 die suddenly due to epileptic-like seizures that are associated with a decrease in inhibitory interneuron firing mediated by muscarinic acetylcholine receptors. Thus, PLC- β 1 is suggested to be involved in muscarinic acetylcholine receptor signal transduction in the cerebral cortex and hippocampus. On the other hand, mice lacking PLC- β 4 show ataxia, which is associated with retardation of the development of the cerebellum. The lower response to the metabotropic glutamate receptor in the cerebellum is suggested to be involved in ataxia. PLC- β 4 has also been shown to be involved in type-1 metabotropic glutamate receptor-mediated long-term

depression. In addition, PLC- β 4 is abundantly expressed in the retina and is shown to play crucial roles in visual responses. In the case of PLC- β 2 knockout mice, unexpectedly from their distribution, hematopoiesis was normal. Furthermore, even though PLC activation and superoxide production were inhibited, chemotaxis was barely affected or rather was enhanced when chemoattractant effects were examined in neutrophils from these animals. Thus, PLC- β 2 is necessary for superoxide production but not for chemotaxis. A crucial role of PI3K in chemotaxis has been demonstrated in mice lacking PI3K γ . Mice lacking PLC- β 3 exhibited an approximately 10-fold decrease in the ED₅₀ value for morphine in producing antinociception. Thus, PLC- β 3 appears to be involved in the negative modulation of μ -opioid-induced antinociception. As expected from the finding that PLC- γ 1 is coupled to various growth factor receptors, the homozygous disruption of PLC- γ 1 resulted in embryonic lethality at embryonic day 9.0. Thus, this enzyme is essential for normal development and growth. PLC- γ 2-deficient mice showed a decrease in mature B cells, a decrease in IgM and IgG levels, a loss of IgM receptor-induced Ca²⁺ response, and defective Fc γ R and Fc ϵ R functions. Thus, PLC- γ 2 plays important roles in the signaling linked to immunoglobulin superfamily receptors. Among PLC- δ types, PLC- δ 4-deficient mice were studied and showed slightly smaller litters. The sperm function of the male animals was depressed; their sperm were unable to initiate the acrosome reaction, an exocytotic event required for fertilization. Thus, PLC- δ 4 is important for the acrosome reaction during fertilization.

fibers whose perikarya are located in the superior cervical ganglia. The preganglionic cell bodies in this chain of neurons are located in the intermediolateral cell column of the upper thoracic cord. These neurons receive synaptic input from cell bodies located in the higher brainstem, most prominently in the paraventricular nuclei (PVN) and suprachiasmatic nuclei (SCN) of the anterior hypothalamus. In turn, the SCN receive a robust neural input via the retino-hypothalamic tract from the ganglion cells of the retina. Thus, the lateral eyes have a multisynaptic connection to the pineal gland and, as noted above, when the neural pathway between the SCN and pineal gland is interrupted, the pineal becomes functionally inept.

Via the neural connections between the eyes and the pineal gland, the prevailing photoperiod exerts a major regulatory influence on the endocrine function of the gland. In general, light perceived by the lateral eyes inhibits the pineal gland, whereas during darkness the gland is endocrinologically active. The perception of light at the retinal level for regulation of the pineal gland relies on different cells and photopigments than does the visual system; that is, the pineal is not regulated by the three cone photopic ocular cells. The predominant wavelengths of light detected by the retinas, which suppress nighttime melatonin production in humans, are in the range of 446–477 nm; the peak absorbance of the photopigment appears different from those in the classic rod and cone cells of the retinas.

BLOOD SUPPLY

The pineal gland, like other endocrine organs, has a perfuse blood supply. This is derived from the posterior choroidal arteries, which are tributaries of the terminal branches of the basilar artery, the posterior cerebrals. Within the gland, the posterior choroid arteries break up into a rich capillary network. Venous blood drains into the large cerebral sinuses that surround the pineal gland.

MELATONIN SYNTHESIS

Melatonin, i.e., *N*-acetyl-5-methoxytryptamine, is the chief secretory product of the pineal gland. The details of the synthesis of melatonin within the gland have been for the most part identified. Melatonin is a metabolite of the amino acid tryptophan, which is taken into the pinealocytes from the blood after its consumption in the diet. Tryptophan is quickly converted

to 5-hydroxytryptamine (serotonin) in pinealocytes; the concentration of this monoamine in the pineal exceeds that of any other organ or group of neurons in the body. The conversion of serotonin to melatonin is a two-step process; both steps have been studied in detail. The synthetic pathway for melatonin is summarized in Fig. 1.

During the night, norepinephrine is released from the postganglionic fibers that end in the vicinity of the pinealocytes. The neurotransmitter then interacts with primarily β -adrenergic receptors, and to a lesser degree with α -receptors, in the pinealocyte membrane to stimulate a cascade of events that promotes the conversion of serotonin to *N*-acetylserotonin (NAS), the immediate precursor of melatonin. This metabolic cascade includes the stimulation of the intracellular second-messenger cyclic AMP (cAMP) and protein synthesis, which are required for the activation of the enzyme serotonin *N*-acetyltransferase. The acetylation of serotonin to NAS is the rate-limiting step in melatonin formation (Fig. 1). NAS is then *O*-methylated to form melatonin. Unlike other endocrine organs that typically store large amounts of the hormone(s)

Figure 1 Synthesis of melatonin (*N*-acetyl-5-methoxytryptamine) from the essential amino acid tryptophan. The activity of the enzyme *N*-acetyltransferase is generally considered rate-limiting in melatonin production.

that they produce, the pineal gland lacks a storage mechanism for melatonin. Rather, once generated, melatonin is quickly released from the pinealocyte.

The route of release of melatonin has been traditionally thought to be directly into the rich capillary plexus that pervades the pineal gland. Studies in sheep, the pineal gland of which is attached to the posterodorsal aspect of the diencephalon like that in human, have shown that melatonin is at least in part discharged from the pineal directly into the ventricular fluid of the third ventricle. This has implications for melatonin's functions in the central nervous system. Simultaneously, melatonin may also be discharged into the blood.

Melatonin Concentrations in Body Fluids

Within the blood and cerebrospinal fluid (CSF), melatonin levels closely track its production in the pineal gland such that at night, when melatonin synthesis within the gland is elevated, concentrations of melatonin in the serum and CSF are likewise high. Typical nighttime serum melatonin concentrations vary from 50 to 150 pg/ml, whereas during the day, serum levels are usually less than 10 pg/ml. In the third ventricular CSF, the melatonin concentrations may be several orders of magnitude, up to 90 nM, higher than in the blood, indicating a direct release of the indole from the pinealocytes into the CSF. Once in bodily fluids, melatonin has access to every cell in the body and is probably taken up by many cells.

Photoperiod and Melatonin Synthesis

The mammalian pineal gland is unique in that its biosynthetic activity is controlled by an environmental variable, namely, the prevailing photoperiod. Pineal melatonin production occurs exclusively during the dark phase of the daily photoperiodic cycle. In modern societies, daily periods of environmental light and darkness have been markedly subverted by the introduction of artificial light sources. If of sufficient intensity and proper wavelength, high nighttime melatonin levels are quickly suppressed by perception of artificial light by the eyes at night. Likewise, during transmeridian travel, the normal 24 h circadian melatonin rhythm is disturbed due to changes in the light/dark cycle.

The SCN are a critical relay in the neural connections between the eyes and the pineal gland. A variety of clock genes in the SCN ensure that these neurons are inherently active during the dark portion of every

24 h period. The active/inactive period of the SCN neurons has a duration of approximately 25 h; thus, it is not normally in synchrony with the prevailing 24 h light/dark cycle. The natural light/dark cycle acting via the retina entrains the circadian SCN rhythm to precisely 24 h.

The ability of light to regulate melatonin synthesis is readily apparent when individuals are exposed to artificial light at night; this exposure is followed by a rapid drop in circulating melatonin levels. The influence of light on the pineal gland is also seen in individuals living at the extremes of latitude. During the winter months, the daily period of light can be very short, in which case the pineal produces more melatonin for a longer duration than during the summer months when day lengths are exceptionally long. The duration of elevated melatonin production is typically proportional to the duration of dark exposure. The circadian melatonin cycle with high levels at night and low values during the day may be disrupted in some individuals, e.g., in blind individuals incapable of light perception and in Smith-Magenis syndrome, where the melatonin cycle free-runs.

Effects of Age on Melatonin Production

Increased age is another factor that significantly changes the amount of melatonin produced in the pineal gland. Pineal melatonin production gradually wanes during aging such that elderly individuals may have only a fraction of the circulating melatonin levels that they had when they were younger. There may be a correlation between health status and melatonin levels during aging, with the healthy elderly seemingly having a better preserved melatonin synthesis cycle.

FUNCTIONS OF MELATONIN

The effects of melatonin in the organism are mediated via direct actions, e.g., free radical scavenging, and indirectly through receptors. Several membrane melatonin receptors have been identified and cloned and they are denoted MT₁, MT₂, and Mel_{1c}, although there are subtypes of each. These receptors (or binding sites) have seven transmembrane-spanning domains, are G protein-coupled, have a nanomolar affinity for melatonin, and have a wide distribution in organisms, with significant between-species variations. Two major locations of membrane melatonin receptors are the SCN, the so-called biological clock, and the pars tuberalis (PT) of the anterior pituitary gland. The signal transduction pathways linking

melatonin receptors to cellular physiology include a pertussis toxin (PTX)-sensitive G protein, which decreases intracellular cAMP. There are available a number of pharmacological agonists and antagonists of the membrane receptors that may prove useful in identifying the functions of the subtypes of melatonin-binding sites. Intracellular binding sites, e.g., to cytoplasmic calmodulin and also molecules in the nucleus, have been uncovered but their role in cellular function remains to be clarified.

Melatonin and Seasonal Reproduction

It is via the daily and seasonal changes in the duration of elevated nocturnal melatonin levels that the brain of vertebrates integrates photoperiodic information into the functioning of the organism. In photosensitive mammals, perhaps the most clearly defined function known to be controlled by the integrated action of the prevailing photoperiod and the changing melatonin rhythm is seasonal changes in reproductive capability. Although this relationship has been unequivocally established, the site at which melatonin intervenes to regulate the neuroendocrine-reproductive axis, e.g., at the SCN, the PT, other hypothalamic nuclei, and the gonadotropes of the anterior pituitary, remains unidentified as do the specific receptors involved. These seasonal reproductive cycles may have a corollary in humans, in which the changing melatonin cycle may drive the annual cycle in seasonal affective disorders. A common misconception is that in terms of seasonal fluctuations in reproduction, melatonin is inhibitory to sexual physiology. In reality, the changing melatonin cycle is merely a signal to identify the season of the year with the status of the reproductive organs, i.e., functional or atrophic, responding according to the physiological needs of the specific organism. Thus, some animals are sexually competent during long days and others are reproductively active during the short days of the year. In both cases, the time of delivery of the young is usually closely correlated with the season that ensures maximal survival of the offspring, i.e., spring and early summer.

Melatonin and Circadian Functions

The daily melatonin rhythm is one of the efferent signals of the biological clock. Whereas the loss of the rhythmic melatonin cycle does not significantly disrupt circadian organization, subtle desynchrony of several physiological functions as well as reentrainment of activity rhythms may occur after surgical removal of the pineal gland.

Melatonin, when administered exogenously, can influence either directly or indirectly the phase and/or period of the circadian clock. This chronobiotic property of melatonin has been used to manipulate the sleep-wake cycle, to synchronize the activity pattern of free-running profoundly blind humans, and to reduce the severity of jet lag. In these situations, the circadian time at which melatonin is administered is critical to the action of the indole. This presumably relates to a changing sensitivity of the melatonin receptor to its ligand.

Anticancer Effects of Melatonin

The anticancer effects of melatonin, which have been well documented at several laboratories, are at least in part mediated via membrane receptors. Thus, the inhibition of growth and proliferation of cancer cells includes changes in intracellular signaling pathways that involve a drop in cAMP, a reduction in the uptake of a key growth factor for cancer cells (linoleic acid) followed by a reduction in the generation of 13-hydroxyoctadecadienoic acid, and a reduction in mitogen-activated protein kinase. This series of events has been proposed to reduce the proliferation of cancer cells, thereby reducing tumor growth. Additionally, via its free radical scavenging actions, melatonin limits DNA damage and, as a consequence, the likelihood of tumor initiation.

Melatonin and Immune Function

Melatonin also has actions on the immune system that seem to be mediated by both membrane melatonin receptors and nuclear binding sites. Melatonin has direct effects on T and B lymphocytes and on monocytes, including the regulation of a number of cytokines. Melatonin influences a variety of immune parameters including both specific and nonspecific immunity. In general, the actions of melatonin at the level of the immune system are immunoenhancing; as a result, exogenously administered melatonin may be contraindicated in conditions where the immune system is already hyperfunctional, e.g., Crohn's disease.

Melatonin as an Antioxidant

Melatonin's ability to directly scavenge a variety of free radicals as well as to promote the activities of several antioxidative enzymes has been well documented (Fig. 2). Although these actions have been

Figure 2 An example of melatonin's free-radical scavenging activity. In this reaction, melatonin scavenges two highly toxic hydroxyl radicals ($\bullet\text{OH}$), with the resulting product being cyclic 3-hydroxymelatonin, which is excreted in the urine.

most eloquently verified using pharmacological concentrations of melatonin, loss of the endogenous nocturnal rise in melatonin due to pinealectomy also exaggerates oxidative damage in many organs, suggesting a role for physiological concentrations of melatonin in restraining free radical damage to essential molecules and subcellular organelles. The antioxidative actions of melatonin may also relate to its ability to reduce electron leakage from the mitochondrial respiratory pathway.

CONCLUDING REMARKS

Via its chief secretory product, melatonin, the physiological relevance of the pineal gland is much more widespread than initially envisaged. Indeed, there may not be an organ in the body or a subcellular organelle that escapes melatonin's direct or indirect influence. Melatonin's ubiquitous actions relate to the several means by which it can exert its effects. Thus, melatonin influences cellular processes through a variety of membrane receptors, possibly through cytosolic and nuclear binding sites and due to its ability to directly neutralize highly reactive free radicals and associated oxygen- and nitrogen-based reactants. More

extensive reviews should be consulted for detailed information on these diverse actions of melatonin.

that do not possess or express reduced pineal tissue, such as some adult salamanders (class Amphibia; order Caudata), geckos (class Reptilia; order Squamata; family Gekkonidae), crocodilians (class Reptilia; order Crocodylia), and some species of owls (class Aves; order Strigiformes), its absence is a derived characteristic (i.e., they have lost their pineal glands in the course of their evolution). It is interesting to note that these groups contain primarily nocturnal species.

Cellular Anatomy

The cellular anatomy of pineal organs among vertebrate groups shares one common feature: the major cell type, the pinealocyte, derives from photoreceptive neurons. Other cell types within pineal organs of diverse groups include neuroglia, endothelial cells, and, in some species, B lymphocytes. In nonmammalian vertebrates, the pinealocyte is characterized by ciliary outer segments with photoreceptor-like conformations; that is, there are nine pairs of microtubules radially arranged at the base of the cilium with no central pair of microtubules, forming the base of the pineal outer segment. The pineal outer segments of nonmammalian vertebrates are diverse in their cellular anatomy, ranging from cone-like photoreceptors in most fish to membranous whorls in birds and some reptiles. In those species in which it has been studied, these outer segments contain high concentrations of classical (e.g., cone opsins) and/or pineal-specific (e.g., pinopsin) opsin-based photopigment molecules. In addition, these cells contain high concentrations of flavin-based cryptochromes, which have been implicated as photoreceptive molecules in plants and insects. Interestingly, even though there is no evidence for photoreception in adult mammalian pineal glands, mammalian pinealocytes retain several of these photopigments. The function of these molecules is not known.

In most amniote vertebrates, pinealocytes project axons to pineal ganglion cells, which in turn project down the pineal stalk to diencephalic and mesencephalic sites within the brain. In addition, in some species, pinealocytes may directly innervate the brain, especially within epithalamic structures such as the habenula, and synapse on blood vessels residing within the pineal parenchyma. This latter motif is retained within several amniote reptile groups, especially lizards, but is lost among the turtles, birds, and mammals. In those groups, the pinealocytes appear to express an endocrine morphology, directly contacting blood vessels within the pineal organ, thereby achieving the designation “pineal gland” in birds and mammals.

Conversely, the pineal organ of amniote vertebrates receives little if any autonomic innervation, whereas the pineal glands of both birds and mammals are heavily innervated by sympathetic fibers arising from the superior cervical ganglion. The picture that emerges is that, in amniotes, the pineal organ is a sensory structure that conveys photic information to diencephalic and mesencephalic structures in the brain. This motif is converted to a neuroendocrine structure in amniotes over the course of evolution, under direct autonomic regulation in reptiles, birds, and mammals. Interestingly, many transitional patterns can be observed among the reptiles, suggesting that comparative analysis of reptilian pineal anatomy, physiology and molecular biology may reveal important clues to the evolution of the epiphysis cerebri.

MELATONIN BIOSYNTHESIS

Melatonin Is a Phylogenetically Ancient Molecule

The indoleamine hormone melatonin is present in pineal and retinal photoreceptor cells in all vertebrate groups studied. It is therefore safe to conclude that melatonin itself is an ancient feature of vertebrate photoreceptors, including pinealocytes. In all vertebrate species studied, melatonin is produced at higher levels during the night than during the day. Furthermore, in most species, this rhythm continues in constant darkness (DD), such that melatonin levels are high during the animal’s “subjective night.” Thus, melatonin rhythmicity is a circadian rhythm in most vertebrates, the result of an endogenous circadian oscillator.

In fact, the hormone is also produced by several invertebrate species, higher plants and microbes, although the biosynthetic pathways for melatonin production in these groups appear to be different from those that produce melatonin in vertebrate photoreceptors. Indeed, to punctuate this distinction, melatonin is produced primarily during the day in the fruit fly *Drosophila melanogaster*. It is therefore not clear whether melatonin is an ancient feature of all photoreceptive tissues or rather arises as a derived feature in each of these groups independently. More comparative research at the molecular level will be required to determine these relationships.

Vertebrate Melatonin Biosynthesis

In all vertebrate pineal organs, tryptophan is taken up by pinealocytes and converted to 5-hydroxytryptophan

(5-HTP) by tryptophan hydroxylase (EC 1.14.16.4). Then, aromatic amino acid decarboxylase (EC 4.1.1.28) converts 5-HTP to serotonin (5-HT). During the night, 5-HT is converted to *N*-acetylserotonin (NAS) by arylalkylamine-*N*-acetyltransferase (AANAT; EC 2.3.1.87). NAS is the primary substrate for hydroxyindole-*O*-methyltransferase (EC 2.1.1.4), which converts NAS to melatonin.

The major biosynthetic enzyme responsible for melatonin biosynthesis is probably AANAT in that it represents the rate-limiting step in melatonin biosynthesis in many (but not all) species and in that this enzyme is typically regulated at the transcriptional, translational, and posttranslational levels in many (but not all) species. The deduced amino acid sequences of AANAT in mammals, birds, and teleost fish reveal a highly conserved enzyme that bears very little relationship to any other protein in sequence databases. The closest neighbor is the arylamine-*N*-acetyltransferases (aNAT), which are primarily responsible for detoxification of cyclic hydrocarbons and are, along with AANAT, members of the A/B acetyltransferase superfamily. Both aNAT and AANAT are found in all vertebrate taxa, suggesting that these two enzymes diverged before different vertebrate classes diverged from their ancestral stock. Interestingly, an AANAT has been cloned in *Drosophila melanogaster*, which shares characteristics with both aNAT and AANAT, corroborating the view that aNAT and AANAT are homologous enzymes that share a common evolutionary ancestor that predates the emergence of vertebrates. In several species of teleost fish, there are two genes that encode AANAT. In pike and zebrafish, AANAT1 is expressed primarily within the ocular retina, whereas AANAT2 is expressed primarily within the pineal organ. These enzymes are likely the result of gene duplication and divergence, a common phenomenon among teleosts. They are, furthermore, differentially regulated in these two tissues.

PHOTORECEPTION

Visually Evoked Responses

As stated above, the pinealocytes in all vertebrate groups contain opsin-based and possibly flavin-based cryptochrome photopigments. The presence of photopigments raises the possibility that these cells are photoreceptive and indeed they are in many species. Perhaps, the most extensively studied group among the vertebrates in terms of visually evoked electrophysiological responses is the squamate reptiles. In

these animals, pinealocytes and photoreceptors in the associated parietal eye respond by depolarization to photic stimulation. These responses are characterized by chromatic and achromatic responses. This differential response to different wavelengths of light (chromatic response) has been suggested as a mechanism to differentiate dawn from midday from dusk, each of which has different light qualities. Similar responses have been observed in several teleosts and amphibians.

Attempts to demonstrate visually evoked responses in birds and mammals have been difficult. Patch clamping of individual avian pinealocytes has revealed graded photic responses that are dependent on calcium influx.

Inhibition of Melatonin Biosynthesis

Certainly, the best known photic response within the pineal organ is the inhibitory effect of light on melatonin biosynthesis. In all species studied, the biosynthesis of melatonin is restricted to the night and, if the pineal organ is illuminated during the night, melatonin biosynthesis is halted, and melatonin levels decline rapidly.

In nonmammalian vertebrates, including teleosts, reptiles, and birds, this response occurs both *in vivo* and *in vitro*, indicating that photopigments within the pinealocytes themselves mediate this process. The best studied of these is the chick pineal gland, in which light has essentially three effects on melatonin rhythms: (1) light acutely suppresses melatonin biosynthesis, (2) light phase-shifts the circadian rhythm of melatonin release, and (3) light increases the amplitude of the melatonin rhythm. The acute suppression of melatonin by light is believed to result from the activation of opsin-like photopigments, since vitamin A depletion abolishes this effect. Action spectral analysis of chick pinealocytes suggests an opsin-like photopigment with peak absorption of approximately 500 nm. Illumination ultimately down-regulates cyclic AMP (cAMP) and its downstream signal cascades. When cAMP declines, AANAT protein is ubiquitinated and degraded rapidly by proteosomal proteolysis. The mechanisms for the phase-shifting and amplitude effects of light are not known, although it is clear that neither vitamin A-based photopigments nor cAMP is necessary for the effect. It is likely that these effects involve the regulation of the circadian clock itself.

In mammals, the adult pineal gland is not directly photoreceptive. Photoreceptors are restricted to the ocular retinae in mammals. However, remarkably, the traditional rods and cones are only part, perhaps

a minor part, of the light response. Instead, photoreceptive retinal ganglion cells project directly to the hypothalamic suprachiasmatic nucleus (SCN), the central circadian clock of mammals. The SCN in turn projects to the pineal gland via a multisynaptic pathway that includes the sub-paraventricular zone of the hypothalamus, the intermediolateral cell column of the thoracic spinal cord, and pre- and postganglionic fibers of the sympathetic nervous system. This pathway is homologous to a similar innervation of the pineal gland in birds. In nocturnal rodents, sympathetic norepinephrine is released during the night under SCN control, which stimulates β -adrenergic receptors, which in turn stimulates cAMP production. Then, AANAT is stimulated at the transcriptional, translational, and posttranslational levels to increase melatonin biosynthesis. It is not clear whether this exact mechanism also underlies melatonin biosynthesis in other mammalian groups. In sheep, for example, significant α_1 -adrenergic activation is also required. When mammals are illuminated in the middle of the night, sympathetic stimulation is interrupted, and similar to the situation in the photoreceptive chick pineal gland, the decline in cAMP precipitates a proteosomal proteolytic degradation of AANAT. It is believed, but it has not been determined, that the phase-shifting effects of light on melatonin rhythms are also mediated via regulation of sympathetic activity by the SCN. It is interesting to note that pineal glands from neonatal rodents retain photoreceptive properties until they are innervated by sympathetic fibers, suggesting that primitive photoreceptive properties of mammalian pinealocytes are lost during development.

CIRCADIAN OSCILLATION

Nonmammalian Vertebrates

Every class of nonmammalian vertebrate studied contains species that have pineal glands that are capable of both photoreception and generation of circadian rhythms of melatonin both *in vivo* and *in vitro*. These include the agnathan lampreys, teleost fish, squamate reptiles, and birds. Therefore, circadian oscillation within pinealocytes is almost certainly a primitive characteristic. The several exceptions to this rule are very likely derived characteristics, in which the pineal gland has secondarily lost its oscillatory capability. These include the salmonid teleosts, such as salmon and trout, whose pineal organs produce melatonin rhythmically *in vivo*, but when their pineal organ is placed *in vitro*, they express constitutively high levels of the hormone in darkness. However, as stated

above, these pineal organs retain their photoreceptive capability, since illumination suppresses melatonin biosynthesis.

In agnathan lampreys, other species of teleost fish, reptiles, and birds, pineal glands placed *in vitro* express a circadian pattern of melatonin biosynthesis such that melatonin is released during the night if the gland is placed in a light:dark cycle and persists for at least four circadian cycles in DD. In most cases, this rhythm begins to damp after extended *in vitro* analysis. This damping is the result of both individual pinealocytes drifting out of phase with one another and the oscillators within each cell experiencing a reduction in amplitude.

Understanding of the mechanisms of circadian oscillation has undergone a revolution in the past 10 years with the discovery of mammalian "clock genes" and the subsequent cloning and isolation of orthologues of these genes among nonmammalian vertebrates. These genes include the so-called "positive elements" *BMAL1* and *Clock* and "negative elements" *Period 1*, *2*, and *3* and the cryptochromes. These genes are expressed at very high concentrations in the pineal organs of zebrafish and chicks.

The evolutionary relationships among these clock genes and their relatives in other taxa are just beginning to be studied. It is likely that a complete phylogeny of clock genes will soon be known. Interestingly, these clock genes are also expressed within the mammalian pineal gland, even though the gland does not appear to express endogenous circadian rhythmicity. It is likely that the roles of these clock genes have only just begun to be understood.

PINEAL'S ROLE IN VERTEBRATE FUNCTION

"Nonspecific" Effects

A growing body of evidence suggests that melatonin may affect tissues very broadly in a "nonspecific" fashion in that the molecule possesses potent antioxidant activity. Melatonin scavenges hydroxyl free radicals more efficaciously *in vitro* than do many "traditional" antioxidants, such as glutathione. In addition, administration of very high concentrations of the hormone to animals ameliorates many cellular disorders associated with free radical activity. As such, the hormone has been touted as an "anti-aging" therapeutic agent. If this activity holds true in future research, it is likely to be a common mechanism among all animals (and perhaps plants and algae as well, where no melatonin receptor has been identified). However, the evidence

is not strong enough to warrant such a statement at this stage.

“Specific” Effects—Melatonin Receptors

The discovery and subsequent use of the melatonin agonist 2-[¹²⁵I]iodomelatonin as a ligand for the study of high-affinity melatonin binding strongly pointed to specific, high-affinity melatonin receptors. Pharmacological analysis of this binding strongly indicated that melatonin receptors were G_i-GTP-binding protein-associated receptors that were expressed broadly in the brains and bodies of many vertebrate species. The subsequent cloning of a melatonin receptor in the African clawed frog *Xenopus laevis* confirmed this view. Sequence analysis of this melatonin receptor indicated that it was a member of the seven-transmembrane domain G protein receptors and expression of the protein in eukaryotic expression vectors further confirmed this view. Melatonin inhibited the accumulation of cAMP in these cells.

Since the discovery of this first melatonin receptor, at least three related high-affinity melatonin receptors have been isolated, cloned, and characterized in a wide variety of species, ranging from zebrafish to humans. Three very closely related genes encode the Mel_{1A}, Mel_{1B}, and Mel_{1C} receptor proteins in all nonmammalian vertebrates. Interestingly, no Mel_{1C} receptor has been isolated from mammals. Although these receptor proteins appear to be nearly identical in their affinities and specificities, they are differentially expressed. The Mel_{1A} receptor is expressed widely in endothelial and neuronal tissues in all species studied, whereas the Mel_{1B} receptor is predominantly expressed by the retinae. The Mel_{1C} receptor is typically expressed in the nervous system and in cells derived from the neural crest, including melanocytes of the African clawed frog, in which the receptor was first isolated. Each of these receptor subtypes, with the exception of the mammals, is expressed in each class studied. Therefore, the three receptor subtypes are phylogenetically older than the divergence of these vertebrate groups.

Physiological and Behavioral Effects

As stated above, though the affinity and specificity of the known receptor subtypes are similar, the receptors are differentially expressed, at least in the brain. First, in most vertebrates studied, melatonin affects circadian behavior. In many species of fish, reptiles, and birds, rhythmic melatonin is required for circadian behavior. In mammals and many species of birds,

removal of endogenous melatonin by pinealectomy or pharmacological means does not abolish rhythms, although administration of melatonin entrains circadian patterns of activity. The sites of action for this effect are likely to be the hypothalamic SCN or homologous sites within the hypothalamus. However, this aspect of circadian physiology has not been studied in detail.

In nonmammalian vertebrates, melatonin receptor binding predominates in structures involved in vision and visual integration. Concomitantly, several studies have shown that a circadian clock regulates visual system function and that this circadian variation in visual function is at least in part regulated by melatonin. Typically, in diurnal reptiles and birds, visual sensitivity is higher during the night than during the day and visual response (amplitude) is higher during the day than during the night. These changes are similar to what one might expect in dark and light adaptation, respectively. However, these changes occur even if the animals are maintained in constant darkness, showing that a circadian clock regulates the visual system.

Whereas visual function in mammals is also regulated by melatonin, this effect is not as dramatic as it is in reptiles and birds. Instead, melatonin receptors predominate in the SCN and tuberal hypothalamus. Melatonin affects circadian behavior through its effects on the SCN, but in seasonally reproducing mammals, the duration of the melatonin cycle also synchronizes reproductive, metabolic, and pelage functions to the prevailing photoperiod. It is interesting to note that although birds depend on melatonin for circadian activity, the hormone has little effect on seasonal functions in birds. Conversely, whereas the circadian effect of melatonin is limited in mammals, melatonin plays a major role in photoperiodic time measurement. Thus, the photoperiodic role for melatonin is a derived characteristic in this group.

SYNOPSIS

In summary, the epiphysis cerebri, pineal organ, or pineal gland, as it is variously called, is a phylogenetically ancient photoreceptive structure that has diverged dramatically over the evolutionary history of vertebrates. It is a primitive characteristic of all vertebrate classes that has been periodically lost or reduced in function in distinct groups, most of which are nocturnal. Its actions are predominantly through the release of the indoleamine melatonin, either as a neurotransmitter or neuromodulator or as a hormone released directly into the bloodstream. Melatonin is believed to

bear antioxidant characteristics and this function may be its most primitive, since this function is shared with invertebrate and plant species. Its specific actions vary among vertebrate groups, but regulation of circadian and visual function appears to be the most primitive, because it is shared by all groups. In contrast, melatonin's role as a regulator of seasonal/photoperiodic function is likely derived, since it predominates in mammals alone.

Table I Histological Distribution of 281 Pineal Region Tumors Gathered in a Multicentral European Study

| Histological diagnosis | Number/% of total |
|--|-------------------|
| Germ cell tumors | 96/34% |
| Pineal parenchymal tumors | 76/27% |
| Astrocytomas | 52/19% |
| Meningiomas | 20/7% |
| Ependymomas | 13/5% |
| Oligodendrogliomas and mixed gliomas | 7/2% |
| Primary melanomas | 4/1.5% |
| Metastases | 4/1.5% |
| Probable parenchymal tumors with insufficient clinical data or histological material | 9/3% |
| Total | 281/100% |

Adapted from Fauchon *et al.* (2000).

or show intermediate differentiation and do not constitute a unified biological entity.

The revised World Health Organization (WHO) classification on central nervous system tumors divides them into well-differentiated pineocytomas, poorly differentiated pineoblastomas, and mixed pineocytomas–pineoblastomas with intermediate differentiation. A large French and English cooperative study carefully reviewed their results over 24 years; they observed that the presence of more than six mitoses and the presence of necrosis were significantly associated with a poorer outcome, whereas positive immunolabeling for neurofilaments was related to a better survival. This led them to propose a new prognostic classification with four histological grades (Table II). Germ cell tumors, histologically and biologically homologous to gonadal germ cell neoplasms, will characteristically present positive markers for α -fetoprotein (AFP) and β human

chorionic gonadotropin (β -hCG), with more (teratomas) or less differentiation (germinomas), as well as intermediate degrees (yolk sac tumors) of differentiation. Very rarely, pineal region tumors may derive from meningotheial, mesenchymal, ependymal, and choroid plexus elements, giving rise to gangliogliomas, melanocytic neoplasms, atypical teratoid/rhabdoid tumors, meningiomas, cavernous angiomas, and hemangiopericytomas.

CLINICAL PRESENTATION

The clinical presentation of pineal tumors varies depending on age at onset and histology. Over 90% of patients present with raised intracranial pressure, often with obstructive hydrocephalus; presenting symptoms are headache, nausea, vomiting, and blurred vision. Visual signs including diplopia, cranial nerve palsies, papilledema, and ptosis as well as Parinaud's syndrome (failure of upward gaze, pupillary dilation, and diminution of pupillary light reflex) are present in 50 to 70% of patients. Abnormalities of other cranial nerves, ataxia, diabetes insipidus, and hypopituitarism may also be diagnosed at presentation, reflecting compression on the brain, cerebellum, hypothalamus, and pituitary. Pineal tumors can interfere with puberty, due to pressure of the tumor on the hypothalamic centers that govern gonadotropin secretion, excessive melatonin secretion by pinealocyte tumors causing delayed puberty in adolescents, or a reduction of the potential anti-gonadotropic effect of melatonin, which, together with β -hCG secretion by destructive germ cell tumors, could explain precocious puberty in prepubertal children. Melatonin deficiency may produce sleeping disorders or behavioral problems.

Table II Parenchymal Pineal Tumor Classification

| Tumor grade | Morphology | Number of mitoses plus neurofilament (NF) immunostaining (indicative of differentiation) | Prognosis |
|-------------|---|--|-----------|
| 1 | Pineocytoma | 0 plus very positive NF | Good |
| 2 | Transitional, lobulated, or diffuse tumor | < 6 plus positive NF | ↓ |
| 3 | Lobulated or diffuse tumor | ≥ 6 plus positive or negative NF or < 6 plus low expression of NF | |
| 4 | Pineoblastoma | Variable plus positive or negative NF | Bad |

Adapted from Jouvét *et al.* (2000).

Note. This classification differentiates those of intermediate differentiation into two separate groups, with prognostic implications. Data were obtained from a total of 66 patients (11 patients with pineocytomas, ages 10–65 years, 16 patients with pineoblastomas, ages 1–36 years, and 39 patients with intermediate tumors, ages 5–64 years). Median followup was 3.5 years, with overall and event-free survival rates a 5 years, of 60 and 69%, respectively.

Astrocytic Tumors

These lesions may affect persons of any age, from children to adults. Pilocytic astrocytomas usually present before the age of 20 years, with no sex bias, whereas other types are more frequent in adults.

Parenchymal Tumors

Pineocytomas present more often in adults over the age of 25 years, do not show a sex bias, evolve slowly (the interval between onset of symptoms and surgery may last several years), and do not invade contiguous tissue or seed the cerebrospinal fluid (CSF). Reports of metastasizing pineocytomas most likely represent misclassifications as pineocytomas of mixed tumors of intermediate differentiation or as pineoblastomas in the current WHO system classification. With strictly defined tumor series, no metastases and a 5-year survival of 86% have been reported. Presenting manifestations are nonspecific and reflect compression of adjoining structures (tectal plate, aqueduct of Sylvius, cerebellum, brainstem, hypothalamic–pituitary circuits): increased intracranial pressure, neuro-ophthalmologic dysfunction, changes in mental status, dysfunction of the brainstem and/or cerebellum, and hypopituitarism with or without hyperprolactinemia. Rarely, intratumoral hemorrhage (pineal apoplexy) with subarachnoid extravasation may be encountered. Concurrent uveoretinitis in occasional patients with pineocytomas probably reflects the common photoreceptor activity of pineal and retinal cells.

Pineoblastoma, the least differentiated and most aggressive pineal parenchymal tumor, typically appears before the age of 20 years and most often in young children, but there are reports in middle age and later adulthood. There is a slight male bias. Clinical manifestations do not differ from those described for pineocytomas, except that they are of more rapid progression and shorter duration. The interval between initial symptoms and surgery may be less than 1 month. Median postsurgical survival varies from 24 to 30 months. They are both locally invasive and prone to disseminate through the CSF; they are often fatal, but may be controlled in some cases by a multimodal combination of aggressive surgery, radiotherapy, and chemotherapy. The association of a pineoblastoma in a child with familial bilateral retinoblastoma (due to a germ-line retinoblastoma gene mutation) is known as a trilateral retinoblastoma, with a median survival of only 6 months.

Germ Cell Tumors

Approximately 90% of germ cell tumors appear in patients under the age of 20 years. Most arise around the third ventricle, most commonly in the pineal region followed by the suprasellar compartment; 5–10% of patients harbor both lesions. Globally they are more frequent in boys than in girls (2.5:1); however, pineal region germ cell tumors are more frequent in boys and suprasellar lesions are more frequent in girls. An increased risk of intracranial germ cell tumors has been associated with Klinefelter's syndrome, Down's syndrome, and neurofibromatosis type 1.

Other Tumors

Pineal meningiomas, usually slow growing, have an insidious presentation, with Parinaud's syndrome and hearing impairment. Pineal metastases, most frequently of breast or lung origin, may occur, often with other brain metastases; symptoms and signs will reflect the extent of the disease.

DIAGNOSIS

An appropriate tissue specimen for accurate histological diagnosis and determining tumor type is critical to optimize subsequent management.

Serum AFP (synthesized mainly by yolk sac tumors and also by teratomas) and β -hCG (in choriocarcinomas or germinomas) concentrations, if markedly elevated, are of diagnostic utility. It is also recommended that these markers be measured in the CSF for initial staging and, if positive, for follow-up. CSF cytological examination should be delayed for at least 2 weeks after surgery to increase the chance of reflecting true dissemination of viable tumor rather than tumor spillage from the time of operation. In the presence of clearly raised markers, histological verification may not always influence management and is not required by some authors, although others believe that even in patients with markedly elevated tumor markers indicative of germ cell tumors (i.e., hCG > 50 mIU/liter) outcome seems to be better if a histological diagnosis is obtained.

Biopsies may be obtained by classical surgical routes (posterior interhemispheric transcallosal, suboccipital transtentorial, and infratentorial–supracerebellar routes) or may be replaced by microsurgical techniques, with significantly reduced perioperative mortality rates (< 2%). Even though stereotactic sampling under endoscopic control has been tried, it should be stressed that the diagnosis of mixed or intermediate

tumors may be very difficult without extensive tissue sampling, so operative risk should be balanced with the risk of not obtaining an accurate histological diagnosis, with prognostic implications.

IMAGING

A neuroradiological examination, preferably by magnetic resonance imaging (MRI), will disclose the size and extent of the tumor as well as possible metastases, but cannot accurately identify the histological nature of the tumor, which relies on biopsy or serum/CSF tumor markers. In the more malignant tumors (pineoblastomas, germinomas, teratomas), the spine as well as the brain should be imaged, since spreading into the subarachnoid space and the spine is frequent.

Neuroimaging of astrocytic tumors can be highly variable (Figs. 1 and 2); MRI usually shows hypodensity on T1-weighted images and hyperintensity on T2-weighted images; gadolinium enhancement is uncommon, except when active tumor progression occurs.

When comparing parenchymal tumors, pineocytomas appear as noninvasive, solid masses in the posterior third ventricular region and tend to be smaller (< 3 cm in general), rounder, hypodense, homogenous masses with dispersed calcifications, particularly peripheral, that enhance heterogeneously or diffusely on computed tomography (CT) and MRI and present a lesser degree of hydrocephalus (Fig. 3). Macrocystic presentation is rare but small cysts may be present. T1-weighted images are hypointense, whereas T2-weighted images are hyperintense. Hemorrhage and necrosis are exceptional.

Pineoblastomas are larger, lobulated, homogenous tumors, are rarely calcified, and present with a greater degree of hydrocephalus and local invasion of contiguous brain or leptomeninges. They may exhibit distant subarachnoid and extracranial metastases, more frequently in young females. They are hyperdense and enhance homogeneously on CT, whereas on MRI they appear as hypo- to isointense on T1-weighted images and enhance diffusely or heterogeneously with contrast. Hemorrhage and necrosis are common.

Germ cell tumors (except teratomas) appear as solid masses on MRI that are iso- or hyperdense, which enhance after contrast (Fig. 4); small nodular calcifications may be seen on CT scans. Teratomas tend to contain intratumoral cysts next to calcifications and display low-attenuation signals, typical of fat. Hemorrhages are common in choriocarcinomas and mixed neoplasms.

Figure 1 T1-weighted gadolinium-enhanced coronal view (A) and midsagittal view (B) of an MRI of a partially cystic pineal astrocytomas in a 10-year-old girl. Additionally, there is an enlargement of the cisterna magna in the posterior fossa, which may be an arachnoid cyst.

PROGNOSIS

The prognosis of pineal tumors has improved over the years. Major indicators of prognosis are histology and neuroaxis staging. Accurate histological diagnosis is also important to optimize treatment. Thus, the benefit of a histological diagnosis is generally considered to outweigh the risk of biopsy, especially

Figure 2 Axial view of a DP-T2-weighted MRI of a 3.5 cm pineal solid astrocytoma in a 23-year-old woman.

since morbidity and mortality of this procedure are lower with experienced neurosurgical teams.

Mean survival after surgery of astrocytic tumors is approximately 6–8 years with marked individual variation. Malignant progression to glioblastoma, which

Figure 3 Axial view with contrast enhancement of a CT scan of a pinealoma in a 55-year-old woman; calcifications were observed on nonenhanced images. Enlargement of the left ventricular frontal horn is also observed.

Figure 4 Midsagittal T1-weighted MRI of a hypothalamic and pineal dysgerminoma (the latter partially cystic) in a 14-year-old boy. There is also marked tumoral enlargement of the quadrigeminal lamina next to the pineal.

tends to occur after a mean interval of 4–5 years, determines final outcome. Positive glucose consumption with positron emission tomography scans of glioblastoma clearly correlates with cellularity and reduced survival.

Whereas prognosis of pineocytomas is generally good (86% at 5 years), the extent of the disease at the time of diagnosis, as determined by the CSF examination and MRI of the neuroaxis, directly affects the survival of patients with pineoblastomas, and metastases to the CNS and vertebral column are the most common causes of death. Prognosis is even worse in sporadic or familial trilateral retinoblastoma (approximately 6 months). Intermediate or mixed parenchymal tumors (grade 2 and 3 in [Table II](#)) have an intermediate prognosis.

Prognostic factors were investigated in 76 parenchymal pineal tumors identified from 281 pineal region tumors gathered over 5 years from 12 different neurosurgical centers in Europe by two experienced neuropathologists; it is the largest series thus far published ([Table I](#)) and includes patients that were diagnosed and followed for 25 years. Eight patients were lost to follow-up between 1 and 78 months after diagnosis. The median follow-up for the whole patient population was 3.5 years and it exceeded 5 years in 25 of the 76 cases. There was a 1.5:1 (39:27)

female:male sex distribution (not previously observed in smaller series), with a median age of 32 years (range 1 to 65 years). Fifty-seven patients were adults and 19 patients were children with a median age of 2.5 years (range 9 months to 16 years). Positive cytology was seen only in grade 4 tumors (Table II) and positive spinal MRI was seen only in grade 3 and 4 tumors. Median diameter was 33.9 mm (range 10 to 74 mm). Sixty-three patients required a CSF shunt (83%), whereas 74/76 patients underwent surgery at presentation; the other 2 patients were diagnosed at autopsy or from a biopsy obtained at laminectomy for spinal cord compression during follow-up. Tumor removal was attempted in 19% of patients treated between 1972 and 1980, in 42% of patients treated between 1981 and 1990, and in 39% of patients treated between 1991 and 1997. Unifactorial and multifactorial analyses (including sex, age at treatment, tumor size, hydrocephalus, calcifications on imaging, and meningeal seeding) for overall and event-free survival were performed. A second analysis added treatment information (extent of surgery, radiation doses and techniques, and chemotherapy) and a third analysis included the 4-grade histological classification (see Table II). Younger patients were found to have more mitoses, more tumor necrosis, more high-grade tumors, and larger tumors. Chemotherapy and radiotherapy were administered significantly more often to patients with high-grade and large tumors, with high mitotic activity. The impact of radiotherapy on survival was not significant for low-grade tumors, but was significant ($P < 0.02$) for high-grade tumors. Significant variables on survival or disease-free survival included histological grading (as seen in Table I), age < 20 years, tumor diameter ≥ 40 mm, and chemotherapy (which had a negative effect), whereas diameter < 25 mm had a positive effect. Multivariate analysis showed a major role of histological grade alone on disease-free survival, whereas both grade and tumor size had an effect on overall survival. Specifically, 5-year survival was 91% for grade 1, 74% for grade 2, 39% for grade 3, and 10% for grade 4, whereas event-free survival was 100% for grade 1, 96% for grade 2, 42% for grade 3, and 0% for grade 4. The prognostic importance of this classification, especially in the more heterogeneous mixed tumors (grades 2 and 3), would seem to indicate that they might benefit from different therapeutic approaches.

Pure germinomas, which are exquisitely radiosensitive, have an especially favorable prognosis, with a 5-year survival rate after radiotherapy alone of approximately 65–95%. The addition of chemotherapy may allow a comparable prognosis at a reduced

radiation dose. In other germ cell tumors, prognosis is worse, unless total surgical resection is possible (i.e., in the case of mature, noninvasive teratomas), followed by chemotherapy. In general, the greater extent of disease at diagnosis is associated with a poorer outcome, which may be precipitated by metastases to the brain or neuroaxis, metastases to the lung or bone, or abdominal contamination via ventriculoperitoneal shunts.

TREATMENT

Advances in surgery, chemotherapy, and radiation have changed the manner in which pineal region tumors are diagnosed and treated. Open surgery may be replaced by stereotactic or endoscopic approaches to obtain a biopsy and are mandatory to obtain a definite histological diagnosis. Morbidity and cure rates have improved thanks to a greater understanding of the nature of the different tumors, more accurate neurosurgical experience, selective use of chemotherapy, and the introduction of modern irradiation techniques. However, given the rarity of pineal tumors, large prospective multicenter international studies would be desirable to define their optimal management.

Treatment of pineal tumors depends on histology obtained after surgery, which apart from the biopsy can resolve intracranial hypertension with a ventricular shunt (atrial or peritoneal). Partial debulking of the tumor should be performed if possible; total resection is rarely possible (Table III).

Astrocytomas

Treatment for astroglial cell-derived malignant gliomas is local radiotherapy to the tumor (54 Gy), either conventional or stereotaxic, whereas surgery may be curative for the more benign pilocytic astrocytomas.

Pineal Parenchymal Tumors

Pineocytomas require only local radiotherapy to the tumor (54 Gy).

In pinealoblastomas, a high probability of spinal seeding should lead to craniospinal radiotherapy, since they are radiosensitive (25 to 30 Gy on the neuroaxis with a pineal boost of 40 Gy aimed at more effective local disease control). However, routine craniospinal irradiation has been called into question and may not be necessary in patients with negative staging. New techniques of administering radiotherapy, such as highly localized radiosurgery, need to be evaluated, since radiosurgery may control local

Table III Schematic Therapeutic Guidelines for the Treatment of Pineal Region Tumors

| Tumor type | Radiotherapy | Chemotherapy ^a | Surgery |
|---|--|-------------------------------------|--|
| Glial origin | | | |
| Juvenile pilocytic astrocytoma | No | No | Complete resection |
| Intermediate/diffuse/anaplastic/astrocytomas/glioma | Local | No | Debulking |
| Malignant glioblastoma | Local | No | Debulking |
| Parenchymal tumors | | | |
| Pineocytoma | Local | No | Biopsy |
| Intermediate or mixed tumor | Local ± craniospinal | Yes in more undifferentiated tumors | Biopsy |
| Pineoblastoma | Local + (?) routine craniospinal; age < 5 years: lower dose after chemotherapy | Yes (role on final outcome unclear) | Biopsy |
| Germ cell tumors | | | |
| Germinoma | Local + craniospinal (unless convinced of negative staging) | Yes (alone not curative) | Biopsy |
| Non germinatous tumors | Local + craniospinal | Yes (pre- or post surgery) | Resection as much as possible, without increased morbidity |

Note. Initial surgery for histological biopsy and, if necessary, a ventricular shunt should always be performed, with the possible exception of germ cell tumors with diagnostically elevated tumor markers.

^aChemotherapy includes cisplatin, etoposide, and cyclophosphamide or ifosfamide.

progression but is associated with a high risk of marginal recurrence and distant metastases and is therefore not considered the treatment of choice for infiltrative but curable tumors. Furthermore, complications such as ataxic gait and gaze palsy were reported several months after radiosurgery. In comparison to conventional radiotherapy, radiosurgery has the advantage of reducing the radiation dose to surrounding normal brain while augmenting the radiobiological effect on the tumor volume; this reduced total brain dose may be especially important in prepubertal patients with pineoblastomas, in whom total brain irradiation is associated with neurocognitive dysfunction, endocrinopathy, vascular complications, and spinal growth impairment. In these infants, chemotherapy with cisplatin, etoposide, cyclophosphamide, and vincristine, which alone is not curative, may allow a lower dose of radiotherapy to have similar effects. In older children with pineoblastoma, craniospinal irradiation is followed by chemotherapy (even though its effect on final outcome has not been fully defined).

In mixed or intermediate pineal parenchymal cells (grade 2 or 3, Table II), apart from local radiotherapy, craniospinal irradiation and chemotherapy should be considered when there is an increased number of mitoses and less differentiation.

Chang and colleagues reported a series of 11 adults with pineoblastoma (ages 17–59 years), evaluated retrospectively, who were diagnosed between 1975

and 1992. All presented with hydrocephalus and the 5 with positively staged disease had focal or spinal progression after a median of 10 months and died 1 to 20 months after recurrence (median survival time from the date of surgery was 30 months). One patient refused treatment and died 6 months after diagnosis. The 5 patients with negative staging at diagnosis were alive without disease progression for a median of 26 months after follow-up. In view of these findings, the authors recommend initial staging to include examination of the CSF and MRI of the brain and spine; however, the benefits of chemotherapy after craniospinal irradiation also remained unclear in these adult pineoblastomas.

Cohen and colleagues reported results from a randomized clinical trial in children (up to the age of 19 years); pineoblastomas had a better prognosis than other primitive neuroectodermal tumors such as medulloblastomas (located in the posterior fossa) or central neuroblastomas (originating in the cortical regions of the brain) with a 3-year survival and progression-free survival rates of $73 \pm 12\%$ and $61 \pm 13\%$ for the 17 pineal tumors and $57 \pm 8\%$ and $45 \pm 8\%$ for the whole group of 55 supratentorial primitive neuroectodermal tumors ($P < 0.03$). In this randomized study, all patients underwent craniospinal radiotherapy followed by different protocols of chemotherapy, which did not seem to influence outcome significantly; the authors recommend eight cycles of CCNU,

vincristine, and prednisone, since this combination was less toxic than other chemotherapeutic combinations. The presence of initial metastases had an ominous prognosis (with no progression-free survival in these patients) and younger age (< 2 years) was a worse univariate prognostic factor than age > 3 years ($25 \pm 13\%$ versus $53 \pm 9\%$, $P < 0.02$).

Germ Cell Tumors

Surgery is not considered curative in germinomas, which are radiosensitive and should therefore receive local radiotherapy. Unless firmly confident of negative staging (by negative tumor markers—AFP and β -HCG—in blood and CSF and by negative MRI), craniospinal radiotherapy should be offered, given the high probability of spinal seeding. Germinomas are also highly chemosensitive, and excellent responses to postoperative cisplatin and cyclophosphamide have been reported; however, toxicity of chemotherapy, which alone is not curative, should be considered, since the effect of chemotherapy on final outcome is unclear. Survival is high in patients with localized germinomas, using chemotherapy, focal radiotherapy, or craniospinal irradiation; however, focal irradiation alone has a worse outcome. In metastatic germinomas, craniospinal irradiation is the treatment of choice (25–35 Gy to the spine and a local pineal boost of 40 Gy). Lower irradiation doses are being considered, especially if adjuvant chemotherapy is offered. Bifocal lesions in the pineal and hypothalamus should be considered localized germinomas rather than metastatic disease and receive irradiation to both locations.

Other germ cell tumors are less radiosensitive than germinomas, with a poor survival after radiotherapy alone (median survival of under 2 years), and require multimodal treatment. Aggressive tumor resection, which may improve survival, should not justify increased morbidity. Surgical resection after tumor reduction with initial chemotherapy with cisplatin, etoposide, and ifosfamide is a modern alternative. Tumor markers are useful for follow-up. Chemotherapy should be combined with radiotherapy (local up to 54 Gy or craniospinal up to 36 Gy), in which case long-term survival may reach 80%.

Other Tumors

Surgery is the treatment of choice of pineal meningiomas and other localized pineal tumors if possible; alternatively, localized stereotactic radiosurgery may be offered with good long-term prognosis.

Figure 5 T1-weighted midsagittal MRI of a pineal cyst; it is asymptomatic and creates no hydrocephalus.

PINEAL CYSTS

Masses in the pineal region are most commonly non-neoplastic cysts incidentally discovered at autopsy or on a radiographic work-up for symptoms not reasonably attributed to the cyst (Fig. 5). Very rarely can they act as a mass lesion and produce signs of increased intracranial pressure, by compressing the aqueduct (obstructive hydrocephalus) or tectal plate (Parinaud's syndrome). On MRI, they appear as a 1 to 3 cm mass, they are equally as dense as, or slightly denser than, CSF in T-1 weighted image studies, and they brightly enhance in T-2 weighted images, reflecting their fluid nature. Evidence of hemorrhage and peripheral calcification may be found. If asymptomatic, pineal cysts do not generally require treatment; if such a cyst is large enough to increase intracranial pressure, resection may be necessary, with an excellent long-term outcome.

tumors might make surgical resection difficult and traumatic and might explain poor surgical results in patients with macro- or invasive adenomas.

TSH-secreting pituitary adenomas constitutively secrete TSH and exhibit a defect in the negative regulation of TSH by thyroid hormones. High thyroid hormone concentration in the face of normal TSH level is explained, at least in part, by an increased bioactivity of neoplasm-derived TSH. A somatic mutation of TR β gene, impairing negative regulation of α -subunit and TSH β genes, has been reported in a TSH-secreting pituitary adenoma, and it might be one mechanism for the defective regulation of TSH by triiodothyronine (T3) observed in these rare tumors.

Thyrotropin-releasing hormone (TRH) receptors are found on the majority of tumor cells. However, the lack of response of TSH and α -subunit to TRH in the majority of patients with TSH-secreting pituitary adenomas suggested that the TRH receptors are non-functional on these tumors. However, partial or even normal response to TRH is present in other patients, suggesting etiological differences among TSH-secreting tumors. Most studies have revealed high concentrations of different subtypes of somatostatin receptors on TSH-secreting adenomas, explaining the *in vivo* response to somatostatin analogue administration. Somatostatin and its analogues (e.g., octreotide, lanreotide) reduce TSH secretion and TSH bioactivity immediately due to a change in glycoisomer distribution. Dopamine D2 receptors have been detected in TSH-secreting tumors, but the effect of long-term bromocriptine therapy is limited due to incomplete suppression of inappropriate TSH secretion. Finally, estrogen receptors have been found on TSH-secreting tumors and, at least in theory, could accelerate the growth of these tumors during a hyperestrogenic state such as pregnancy.

CLINICAL PRESENTATION

Clinical manifestations of central hyperthyroidism secondary to a TSH-secreting pituitary adenoma are frequently mild and not different from those occurring in the other forms of hyperthyroidism such as autoimmune Graves' disease, multinodular goiter, and toxic nodular goiter. TSH-secreting pituitary adenomas occur at any age and without a female predominance in the majority of the series. Clinical features of hyperthyroidism are progressive in their installation, and the mean latency between onset of hyperthyroidism and correct diagnosis is 4 years. Mild, moderate, and severe thyrotoxicosis with atrial fibrillation and

cardiac failure are observed in such patients. The presence of a goiter is a rule, and about two-thirds of patients have thyroid nodules or multinodular goiters, probably due to sustained TSH stimulation of the thyroid cells over many years. The occurrence of differentiated thyroid carcinoma is very rare. In many patients, tumoral signs and symptoms due to compression of the surrounding nervous structures, such as visual field defects (80%) and headaches (20%), prevail over those due to hyperthyroidism. Unilateral exophthalmos due to orbital invasion by the pituitary tumor is rare. In mixed secreting tumors, clinical findings are dependent on the nature of the hormone cosecreted (e.g., acromegalic features, amenorrhea and/or galactorrhea). In macroadenomas, concomitant hyposecretory syndromes (e.g., impotence, reduced libido) are not rare. TSH-secreting pituitary adenomas have been reported in pregnant women, in patients with multiple endocrine neoplasia type I, and in atypical McCune-Albright syndrome.

HORMONAL EVALUATION

TSH-secreting pituitary adenomas are now diagnosed with the introduction of ultrasensitive assay for TSH routinely performed as firstline thyroid function tests. Detectable or elevated TSH concentration with biochemical hyperthyroidism (increased free thyroid hormone concentrations) exclude primarily hyperthyroidism such as Graves' disease. Although TSH pulsatility is respected, the physiological circadian TSH variation is absent. Increased plasma α -subunit level and increased α -subunit/TSH molar ratio (i.e., greater than 1) are considered as diagnostic tools, but α -subunit level is usually normal in patients with TSH-secreting pituitary microadenomas. Recent studies show a relationship between hypersecretion of other pituitary hormones and tumor volume; high prolactin level and/or elevated growth hormone and insulin-like growth factor-1 (IGF-1) concentrations are reported in macroadenomas. In many patients with TSH-secreting pituitary adenomas, dynamic tests reveal a decrease or lack of response of TSH during the TRH test, absence or inappropriate negative feedback of thyroid hormone on TSH secretion (T3 suppression test), and/or a marked decrease in TSH level after subcutaneous injections of somatostatin analogue octreotide.

PITUITARY IMAGING

The presence of a pituitary tumor in a patient with inappropriate secretion of TSH, although strongly

suggestive, is not diagnostic of a TSH-secreting pituitary tumor given that pituitary incidentalomas have been found on magnetic resonance imaging (MRI) in up to 10% of normal individuals. In patients with TSH-secreting pituitary adenomas, there is no correlation between serum TSH levels and tumor size. On the other hand, the development of a TSH-secreting tumor is rare in patients with resistance to thyroid hormone syndrome. In the oldest series, many patients presented with macroadenomas with suprasellar and sphenoidal extension, whereas in more recent reports, MRI frequently revealed medially localized microadenomas. Several observations of patients with neoplastic-inappropriate secretion of TSH have been reported with normal MRI, and the diagnosis of TSH-secreting pituitary adenoma has been made with bilateral petrous sinus sampling with TRH stimulation test, ¹¹¹indium pentreotide scan, or ¹¹C methionin PET scan.

DIFFERENTIAL DIAGNOSIS

Elevated levels of total thyroid hormones and inappropriately normal or elevated TSH levels might be related to increased levels of thyroxine-binding proteins, familial dysalbuminemia, treatment with drugs (amiodarone), or the presence of heterophilic antibodies or autoantibodies able to interfere, depending on the methodology used, with the measurement of TSH and thyroid hormones. In fact, the differential diagnosis between a TSH-secreting pituitary adenoma and a resistance to thyroid hormone syndrome might be difficult because age, sex, TSH, and free thyroid hormone concentrations are not different. The diagnosis of a

TSH-secreting pituitary adenoma is likely in the presence of an absence of family history, an elevated serum α -subunit level with a high α -subunit/TSH molar ratio, an absence of circadian TSH variation, a high level of sex hormone-binding globulin (SHBG), an absent or impaired TSH response to TRH administration, an absent TSH suppression after oral administration of T₃, and a long-term response of thyroid parameters to somatostatin analogue injections. The diagnosis of central hyperthyroidism secondary to a TSH-secreting pituitary adenoma is confirmed by the finding of a pituitary lesion on MRI and by genetic analysis with the absence of mutation in the sequence of the TR β gene (Table I). Finally, few cases of coexisting Graves' disease or resistance to thyroid hormone syndrome and TSH-secreting pituitary adenoma have been reported.

TREATMENT

In patients with TSH-secreting pituitary adenomas, the goal of therapy is to restore euthyroidism in hyperthyroid patients and to eliminate the symptoms of mass effect in patients with large tumors. Early diagnosis and correct treatment of these rare tumors prevent complications, such as visual abnormalities due to compression of optic chiasma and hypopituitarism, and also might improve the cure rate. The success of treatment depends on the criteria used. An early test of cure might be an undetectable TSH concentration 7 days after surgery (with measured TSH level reflecting tumoral TSH) when the normal thyrotrophs are suppressed by the thyroid hormones, whereas normalization of dynamic tests (e.g., TRH

Table I Differential Diagnosis Between TSH-Secreting Pituitary Adenoma and Resistance to Thyroid Hormone Syndrome

| | TSH-secreting adenomas | Resistance to thyroid hormone |
|-----------------------------------|------------------------|-------------------------------|
| Family history | Absent | Possible |
| Increased free thyroid hormone | + | + |
| Normal or high TSH | + | + |
| Circadian TSH secretion | Absent | Present |
| SHBG | Increased | Normal |
| α -subunit level | Increased | Normal |
| α -subunit/TSH molar ratio | >1 | <1 |
| Response to TRH test | Absent | Normal |
| Response to T ₃ test | Absent | Normal |
| Hormonal cosecretion | + | - |
| MRI | Adenoma | Normal |
| Genetic analysis | - | + |

test, T3 suppression test) might represent a later test of cure. In any case, long-term follow-up is necessary to detect relapse and recurrence.

Transphenoidal surgery is the firstline therapy in patients with TSH-secreting pituitary microadenomas. The occurrence of inappropriate secretion of antidiuretic hormone seems to be frequent after surgery of such tumors. Pituitary surgery alone leads to normalization of thyroid hormone secretion and disappearance of the pituitary mass in approximately 50% of patients, leads to normalization of thyroid parameters despite incomplete tissue removal in approximately 25% of patients, and is unsuccessful in nearly 30% of cases. Therefore, the results of surgery are rather disappointing in patients with TSH-secreting pituitary adenomas. However, an increase in the surgical rate has been reported in the more recent series, probably reflecting the early diagnosis of these tumors.

Conventional radiotherapy and stereotaxic radiosurgery are associated with low percentage remission of hyperthyroidism, underscoring the relative resistance of TSH-secreting pituitary adenomas to external radiotherapy. Also taking into consideration the long time period necessary for the full effect to be realized and the well-known late side effects (e.g., hypopituitarism, impaired cognitive function), radiotherapy is now prescribed less frequently in patients with central hyperthyroidism related to TSH-secreting pituitary adenomas.

Medical treatment is an alternative option to pituitary surgery in patients with TSH-secreting pituitary tumors. Dopamine agonists are an effective treatment in mixed TSH/prolactin-secreting pituitary adenomas, whereas success is limited with bromocriptine treatment in patients with pure TSH-secreting pituitary adenomas. The presence of somatostatin receptors on TSH-secreting pituitary adenomas has allowed consideration of treatment with somatostatin analogues in patients with TSH-dependent hyperthyroidism related to TSH-secreting pituitary tumors. Somatostatin analogue octreotide suppresses TSH secretion in more than 90% of TSH-secreting pituitary adenomas, normalizes thyroid hormone concentration in approximately 75% of patients, and decreases adenoma size in approximately 50% of cases with an amelioration of visual disturbances in patients with macroadenomas. However, the effects of somatostatin analogues are reversible, with the need for long-term administration, with possible tachyphylaxis requiring increasing doses of the drug to maintain good control of the disease in 10% of cases, and

with true resistance in few patients. This treatment is expensive and might be associated with side effects such as cholelithiasis and carbohydrate intolerance. In the oldest reports, long-term medical therapy with somatostatin analogues was indicated adjunctively in patients with TSH-secreting pituitary adenomas who failed to be cured after surgery or who were awaiting the full effect of radiotherapy. The use of somatostatin analogues as primary therapy was generally reserved for patients who refused surgery or who were poor surgical candidates. Recent studies have demonstrated that primary treatment with somatostatin analogues might be a reasonable option in patients with TSH-secreting pituitary tumors to preoperatively control the TSH-dependent hyperthyroidism and that long-term treatment is effective in patients with TSH-secreting macroadenomas or invasive tumors treated with surgery and/or pituitary radiotherapy as well as in previously untreated individuals. Finally, long-acting somatostatin analogues (e.g., Sandostatin LAR, Somatuline LP), injected intramuscularly every 10 to 28 days, are useful therapeutic tools to improve compliance of patients and to facilitate the medical treatment of TSH-secreting pituitary tumors in patients who need long-term somatostatin analogue therapy.

CONCLUSION

TSH-secreting pituitary adenomas are a rare cause of hyperthyroidism. The main prognostic factors of these adenomas are size and invasiveness of the tumors, duration of symptoms, and intensity of hyperthyroidism. The early recognition of central hyperthyroidism due to these pituitary tumors is possible with the availability of sensitive TSH assays and the improvement in pituitary imaging. Therefore, the spectrum of the diagnosis and treatment of these rare pituitary tumors has changed during the past decade. Patients present with mild or moderate symptoms and signs of hyperthyroidism, hormonal evaluation shows increased free thyroid hormone concentrations with detectable serum TSH levels, and MRI leads to increase the percentage of patients with microadenomas. On the other hand, transphenoidal surgery remains the treatment of choice for patients with TSH-secreting pituitary microadenomas, whereas long-acting somatostatin analogue administration seems to be indicated as a primary treatment in patients with macroadenomas or invasive pituitary tumors.

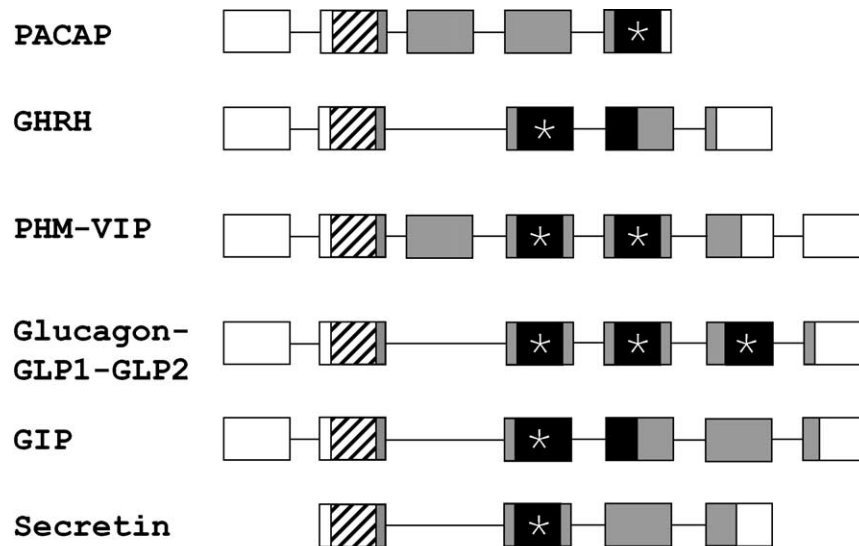

Figure 2 Organization of the genes encoding the PACAP/glucagon superfamily members. White boxes represent 5'- and 3'-untranslated regions; crosshatched boxes represent signal peptides; black boxes represent bioactive superfamily members, and shaded boxes represent N- and C-terminal peptides and intervening domains. Introns are depicted as lines, but are not drawn to scale. PACAP, pituitary adenylate cyclase-activating polypeptide; GHRH, growth hormone-releasing hormone; PHM, peptide histidine-methionine; VIP, vasoactive intestinal peptide; GLP1, glucagon-like peptide-1; GLP2, glucagon-like peptide-2; GIP, glucose-dependent insulinotropic polypeptide.

There are three types of PACAP receptors, each encoded by a separate gene. One of these receptors, the PAC₁ receptor, is specific for PACAP. The other two receptors, VPAC₁ and VPAC₂, bind both PACAP and VIP. The most interesting of these three receptors is PAC₁ because it is not only specific for PACAP, but has nine variant forms. These variants have insertions in the third intracellular loop, deletions in the extracellular domain, or substitutions in the second and fourth transmembrane regions. The effect is that some of the variants couple to different intracellular signaling pathways that act through second messengers such as cyclic AMP (cAMP), inositol triphosphate, and calcium ions. In contrast, the receptors shared with VIP do not have variant forms; they induce postreceptor effects primarily through cAMP.

The target tissues for the action of PACAP are those expressing the receptors. The PAC₁ receptors are widely distributed in the brain. VPAC₁ and VPAC₂ receptors are in the brain with some concentration in the hippocampus and hypothalamus, but are far less abundant than PAC₁ receptors in the brain. In peripheral tissues, PAC₁ receptors are found in the eye, pituitary, adrenal medulla, pancreas, liver, ovary, lung, gut, and lymphoid tissue. The VPAC₁ receptors are in the eye, adrenal gland, pancreas, liver, testis, lung, gut, and lymphoid tissue. The VPAC₂ receptors are in similar

locations as well as in the pituitary and ovary. There is less overlap among receptor location than the list suggests as the receptors may be expressed only in specific cells within the organs and at specific times.

The functions of PACAP are diverse, but the physiological stimulus that releases PACAP from nerve endings or cells has not been elucidated. Regardless of the control of PACAP, this hormone has a number of functions. PACAP stimulates the release of other hormones; it releases insulin and glucagon from the pancreas, catecholamines from the adrenal medulla, glucocorticoids from the adrenal cortex in some species, and growth hormone from the pituitary gland. PACAP acts on blood vessels to cause vasorelaxation. In the developing nervous system, PACAP acts to alter proliferation and differentiation. PACAP's actions have been examined in mice in which either the PACAP gene or the receptor (PAC₁) gene has been knocked out by targeted disruption of the gene. These studies show that PACAP plays a role in behavior and in lipid and carbohydrate metabolism, including the response to metabolic stress, such as an insulin challenge. One hypothesis to explain the many actions of PACAP is that it is used for responses to environmental or metabolic stress.

In regard to disease, PACAP is overexpressed in a number of tumors including gliomas, neuroblastomas,

and pheochromocytomas and in tumors of the pancreas, ovary, and pituitary. However, solid evidence is lacking as to symptoms associated with alterations in the human genes encoding PACAP or its receptors.

VIP

Vasoactive intestinal peptide was named because it was isolated from the intestine, but later it was discovered that VIP is widely distributed in the central and peripheral nervous systems. VIP is closely related to PACAP in peptide structure, gene organization, distribution, and shared receptors. VIP is a 28-amino-acid peptide that is 70% identical at the amino acid level with PACAP₁₋₂₇ in humans (Fig. 1). Only one gene for VIP is present in humans and it encodes a large precursor containing both PHM and VIP (Fig. 2). The two hormones are on separate exons (exons 4 and 5). Although the PHM-VIP gene has seven exons, it is very close in structure to the PACAP gene in the first five exons. The final two exons in VIP encode only a nonfunctional peptide and the 3'-untranslated region.

Peripheral nerves with VIP are distributed to the intestine, lungs, pancreas, and adrenal. Also, VIP has been found in gonadal and immune cells. A specific receptor for VIP has not been reported, but two different receptors are shared with PACAP (VPAC₁ and VPAC₂). Both receptors are seven-transmembrane G protein-coupled receptors. These two receptors are widespread, as discussed above for PACAP. A variety of functions are described for VIP. In the brain, VIP is described as part of a "visceral forebrain system" that can superimpose control over the brainstem center for cardiovascular, respiratory, and gastrointestinal functions. Like PACAP, VIP is a vasorelaxant. VIP can regulate other hormones; VIP releases prolactin and at times growth hormone (GH) and luteinizing hormone from the pituitary and it releases insulin or glucagon from the pancreas depending on the glucose level in the blood. VIP has some effect on release of the catecholamines from the adrenal and indeed is in the same nerve terminals as PACAP. VIP is expressed early in the embryonic brain and is reported to increase growth and proliferation. Although inhibition of VIP in embryos resulted in microcephaly, this experiment could not be repeated by other researchers.

A connection with disease has been observed in that pancreatic and bronchial tumors known as VIPomas can result in a watery diarrhea syndrome. The symptoms are probably related to VIP's action on the exocrine pancreas and intestine to alter secretions and absorption of water and ions in the gut. These tumors

may be derived from neural tissue innervating the pancreas, intestine, or bronchial tubes, as the highest levels of VIP are found in neuroblastomas. In addition, VIP has been shown in animal models to prevent lung injury, improve survival in acute respiratory disease syndrome, and protect cardiac and neural tissue.

PHM

Human PHM is a 27-amino-acid peptide encoded by exon 4 of the same gene that encodes VIP (Fig. 2). Cells express and release PHM and VIP together, so PHM expression has the same wide distribution as VIP in the gastrointestinal tract as well as in the central and peripheral nervous systems.

PHM acts as a less potent version of VIP, exerting similar biological effects, including the release of prolactin, insulin, and glucagon. PHM possibly acts through its ability to weakly bind to G protein-coupled VPAC₁ and VPAC₂ receptors. A specific PHM receptor, for which there is evidence based on binding studies, has not yet been isolated and characterized in humans. There are no disorders or diseases that are unique to PHM, although an aberrant profile of expression and amounts of PHM and VIP are seen in some disease states. VIP is of more interest for therapy because of its increased potency compared to PHM.

GHRH

GHRH is well established as a hormone made in the brains of mammals. In humans, GHRH is a 44-amino-acid peptide (Fig. 1) that is released from nerve cells in brain and then binds to pituitary cells to release GH. In humans, GHRH is encoded by a single gene, with a GHRH-coding region that extends across exon 3 and part of exon 4 (Fig. 2). GHRH has a long evolutionary history in which GHRH shared a gene with PACAP until the appearance of mammals.

The distribution of GHRH is primarily in the brain, although it is reported to be present in the gut, gonads, placenta, pancreas and immune cells. There are both long and short versions of the GHRH receptor, which is the usual seven-transmembrane G protein-coupled receptor. The target organs for GHRH are primarily the pituitary and brain, although low levels of receptors are reported for the gonads, placenta, and kidney. The function of GHRH is to increase the synthesis and release of GH from somatotrophs in the pituitary, but also to stimulate these somatotroph cells for proliferation, differentiation, and growth. Centrally, GHRH is implicated in

the control of food intake and enhancement of sleep. In the periphery, GHRH is reported to release insulin and to have a role in the gut, in reproduction, and in fetal growth.

Rare tumors that overexpress GHRH can occur in humans, especially in the pancreas, gastrointestinal tract, and lung. The symptoms in adults are typical of acromegaly with enlarged hands, feet, and jaw. Two such tumors were used for the first structural determination of human GHRH.

GLUCAGON

The glucagon gene encodes a precursor with a number of peptides, three of which are bioactive (Fig. 2). Differential cleavage of this precursor results in glucagon production in the pancreas, but production of GLP-1 and GLP-2 in the intestine. In the pancreas, alpha cells use a proteolytic cell-specific enzyme, prohormone convertase, to produce glucagon (active), glicentin-related pancreatic peptide (inactive), and the major proglucagon fragment containing uncleaved GLP-1 and GLP-2 (inactive). In contrast, cells of the terminal small intestine and large intestine cleave proglucagon into glicentin (inactive), GLP-1 (active), and GLP-2 (active). Mature glucagon is a 29-amino-acid peptide, which includes an N-terminal histidine that is vital for biological activity.

The glucagon receptor is a G protein-coupled receptor that stimulates adenylate cyclase, resulting in increased intracellular cAMP and increased protein kinase A activity downstream. It has homology with the receptors for the other PACAP/glucagon superfamily members. Glucagon receptor mRNA is also present outside the liver in kidney, heart, stomach, pancreatic islets, spleen, thymus, adrenal, and skeletal muscle, although the functions in these tissues are not yet known.

Glucagon controls glucose metabolism by activating gluconeogenesis and glycogenolysis in the liver, effectively counteracting the action of insulin. Also, glucagon is synthesized in the CNS where it is thought to play a role in the regulation of peripheral glucose levels.

The glucagon pathway is both a contributor to the symptoms of diabetes and a candidate for the treatment of diabetes. Diabetes is a disorder involving reduced or absent insulin production and secretion. Glucagon increases to excess in proportion to a lack of insulin because transcription of the glucagon gene is normally inhibited by insulin. Excess glucagon results in hyperglycemia. In diabetes, glucagon favors glucose

production in the liver, indirectly compounding the effect of low insulin in ketone production. The glucagon receptor is one target of therapy for diabetic patients with excessive glucose production. Glucagon receptor antagonists represent an avenue to decrease liver glucose production and lower the blood glucose of diabetic patients.

GLP-1

The full-length N-terminal-extended forms of GLP-1 (1-37 and 1-36 amide) were initially found to have little biological activity. Removal of the first six amino acids was necessary for full biological activity. Cells in the intestine produce the two biologically active forms (GLP-1₇₋₃₆ and GLP-1₇₋₃₇), both of equal potency, but the major circulating form is GLP-1₇₋₃₆. The enzyme dipeptidyl-peptidase IV cleaves the two N-terminal amino acids from the active peptide, rendering a peptide (GLP-1₉₋₃₆) with little or no biological activity. The GLP-1 receptor is expressed in the gastrointestinal tract, pancreatic islets, kidney, lungs, heart, CNS, and possibly adipose tissue.

Major actions of GLP-1 are reported in the pancreas and the central nervous system. GLP-1 is released from intestinal cells in response to nutrients in the gut and then enhances the synthesis and release of insulin. At the same time, GLP-1 suppresses gastric emptying and directly or indirectly suppresses secretion of glucagon. GLP-1 helps to clear glucose following a glucose challenge. Another important action of GLP-1 is its ability to stimulate islet cell proliferation and growth as shown in mice and cell line model studies.

In the central nervous system, GLP-1 is reported to suppress food intake. Although it is not yet understood if the mechanism involved is direct or indirect, brain GLP-1 is not essential for physiological control of nutrient intake and body weight regulation *in vivo*. Another role for the GLP-1 is in the stress response. For example, mice with targeted disruption of the GLP-1 receptor gene have exaggerated levels of corticosterone in stress tests. The expression of GLP-1 receptors in extrapancreatic tissues suggests that GLP-1 may have other actions. In rats, intravenous injection of GLP-1 increases heart rate and blood pressure.

GLP-1 is a candidate in the treatment of diabetes. GLP-1 lowers blood glucose as well as appetite in diabetic patients, although the long-term therapeutic potential of GLP-1 in treating diabetes is still unknown. Analogues of GLP-1 resistant to degradation

in the body will likely meet the criteria for a therapeutic agent.

GLP-2

GLP-2 is 33 amino acids long and is located following GLP-1 on their common gene (Fig. 2). Tissue-specific posttranslational processing results in the production of GLP-2 in the intestine and brain but not the pancreas. The active circulating form of GLP-2 is GLP-2₁₋₃₃, whereas GLP-2₃₋₃₃ is inactive due to processing by dipeptidyl-peptidase IV cleavage. The GLP-2-specific receptor is a G protein-coupled receptor expressed in the stomach, small bowel, and colon, as well as the hypothalamus.

GLP-2, like GLP-1, is involved in nutrient assimilation and energy homeostasis. However, an increasing number of functions unique to GLP-2 are being uncovered. GLP-2 inhibits gastric secretion and affects intestinal permeability. Acute GLP-2 infusion in rats results in increased intestinal hexose transport. Larger intestinal surface area results from the growth-stimulating properties of GLP-2 in the intestine. GLP-2 stimulates the proliferation of crypt cells, resulting in villi of greater height. Apoptosis of enterocytes following intestinal injury appears to be inhibited by GLP-2, which has led to further study for a direct role for GLP-2 receptor activation in reducing certain cell death events. The bioactive properties of GLP-2 related to the protection and restoration of intestinal cells are being tested for their potential in treating human gastrointestinal diseases.

GIP

GIP is a 42-amino-acid peptide hormone encoded by a single gene. GIP mRNA is expressed only in the gut, specifically in the K cells, the majority of which are located in the proximal duodenum. GIP is secreted from these cells on stimulation by nutrients in the gut. GIP, along with GLP-1 and GLP-2, is inactivated by the enzyme dipeptidyl-peptidase IV, which cleaves the two N-terminal amino acids from the peptide to produce inactive GIP₃₋₄₂. Mice that lack the ability to produce dipeptidyl-peptidase IV have significantly increased levels of GIP. GIP has a specific 59 kDa G protein-coupled receptor. Unlike its ligand, GIP receptor mRNA is widely distributed in peripheral organs including the pancreas, gut, heart, brain, adipose tissue, and adrenal cortex.

GIP was initially discovered and named for its ability to inhibit gastric acid secretion. Later it was

found that at physiological levels, GIP stimulates insulin synthesis and release in rodents and humans. The function of GIP as an insulinotropic agent stimulating insulin synthesis and release depends on an increase in blood glucose levels, resulting in the name change to glucose-dependent insulinotropic polypeptide to reflect these findings. Also, GIP appears to compensate for lost GLP-1-regulated insulin release in studies where the GLP-1 receptor gene has been disrupted. GIP may have a more restricted role in glucose homeostasis than GLP-1, as GIP has been shown to regulate glucose absorption and glycemic excursions only following enteral glucose challenge.

SECRETIN

Secretin has retained a basic 27 amino acid length. The structure of the secretin gene is different in many ways from the genes for other PACAP/glucagon superfamily members. Most notably, it contains only four exons, with exon 1 serving for both the transcription and translation start sites. These and other properties may reflect the long period of time since the secretin gene diverged from the other PACAP/glucagon superfamily members.

Secretin is synthesized in endocrine S cells of the small intestine and in beta cells of the developing pancreas. There are inconsistent reports of secretin mRNA expression in other tissues including brain, heart, lung, kidney, and testis. Secretin mRNA and secretin protein reach their highest levels in the developing intestine 2 days before birth, whereas they peak in the developing pancreas at day 19, but are not detectable in the adult pancreas. The synthesis and secretion of secretin in the fetus are likely under regulation by different mechanisms, as the stimuli from nutrients are not yet a factor compared to postnatal animals.

A secretin-specific receptor has been cloned and characterized in humans. There are multiple subtypes of this G protein-coupled receptor. Secretin receptor mRNA is expressed in the gut and related organs and in the spermatids of the testis, although it has not been detected in brain.

Many actions have been assigned to secretin since its discovery. The well-known functions of secretin at physiological doses are actions on gut, liver, and pancreas. Secretin, which is released in the small intestine in response to gastric acid and fat, acts on the pancreas to release water and a bicarbonate-rich fluid to neutralize the acidity. Also, secretin stimulates gastric pepsin secretion and inhibits gastric acid secretion and

gut motility. Secretin has been shown to stimulate the release of somatostatin in the small intestine. In PC12 cells, secretin is able to stimulate tyrosine hydroxylase, an enzyme involved in catecholamine synthesis. Injection of physiological amounts of secretin in adults has coincided with the release of insulin and improved glucose tolerance. A specific disease has not been directly connected with a problem in secretin production.

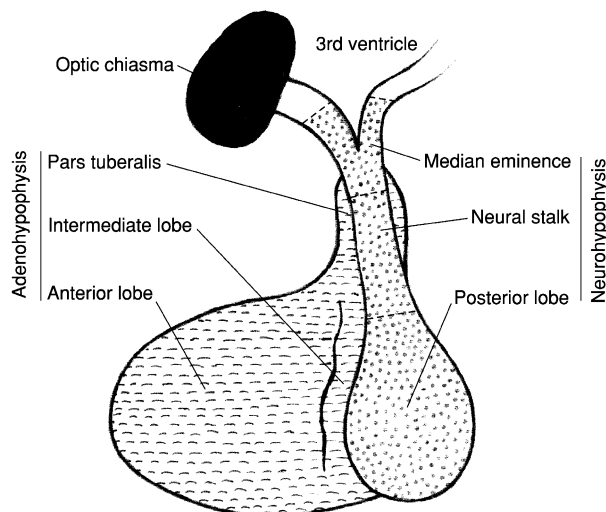

Figure 1 Schematic of the divisions and subdivisions of the pituitary as seen in a midsagittal section of the gland.

pituitary. The optic chiasma lies directly above the sellar diaphragm ahead of the hypophysial stalk. Growth of a pituitary tumor may compress the chiasma and impair vision. The tuber cinereum of the hypothalamus also lies above the roof of the sella. Space-occupying lesions in the pituitary may compress and compromise the tuber cinereum and cause hypothalamo-hypophysial dysfunctions. The lateral walls of the sella are close to the cavernous sinuses containing the internal carotid arteries and several nerves including the oculomotor, trochlear, and abducens nerves and the first two branches of the trigeminal nerve. The sphenoid sinus, separated from the sella by a thin layer of bone, is inferior to the

pituitary. In the case of a pituitary tumor, this bone may be resorbed and eroded, leading to tumor penetration into the sinus.

Blood Supply

The blood supply of the pituitary derives from two groups of arteries: from above, the right and left superior hypophysial arteries; from below, the right and left inferior hypophysial arteries. Both groups of arteries arise from the internal carotid arteries. The superior hypophysial arteries supply blood to the median eminence and proximal portion of the pituitary stalk. Here these arteries break up into a primary capillary plexus. The capillaries of this plexus rejoin to form the long portal vessels that traverse the pituitary stalk and break up into a secondary capillary plexus in the anterior lobe of the pituitary in close relationship to the cells of anterior pituitary. This hypophysial portal vascular system is of the utmost importance in regulating hormone secretion of the anterior pituitary. The posterior pituitary receives its blood supply from the inferior hypophysial arteries. Some vessels from the posterior lobe penetrate into the anterior pituitary (short portal vessels).

Venous blood leaves the pituitary through dural channels and enters the cavernous sinuses, which drain to the inferior petrosal sinus and the internal jugular vein. There may be anastomoses between the petrosal sinuses, which can lead to confusing observations with petrosal sinus sampling.

Although most blood flow is from the hypothalamus to the pituitary, there is evidence that some blood may flow in the opposite direction, from the anterior pituitary to the hypothalamus.

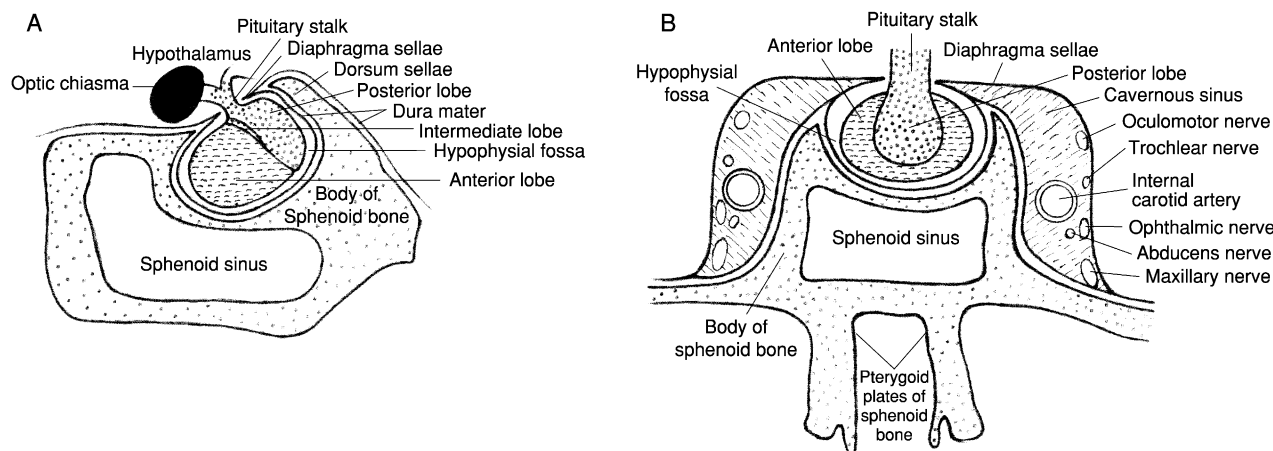

Figure 2 Schematic of the location and topography of the pituitary in a midsagittal section (A) and a coronal section (B) of the sphenoid bone.

Innervation

The anterior lobe is poorly innervated. A few nerve fibers reach the anterior pituitary along the blood vessels. These nerve fibers are not believed to have major importance in the control of hormone secretion. The posterior pituitary contains the axon terminals of the supraoptic and paraventricular neurons, synthesizing and releasing oxytocin and vasopressin. In addition, the intermediate pituitary and the posterior pituitary are innervated by hypothalamic dopaminergic neurons of the periventriculo-hypophysial and the tuberohypophysial dopaminergic system.

EMBRYOLOGY

The adenohypophysis originates from an evagination of the epithelium covering the vault of the stomodeum (primary oral cavity). The neurohypophysis develops as a process growing downward from the floor

of the diencephalon, i.e., as an evagination of the third ventricle of the brain (Fig. 3). During embryonic development, the adenohypophysial primordium becomes located anterior to the neural primordium.

Development of the Adenohypophysis

The epithelium of the stomodeum (primitive oral cavity) becomes thicker just ahead of the pharyngeal membrane (Fig. 3A). This flat primordium invaginates and penetrates the connective tissue in the direction of the diencephalon, forming a diverticulum, Rathke's pouch (Fig. 3B). Initially, Rathke's pouch is composed of a small, thin-walled vesicle in the roof of the primitive oral cavity. It subsequently expands in the direction of the evagination of the third ventricle and will be situated just ahead of the evagination (Fig. 3C) and then it adheres to it. Rathke's pouch is attached to the stomodeal vault by a stalk (cranio-pharyngeal canal), which regresses, is obliterated, and

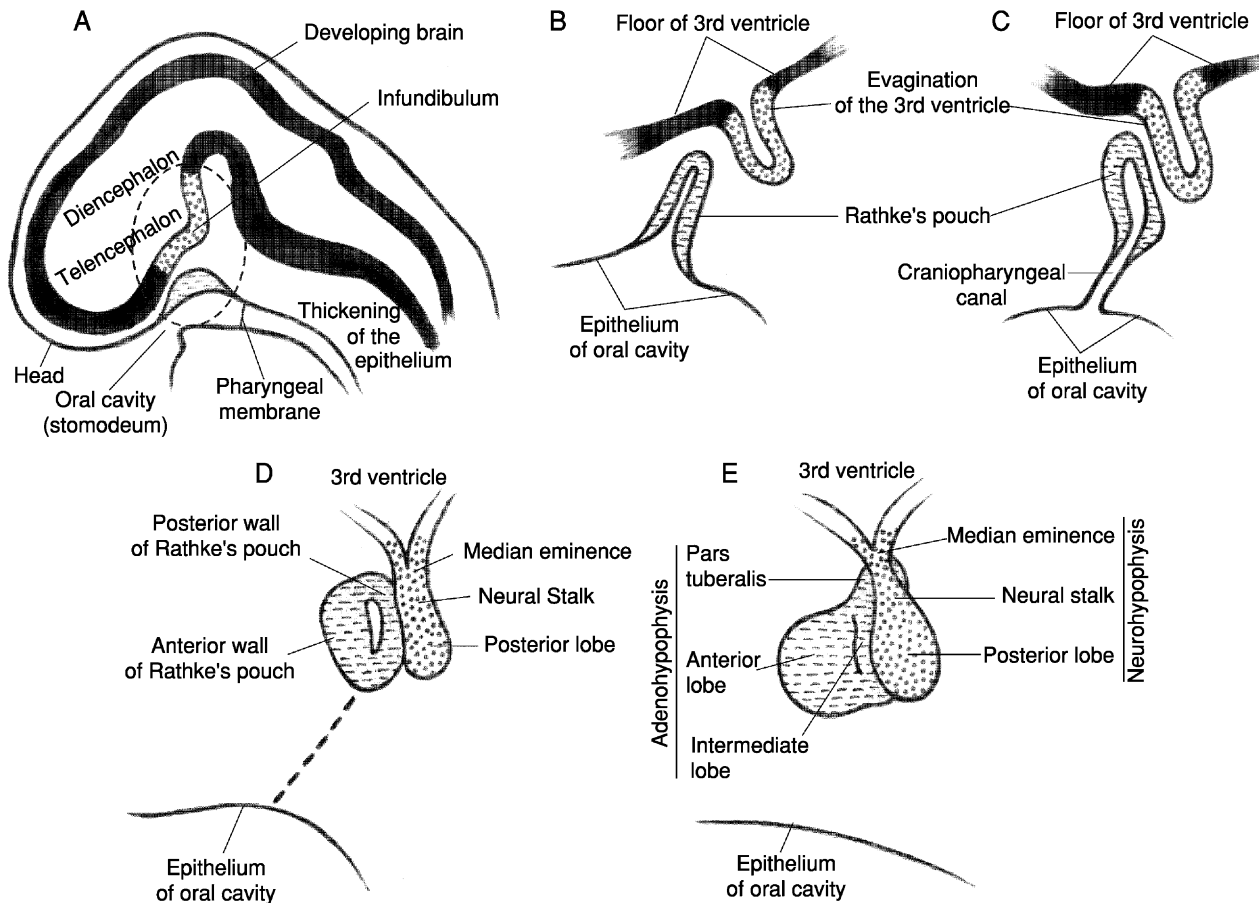

Figure 3 Schematics of the development of the pituitary as seen in midsagittal sections. The drawings show the various stages of development: (A) very early stage; (B, C) intermediate stage; (D) nearly developed stage; and (E) completely developed stage.

usually disappears (Fig. 3D). Parts of it, however, may persist in a more or less differentiated and sometimes functional condition. Nests of adenohypophysial tissue may be deposited along the route of the cranio-pharyngeal canal. Remnants of the pharyngeal hypophysis may be capable of hormone synthesis and may give rise to ectopic adenomas. Occasionally, cranio-pharyngiomas (tumors) develop in the pharynx or in the sphenoid bone of the skull, but most often they form in or above the sella turcica of the sphenoid bone at the base of the skull.

Just behind the pharyngeal membrane, the entodermal epithelium also forms a pouch, the pouch of Sessel. This structure is involved in the formation of the adenohypophysis in lower vertebrates. However, this involvement decreases as the evolutionary scale increases and disappears completely in primates and human. In human, it sometimes persists and may cause certain tumors.

Development of the Anterior Lobe

The anterior lobe develops from the anterior wall of Rathke's pouch. Cells of this wall proliferate actively and give rise to the anterior lobe of the pituitary gland (Fig. 3D). Proliferation occurs in such a way that a small basin is formed, separated into two compartments by a median cellular septum. The compartments disappear progressively, due to the growth of the wall. The median septum forms the pars medialis and the lateral portions form the lateral part of the anterior lobe. The extensive proliferation of the anterior wall of Rathke's pouch reduces the lumen to a narrow residual cleft (Fig. 3E). It is usually not recognizable in the adult gland and is represented by a zone of cysts.

Acidophilic cells are detectable in the anterior lobe of the human embryo at approximately the third month of gestation; basophilic cells can be detected somewhat later. Adrenocorticotrophic hormone (ACTH)- and growth hormone (GH)-synthesizing cells are identifiable by the end of the second month of gestation. This is followed by the production of glycoprotein hormones. Blood vessels grow into the anterior lobe and establish a direct neurovascular link between the anterior lobe and the hypothalamus at approximately the eighth week of gestation. The mammothroph cell type (prolactin-producing) appears late, at approximately the fifth month of gestation. Hormone-producing cells differentiate in the absence of a hypothalamic influence. In anencephaly, all cell types of the anterior lobe except corticotrophs develop and are capable, to some extent, of hormone synthesis and release.

Development of the Intermediate Lobe

The posterior wall of Rathke's pouch gives rise to the intermediate lobe of the adenohypophysis (Figs. 3D and 3E). In humans, cells of the posterior wall of Rathke's pouch do not proliferate; instead, they form the poorly defined intermediate lobe, which becomes an inconspicuous, discontinuous layer.

Development of the Pars Tuberalis

The pars tuberalis of the adenohypophysis develops from the anterior wall of Rathke's pouch. The cells of the median septum of the anterior wall of Rathke's pouch proliferate upward along the pituitary stalk, which becomes gradually encircled by the cellular expansion of the developing pars tuberalis (Fig. 3E).

Development of the Neurohypophysis

The neurohypophysis develops from the evagination of the wall of the third ventricle (Fig. 3). The floor of the third ventricle becomes depressed and produces the infundibulum (Fig. 3A). This depression penetrates progressively toward the adenohypophysial primordium. Its ventral end forms a diverticulum (Figs. 3B and 3C). The wall of the diverticulum thickens and its lumen gradually fills, forming the neural or posterior lobe, which is attached to the posterior wall of Rathke's pouch (Fig. 3D). It remains to be connected to the diencephalon part of the brain by the thin neural stalk. The ascending part of the infundibulum is the median eminence. The median eminence, the neural stalk, and the posterior lobe (or neural lobe or infundibular process) form the neurohypophysis (Fig. 3E). The neural lobe differentiates and specific neuroglial cells, called pituicytes, appear in it. The neurohypophysis is then colonized by axons coming from the hypothalamic paraventricular and supraoptic nuclei. In the human, neurosecretory material, characteristic of the posterior pituitary, is demonstrable at approximately the fifth month of gestation.

HISTOLOGY

Adenohypophysis

Anterior Lobe (or Anterior Pituitary or Pars Distalis)

The anterior lobe accounts for approximately 75–80% of the whole gland. It is highly vascular and contains various cell types. The lobe is largely enclosed by a dense collagenous capsule and is composed of glandular cells arranged in irregular cords or clumps, which are intimately related to an extensive system of dilated capillaries (sinusoids) of the blood

vascular system. Reticular fibers surround the cords of parenchymal cells and are also present close to the wall of the sinusoids.

The glandular cells were originally classified as chromophilic and chromophobic on the basis of their avidity or lack of affinity for the dyes used in routine staining of histological sections. The chromophilic cells were subdivided into acidophilic and basophilic cells on the basis of staining with combinations of an acidic dye and a basic dye. In the human pituitary, acidophilic cells are most numerous in the posterolateral portions of the anterior lobe. They are rounded, small cells with a well-developed Golgi complex and rod-shaped mitochondria. The basophilic cells are larger and less numerous.

The most meaningful method applied at both the light and electron microscopic levels for identification of the cells producing various hormones involves the use of immunocytochemical procedures. Antibodies to a specific hormone induced in another species are conjugated with horseradish peroxidase or with fluorescence dyes. These labeled antibodies are reacted with sections of the anterior lobe and the sites of the antigen in the tissue are localized by the histochemical method for peroxidase or by fluorescence microscopy.

The anterior pituitary produces six hormones: GH (or somatotropin), prolactin, thyrotropin (TSH), ACTH, and two gonadotropins—follicle-stimulating hormone (FSH), and luteinizing hormone (LH). The acidophilic cells secrete simple proteins (somatotropin and prolactin) and the basophils secrete glycoprotein hormones (TSH, FSH, LH, and the precursor of ACTH). It has become a common practice to use the terms of the hormone secreted (ACTH cell, TSH cell, FSH/LH cell) or the name of the target organ stimulated (corticotroph, thyrotroph, gonadotroph) to denote the cell type. In addition to these cells, some other cell types, such as folliculostellate cells and null cells, are also found in the pituitary.

Somatotrophs

Somatotrophs represent approximately 50% of the anterior lobe cells. They are found in groups along the sinusoids and are located mainly in the two lateral wings of the anterior lobe. The cells are usually medium-sized and contain numerous spherical, evenly electron-dense granules, the majority being 350 to 500 nm in diameter. They have a well-developed endoplasmic reticulum and secrete GH. Immunocytochemical observations strongly suggest that the somatotrophs are not a uniform mass of cells. It appears that they consist of several subpopulations, all of which express somatotropin, but are also capable

of producing other hormones, such as prolactin and TSH, in special circumstances. There is evidence that transdifferentiation of GH-/prolactin-synthesizing cells (somatomammotrophs) may contribute to the mass of prolactin-producing cells during development of prolactin cell hyperplasia in human pregnancy and further, that somatotrophs may transform into large thyrotroph cells in rats during experimental hypothyroidism.

Mammotrophs

Mammotrophs (or lactotrophs or prolactin cells) produce prolactin and constitute 10 to 25% of the anterior lobe cells. They are relatively small cells, are distributed individually in the interior of the cell cords, and are located throughout the entire anterior lobe. The cells are especially numerous at the posterolateral and posteromedial edges of the adenohypophysis. Two types of lactotrophs can be distinguished. The majority of the cells are small or medium in size and sparsely granulated. The secretory granules are spherical and evenly electron-dense, measuring 150 to 350 nm in diameter. The other, less frequently occurring type is densely granulated and the granules are larger (300 to 600 nm). The number of prolactin cells varies considerably. In pregnancy and lactation, lactotrophs are increased in number. During pregnancy, the cells undergo considerable hypertrophy: their Golgi complex enlarges and the endoplasmic reticulum becomes more extensive; multiple layers parallel to the cell membrane develop and the granules become larger (550 to 600 nm in diameter) and often irregular in outline. The mammotrophs are most active during lactation. After weaning has occurred, lysosomes play an important role in the elimination of excess secretory granules and the hypertrophied cellular organelles involved in the lactation period of active protein synthesis. Lysosomes fuse with the secretory granules to form autophagic vacuoles. The secretory granules are degraded by hydrolytic enzymes in these vacuoles. This procedure of disposal of secretory product that is no longer needed is called crinophagy. Excess cytomembranes and ribosomes are also enclosed in vacuoles and degraded by autophagy.

Thyrotrophs

Thyrotrophs, secreting TSH, are located mainly in the anteromedial part of the anterior lobe and constitute less than 10% of the lobe. The cells are medium or large in size and polygonal with long cytoplasmic processes. In electron micrographs, they are characterized by spherical secretory granules, are variably electron-dense, measure 100 to 200 nm in diameter,

and often line up along the cell membrane, with short stacks of rough endoplasmic reticulum membranes and a Golgi complex with flattened sacculi and several vesicles. In hypothyroidism, thyrotrophs increase in size and number and transform into so-called thyroidectomy cells or thyroid-deficiency cells. These cells are large and contain widely dilated endoplasmic reticulum membranes, conspicuous Golgi complexes, and a varying number of secretory granules.

Gonadotrophs

Gonadotrophs synthesize both gonadotropic hormones, FSH and LH. These cells are larger than other cells of the anterior lobe, constitute approximately 15 to 20% of the lobe, and are located throughout the anterior pituitary. They are near capillaries and often in close proximity to mammotrophs, suggesting the possibility of paracrine action between the two cell types. FSH and LH are located mostly in the cytoplasm of the same cells, but there are also gonadotrophs that show only FSH or LH positivity. In electron micrographs, the rough endoplasmic reticulum is prominent and forms slightly dilated stacks; the Golgi complexes are conspicuous. The secretory granules represent two populations: the diameter of one granule type is 150 to 250 nm and that of the other type is 350 to 450 nm. Following castration, the size and number of gonadotrophs increase and the cells show enlargement of the cytoplasm, proliferation, and dilation of the endoplasmic reticulum membranes.

Corticotrophs

Corticotrophs (or corticotropin- or ACTH-producing cells) are located mainly in the central part of the pituitary. Some cells are scattered in the lateral wings. They represent 10 to 15% of the anterior lobe cells. Corticotrophs are medium-sized or large oval cells and show ACTH, β -lipotropin, and β -endorphin immunoreactivity (proopiomelanocortin-derived peptides). In electron micrographs, they have well-developed rough endoplasmic reticulum membranes and are usually numerous, spherical, irregular secretory granules measuring 250 to 400 nm, showing varying electron density. The granules tend to be located adjacent to the cell membrane. In addition, the presence of type 1 filaments, which are bundles of filaments located mainly in the perinuclear area, are a characteristic feature of corticotrophs.

Folliculostellate Cells

Folliculostellate cells, called also follicular cells, are mostly agranular cells with branching processes

among the secretory cells. There are data indicating that they are derived from granulated cells after having been joined by junctional complexes around damaged and ruptured adenohypophysial cells and are capable of forming follicles. Folliculostellate cells produce several substances (interleukin G, follistatin, etc.). It is assumed that these cells play an important role in the paracrine mechanisms controlling pituitary functions.

Null Cells

Null cells are relatively small, chromophobic cells that do not contain known anterior pituitary hormones in their cytoplasm. The cells have all the cytoplasmic organelles necessary for secretion. They contain secretory granules that may contain hormone fragments, precursors, or biologically inactive substances. They may represent resting cells, precursors of various cell types, or an unknown cell type.

It should be mentioned that the majority of what were originally called chromophobic cells contain specific granules with hormone content. The cells classified as chromophobes by light microscopy are not a homogenous population. Some are evidently chromophils agranulated to the point at which their specific nature is not detectable. There seems to be a considerable degree of cytological specialization among the cells normally classified as chromophobes. It is probable that many of the apparent chromophobes have already been determined and are capable of differentiating into only one of the chromophil types.

Intermediate Lobe

There is considerable variation among species in the degree of development of the intermediate lobe. It is poorly developed in the human. It contains a few dilated cavities lined by a single layer of cuboidal or columnar epithelial cells and is filled with an amorphous proteinaceous material. Many cells lining the cystic cavities and cells between the cysts give a positive immunostaining for proopiomelanocortin-derived peptides. These cells are smaller than the corticotrophs in the anterior lobe.

Pars Tuberalis

The pars tuberalis is an upward extension of the anterior lobe and is attached to the neural stalk. It contains small groups of cells that produce mainly glycoprotein hormones, gonadotropins and thyrotropin. The functional significance of the pars tuberalis is not known.

Neurohypophysis

The human neurohypophysis consists of approximately 10,000 axons and terminals of neurosecretory cells located in the hypothalamic supraoptic and paraventricular nuclei. The unmyelinated fibers of the neurosecretory cells descend, converge, and form the supraoptico- and paraventriculohypophysial tract or pathway. These fibers descend through the median eminence and neural (or infundibular) stalk into the neural lobe of the hypophysis and make up the bulk of the substance of the lobe.

Median Eminence and Infundibular Stalk

The median eminence is made up of two layers: the external layer and the internal layer. Not the capillary loops but the hypophysiotrophic neurons whose axon terminals are in the external layer are producing the neurohormones. This layer is a key structure of the neurovascular contact between the hypothalamus and the anterior pituitary.

The internal layer of the median eminence and the infundibular stalk contain the descending unmyelinated axons of the supraoptico- and paraventriculohypophysial tract, terminating in the posterior pituitary, transporting the neurosecretory material from the hypothalamic neurons to the posterior lobe at a rate of 1 to 4 mm/h. In histological preparations stained with chrom-alum hematoxylin, deeply stained neurosecretory material is seen in aggregations of varying sizes throughout the infundibular stalk and neural lobe. These aggregates are called Herring bodies. In electron micrographs, they are found to be large aggregations of the small secretory granules. The axons of these neurosecretory neurons vary greatly in caliber and have numerous dilations along their length. Approximately 60% of all neurosecretory material resides in these dilations and approximately 30% resides in axon endings in the posterior pituitary.

Posterior Lobe (or Neural Lobe, or Infundibular Process)

The posterior pituitary is made up of axons and axon endings of the neurosecretory neurons of the hypothalamic supraoptic and paraventricular nuclei synthesizing oxytocin and vasopressin (called also antidiuretic hormone) and also contains an intrinsic population of cells called pituicytes, which resemble astrocytes and do not appear to be secretory. Axons of the neurosecretory neurons terminate blindly in close relation to the basal lamina of a rich capillary plexus.

The neurosecretory material is stored in granules at the dilated blind endings of the axons and are released as needed. The neurosecretory granules have a diameter of 100–200 nm, are surrounded by a membrane, and are more numerous apposed to fenestrated blood capillaries. The neurosecretory material consists of oxytocin or vasopressin and a binding protein (neurophysin) specific for each hormone. The hormone–neurophysin complex is synthesized as a single, long peptide on ribosomes attached to the membranes of the rough endoplasmic reticulum. The endoplasmic reticulum is a cell organelle from where the synthesized material is passed onto the Golgi complex. As the granules pass down axons of the supraoptico- and paraventriculo-hypophysial tract, proteolysis of the precursor occurs, yielding the hormone and its specific neurophysin. Vasopressin and oxytocin are stored in the posterior pituitary and are released into the blood by impulses in the nerve fibers from the hypothalamus.

In addition to the axons from hypothalamic nerve cells, approximately 25–30% of the volume of the posterior pituitary consists of a distinctive type of glial cell, called a pituicyte. Pituicytes are highly branched cells with processes that form a three-dimensional network ensheathing the neurosecretory axons. Their cytoplasmic processes meander among groups of preterminal secretory axons and often intimately envelop their granule-filled terminal expansions. In the human, they are highly variable in size and shape. The cytoplasm of the pituicytes may contain lipid droplets and pigment. The processes of pituicytes are connected by gap junctions. Pituicytes are believed to have a trophic and supportive function and to maintain the appropriate ionic composition of the extracellular fluid compartment.

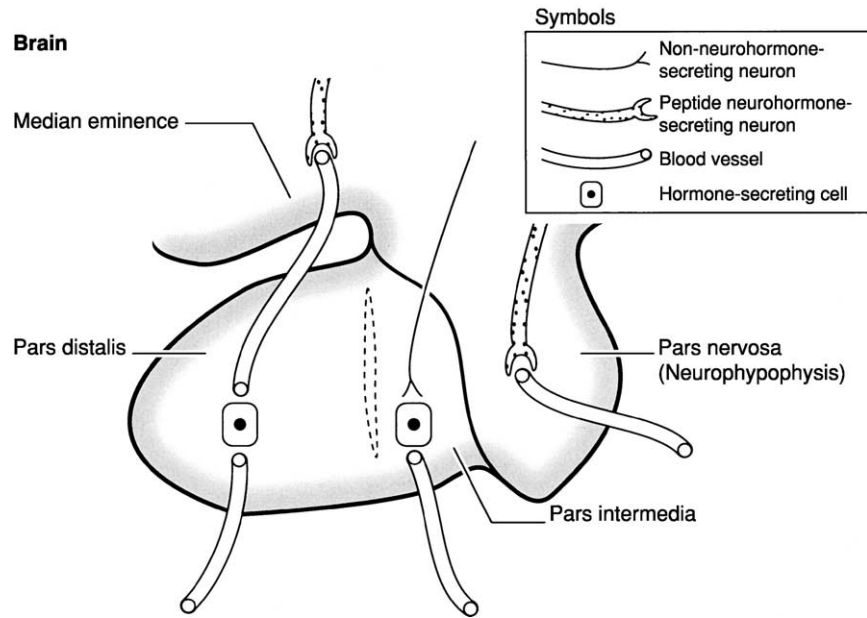

Figure 1 Diagrammatic representation of the relationship of the brain with different parts of the pituitary gland.

PARS DISTALIS

Evolution of the Brain–Pituitary Connection

The method of delivery of the brain neuropeptide hormones that regulate secretion of pars distalis hormones has evolved differently in different vertebrate groups. In the most primitive vertebrates, the Agnatha (hagfish and lampreys), the simplest relationship exists. The Agnatha have a broad, thin neurohypophysis in which the releasing hormone-bearing neurosecretory axons end. Applied to this is an equally broad and thin coextensive adenohypophysis (hagfish) or pars distalis (lampreys). Regulatory neuropeptides merely diffuse between the two.

In the bony fishes, the neurohypophysis is intimately interdigitated with the pars distalis. Secretory cells of the pars distalis are directly innervated or are near the endings of brain neurosecretory axons.

In all other vertebrates, the relationship is as illustrated in Fig. 1. The regulatory neurosecretory axons end on blood vessels in the adjacent brain in a region known as the median eminence. From this location, portal blood vessels extend into the pars distalis.

Dependence on diffusion in the simplest arrangement dictates that the pars distalis must be thin and may be broken up into follicles. Direct innervation and vascular relationships allow the pars distalis to be larger, more globular in shape, and more compact.

Additional Lobes of the Pars Distalis

In several of the fish groups, there are lobes or lobules of glandular tissue in addition to the main structure of the pars distalis. In the selachians (e.g., sharks and rays), there is a so-called “ventral lobe,” which may remain attached to the pars distalis by a stalk and which is known to secrete gonadotropic and thyrotropic hormones.

The puzzle that these additional pars distalis structures present is that they appear to be outside of the brain’s control. What is the significance of a hormonally active pars distalis system that is not under brain control? This question and its evolutionary value need to be studied.

INVERTEBRATE EVOLUTIONARY HOMOLOGUES OF THE PITUITARY OR HYPOTHALAMO–HYPOPHYSEAL SYSTEMS

All vertebrates have a complex pituitary gland system that is regulated by the brain. This must have required an extensive evolutionary history that preceded its appearance in the earliest vertebrates. The logical place to look for an anatomical precursor homologous system is in the protochordates, the organismal group most closely related to the vertebrates.

The Cephalochordate Brain–Hatschek’s Pit System

The cephalochordates (amphioxi) present the best invertebrate homologous structure. It consists of two elements, a shallow pouch-like ingrowth from the mouth, Hatschek’s pit, and a lobe of the brain, the infundibulum. The infundibulum is a down-growth from the brain that extends around the notochord and makes near contact with Hatschek’s pit. The part of Hatschek’s pit that is so contacted contains a peptide that is immunoreactive with an antibody to vertebrate pituitary luteinizing hormone. The additional functional properties of this pituitary-like system require further study.

The Neural Gland–Neural Ganglion System of Urochordates (Ascidians)

In the “anterior” region of ascidians, there is a concentration of nerve cells, the neural ganglion, sometimes referred to as the brain. It is in contact with a rounded, glandular-appearing structure, the neural gland. The neural gland opens to the mouth cavity through a short duct. The brain–pituitary homology of this system is strengthened by the presence of the vertebrate brain hormone gonadotropin-releasing hormone (GnRH) in the system. GnRH is found also in the network of nerves derived during development from the neural ganglion.

The GnRH Cells of Hemichordates

The hemichordates are the least studied and the most primitive members of the chordate group. They are worm-like burrowing animals. Unlike the cephalochordates and urochordates, they have no organ structures reminiscent of the vertebrate pituitary system. However, they do have many integumentary nerve-like cells that contain numerous large granules in which there is GnRH. These mulberry cells are

oriented such that they appear to secrete GnRH externally. It has been suggested that in the hemichordates, the primitive function of GnRH is as a pheromone, a chemical released into the environment that affects other members of the same group. GnRH is believed to integrate in this way the simultaneous sexual ripening and shedding of gametes in whole populations of a species, thus ensuring success in fertilization.

This illustrates the exciting possibility that the three protochordate groups provide a pattern of evolution of the vertebrate hypothalamo–hypophyseal system. That is, GnRH may have been at first a reproductive pheromone produced by the nervous system in response to environmental signals. It could have begun to have an internal function as well as pheromonal activity in the urochordates. Finally, GnRH from the nervous system could have assumed an endocrine role in cephalochordates by taking over control of an epithelial gonadotropin-secreting structure, such as Hatschek’s pit. Hatschek’s pit strongly resembles the vertebrate embryonic adenohypophyseal diverticulum of the mouth, not only in structure and position, but also in its content of gonadotropin. This is an attractive and satisfying evolutionary scenario. It only requires more study and more pertinent facts to either establish or discredit it.

Figure 1 Relationship between heights expressed as percentiles and standard deviations of the mean.

scheduled approximately at the same hour (morning is recommended).

Parental Height

Parental height is also essential to assess a child's stature; real measures are much better than self-reported heights. Target height can then be estimated by simply averaging the parents' height (adding 13 cm to the mother's stature for males or by subtracting these 13 cm from the father's height for females). The resulting "midparental height" represents the target height for the a given child within a ± 10 cm range; there is a 95% probability the child will reach that height.

Figure 2 Correct handling of patient's head to obtain precise and repeatable measurements.

Standard Deviation Score

When reporting a child stature simply as "below the 3rd centile" one does not provide any information on how far his or her stature deviates from normal; furthermore, in clinical studies one could not group patients as simply "below the x th centile" or directly compare different statures of patients of different heights. Therefore the best way of representing stature data is the worldwide adopted standard deviation score (SDS):

$$\text{SDS} = (x - \hat{Y}) / \text{SD}$$

where x is the child's height (in cm), \hat{Y} is the mean stature for age, and SD is the standard deviation of mean stature for age. With this simple method one can very easily appreciate changes in growth (either spontaneous or due to treatment). For example, when a child's stature changes from a score of -3.4 to a score of -2.9 in a 6 month period, this means that the child is gaining centimeters toward the normal range. With this method, patients with different ages and degrees of short stature can be grouped and their SDS treated statistically.

Growth Velocity

The precise measurement of height is the first step of the assessment of growth pattern, which is an important parameter. In fact, the current stature could simply reflect a slowed growth during intrauterine life or early years that has not yet been recovered. A better source of information on growth is provided by assessing growth rate: changes in height plotted versus time. Considering the intrinsic error in measurements and the expected changes in growth for a given age, the minimum interval between two subsequent measures should be 3 months; however, the minimal length of time to extrapolate yearly growth velocity should be at least 6 months (the ideal would be an entire year of observation with four measurements at 3-month intervals). Height velocity, expressed in cm/year, can be estimated by plotting longitudinal measurements of stature on the appropriate growth chart. It varies with age and sex: in the first 6 months of life a boy can grow 15 cm (i.e., 30 cm/year); this gradually slows down to about 9 cm/year at 2 years, and to 5 cm/year of mean velocity at 10 years. Within the next 2–3 years the pubertal spurt re-accelerates to a maximal growth velocity of 12–14 cm/year, this however almost closes the epiphyseal cartilages, leaving only a few centimeters to be gained until growth is completed.

According to the mathematical model of growth elaborated by J. Karlberg, one can distinguish three different phases of growth: infancy, childhood, and puberty. They are integrated to accomplish a non-linear pattern; they also reflect different underlying biological mechanisms: during infancy, as well as during fetal life, nutritional and metabolic factors play the major role, while growth hormone (GH) comes into play mostly during the second phase; both GH and sex hormones interact during pubertal growth. Estrogens are particularly involved: even in males estradiol is the most active steroid acting on hypothalamic centers responsible for growth hormone secretory peaks that are particularly elevated in pubertal subjects.

DIAGNOSTIC APPROACH TO SHORT CHILDREN

Once stature has been accurately determined and found to be pathological, and growth rate has also been recorded as slower than expected for age and sex, the diagnostic approach implies further steps. Physical examination could have already shown possible dysmorphic features such as those of Down's and Turner's syndromes, Noonan syndrome, etc.; hypothyroidism and rickets also exhibit typical body proportions. Maternal medical history is very important as far as ascertaining exposure to alcohol, smoking, or other toxins during pregnancy.

Bone Age

Bone age reflects the biological maturation of the child. Different techniques exist to assess skeletal maturation; the most widely used is an X-ray of the left hand and wrist. The Greulich and Pyle method consists of matching the overall appearance of the bones to the standards shown on the atlas and consequently to assign the closest age. The Tanner–Whitehouse technique (known as TW2) is relatively more complex: it assigns a score to each of 20 bones of the wrist so that all contribute to the final calculation of bone age. Bone age is delayed in most growth disorders and in itself it has no diagnostic value, although it can be used together with chronological age and height to predict final height more accurately than by simple midparental stature. Equations that incorporate height velocity and the occurrence of menarche (for pubertal girls) can also be used for this purpose. Children with delayed bone maturation and short stature have a larger chance of recovering from growth defects (either spontaneously or following

therapy) than those in whom bone age and chronological age are similar.

Growth Charts

The standard reference charts on which a child's height should be plotted vary from country to country; in Britain and other European countries, the Tanner and Whitehouse charts are commonly used, while in the United States the NCHS (National Center for Health Statistics) tables are more common. Although some of these charts are based on data collected 30 years ago, they are still appropriate. When considering children of different ethnic or racial origin, standards charts for these groups should be consulted whenever possible. Distance charts (i.e., stature plotted against age) can be either cross-sectional or longitudinal: the former are built from data collected in large samples of children of an entire age range at the same time, whereas the latter are based on measurements collected from smaller samples of the same children that have been followed for several years until complete bone maturation. If the purpose is simply to screen a population or to search for differences between two different populations the cross-sectional charts are suitable. On the contrary, if one wants to follow the growth pattern of a single patient, the longitudinal type charts are more appropriate.

It must be taken into account that growth velocity might be in the normal range in two of the most common causes of short stature: genetic short stature (also called familial short stature) and in constitutional delay of growth. Therefore, not only could stature per se be insufficient for a diagnosis, but in some cases even growth rate may not be enough for the complex assessment of growth failure.

Clinical Evaluation

Children growing at a rate lower than the 5th centile for their age should undergo a careful overall medical investigation taking into consideration all possible causes starting from malnutrition (in turn secondary to malabsorption, celiac disease, etc.), lung and heart diseases, renal failure, etc. (Table I) reports the most frequently observed causes of growth failure; it should be stressed that the endocrine diseases represent only a small percentage of the affected patients. The endocrine assessment should consider, for instance, hypothyroidism, Cushing's disease, and GH deficiency in all its variants. Hypothyroidism can easily be ruled out by measuring FT4 and TSH plasma levels, while

Table I General Causes of Short Stature

Primary growth defects (intrinsic growth plate defects)

- Chondrodysplasias
- Chromosomal short stature
 - Turner's syndrome
 - Down's syndrome
 - 18 q deletions
- Genetic short stature
 - Familial short stature
- Intrauterine growth retardation
 - Intrinsic fetal abnormalities
 - Maternal abnormalities
 - Placental disorders

Secondary growth defects (low growth velocity)

- Severe malnutrition
- Renal diseases
- Chronic liver diseases
- Hematologic disorders
- Diabetes mellitus
- Chronic pulmonary diseases
- Cardiac diseases
- Gastrointestinal diseases (inflammatory and celiac disease)
- Malignancies and/or chemotherapy and/or radiotherapy
- Corticosteroid treatment
- Immunological diseases (AIDS)
- Vitamin D deficiency or resistance
- Endocrine diseases (GH deficiency and related disorders, Cushing's syndrome, hypothyroidism)

Delayed growth

- Constitutional delay of growth and puberty
- Malnutrition of moderate degree
- Mild underlying medical disease

Final short stature due to early accelerated growth

- Precocious puberty
- Virilizing forms of congenital adrenal hyperplasia

Cushing's disease can be suggested on the basis of the three most common symptoms reported in affected children: typical body features, weight gain, and short stature; the diagnosis can be confirmed by hormonal tests and imaging procedures.

GH DEFICIENCY

Clinical Aspects

GH deficiency (see (Table II) for classification) can be attributed to either congenital or acquired forms. All the forms have in common the most relevant clinical sign: growth defect. In both in the United States and Europe the prevalence appears to be 1:4000 children of school age. A severe form of congenital GH

Table II GH Deficiency and Related Disorders

Hypothalamic-pituitary abnormalities

- Genetic
 - Abnormalities determining multiple hormone deficiencies
 - Molecular defects of GH-RH
 - Molecular defects of the GH-RH receptor
 - Isolated deficiency (type I A, type I B, type II, type III)
 - Bio-inactive growth hormone
- Congenital malformations
- Trauma
- Inflammatory disorders
- Tumors involving hypothalamus or pituitary and radiation
- Psychosocial dwarfism
- GH neurosecretory dysfunction
- Prader-Willi syndrome

Growth hormone insensitivity

- Abnormalities of GH receptor and postreceptor defects
- Primary defects of IGF-1 biosynthesis
- Genetic insensitivity to IGF-1

deficiency can be suspected at birth by the association of small birth size and micropenis; in patients with multiple pituitary deficiencies (in particular the association of GH and ACTH deficiency), postnatal spontaneous hypoglycemia might be a relevant symptom. In congenital forms the growth rate remains low and, within the first year, the patient's length can already be 3-4 standard deviations below the expected mean values.

In the acquired forms (which represent about 25% of all the patients with GH deficiency), both stature and growth rate can be normal until the appearance of the underlying disease, then they fall to lower percentile lines and other clinical features such as obesity, delayed puberty, and visual field defects may appear.

In the complete (congenital) form, the triad of short stature, bone age retardation, and absent growth hormone response to provocative test is of diagnostic relevance. Low levels of insulin-like growth factor-1 (IGF-I), the main peripheral effector of growth promoting action of GH, generally accompany this triad.

Causes of GH Deficiency

Hypothalamic-Pituitary Dysfunctions

Because many hypothalamic dysfunctions disturb pituitary function, it is frequently impossible to distinguish between the two locations of the defect. Several genetic causes such as errors of Pit1 gene and Prop-1 mutations (the transcription factors responsible for the control of the genes of GH and other pituitary hormones) have been reported (see Table II). GHRH

receptor gene defects located on chromosome 7 may induce GH unresponsiveness, and, finally, mutations of the GH-1 gene (the one encoding for growth hormone) have been described.

Congenital Malformations of the Hypothalamic-Pituitary Region

The septo-optical displasia is one example in which anatomical abnormalities of this region are accompanied by GH, ACTH, and other pituitary deficiencies. This is due to mutations in the HESX1 gene.

Trauma of the Brain and/or the Hypothalamus

Trauma of the brain and/or the hypothalamus may cause multiple pituitary insufficiencies; difficult delivery or hypoxemia in the perinatal period are also part of this condition.

Inflammation

Fungal, viral, and bacterial infections as well as granulomatous diseases involving this area may lead to pituitary insufficiency.

Tumors

In addition to tumors of this brain area (meningiomas, gliomas, ependymomas, etc.), craniopharyngiomas are rather frequent in children. Radiation therapy, used on some of these tumors or in hematologic disorders, may determine GH deficiency.

Psychosocial Dwarfism

Psychosocial dwarfism is the consequence of a severe form of emotional deprivation frequently ascribed to a familiar or to social inadequate conditions in which GH secretion is low and behavioral abnormalities of eating habits are also common. The reversibility to a condition of normal GH secretion in these children may confirm the diagnosis.

GH Neurosecretory Dysfunction

In affected patients, GH responses to provocative tests are normal but IGF-I is low; the diagnostic clue is the greatly decreased spontaneous peaks of GH secretion observed during a 24 hour continuous sampling.

GH RESISTANCE SYNDROMES

In GH resistance syndromes, the common feature is represented by lack of GH action in spite of elevated plasma levels of the hormone; IGF-I is generally low in these forms and the growth defect is particularly severe. Zvi Laron first described such a syndrome in 1965, years before the somatomedin hypothesis was

presented. It is now accepted that mutations in the extracellular domain of the GH receptor are present in patients with these clinical features. About 200 patients in the Mediterranean area and 20 in Ecuador have been reported thus far.

In GH resistance (or insensitivity), IGF-I is also unresponsive to induction test with hGH; there are studies under way showing positive growth acceleration in these patients during treatment with human recombinant IGF-I.

A SHORT REVIEW OF GH AND IGF-I PHYSIOLOGY

GH, a polypeptide hormone of 191 amino acids with molecular weight of about 22,000, is produced by specific cells of the anterior pituitary and is released in bursts lasting only minutes, followed by long periods during which plasma levels are almost undetectable. The most frequently observed peaks are those following meals and those in the first part of slow-wave sleep. The physiological basis for this pulsatile secretory pattern is found in the hypothalamic nuclei (in particular the ventromedial nucleus) where the two main hypothalamic factors controlling GH are produced: growth hormone-releasing hormone (GHRH, positive regulator) is mainly responsible for the secretory peaks, but its activity is evident only when the other factor, somatotrophic-releasing inhibiting factor (SRIF, negative regulator), is inhibited. These two hormones, together with other hypothalamic factors such as GH-releasing peptides and neurosecreted amines interplay with each other: GH released, in every minute, is then the algebraical result of these opposite forces (Fig. 3). Feedback mechanisms also play a role both at hypothalamic and at pituitary level controlling plasma GH levels and IGF-I values. Moreover, ultrashort feedback mechanisms are also exerted by the levels of the two neuroregulatory hormones GHRH and SRIF, which influence each other, acting back on hypothalamic neurosecretory amines.

GH in itself has little effect on bone and cartilage development, but its growth-promoting activity is mediated by substances that are induced by the hormone: GH-free serum has mitogenic properties in cell cultures and insulin-like activity in adipose tissue and promotes the incorporation of amino acids and sulfate into the cartilage. In 1972, W. H. Daughaday proposed the somatomedins hypothesis to explain these effects. It is now recognized that the most important of these substances is IGF-I, produced in the liver and kidney as well as in the growing cartilages. What is

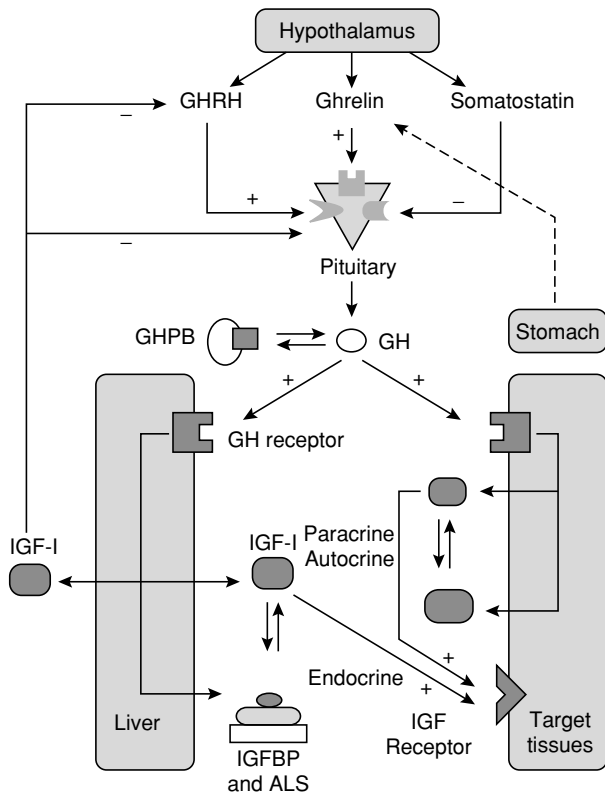

Figure 3 Regulation of growth hormone secretion and interplay among the main influences.

actually measured in the plasma is mostly the IGF-I coming from the liver and kidney, although IGF-I mediating the growth effect of GH is mainly the amount locally generated in chondrocytes under stimulation by GH. However, plasma IGF-I levels provide a reliable indicator of the effective amount of GH produced, since it is found to be very low in almost all the conditions of endocrine-mediated growth defect. When measured in a given patient after a short cycle (2 days) of exogenous hGH administration (induction test) it also provides relevant information about sensitivity to GH.

In conclusion, IGF-I reflects the integrated concentrations of the previously secreted GH (i.e., in the preceding 24–36 hours); at variance with the pulsatility of GH, their levels are quite stable during the day. Although IGF-I levels may be low even in conditions different from GH deficiency (hypothyroidism, renal diseases, etc.), they reflect GH spontaneous secretion better than the provocative tests. At present, however, these tests remain the gold standard for the diagnosis of GH deficiency.

ASSESSMENT OF GH SECRETION

From the previously discussed considerations, and due to the pulsatile nature of GH secretion, it emerges that baseline plasma GH levels are very frequently found undetectable if single random samples are taken, even in normal subjects. Therefore, to confirm a diagnosis of GH deficiency, subsequent samples must be obtained in standard conditions and appropriate stimulation tests should be performed. Some of the following standardized tests are considered useful for initial screening purpose: (1) a post-prandial (3–4 hours after a protein-rich meal) or (2) a post-exercise sample (30 min after a strenuous exercise) that shows GH levels above the cutoff value of 10 ng/ml could rule out GH deficiency and avoid further testing. These procedures, however, are not very common, and consequently the most widely used tests have been: (1) arginine infusion (0.5 g/kg by slow i.v. infusion within 30 min) and (2) insulin-induced hypoglycemia (0.1 U/kg as i.v. bolus). These tests are not devoid of side effects and should be performed by trained personnel in appropriately equipped centers.

The main defect of these two tests is their high false positive rate: from 10 to 20% of normal children fail to respond to the test substances and would then be wrongly diagnosed as GH deficient. Moreover, approximately 30% of normal children will show discordant response to the two tests. The basis for interpreting this discrepancy is to be found in the interplay between the two neurohormones GHRH and SRIF: a GH response to the stimulations mentioned above would be possible only when the stimulus arrives during a decreasing phase of SRIF (and the reciprocal GHRH increase).

One of the main problems common to the various provocative tests resides in the interpretation of the results: different countries have adopted different cutoff levels to separate normal from pathological responses. Cutoff values ranging from 5 to 10 ng/ml of GH at the peak are widely accepted. It must also be considered that the commercial kits used for the assay of GH in plasma with monoclonal antibodies have reached a level of sensitivity much higher than that obtained at the time when the set points of these test were established. Some authors have proposed a provocative test based on the administration of arginine (0.5 g/kg i.v.; supposed to act by shutting off the endogenous SRIF tone) together with an intravenous injection of synthetic GHRH (1 μ g/kg). This double test is a very potent GH secretory stimulus, and the cutoff limit for normal subjects has been set to 20 ng/ml. The main advantage of this test is its greater

capability of discriminating normal from pathological responses (GH deficiency) due to the minimal number of false positives.

In conclusion, it is recommended that each Pediatric Endocrinology Center should adopt two or three provocative tests, and use always the same tests, after having established its own limits of normal responses. Baseline IGF-I levels are also of great help: GH-deficient patients generally have very low levels (i.e., below -2 SDS of IGF-I). However, the provocative tests for GH secretion retain some limits: they are not physiological, they are poorly reproducible, and the normal range of responses is arbitrary.

These reasons emphasize the recommendation that the poorly growing child should undergo a complete examination, including psychological, medical, and hormonal aspects. GH deficiency remains a clinical diagnosis, corroborated by auxological data concerning the growth pattern, by medical history, and by biochemical tests; it is not the simple observation of hormonal levels below a set value.

IMAGING

Once this clinical diagnosis is obtained a magnetic resonance image of the pituitary and hypothalamic area is mandatory. It can show morphological abnormalities: pituitary stalk agenesis or interruption, pituitary hypoplasia, or other lesions. In acquired forms it will show the cystic or solid lesion damaging pituitary/hypothalamic function.

TREATMENT

The starting dose of hGH to be used in children with GH deficiency is in the range of 0.6 to 0.7 mg/kg body weight per day. It must be administered in the evening at bedtime, in order to mimic the nocturnal spontaneous GH secretory peaks. Daily subcutaneous injections are recommended, although different devices for administration (such as needle-free percutaneous jet injector systems and long acting intramuscular preparations requiring only fortnightly injections) have been used. Pen devices (either with almost painless needles or the new needle-free devices) have almost completely replaced the old use of syringes; they are accurate and easily by the children themselves. The treatment efficacy is generally monitored by regular assessment of growth rate.

The growth-promoting effects observed with the treatment are a function of the administered doses: increased doses lead to accelerated growth rates. Moreover, the younger the patient age at the beginning of treatment, the better the final results that will be obtained. The administered doses must be regularly re-set according to the effects on weight/height obtained.

Until about 1990, GH therapy was discontinued after growth rate was observed to be greatly decreased and cartilages closed, but now that metabolic effects of GH are better understood the treatment regimen has gradually changed to "adult" doses (such as 0.04–0.06 mcg/kg/week; given daily or on alternate days). Reports confirming preliminary positive effects on bone mineral density, muscle strength, exercise performance, cardiovascular function, and body composition are encouraging this view.

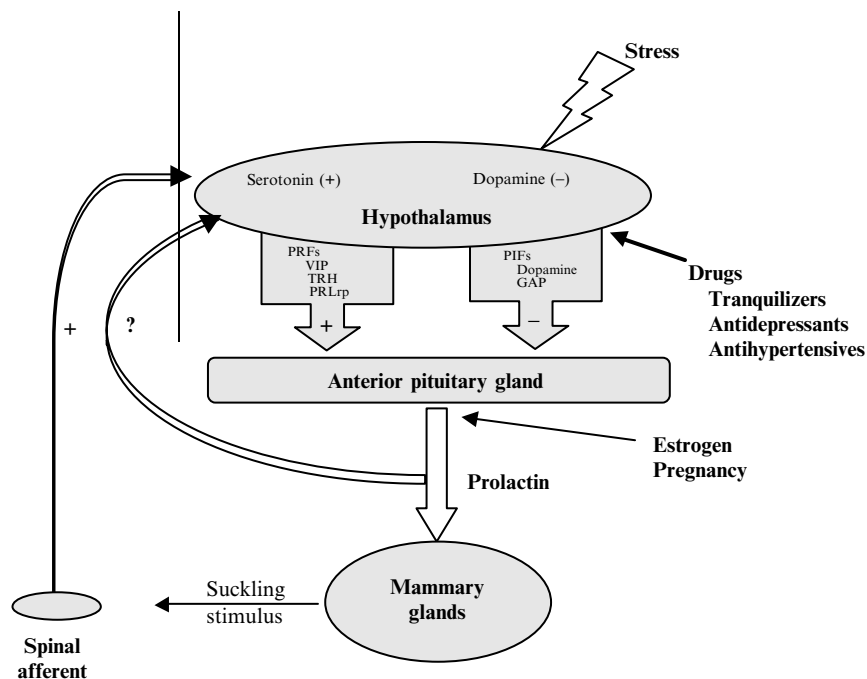

Figure 1 Relationship between hypothalamic–pituitary–mammary gland axis and control of prolactin secretion. The primary target organ of prolactin is the breast. Suckling activates neural pathways to the hypothalamus. An appropriate increase in prolactin-releasing factors (PRFs) or a decrease in prolactin inhibitory factors (PIFs) affects prolactin release. Within the hypothalamus, serotonergic pathways are stimulatory and dopaminergic pathways are inhibitory to prolactin release. Prolactin release is stimulated by a number of PRFs including vasoactive intestinal peptide (VIP), thyrotropin-releasing hormone (TRH), and prolactin-releasing peptide (PRLrp). Prolactin is inhibited by PIFs, predominantly dopamine. GAP, gonadotropin-associated peptide.

addition, suckling activates neural afferent pathways that go through the spinal cord to the hypothalamus, where increases in PRFs or decreases in PIFs influence prolactin release during this time period.

Prolactin is released in a sleep-related circadian rhythm characterized by pulses superimposed on a continuous basal secretion in both men and women. Approximately 350 μg of prolactin is secreted daily. The highest plasma concentrations occur during nocturnal sleep, peaking between 3 AM and 5 AM and falling rapidly during the first hour of waking, with the lowest concentrations occurring by late morning. There is a midday surge of prolactin and cortisol secretion in response to a high-protein and/or high-fat meal. (Carbohydrates do not affect prolactin levels.)

Estradiol augments the nocturnal prolactin rise, making serum prolactin concentrations highest during the reproductive years in women. With the onset of puberty in girls, serum prolactin levels rise significantly, reaching a peak at midcycle and remaining elevated during the luteal phase. The prolactin pulses are amplified during the high-estrogen phases of the menstrual cycle, resulting in increased serum prolactin levels.

ETIOLOGY OF HYPERPROLACTINEMIA

Various physical and/or emotional stress-inducing stimuli, such as pregnancy, suckling, prolonged breast manipulation, coitus, physical exercise, and surgery, may induce hyperprolactinemia. Stress can inhibit the release of hypothalamic prolactin inhibitory factors, which increases the secretion of prolactin and galactorrhea. Tactile stimulation of the breast and nipple increases prolactin levels; said stimulation is responsible for the rise in serum prolactin seen 20–30 min after breastfeeding is initiated.

PREGNANCY AND PROLACTIN

Maternal serum prolactin levels rise in a linear fashion beginning in the first trimester, reaching concentrations 10 times higher than those in a nonpregnant woman at term, as high concentrations of estrogen induce hyperplasia and hypertrophy of the pituitary lactotrophs, resulting in enlargement of the pituitary to twice its normal size. Similarly, in the fetus, prolactin synthesis, storage, and secretion can be

demonstrated after the 12th week of gestation. Pituitary lactotrophs can be first detected at 18 weeks gestation with a sharp increase in fetal serum levels from 22 weeks gestation to term. By the end of the neonate's first day, prolactin levels progressively decline to normal. Not only is prolactin important in intrauterine fetal tissue differentiation and organ development, but experimental evidence has also demonstrated that fetal prolactin may participate in kidney osmoregulation, lung maturation, and the regulation of salt and water balance.

During parturition, prolactin secretion follows a multiphasic pattern, not demonstrable in patients undergoing elective cesarean delivery. The level of prolactin rises throughout pregnancy and precipitously falls during active labor, reaching a nadir approximately 2 h prior to delivery. A surge of prolactin release then occurs immediately before and after delivery, achieving a peak within 2 h postpartum. Prolactin also exerts mammogenic and lactogenic effects on the mammary gland.

SIGNS AND SYMPTOMS OF HYPERPROLACTINEMIA

Irregular menses and galactorrhea are the most frequently observed abnormalities associated with hyperprolactinemia. Women may also present with decreased libido and infertility, whereas men may display decreased libido, infertility, gynecomastia, or impotence.

Galactorrhea, defined as a watery, milky breast discharge containing neither pus nor blood, can be confirmed by the presence of milk, which is ascertained by examining a sample of breast secretion for the microscopic presence of fat droplets on a glass slide. Oligomenorrhea and amenorrhea frequently occur with hyperprolactinemia as well. Dopamine and norepinephrine are neurotransmitters that influence the synthesis and secretion of gonadotropin-releasing hormone (GnRH), luteinizing hormone (LH), and follicle-stimulating hormone (FSH). Any abnormalities in their synthesis or secretion will result in menstrual irregularities. Primary or secondary amenorrhea results from hyperprolactinemia directly inhibiting GnRH secretion, consequently inhibiting the release of LH and FSH. This negative feedback can be overcome by exogenous administration of GnRH, which produces abnormally high levels of LH and FSH. Hyperprolactinemia may also alter the frequency or amplitude of GnRH pulses through changes in dopamine release, which also produce further menstrual abnormalities. Only one-third

of women with amenorrhea demonstrate clinical galactorrhea despite hyperprolactinemia.

FACTORS AFFECTING PROLACTIN SECRETION

Drugs

The most common causes of hyperprolactinemia are medications that alter the inhibitory actions of dopamine. These agents include neuroleptics, which block dopamine receptors, the tricyclic antidepressants and monoamine oxidase inhibitors, which facilitate several possible stimulatory pathways, serotonin reuptake inhibitors, opiates, and cocaine, and the antihypertensive medications including α -methyldopa, reserpine, and verapamil. Protease inhibitors have been shown to cause hyperprolactinemia, although the mechanism is unknown.

Hypothyroidism

Primary hypothyroidism, which exists in approximately 3 to 5% of women with galactorrhea and hyperprolactinemia, is characterized by low serum levels of thyroxine (T4) and decreased negative feedback on the hypothalamic-pituitary axis. Decreased levels of triiodothyronine (T3) and T4 increase the sensitivity of pituitary cells, which easily respond to normal or slightly elevated levels of TRH. Therefore, when thyrotrophs and lactotrophs are stimulated by TRH, there is an exaggerated response, resulting in increased levels of both thyroid-stimulating hormone (TSH) and prolactin (PRL) secretion. Along with the diminished negative feedback seen in primary hypothyroidism, patients may also experience an alteration in the positive feedback loop between T4 and dopamine, in which decreased dopamine secretion will also lead to elevated levels of serum TSH and PRL.

Women with galactorrhea should undergo measurement of both serum PRL and TSH as the initial diagnostic tests to distinguish primary hypothyroidism from a TSH-secreting pituitary adenoma. Primary hypothyroidism, such as Hashimoto's thyroiditis, will exhibit elevated serum TSH, whereas a TSH-secreting pituitary adenoma will also exhibit elevated serum T3 levels and symptoms of hyperthyroidism, along with elevated serum TSH levels.

Renal Disease

Individuals with acute or chronic renal failure will develop hyperprolactinemia as a result of delayed

clearance of PRL. They also have a reduced PRL response to TRH stimulation resulting from pituitary dysfunction. When such individuals take medications known to alter the hypothalamic regulation of prolactin, such as methyl dopa or metoclopramide, prolactin levels may rise to over 2000 ng/ml. Treatment other than that indicated for renal failure is rarely necessary.

DISORDERS OF PROLACTIN SECRETION

Craniopharyngiomas

Two hundred fifty new cases of craniopharyngiomas are diagnosed annually in the United States. These tumors, which are the nonpituitary tumors most commonly associated with hyperprolactinemia, arise from epithelial remnants of Rathke's pouch that can be found distributed along the pituitary stalk from the pars distalis to the floor of the third ventricle. Fifty-five percent of these tumors are cystic, whereas 15% are solid; however, 30% of patients express both solid and cystic components. Craniopharyngiomas are typically diagnosed during the second and third decades of life, but calcifications within these tumors can be noted during childhood by plain skull X-rays and computerized tomography (CT) scans.

A craniopharyngioma damages the hypothalamus or extends into the sella turcica, interfering with the transport of hypothalamic hormones and neurotransmitters, resulting in pituitary dysfunction. The levels of growth hormone (GH), TSH, adrenocorticotrophic hormone (ACTH), and antidiuretic hormone are all diminished. In addition, a deficiency in gonadotropins (FSH, LH) produces amenorrhea. The degree of impairment depends on the extent of involvement with either the hypothalamus or the pituitary stalk. Expansion of the craniopharyngioma into the optic chiasm produces local compression, demanding surgical resection or decompression. Survival rates of 80% have been reported for surgical resection followed by radiotherapy and many patients will require subsequent hormone replacement therapy.

Prolactin-Secreting Adenoma

Prolactin-secreting adenomas are the most common pituitary tumor. Microadenomas, which are adenomas of less than 1 cm diameter confined to the sella turcica, constitute the majority of prolactin-secreting adenomas. In contrast, prolactin-secreting macroadenomas, which are adenomas of more than 1 cm diameter extending beyond the sella turcica, are very rare.

Galactorrhea and hyperprolactinemia are common findings in women with pituitary prolactinomas. Ten percent of women with galactorrhea and radiologic evidence of a pituitary tumor have normal serum PRL levels and approximately 50% of women with hyperprolactinemia will demonstrate radiographic changes of the sella turcica compatible with an adenoma. Most women have normal basal levels of FSH and LH and produce a normal or elevated response following administration of GnRH.

Numerous retrospective and prospective studies have demonstrated that hyperprolactinemia with or without a microadenoma nearly always follows a benign clinical course without treatment, with spontaneous remissions occurring in a substantial portion of women. However, data from several series of patients with microadenomas observed over long periods of time without treatment demonstrated that the risk of progression from a microadenoma to a macroadenoma was 7%. In another series of patients carefully observed for up to 15 years, Jeffcoate and co-workers found that approximately one-third of patients who were either untreated or treated with dopamine agonists intermittently had a return to normal levels of prolactin off all therapy. Patients who experienced a pregnancy during this interval had a higher rate of remission than patients who did not (35% versus 14%, respectively).

Multiple Endocrine Neoplasia Type I

Prolactinomas occur in approximately 20% of patients with multiple endocrine neoplasia type 1 (MEN1). The MEN1 gene, localized to chromosome 11q13, is a constitutive tumor suppressor gene in that an inactivating mutation results in tumor development. Prolactinomas occurring in patients with MEN1 may be more aggressive than sporadic prolactinomas.

Prolactinomas and Pregnancy

Numerous studies suggest that pregnancy exerts beneficial effects on women with functional hyperprolactinemia or prolactin-secreting microadenomas and increases the chance that hyperprolactinemia will spontaneously regress. Following parturition, mean prolactin levels decrease in approximately half of all women with hyperprolactinemia, eventually normalizing in approximately one-third of these patients. There is also an increased frequency of empty sella syndrome in multiparous women compared with nulliparous women due to autoinfarction of lactotrophic adenomas in pregnancy. Breastfeeding does

not stimulate tumor growth; hence, postpartum women with prolactinomas can safely breastfeed their infants. Hyperestrogenism associated with oral contraceptives or estrogen replacement therapy does not cause significant growth of macroadenomas.

Lactotroph Hyperplasia

Women with elevated prolactin levels without clinical evidence of a prolactin adenoma are given the clinical diagnosis of functional hyperprolactinemia, which may arise from decreased dopamine inhibition resulting in hyperplasia of lactotrophs. This diagnosis can be made only at the time of surgical exploration of the pituitary gland. Lactotroph hyperplasia has also been reported to be due to pituitary enlargement with suprasellar extension.

Empty Sella Syndrome

Empty sella syndrome is characterized by herniation of the subarachnoid membrane into the sella turcica through a defect in the pituitary sella diaphragm, which allows the cerebrospinal fluid (CSF) that fills the subarachnoid space to protrude into the sella turcica whenever intracranial pressure increases. This in turn compresses the pituitary gland and remodels the contour of the sella.

Primary empty sella syndrome results from a congenital defect in the pituitary sella diaphragm. This defect may coexist with pituitary adenomas that secrete PRL, GH, or ACTH or reflect alterations in the circulatory dynamics of the CSF. Secondary empty sella syndrome may occur after either radiation therapy or surgical intervention in the sellar region.

Diagnosis

On radiographic examination, the empty sella appears symmetrically enlarged, with or without the erosion of bone. Definitive diagnosis can be made by magnetic resonance imaging (MRI) or CT scan utilizing metrizamide, a contrast medium injected into the CSF through a lumbar puncture, which fills the intrasellar defect, thus confirming the diagnosis.

Endocrine Dysfunction

Although endocrine abnormalities are uncommon, pituitary dysfunction, panhypopituitarism, and pituitary adenoma may coexist with empty sella syndrome in some patients. Galactorrhea with normal or moderately elevated levels of serum PRL may also be present. The elevation in PRL may reflect arachnoid herniation

that compresses the pituitary stalk, interfering with the transport of dopamine.

Acromegaly

Galactorrhea and elevated serum PRL may exist in women with acromegaly. *In vitro* studies with GH-secreting pituitary adenomas demonstrate that these tumors may secrete both PRL and GH. The galactorrhea that occurs in women with acromegaly is thought to derive from increased secretion of PRL rather than the lactogenic properties of growth hormone.

Sheehan Syndrome/Autoimmune Lymphocytic Hypophysitis

Sheehan syndrome results from infarction of the anterior lobe of the pituitary gland as a direct result of a major hemorrhage in pregnancy that reduces the blood supply to the gland. Women with this syndrome are unable to lactate postpartum and do not show serum responses of GH, cortisol, or PRL to insulin-induced hypoglycemia. There is also blunted LH, FSH, PRL, and TSH response to TRH and GnRH in patients with complete infarction of the anterior pituitary. Autoimmune lymphocytic hypophysitis involves selective loss of PRL-producing cells and occasionally other anterior pituitary hormones.

DIAGNOSTIC EVALUATION

In evaluating a woman who presents with galactorrhea or amenorrhea, a detailed history and physical examination must be obtained to exclude the use of drugs that have prolactin-stimulatory properties; in addition, a panel of screening tests including blood chemistries, thyroid function tests, prolactin levels, and a pregnancy test must be performed to exclude all physiologic causes of hyperprolactinemia other than hypothalamic-pituitary disease.

A radiologic evaluation of the hypothalamic-pituitary region should then ensue to exclude a mass lesion such as a macro- or microadenoma. CT scans provide information on the bony structure of the sella turcica but provide less information on soft tissue lesions, such as extrasellar extension and empty sella turcica. MRI, on the other hand, is more sensitive and expensive than CT, providing better contrast resolution. MRI is a more effective method for detecting an empty sella, optic chiasm, optic nerves, cavernous sinuses, and carotid arteries.

TREATMENT

Treatment options include observation with careful follow-up, medical therapy, surgery, and irradiation.

Observation

Periodic observation can be utilized for patients with galactorrhea, regular ovulatory cycles, and normal or slightly elevated serum prolactin levels (less than 40 mg/ml). Treatment with a dopamine agonist or estrogen is unnecessary in these patients. If anovulation with unopposed estrogen secretion occurs, cyclic progestins or oral contraceptives should be administered to induce regular uterine bleeding.

Patients with documented radiologic evidence of microadenomas should be monitored closely for interval growth. In 93% of patients with microadenomas, there is no demonstrable enlargement over 4- to 6-year observation periods. Hence, serial prolactin levels with follow-up scans are sufficient. If prolactin levels rise significantly, repeat scanning is indicated. A microadenoma documented to have undergone interval growth requires therapy as the tumor may be one of the 7% that will grow to become a macroadenoma.

Medical Therapy

Dopamine Agonists

Bromocriptine, a dopamine agonist, binds to dopamine receptors and inhibits pituitary prolactin secretion. Administration of bromocriptine also induces a cyclic and physiologic estrogen secretion and is useful in treating symptomatic galactorrhea and inducing ovulation. Doses of 2.5 to 5 mg/day are sufficient to suppress prolactin levels and restore ovulatory function; however, higher doses, up to 10 mg/day, may be necessary. Discontinuation of therapy results in a return of hyperprolactinemia, galactorrhea, and amenorrhea in 70% of women. After 1 year of bromocriptine treatment, 10% of women experience complete regression of their microadenomas. In these patients, therapy should be discontinued for 6 weeks every year to determine whether prolactin levels have normalized and regular menses have resumed.

Side Effects of Dopamine Agonist Therapy

Nausea, vomiting, fatigue, headaches, dizziness, and syncope have been observed as side effects in 50–70% of women following oral administration of bromocriptine. Most of these side effects are mild and transient if administered at bedtime and/or with food. Orthostatic hypotension may also occur and can be

avoided if the initial dosage is taken at bedtime. Approximately 10% of patients experience severe side effects requiring discontinuation of bromocriptine. Avoidance of these side effects can be attained by intravaginal administration of bromocriptine, which allows usage of a lower dosage, once-daily treatment, and slower absorption, all of which minimize the side effects. Bromocriptine does not interfere with sperm function, as women using vaginal bromocriptine have become pregnant and delivered normal infants. Bromocriptine is also available as a long-acting injectable form (depot bromocriptine), which is as effective as the oral form and has similar side effects.

Ovulation Induction

Ovulation following administration of bromocriptine can occur in almost all women with hyperprolactinemia. Approximately 50% will ovulate after receiving 5 mg/day of bromocriptine, whereas 50% will require higher doses. In women with pituitary adenomas, the mean length of treatment necessary to induce ovulation is 16 weeks, whereas patients without adenomas usually respond within 10 weeks.

Treatment during Pregnancy

Once pregnancy is confirmed, bromocriptine therapy should be discontinued unless a macroadenoma is present, for which treatment may be maintained throughout pregnancy or reinstated for tumor enlargement. Microadenomas have not been demonstrated to grow substantially during pregnancy. However, frequent visual field examinations are encouraged at 20, 28, and 38 weeks gestation, with follow-up MRI or CT scan for suspected headaches or abnormal examinations. If there is evidence of suprasellar extension, bromocriptine treatment should be instituted or increased and maintained for the remainder of pregnancy. Bromocriptine has not been shown to carry an increased risk of fetal malformations and its use can be discontinued postpartum to allow breastfeeding.

Treatment of Macroadenomas

During pregnancy, women with macroadenomas that fail to demonstrate regression to bromocriptine therapy may be candidates for adenomectomy, as no increased surgical morbidity has been reported. Bromocriptine has been shown to produce regression of macroadenomas within 3 to 6 months of initiating therapy. Repeat MRI or CT scans should be repeated 6 months after initiation of therapy and bromocriptine should be continued as long as the adenoma continues to regress. Prolactin values cannot be used

to gauge the response to treatment as levels may not correspond with tumor regression. In addition, surgery should be considered in patients who do not demonstrate a response to bromocriptine therapy. Cabergoline, a drug that binds with high affinity to pituitary dopamine receptors, and Pergolide, a drug approved by the U.S. Food and Drug Administration for the treatment of Parkinson's disease, are additional medications comparable to bromocriptine in efficacy and tolerance and both demonstrated reductions in prolactin levels and tumor size. Pergolide is longer-acting and more potent than bromocriptine and is better tolerated in some patients, whereas Cabergoline can be given once weekly and may have fewer side effects than bromocriptine.

Surgical Therapy

Transsphenoidal surgery (via sublabial incision) is the surgical procedure used for microadenomas and most macroadenomas that allows microsurgical exploration of the sella turcica, permitting removal of the pituitary tumor, while preserving the functional capacity of the remaining gland. Surgical success rates are highly dependent on the experience and expertise of the surgeon, as well as the size of the tumor. Cure rates of 50 to 80% have been reported in patients with microadenomas, using resumption of menses, euprolactinemia, and cessation of galactorrhea as endpoints. In patients with macroadenomas, long-term cure rates between 10 and 30% have been reported, suggesting that surgery should be performed before the adenomas reach diameters greater than 1 cm. Reported complications include transient or chronic diabetes insipidus, hemorrhage, meningitis, cerebrospinal fluid leak, and panhypopituitarism. The reported mortality and morbidity rates from transsphenoidal surgery for microadenomas are 0.3 and 0.4%, respectively.

Given the favorable results of bromocriptine therapy, surgical excision of macroadenomas should be performed only if complete or partial failure of medical therapy or poor patient compliance occurs. In addition, maximum reduction of tumor size should be obtained with bromocriptine therapy before

attempted surgical excision. Postsurgical bromocriptine therapy should be continued to prevent rapid regrowth of the adenoma.

Radiation Therapy

Due to the excellent therapeutic responses to medical therapy and transsphenoidal surgery, radiotherapy is not considered the primary mode of treatment for pituitary adenomas. A dose of 4500 rad of cobalt may be used to arrest progression of tumor growth. Regular menses usually do not return after treatment and galactorrhea may not be corrected for up to 1 year. Secondary hypothalamic or pituitary damage is also prone to occur with radiation therapy as adenoma tissue is often more resistant to treatment than surrounding structures. Proton-beam and heavy-particle irradiation methods may be used as alternatives to cobalt irradiation and have been shown to be associated with increased visual-field defects or oculomotor palsies. Consequently, this form of therapy should be reserved for patients who are unresponsive to medical and surgical management.

somatotroph or corticotroph adenomas. Only 6% are completely negative for all pituitary hormones.

CRANIOPHARYNGIOMAS

Craniopharyngioma is a frequent if not the most frequent sellar and suprasellar tumor of childhood and adolescence (up to 9 or 10%). Most patients with such a tumor are children and young adults, but craniopharyngiomas have also been described in newborns and elderly patients. The tumor is usually suprasellar but may extend to the sella. It probably derives from remnants of the Rathke's pouch. The tumor may sometimes achieve huge proportions (up to 12 cm; giant cystic craniopharyngioma) and grow well beyond the suprasellar region. Rarely, tumors may be confined in the chiasm or optic nerve. Craniopharyngiomas are the most heterogeneous tumors of the sellar region. They are mostly cystic or cystic solid, filled with a lipid and cholesterol-rich viscous fluid. Magnetic resonance imaging (MRI) is superior to computed tomography (CT) in determining the full extent of the tumor. The pituitary is generally pushed toward the bottom of the sella. Calcifications are frequent (75% of the cases in childhood and 35% in adulthood). Areas of the tumor may degenerate, leading to an intense inflammatory and foreign body giant cell reaction.

Despite being histologically benign, craniopharyngiomas are rather biologically aggressive tumors, often invading or infiltrating the surrounding neurological structures, such as the hypothalamus and the optic nerve. Malignant transformation has been described.

The clinical presentation of craniopharyngiomas is directly related to their location and growth behavior. If they compress the optic pathways and infiltrate the hypothalamus and the third ventricle, they can cause visual disturbances, dysfunction of the hypothalamo-pituitary axis, and hydrocephalus.

The most frequent endocrine signs are partial anterior pituitary deficiency (mostly short stature due to growth hormone deficiency), hyperprolactinemia due to compression of the pituitary stalk and/or infiltration of the hypothalamus interfering with the dopamine secretion that normally suppresses pituitary prolactin secretion, and diabetes insipidus. Most unexpected, the syndrome of inappropriate secretion of antidiuretic hormone has also been reported in rare cases.

The optimal treatment for craniopharyngiomas is controversial. For some authors, radical surgical excision, if feasible, constitutes the only chance at a cure, whereas for others the complications of radical

surgery outweigh the benefits and they propose only partial resection followed by radiotherapy. The growing consensus seems to be that the goal should not be to aim for radical resection at all costs in every patient but to reserve this procedure only for tumors for which it can be achieved without damaging vital structures. It has been shown that subtotal excision followed by adjuvant radiotherapy produces excellent results, with 10-year recurrence-free survival rates of 80–90%.

Alternative therapies to surgery have also been developed. One is the stereotactically guided instillation of β -emitting isotopes directly into the craniopharyngioma cysts. Another option is stereotactic radiosurgery with a gamma-knife.

MENINGIOMAS

Meningiomas are tumors of arachnoid and meningotheelial cells. They represent approximately 25% of intracranial tumors in women and 13% in men. The reason for this gender difference may be related to the expression of sex steroid receptors by these tumors. Indeed, they contain estrogen receptors and may increase in size during pregnancy or even during the menstrual cycle. Twenty percent of meningiomas arise in the sellar and parasellar regions. Sella involvement by a meningioma is usually due to the extension of a suprasellar meningioma that invades the pituitary. Intrasellar meningiomas mimic nonfunctioning pituitary adenomas. It is therefore sometimes very difficult to distinguish a suprasellar meningioma with intrasellar extension from a silent pituitary adenoma with suprasellar extension. They can both present with visual disturbances, partial or complete hypopituitarism, hyperprolactinemia, or a combination of these signs. Deterioration of cognitive function, confusion, and memory loss may also occur in 20% of patients. Interestingly, a few patients have had concomitantly pituitary adenoma and sellar meningioma and one patient developed an intrasellar meningioma 8 years after radiotherapy treatment for a pituitary prolactinoma. MRI is superior to CT in delineating the lesion, but unless a dural origin of the tumor can be clearly demonstrated, radiographic distinction from pituitary adenoma is difficult.

The treatment of choice is surgical resection. However, meningiomas are highly vascular and intraoperative bleeding can be a complication in approximately one-third of cases. This complication can be prevented by selective preoperative endovascular embolization. Stereotactic radiosurgery has been proposed as an excellent alternative therapy.

GANGLIOCYTOMAS

Gangliocytomas are rare hypothalamic or intrasellar tumors composed of mature neurons without a glial component. If a glial component is present, the tumors are called gangliogliomas. Gangliocytomas are either pure gangliocytomas or mixed adenoma–gangliocytomas since the latter have a second component that is indistinguishable from pituitary adenoma. This adenomatous component may be mixed or form a separate, discrete nodule.

Interestingly, the ganglionic component that resembles hypothalamic neurons has been shown to produce and secrete various hypothalamic-releasing hormones, such as growth hormone-releasing hormone, gonadotropin-releasing hormone (GnRH), and corticotropin-releasing hormone, but also other hormones such as gastrin and vasopressin, and, rarely, pituitary hormones. Most of the mixed tumors are associated with endocrine syndromes, such as acromegaly, Cushing's disease, and other endocrine disturbances (hyperprolactinemia), whereas most of the pure gangliocytomas are endocrinologically silent. The mixed adenoma–gangliocytomas could be due to the growth of the adenoma secondary to stimulation by the hypothalamic-releasing hormones secreted by the gangliocytoma.

GRANULAR CELL TUMORS

These are benign tumors of the neurohypophysis, roughly evenly distributed between the infundibulum and the posterior lobe. They are mostly asymptomatic since they only rarely become large enough to produce symptoms. There is a female predominance and most lesions present in the fourth or fifth decade. The most common presentation is visual disturbances and/or hypopituitarism. Despite their location in the neurohypophysis and the infundibulum, diabetes insipidus is very rare. Radiological sellar changes are only observed in approximately 50% of cases. Treatment is surgical, with postoperative radiotherapy for incompletely resected lesions.

GLIOMAS

Glioma of the optic nerve occurs predominantly in children and adolescents. It is often associated with neurofibromatosis type 1 (NF-1), and bilateral optic pathway gliomas are even diagnostic for NF-1. Loss of vision is obviously the main clinical manifestation, but depending on the tumor's extension, glioma may cause hydrocephalus and endocrinopathy, such as

hypopituitarism, diabetes insipidus, or precocious puberty.

In children, histologically these tumors are usually of a low-grade glioma called pilocytic astrocytoma. Optic gliomas in adults are usually anaplastic astrocytomas, which are highly infiltrative and aggressive lesions. The prognosis is very poor with a few exceptions. Gliomas involving only the pituitary gland are very rare. They can be mistaken as nonfunctioning pituitary adenomas by causing hypopituitarism often associated with hyperprolactinemia due to the pituitary stalk compression.

Treatment of gliomas in children is a matter of debate between the indication for surgery and the role of radiotherapy and chemotherapy. In most cases, there is a need for lifelong hormonal substitution due to the persistent endocrinopathy.

CHORDOMAS

Chordomas are rare, slowly growing, locally aggressive tumors arising in the midline, almost always involving the clivus area. Chordomas of the clivus are infiltrative and present with headache, visual symptoms, intracranial hypertension, and/or anterior pituitary insufficiency. Radiological evaluation should include both CT to determine the extent of bone involvement and MRI to delineate accurately the soft tissue infiltration. Treatment is predominantly surgical with or without radiotherapy. It seems that patients treated with surgery and radiotherapy do better than those treated with either approach alone. It is fortunate that chordomas rarely occur in children since they are very aggressive in patients younger than 5 years of age.

GERM CELL TUMORS

These tumors are classified as germinomas, teratomas, embryonal carcinomas, yolk sac tumors, or choriocarcinomas depending on their stage of embryonic development. Germinomas and teratomas are the most frequent. These tumors occur mostly in people younger than 20 years of age, with a peak age of diagnosis of 10–12 years, and males seem to be more affected than females. They commonly arise in the pineal region, followed by the suprasellar region. Rarely, they can arise from the pituitary fossa or even be limited to it. Interestingly, intracranial germ cell tumors have been reported in association with Klinefelter's syndrome. If the tumor contains syncytiotrophoblastic cells, it can secrete β -human chorionic

gonadotropin (β -hCG) as well as α -fetoprotein in the blood and cerebrospinal fluid (CSF). Measurements of these markers are important for follow-up since monitoring their levels in the patient's blood and CSF will allow early detection of recurrence. Angiotensin converting enzyme is also sometimes secreted by germinomas.

Mass effect or precocious puberty are the most common presenting symptoms of the suprasellar germ cell tumors. Hypopituitarism, diabetes insipidus, visual disturbances, hydrocephalus, intracranial hypertension as well as symptoms due to hypothalamic compression, such as bulimia, anorexia, psychosis, or seizures, can all be observed.

Interestingly, tiny germinomas in the pituitary stalk have been shown to be responsible for what was first considered to be "idiopathic" central diabetes insipidus. Precocious puberty may be caused by the tumoral secretion of β -hCG, which directly stimulates the Leydig cells of the testes to produce androgens, resulting in sexual precocity. Association with a pituitary adenoma has been described.

Since the histologic type is a major determinant of therapy and prognosis, a biopsy of suspected germ cell tumors should be performed before therapy is initiated. Mature teratomas are usually benign and can be cured by surgical resection alone. Pure germinomas are highly radiosensitive, and radiotherapy achieves excellent results. However, the other types of germ cell tumors are more aggressive and often need to be treated with a combination of surgery, radiotherapy, and chemotherapy. For these tumors, survival rates are approximately half of those for pure germinomas.

HYPOTHALAMIC HAMARTOMAS

Hamartomas are benign hyperplastic malformations composed of a fibrosis glial matrix with mature ganglion cells that resemble hypothalamic neurons. The lesions sometimes contain myelinated nerve fibers. These tumors are slow growing and rarely invasive. Approximately 90% of patients develop precocious puberty of central origin. There is often a neurodevelopmental delay, with low IQ and seizures. There is also a tendency for patients to become obese in late childhood and adolescence. Some tumors have been shown to express GnRH, which may explain the association with precocious puberty. It has also been proposed that hamartomas may either mechanically stimulate the median eminence to secrete GnRH or interrupt interneuronal pathways that tonically inhibit the GnRH-secreting neurons in the median eminence,

allowing these neurons to be disinhibited and to secrete GnRH.

The treatment of choice of the precocious puberty is the blockade of GnRH action using GnRH analogs. It is not necessary to attempt a total neurosurgical removal of the lesions because the hamartomas in most instances do not appear to progress. Surgery should therefore be restricted to patients who have signs of increased intracranial pressure or neurologic deterioration from progressive growth of the hamartoma.

METASTASES

Metastasis to the pituitary gland is not uncommon, occurring in 1–5% of cancer patients. Metastases more frequently affect neurohypophysis than adenohypophysis. Any tumor can metastasize to the pituitary gland, but the most frequent are carcinomas of the breast and lungs, which represent 50 and 20% of cases, respectively. Among other carcinomas spreading to the pituitary gland are those of the stomach, kidney, thyroid, prostate, ovary, and thymus and melanomas and hematologic malignancies. In patients with disseminated cancer, pituitary metastases are often asymptomatic and are found incidentally at autopsy. The pituitary metastasis may be the first sign of cancer or no primary tumor may be identified. A metastasis can grow rapidly and the presenting symptoms include visual field defects due to chiasma compression, ophthalmoplegia, and ptosis secondary to infiltration into the cavernous sinus. It can rapidly lead to hypopituitarism. The involvement of the infundibulum or the posterior pituitary can lead to diabetes insipidus. No radiological characteristics allow one to distinguish a metastasis from a pituitary adenoma. Interestingly, metastases have also been shown to spread into a previously existing pituitary adenoma, leading to a rapid increase in size of the adenoma.

HEMATOLOGICAL PATHOLOGIES

Leukemias and lymphomas can infiltrate the pituitary region. True intraparenchymal deposits are very rare, but periglandular infiltration is observed in approximately 50% of cases of adult lymphoblastic leukemia. Endocrine functions do not appear to be affected except in patients who present with a syndrome of inappropriate secretion of antidiuretic hormone. Rarely, pituitary infiltration may produce a major enlargement of the gland, causing visual disturbances.

Plasmacytoma can also involve the sella and mimic nonfunctioning pituitary adenoma. Langerhans cell

histiocytosis (LCH), formerly known as histiocytosis X, is also a rare cause of lesions in the sellar region. The lesions usually affect the hypothalamus or the pituitary stalk, but they may also arise in the sella turcica, mimicking a pituitary adenoma. Several formerly distinct pathologies are currently classified under the denomination of LCH: eosinophilic granuloma, Hand-Schüller-Christian disease, and Lettere-Sieve disease. LCH is a proliferation and dissemination of abnormal histiocytic cells of the Langerhans system, mixed with eosinophils, foamy macrophages, and lymphocytes. Langerhans cells express S-100 protein and the CD1a antigen. They also contain peculiar intracytoplasmic organelles, called Birbeck granules, which are pathognomonic.

LCH occurs mostly in children, and besides the lesions in bones, skin, and lungs, diabetes insipidus and growth failure are the most frequent manifestations. LCH can also produce isolated hypothalamic involvement. For lesions causing mass effect, the treatment is surgery with or without radiotherapy.

Erdheim-Chester disease is a rare non-LCH affecting multiple organ systems. Among patients with central nervous system involvement, the most frequent manifestations are diabetes insipidus, cerebellar syndromes, and orbital lesions (exophthalmia). When the disease involves the hypothalamus, the pituitary stalk, or the pituitary, pituitary insufficiency may also be observed in addition to diabetes insipidus. Erdheim-Chester disease usually appears in adulthood and has histological characteristics different from those of LCH since there are no Birbeck granules and the histiocytes do not express CD1a and only occasionally express S-100, but they do express CD68.

Rosai-Dorfman disease is another rare histoproliferative disease that may have central nervous system manifestations, which are commonly dura based, resembling meningiomas. One case of this disease presenting as a pituitary tumor has been reported. In this disease, the proliferative histiocytes exhibit cytoplasmic staining against S-100.

SARCOIDOSIS

Sarcoidosis involves the central nervous system in approximately 10% of cases. In this situation, hypothalamic and/or sellar localizations are most frequent. In most cases, central nervous system involvement is associated with the presence of the disease in other organs (e.g., the lungs and lymph nodes), which greatly facilitates the diagnosis. However, isolated pituitary involvement is possible, making the etiological

diagnosis of pituitary insufficiency and/or pituitary mass difficult.

Diabetes insipidus occurs in 30–40% of patients, whereas endocrine dysfunction of the anterior pituitary is variable, with hyperprolactinemia present in approximately half of cases. Sarcoidosis of the sellar region may be complicated by aseptic meningitis and cranial nerve palsies. Measurement of blood angiotensin converting enzyme concentration may help the diagnosis. If hypothalamo-pituitary involvement is the sole manifestation of sarcoidosis, it may be necessary to perform a pituitary biopsy to make an accurate diagnosis and determine the best treatment. Glucocorticoids may have good efficacy on the symptoms due to the mass effect, but they often do not eliminate the lesions or fully restore the function of the disturbed endocrine axes.

TUBERCULOSIS

Intracranial tuberculomas account for 0.15–4% of space-occupying lesions in developed countries, but tuberculosis involving the sella and parasellar regions is very rare, with only approximately 40 cases reported in the literature. Pituitary tuberculomas present with signs of a mass lesion, headache, visual disturbances, hypopituitarism, and, in some cases, diabetes insipidus. On imaging, tuberculosis lesions can appear as an intrasellar-enhancing mass or as a parasellar mass. Tuberculosis can also present with thickening and enhancement of pituitary stalk or the meninges, with the latter suggesting an inflammatory process. The lesions are quite aggressive toward the endocrine functions of the pituitary. Not all patients with tuberculosis of the pituitary region have signs of active tuberculosis elsewhere, making the diagnosis of tuberculosis difficult. It may require a surgical biopsy of the lesion. The surgical specimen shows an inflammatory lesion containing granulomas with epithelioid cells and giant cells, and occasionally central caseating necrosis, but without acid-fast bacilli on staining or after culture. However, polymerase chain reaction examination of the CSF or of the biopsy for *Mycobacterium tuberculosis* DNA may be very useful in the diagnosis. The treatment is obviously antituberculosis chemotherapy.

WEGENER'S GRANULOMATOSIS

Wegener's granulomatosis can sometimes involve the central nervous system, leading to cerebrovascular lesions and/or meningitis. Rarely, the posterior and anterior pituitary may be involved, leading to diabetes insipidus, hyperprolactinemia, and/or anterior

pituitary insufficiency. Usually, symptoms caused by pituitary involvement occur after or concomitantly with the general symptoms of the disease. Rarely is pituitary dysfunction the sole or first expression of the disease.

INTRASELLAR ABSCESS

Pituitary abscess is a rare but potentially life-threatening pathology caused either by hematogenous seeding of the gland or by direct extension of an adjacent infection. The abscesses can be due to a broad spectrum of bacterial microorganisms or fungi. A pre-existing tumor is evident in some cases. Infectious processes can present with symptoms undistinguishable from those of patients with pituitary tumors. The most common clinical features are headache, visual disturbances, and pituitary insufficiency. Surprisingly, evidence of a serious infection is not common. An exact diagnosis may often require surgical biopsy. Broad-spectrum antibiotic therapy is usually used at the beginning of treatment and subsequently narrowed or stopped according to the results of the cultures.

LYMPHOCYTIC HYPOPHYSITIS

Lymphocytic hypophysitis occurs most often in women during the latter half of pregnancy or the postpartum period as well as in 20–30% of patients with coexisting autoimmune diseases, such as thyroiditis, adrenalitis, or autoimmune hypoparathyroidism. Anti-pituitary antibodies have been detected in a minority of patients. Histologically, it is an extensive inflammatory infiltration of glands consisting of B and T lymphocytes and plasma cells. Often, it presents as a mass lesion of the sella turcica, simulating a pituitary adenoma. Headache is often the main symptom; there is also anterior pituitary insufficiency, which is often only partial. Visual field defects may also occur. Diabetes insipidus is rare except when there is infiltration of the infundibulum. Lymphocytic hypophysitis may also result in isolated hormone deficiencies, especially ACTH. Conservative management may lead to resolution. Transsphenoidal surgery, however, is both diagnostic and therapeutic and should be performed in cases with progressive compression. Although glucocorticoid therapy may result in a decrease in the size of the pituitary mass through a reduction of the inflammatory process in a few patients, these cases are difficult to distinguish from those of spontaneous shrinkage.

CYSTS

Rathke's Cleft Cyst

Rathke's cleft cysts originate from the remnants of Rathke's pouch, which may fail to obliterate completely, leaving cystic remnants at the interface between the anterior and posterior lobes of the pituitary. This lesion is quite common; it is found in 13–33% of autopsy pituitaries. Most of these cysts are intrasellar with or without suprasellar extension. The cyst lumen is filled with mucus, cell debris, and cholesterol crystals. Most of these cysts are asymptomatic and are found at autopsy. When symptomatic, they often have a suprasellar extension and present clinical symptoms due to the mass effect: headache, visual field defects, hyperprolactinemia, partial anterior pituitary insufficiency, and, rarely, diabetes insipidus. Rupture of a cyst may produce aseptic meningitis and Tolosa–Hunt syndrome, which is a painful ophthalmoplegia. A progressive enlargement of the cyst can lead to an empty sella. These cysts may mimic craniopharyngiomas in radiologic appearance. Surgical decompression with drainage is the treatment of choice when they become symptomatic. Except for pituitary insufficiency, most deficits may resolve at least partially, and recurrence is unusual.

Dermoid and Epidermoid Cysts

Symptoms of these cysts arising in the sellar and parasellar regions produce a mass effect resulting more often in visual field defect than anterior pituitary insufficiency. Rupture of the cyst may cause chemical meningitis secondary to spillage of keratinous debris. The transformation into a squamous cell carcinoma in the cyst is very rare. The unusual presentation includes subarachnoidal hemorrhage and stroke. These cysts may coexist with arachnoid cysts. Treatment is surgical.

laboratory findings resembling those of Cushing's syndrome and are called "pseudoCushing's states."

ETIOLOGY OF CUSHING'S SYNDROME

Cushing's syndrome recognizes two main etiologies: ACTH-dependent and ACTH-independent. In the former, glucocorticoid hypersecretion is due to continuous stimulation of the adrenal by ACTH produced by pituitary or extrapituitary tumors (i.e., ectopic ACTH secretion). Conversely, in ACTH-independent Cushing's syndrome, the adrenal produces cortisol autonomously due to benign or malignant neoplastic transformation (i.e., adenoma or carcinoma); stimulation by aberrant receptors specific to catecholamines, serotonin, or peptides such as gastrointestinal inhibitory peptide (GIP), glucagon, thyrotropin-releasing hormone, leptin, interleukin-1, luteotropin, and vasopressin; or genetic causes (e.g., primary pigmented nodular adrenal hyperplasia [PPNAD], possibly part of Carney's complex). Cases due to aberrant receptors generally present as macronodular adrenal hyperplasia, whereas the adrenal is not enlarged in PPNAD. Cushing's syndrome due to administration of exogenous glucocorticoids also is included with ACTH-independent forms.

DIAGNOSIS OF CUSHING'S SYNDROME

The diagnosis of Cushing's syndrome is usually made on the basis of clinical and laboratory data rather than on the radiographic visualization of the pituitary tumor. Traditionally, diagnostic milestones for the screening of this disorder are considered the detection of elevated 24-h urinary-free cortisol (UFC) levels (indicating increased glucocorticoid production), absent cortisol suppression by dexamethasone (the set point for ACTH suppressibility by glucocorticoids is altered, thus larger doses of exogenous glucocorticoids are needed to inhibit pituitary-adrenal secretion), and altered cortisol circadian rhythm with elevated late-evening cortisol levels. Although most patients with Cushing's syndrome do have increased UFC levels and fail to suppress serum cortisol values below 1.8 $\mu\text{g}/\text{dl}$ after an overnight low-dose (1 mg orally) dexamethasone suppression test, false-positive results may be found, resulting in suboptimal diagnostic specificity. Similarly, increased midnight serum cortisol ($>7.5 \mu\text{g}/\text{dl}$) reportedly has an excellent sensitivity for the diagnosis of Cushing's syndrome, but

its specificity remains uncertain when applied to patients with pseudoCushing's states. Furthermore, the test is burdened by costs of inpatient admission. As an alternative, measurement of late-night cortisol in saliva can be easily performed at home and yields good diagnostic accuracy at far lesser expense. However, each of these tests fails to reliably identify all patients with Cushing's syndrome, so further testing may be required. Second-line tests are stimulation with desmopressin, a vasopressin analogue that elevates plasma ACTH and cortisol levels in the majority of patients with Cushing's disease but not in normal individuals or patients with pseudoCushing's, and/or combined dexamethasone-corticotropin-releasing hormone (CRH) stimulation. In the latter test, CRH stimulation is performed after 2 days of 2 mg dexamethasone daily (orally), and attainment of plasma cortisol levels greater than 1.4 $\mu\text{g}/\text{dl}$ favors the existence of Cushing's syndrome. However, the complexity and cost of these procedures call for specialized endocrine centers. Indeed, this and the subsequent diagnostic steps are best performed by endocrinologists experienced with the disease, as recommended by a recent consensus conference.

DIAGNOSIS OF CUSHING'S DISEASE

Noninvasive Testing

Once the diagnosis of Cushing's syndrome has been established, plasma ACTH levels should be measured to ascertain the site driving excess glucocorticoid secretion. ACTH levels within or above the normal range ($>10 \text{ pg}/\text{ml}$) reasonably rule out primary adrenal disease and indicate ACTH-dependent Cushing's syndrome. At this stage, a pituitary source of ACTH secretion can be expected in 85% of cases, with the remaining 15% presenting an extrapituitary etiology, mostly neuroendocrine tumors (e.g., bronchial and midgut carcinoid tumors and small cell lung carcinomas).

Baseline ACTH levels may also provide a clue as to the origin of ACTH secretion given that ectopic ACTH production is often characterized by extremely elevated plasma ACTH levels. However, there is considerable overlap with ACTH levels measured in Cushing's disease, and other tests need to be performed. These tests rely on the fact that the tumoral corticotrope, although partly autonomous, does still retain some features of normal corticotropes (i.e., sensitivity to glucocorticoid feedback and CRH stimulation). In contrast, ACTH-producing cells outside the pituitary by and large do not possess these

features and, therefore, are not likely to respond to glucocorticoid or CRH administration. However, it should be mentioned that, as for the diagnosis of Cushing's syndrome, none of these tests is 100% accurate and false-positive or false-negative results may be observed.

Historically, inhibition with high doses of dexamethasone (8 mg overnight or 2 mg every 6 h for 48 h) was the first test used for the differential diagnosis of ACTH-dependent Cushing's syndrome. A 50 or 80% suppression of endogenous cortisol secretion (evaluated in serum or 24-h urine) will identify 70 to 90% of patients with a pituitary adenoma but may also yield a false-positive response in up to 30% of patients with ectopic ACTH secretion. Given this low diagnostic accuracy, this test is best employed to confirm a high suspicion of Cushing's disease using strict criteria for cortisol suppression (e.g., 80 or 90% suppression from baseline). Thus, only a marked decrease in cortisol should be taken as indicative of Cushing's disease.

Over the past two decades, stimulation with CRH has been accepted as the most accurate noninvasive tool to discriminate pituitary from ectopic sources of ACTH secretion. In the majority of patients with Cushing's disease, intravenous administration of 1 μ g/kg body weight or 100 μ g ovine CRH causes a marked rise in plasma ACTH and cortisol, whereas the hormonal response is modest or absent in patients with ectopic ACTH syndrome. The test is well tolerated, with mild, short-lived facial flushing and tachycardia as the most common side effects and with more severe reactions, such as hypotension and chest pain, occurring only rarely. Criteria consistent with Cushing's disease are a rise in plasma ACTH of at least 50% over baseline and a 20 to 50% maximal cortisol increase. These cutoffs will identify 85% of patients with Cushing's disease and yield only a small number of false positives.

Invasive Testing

When the diagnosis of Cushing's disease cannot be firmly established by noninvasive procedures, inferior petrosal sinus sampling (IPSS) has to be performed, preferably in a highly specialized center. This technique involves sampling both the right and left inferior petrosal sinuses, which drain the respective hemipituitaries, and calculating the ratio between petrosal and peripheral plasma ACTH concentrations obtained before and after stimulation with CRH. The rationale for this procedure is the presence of higher ACTH

levels in the veins draining the pituitary if the gland harbors an adenoma, whereas petrosal ACTH levels will not differ from peripheral concentrations if the tumor is elsewhere in the body. A baseline center/periphery ratio greater than 2 and/or greater than 3 after CRH stimulation is indicative of a pituitary source of ACTH hypersecretion ("gold standard criteria"). However, the occasional patient with Cushing's disease may fail to meet these criteria, possibly due to anomalous venous drainage. Thus, the diagnosis of ACTH-secreting pituitary adenoma cannot be completely excluded if no center/periphery gradient is detected. We usually perform IPSS if CRH and dexamethasone testing yield contradictory results and pituitary imaging fails to clearly visualize an adenoma. IPSS may also provide useful information for identification of the site of the adenoma within the pituitary, but its predictive value falls short of two-thirds and so may be misleading in more than 30% of cases.

IMAGING

ACTH-secreting tumors are visualized by magnetic resonance imaging (MRI) with gadolinium enhancement in slightly over 50% of cases due to their exceedingly small size (mostly 3–5 mm). The detection rate of MRI seems only slightly higher than that of computed tomography (CT) but may increase with the advent of dynamic procedures. It is worth emphasizing that pituitary imaging may also visualize other small lesions (e.g., incidentalomas) that may be erroneously interpreted as ACTH-secreting adenomas. Thus, only lesions greater than 5 to 6 mm in patients where the diagnosis of Cushing's disease is established by testing can be interpreted as adenomas.

SPECIAL FEATURES

ACTH-Secreting Pituitary Macroadenomas

The vast majority of ACTH-secreting pituitary adenomas are less than 10 mm in diameter and, hence, are microadenomas. In about 10% of patients, Cushing's disease is due to a pituitary macroadenoma (i.e., a tumor >1 cm in diameter). In addition to features of glucocorticoid excess, approximately one-third of these patients present neurological symptoms and signs such as frontal and occipital headache and visual field defects due to compression of the optic chiasm. Patients with macroadenomas often show high baseline plasma ACTH immunoreactivity, albeit with reduced bioactivity, and may fail to respond to CRH or suppress after

high-dose dexamethasone. A peculiar variant of macroadenoma is a pituitary ACTH-secreting tumor developing in patients adrenalectomized for Cushing's disease (i.e., Nelson's syndrome).

ACTH-Secreting Pituitary Carcinomas

Pituitary neoplasms are classified into three groups according to their behavior—benign adenomas, invasive adenomas, and carcinomas—with benign adenomas representing the majority. Invasive adenomas account for 10 to 30% of all pituitary tumors and can infiltrate the dura mater, cranial bone, or sphenoid sinus. These tumors are only locally invasive and do not metastasize. Very rarely (fewer than 40 cases have been described), Cushing's disease originates from an ACTH-secreting pituitary carcinoma. Because of the uncertainties in identifying a carcinoma at pathological examination, the diagnosis of malignancy is assigned to neoplasms that have metastasized to the central nervous system or outside the cerebrospinal axis via hematogenous or lymphatic spread, mostly the liver (70%) or bones and lungs (less frequently).

THERAPY

The aims of treatment are removal of the pituitary adenoma, correction of hypercortisolism, and preservation of pituitary function. Pituitary exploration by transsphenoidal surgery is the treatment of choice. The majority of microadenomas can be resected by selective adenomectomy, resulting in approximately 80% cure rates. When no adenoma can be found at surgery, hemi- or total hypophysectomy can be performed, although even these procedures are not necessarily curative. Likewise, debulking of pituitary macroadenomas is successful in only one-third of cases and may be followed by tumor regrowth. Remission of hypercortisolism is defined by the detection of low to undetectable serum cortisol levels (e.g., $<1.8 \mu\text{g/dl}$), normalization of UFC, and normal cortisol inhibition after low-dose dexamethasone. Other parameters, such as baseline ACTH levels and response to CRH or desmopressin, are more useful as predictors of relapse.

Following successful removal of the ACTH-secreting pituitary tumor, the hypothalamic-pituitary-adrenal axis is transiently suppressed because normal ACTH-secreting cells have been inhibited by long-standing

hypercortisolism. Thus, patients will typically require glucocorticoid replacement therapy for 5 to 18 months.

If the patient is not cured by surgery, a second transsphenoidal exploration, radiotherapy, medical treatment, or bilateral adrenalectomy may be chosen as an alternative. Repeat pituitary surgery may be performed, but the likelihood of cure is not greater than 50%. Pituitary radiotherapy can be used in both adult and pediatric patients but takes months or years to be effective and, therefore, requires adjunctive medical therapy. Cure rates vary from 40 to 70%. Unfortunately, a variable degree of hypopituitarism occurs in nearly 50% of treated patients, although this proportion could be smaller with the new forms of stereotactic radiotherapy (e.g., radiosurgery). Moreover, a number of other complications, such as optic nerve damage and neoplastic transformation of adjacent tissues, should not be underestimated.

Medical therapy is not considered the primary therapy for Cushing's disease but is used in conjunction with radiotherapy or preoperatively to improve the patient's clinical condition before surgical treatment. Drug therapy targeted at pituitary ACTH secretion using compounds such as dopamine agonists (e.g., bromocriptine, cabergoline), serotonin antagonists (e.g., cyproheptadine, ritanserine, ketanserin), γ -aminobutyric acid agonists (e.g., valproic acid), and somatostatin analogues (e.g., octreotide) is efficacious only in anedoctal cases. Conversely, medical therapy aimed at the adrenal is more effective and includes several inhibitors of adrenal steroidogenesis. Ketoconazole, an antifungal drug that also inhibits adrenal cortisol synthesis, has been shown to effectively suppress cortisol levels in approximately 70% of patients with Cushing's disease. The major side effects include alterations in hepatic function, gastrointestinal discomfort, and (at high doses) impairment of testicular function. Liver function tests should be monitored during therapy. If ketoconazole is not effective or well tolerated, other adrenal enzyme inhibitors such as metyrapone, aminoglutethimide, and *o,p'*DDD (mitotane) can be used. A combination of various drugs at lower doses can minimize side effects. Etomidate, an imidazole derivative related to ketoconazole, has been used intravenously to rapidly lower cortisol levels during emergencies or in patients who cannot take medications by mouth. All of these compounds strongly suppress adrenal cortisol synthesis, and steroid replacement therapy may be required. Mifepristone (RU-486), a glucocorticoid receptor

antagonist, has been used with some efficacy in a small number of patients with Cushing's disease, especially in glucocorticoid-related psychoses. However, monitoring its efficacy and counteracting overtreatment remain unsolved problems that hamper its widespread use.

Bilateral adrenalectomy was used extensively prior to the advent of transsphenoidal pituitary surgery, although it was burdened by high peri- and postoperative risks. Nowadays, the development of laparoscopic approaches allows this operation to be performed with far greater ease and safety. Removal of both adrenals might need to be performed in patients who do not achieve disease control by pituitary surgery and/or radiotherapy. Patients require lifelong replacement therapy with glucocorticoids and mineralocorticoids and may develop an ACTH-secreting pituitary macroadenoma (i.e., Nelson's syndrome). The risk of Nelson's syndrome (~15%) may be reduced by associating adrenalectomy with pituitary radiotherapy.

METHODS FOR ESTABLISHING CLONALITY

X-Chromosome Inactivation

This is the “gold standard” method for assessment of clonality. In any tissue fragment that contains several cell generations, there will be an approximately equal complement of cells with paternal and maternal X chromosomes inactivated. Fortunately, there are several genes on the X chromosome that are “polymorphic”; that is, each allele can be distinguished by the presence or absence of a restriction enzyme site or the number of tandem repeats. The number of CAG repeats in the human androgen receptor gene (HUMARA) on each X chromosome is determined by polymerase chain reaction (PCR) amplification with primers spanning the microsatellite repeat sequence, after the template DNA has first been digested with the methylation-sensitive enzyme *HpaII*. Although restriction fragment length polymorphism (RFLP)–Southern blotting avoids any possibility of PCR artifacts, the latter method becomes the only practical one when sample size is small, since it can be performed with small amounts of DNA extracted from sections of archival paraffin-embedded tissue.

There are two limitations to X-chromosome inactivation analysis:

1. It can only be performed on samples from women
2. A reasonable amount of starting DNA is required, so very small samples cannot be analyzed.

Autosomal Allelic Deletion (Loss of Heterozygosity)

The demonstration that a tissue or tumor contains only one of two heterozygous alleles is also evidence that the sample is monoclonal; this method of analysis does not depend on the X chromosome and so can be applied to samples from men. However, it does depend on the degree of constitutive heterozygosity of DNA markers or microsatellite polymorphisms at a given locus. The key advantage is that these polymorphisms are frequent and evenly spaced across the genome, so this is generally more informative than either RFLP or X-inactivation analysis. Where there have been direct comparisons in women, autosomal loss of heterozygosity (LOH)–determined clonality is confirmed by X-chromosomal clonality (see Fig. 1 for comparison). In general, therefore, PCR-based techniques for clonality analysis are preferred when the source of DNA is limited. It has been argued that because of the extreme sensitivity of PCR, any contamination of tumor DNA with “normal” constitutive DNA (such as that derived from entrapped leukocytes, blood vessels, or fibrous

Figure 1 Clonality determined by LOH and X-chromosome inactivation analyses. Analysis of LOH at the microsatellite locus D13S1246 in a nonfunctioning tumor reveals uniform loss of either the upper or lower allele, indicating monoclonal tumors (top). A similar interpretation is revealed by the loss of the lower allele at the HUMARA locus in T26.1 and the upper allele in the recurrences T26.2 and T26.3. T26.2a and T26.2b are separate fragments from the same tumor sample (the first recurrence). B, blood; T, tumor; the number shown indicates patient number; .1 denotes first tumor; .2 denotes second tumor.

tissue) may obscure the ability to detect LOH or loss of one X chromosome allele but in practice this is not an issue.

CLONALITY OF PITUITARY TUMORS

It is just over 10 years since the first reports appeared on the clonality of sporadic adenomas assessed by X-chromosome inactivation. These indicated that all pituitary tumor subtypes were monoclonal. Subsequently, autosomal allelic deletion analysis by RFLP–Southern blotting from whole tissue or by PCR microsatellite analysis of archival sections has confirmed monoclonality in much larger numbers of all the major subtypes of adenoma. Although monoclonality is the rule, this concept has been challenged.

Of particular interest with respect to the potential influence of the hypothalamus in the initiation of pituitary tumors are the corticotrophinomas. Levy uses this subtype to build an argument for physiological multiple monoclonality within anterior pituitary corticotrophs. If his argument is correct, it might be expected that a proportion of corticotroph adenomas may be polyclonal by X-inactivation and LOH analysis and this is indeed the case.

However, both micro- and macro-corticotrophinomas whose tumor fragments are macroscopically homogenous generally show a monoclonal pattern, though there are some exceptions (see below). However, predictably, a pituitary biopsy that showed multifocal hyperplastic corticotroph nodules from a patient with ectopic CRF production was polyclonal. Unpublished data by the authors adds to this debate in that some microcorticotrophinomas were found to be polyclonal and others to be monoclonal. However, in patients with Cushing's disease apparently cured by removal of nonadenomatous hyperplastic or normal pituitary tissue, this has, without exception, been polyclonal. The proportion of unambiguous adenomas that turn out to be polyclonal remains to be determined but if it were on the order of 30%, this would provide substantial support for the multiple monoclonality concept.

DOES MONOCLONALITY EQUATE WITH "TUMOR"?

A review by Levy challenges the assumption that monoclonality is synonymous with neoplasia in the pituitary. The grounds put forward for this are as follows:

1. The rare cyclic adrenocorticotropic hormone (ACTH) secretory activity by corticotroph adenomas with return to normality at intervals.

2. The expression of multiple hormones (both pituitary and hypothalamic) by subsets of cells within the adenoma.

3. During normal pituitary development, there is nonrandom dispersion of cell types such that there are clusters of particular cell types in discrete regions of the pituitary. These might have arisen by repetitive and controlled division from a single progenitor cell, thus giving rise to "physiological" zonal clonality within a "normal" gland.

4. There are precedents for microscopic monoclonality, in the absence of neoplasia, in other tissues. Smooth muscle cells in atherosclerotic plaques exhibit a monoclonal pattern and the normal aorta appears to be a mosaic of small overlapping monoclonal "tiles." The same appears to hold true of the bladder epithelium and uterus. Regenerating liver nodules are frequently monoclonal but not neoplastic, though presumably they have the potential to become so as hepatocellular carcinoma frequently develops in certain types of cirrhotic livers.

Levy proposes that an expansion of a "normal" monoclonal population of cells could occur in response to a growth stimulus from outside or within the pituitary to produce a histologically discrete adenoma that is truly neoplastic with respect to unrestrained cell division. If there were several normal monoclonal clusters, all with different genetic and functional characteristics, that responded to the same stimulus, this could produce an oligoclonal tumor, which by conventional clonality analysis would appear polyclonal. So "monoclonality" of discrete areas might be normal but this could only be tested by carefully examining a normal pituitary gland in multiple discrete areas, which remains to be carried out. Furthermore, if Levy's idea of oligoclonal tumors is true, it may be possible to detect the different clones by examining multiple biopsies from different regions of the same tumor.

Undoubtedly, in the majority of pituitary adenomas monoclonality indicates neoplasia. The most persuasive evidence for this is data from recurrent tumors, a significant proportion of which show additional genetic changes in recurrent/regrown tumors. However, data from recurrent/regrown tumors, and also from several examples of pituitary carcinomas with metastases, provide evidence in support of a multiple monoclonal nature of the primary/initial tumor.

MULTICLONALITY OF PITUITARY TUMORS

Evidence from Recurrent Tumors

No study has previously examined initial and recurrent/regrowth pituitary tumors from the same individual for clonality or allelic deletions. Therefore, paraffin-embedded samples from patients who had two or more pituitary operations separated by at least 1 year were obtained. All clinical subtypes were represented. Most initial and recurrent tumors were invasive, meaning that tumor was present in one or both cavernous sinuses or invading into the sphenoid sinus.

Tumors from 33 patients showed allelic loss in the first and subsequent tumors at one or more loci. On the basis of LOH pattern in first and subsequent tumors, two common LOH patterns were seen; in pattern A, LOH observed in the original tumor was identical (preserved) to that in the patient's subsequent tumor(s) and in some cases this was accompanied by additional losses (Fig. 2A); in pattern B, LOH was observed in the first sample but both alleles were retained (loss to retention) in a subsequent sample(s) (Fig. 2B). In some cases, this was accompanied by additional losses. From the patterns of LOH observed, it is suggested that LOH pattern A is consistent with a single monoclonal origin, since within each individual patient, the loss pattern seen in the first tumor is preserved in subsequent samples. An example is shown in subject 23, where loss at the marker *D13S153* is seen in the first (23.1) and subsequent tumors (23.2) with an additional loss at the marker *PYGM* in the recurrence (23.2) consistent with a progressive accumulation of losses with time (Fig. 2A). This single monoclonal interpretation was seen with all the tumor subtypes.

In samples showing retention of heterozygosity in the second or subsequent samples (loss pattern B, Fig. 2), this could most likely be explained by the second sample being derived from a distinctly separate clone, although both are monoclonal tumors. For example, in patient 6 (Fig. 2B), the tumor showed loss at four of the microsatellite markers, whereas in the second sample (6.2), retention of heterozygosity at three of these markers was observed, making it highly unlikely that this sample is clonally related to the first. The possibility that retention of heterozygosity is due to contamination by normal tissue is excluded since LOH is still found in tumor 6.2 at the marker *D13S1246*, indicating monoclonality. Again this interpretation applied to all tumor subtypes. The above interpretation of clonality by X-inactivation

Figure 2 Examples of LOH in recurrent pituitary tumors representing a common plus additional deletion in the regrown nonfunctional tumor from a 30-year-old woman (A, Patient No. 23, loss pattern A) or a “loss-to-retention” pattern in a 29-year-old man with a nonfunctional tumor (B, Patient No. 6, loss pattern B). In this example, markers interferon- α (9P), D10S217, and D13S155, which are lost in the first sample (T6.1), are retained in the recurrence (T6.2), which is still monoclonal as evidenced by LOH at locus D13S1246. Thus, the second sample is of a different clonal origin than the first. B is the matched blood DNA sample.

analysis in the female patients with informative HUMARA or PGK-1 alleles was confirmed.

Thus, up to 60% of recurrent/regrown pituitary tumors appear to be clonally distinct from the first tumor. Perhaps even differing clonality of recurrent tumors is the rule rather than the exception.

Evidence from Individual Cases with Metastases

Further evidence for more than one clone in pituitary tumors is available from rare case reports of carcinomas with metastases. In a woman with recurrent Cushing’s syndrome, the primary pituitary tumor, its recurrence, and a cervical lymph node metastasis were examined. Morphologically, all samples were identical with both ACTH and growth hormone immunopositivity. With the autosomal LOH analysis, the primary and recurrent tumors showed loss of the same allele at four loci, whereas the metastasis showed retention of heterozygosity at two of these loci. This pattern is consistent with a different clonal origin of the metastasis (as in the example in Fig. 2B).

The authors have also examined another case of a nonfunctioning tumor in a man who, 5 years after his initial pituitary surgery, developed dural metastases. All three metastases/seedlings were from the same clone but this was a different clone from the original pituitary tumor. Immunohistochemically, the original tumor and the dural metastases were identical.

How should the aforementioned data be interpreted with respect to tumor initiation/progression? Given that a significant proportion of recurrent/regrown tumors have different clonal origins, are two or more clones present from the very beginning of the tumor? Or does the second independent clone arise later in the progression of the pathogenic process? Figure 3 is an attempt to represent two possible options diagrammatically in relation to hypothetical genetic damage (“hits”). Scenario 1 is on the left-hand side of Fig. 3 and envisages that the first hit results in hyperplasia of several cells of a given lineage. This hit may be exogenous or endogenous to the pituitary. The authors favor an exogenous source, such as hypothalamic stimulation, since this is more likely to be cell subtype specific. If the stimulus to hyperplasia was from within the pituitary, e.g., growth factor overexpression, this might be expected to target cells of several lineages simultaneously. Hyperplasia, with its associated increased rate of cell turnover, then predisposes these cells to a second hit that occurs in one or more cells (A and B), causing different genetic changes (LOH) in each. The changes in cell A produce more rapid cell division than in cell B such that clone A becomes dominant, although clone B grows slowly. At surgery, the dominant clone is removed and this is monoclonal by LOH analysis. Depending on the completeness of surgical removal, a recurrence may derive either from the remnants of clone A, with or without additional genetic damage (LOH), or from clone B. It is also conceivable that clone A might produce factors that inhibit the expansion of clone

Figure 3 Two possible scenarios to explain the differing clonal origins of recurrent/regrown tumors. Time, in years from initiation, is indicated, proceeding from the top to the bottom of the figure. “Hits” denote events leading to genetic damage and ultimately LOH, without defining what these might be. A large X represents surgical removal and elimination of the relevant clone of the tumor. LOH denotes loss of heterozygosity, with 1 and 2 being different.

B, since growth-inhibiting as well as growth-stimulating factors may be produced from pituitary tumors. Scenario 2 is on the right-hand side of Fig. 3 and is not predicated by preexisting cellular hyperplasia but assumes that the first hit targets two individual normal cells of the same subtype contemporaneously. The second hit then affects only cell A (not cell B at this

time), enabling clone A to develop while cell B does not expand into even a minor clone but retains its predisposition to expand if it sustains its second hit at a time before or after removal of clone A (the initial tumor). The authors believe this scenario to be less likely than the first in most cases for the following reasons:

1. Statistically, the first hit would be expected to randomly target any cell of any lineage, not cells of the same lineage, unless this hit was cell subtype specific. If this were the case, clone tumor A and clone tumor B would be expected to be of different subtypes. Clinically, this is rare since most recurrences/regrowths are of the same cell subtype as the original tumor, with very few rare exceptions, e.g., silent corticotrophinomas, which are originally nonfunctional (though by definition ACTH immunopositive) and then change phenotype to become highly functional).

2. If cell B sustained genetic damage and did not expand until some time (months to years) later, there would be a greater chance that it would be eliminated through apoptosis, which in fact may be enhanced because of the genetic change and which does occur in the pituitary albeit at a slow rate.

The results from the two cases with metastases are perhaps more difficult to interpret. In the first case, the lymph node metastasis (albeit in the territory of jugular vein drainage) must presumably have arisen by hematogenous spread. Did this occur at the time of primary or second surgery to the pituitary? The answer cannot be determined, and the interpretation is compatible with either contemporaneous or later independent clonal development.

The second case is perhaps easier to interpret in that it is suspected that the dural deposits arose as a result of seedlings shedding at the time of first surgery into the cerebrospinal fluid (CSF) (the patient did have a transient spontaneously closing CSF leak after surgery). If this is the case, then there must have been at least two clones present at the time of the first surgery, though clearly one was dominant given that the initial tumor was monoclonal (or it was multiclonal and the fragment that was analyzed was from only one of the clones).

EVIDENCE OF DIFFERING CLONAL ORIGIN FROM OTHER TUMOR TYPES

One crucial question to be answered in LOH and clonal analysis studies relates to that of sampling bias. How does one know that the extracted DNA, especially from a small biopsy represented on a slide, is representative of the whole tumor? Intratumoral DNA heterogeneity has been found in prostate, breast, and colorectal carcinomas by LOH analysis. How are these data to be interpreted? One distinct possibility is that these solid tumors are composed of several distinct clones of cells, some of which may have greater malignant potential than others. This might explain why in

the aforementioned cancers the prognostic significance of DNA aberrations has been inconclusive. One of these studies formally assessed clonal composition by X-chromosome inactivation and showed that separate areas within a given tumor showed an identical X-inactivation pattern, although LOH analysis was variable within a given tumor. The authors would interpret this as a single clonal origin for the tumor but different subclones sustaining accumulating genetic damage as cells within the tumor progress at different rates. What has not yet been determined is whether similar genetic heterogeneity applies in larger pituitary tumors, although studies on patients with metastases suggest that this is a possibility.

Is it a surprise that many pituitary tumors might be multiclonal? In the sense that these are generally benign adenomas rather than carcinomas, perhaps it is, but there are several examples in other tumors, some benign and some malignant, of different clonal derivations. In multinodular goiters, coexisting individual nodules may be either polyclonal or monoclonal and if monoclonal, the clones may be different. This clearly indicates that whatever the goitrogen(s), it is capable of targeting several cells of the same lineage, possibly contemporaneously. Another study indicated that solitary follicular thyroid adenomas or carcinomas are monoclonal although nodules from multinodular goiters are largely polyclonal.

Although solitary parathyroid adenomas are monoclonal, monoclonal parathyroid tissue is common in hyperplastic glands from patients with uremic hyperparathyroidism as well as in patients with primary parathyroid hyperplasia. Histological categories of nodular versus diffuse hyperplasia did not predict clonal status. Thus, the chronic stimulation of uremia induces hyperplasia followed by monoclonal expansion from this pool of cells in the parathyroid gland. So why could the same thing not happen in the pituitary? In contrast, a polyclonal pattern of X-chromosome inactivation was observed in medullary carcinomas of the thyroid from both MEN2 patients and sporadic cases. This is a rather unexpected finding given earlier studies that were more suggestive of a single clone of origin of MTC with distinctly progressive subclones. In benign pancreatic endocrine tumors, polyclonality is the rule and progresses to monoclonality as a single, more aggressive clone develops the potential for invasiveness and metastatic spread. In this example, too, the clonality pattern could not be predicted on the basis of histochemistry, proliferation index, or growth pattern. Somewhat surprisingly, sporadic gastrinomas occurring at multiple sites in the same patient appear to have the

same clonal origin, whereas in MEN1 patients multiple gastrinomas may be of independent clonal origin.

The presence of precursor populations of cells with different clonal composition appears quite commonly in other organs prior to the development of invasive cancer (e.g., cervix, bladder cancers), although when these cancers are multifocal they appear to have the same clonal origin. Similarly, in prostatic intraepithelial neoplasia and multifocal prostate cancer, the distribution of LOH indicates areas of similar and differing clonality.

The aforementioned evidence indicates several things about cancer clonality:

1. morphology cannot predict clonality;
2. clonality within a given tumor may be multiple or single;
3. multiple tumors arising on the background of hyperplasia may be of identical or differing clonality;
4. multiple "sporadic" tumors within an organ may be of differing clonal origin.

One should therefore not be surprised that pituitary tumors may consist of an admixture of clones and that their recurrences/regrowths may be from any one of such clones. Thus, although the early available evidence indicated that pituitary tumors appear largely monoclonal, it is simplistic to assume that this is inevitable and that these cannot be multiclonal at the outset. These observations would be entirely compatible with an initiating stimulus resulting in cell subtype-specific hyperplasia, which itself gives rise to several distinct clones with variable potential to

develop into tumors. Such stimuli might include hypothalamic tropic factors, intrapituitary growth factors, or pituitary-specific oncogenes.

suggesting that continuous stimulation by thyrotropin-releasing hormone (TRH) may lead to thyrotroph adenoma. TRH has also been shown to be expressed in the pituitary and by the different types of pituitary adenomas.

TRH signaling appears to be intact in pituitary adenomas as evidenced by intact binding and normal release of thyroid stimulating hormone (TSH) and prolactin (PRL) in response to TRH exposure. TRH receptor expression and structure are grossly unaltered even in thyrotroph adenomas. TRH mRNA is alternatively spliced in some pituitary tumors with deletion of exon 3 resulting in a truncated product that does not bind TRH. The relatively higher levels of the truncated forms compared to the full-length form of the TRH receptor in lactotroph adenomas may explain some of the paradoxical *in vivo* responses to TRH administration.

Growth Factors and Their Receptors

Transforming Growth Factor- α

Transforming growth factor- α (TGF- α) is expressed as a membrane-anchored protein by human adenohypophysial cells and tumors. TGF- α may alter pituitary production of GH, PRL, and TSH as well as cell proliferation. Estrogen stimulation has been implicated in pituitary tumorigenesis and TGF- α appears to mediate some estrogenic effects. Targeted overexpression of TGF- α to the pituitary results in lactotroph adenomas, providing compelling evidence for the significance of this growth factor in pituitary tumorigenesis.

Epidermal Growth Factor and Its Receptor

Epidermal growth factor (EGF) is detectable by immunohistochemistry in most adenohypophysial cells and its mRNA is expressed with marked variation in all types of functional and nonfunctional adenomas. EGF potently stimulates PRL and adrenocorticotrophic hormone secretion with variable effects on rat pituitary cell proliferation. The selective expression and specific effects of EGF suggest that the pituitary is an important target site for this growth factor's action.

The common receptor of EGF and TGF- α , EGF receptor (EGF-R), is a 170 kDa plasma membrane tyrosine kinase product of the proto-oncogene *v-erbB*. EGF-R is overexpressed in several types of human cancers and in most instances this overexpression is accompanied by TGF- α expression; expression of this receptor appears to correlate with tumor aggressiveness. EGF-R is expressed by human pituitary adenomas with the highest levels in recurrent somatotroph adenomas and suggesting a selective mechanism for the EGF/EGF-R family in the growth of aggressive

somatotroph tumors. The importance of the EGF-R in the somatotroph is further supported by the selective loss of somatotrophs in transgenic mice overexpressing a dominant-negative EGF-R mutant lacking the intracellular protein kinase domain (EGFR-tr). These findings point to EGF-R as an integral component in the differentiation and proliferation of somatotrophs.

Fibroblast Growth Factors and Their Receptors

Basic fibroblast growth factor (bFGF, also known as FGF-2) is one of an expanding family of at least 23 members of ligands with variable mitogenic, angiogenic, and hormone regulatory effects. FGF-2 immunoreactivity was described originally in non-hormone-producing bovine pituitary folliculo-stellate cells and has since been shown to regulate GH, PRL, and TSH secretion by the rodent pituitary. In the human pituitary, in contrast, FGF-2 is produced by adenohypophysial cells that constitute pituitary adenomas. Pituitary-derived FGF-2 has been shown to stimulate replication of PRL-secreting cells but also may inhibit DNA synthesis in pituitary adenoma cells, suggesting that some forms of the growth factor or its receptor may act as growth inhibitors. Elevated concentrations of FGF-2-like immunoreactivity have been documented in patients with multiple endocrine neoplasia type 1 (MEN1) and in patients with sporadic pituitary adenomas. The FGF-related *hst* has been found in transforming DNA of human PRL-secreting tumors and facilitates lactotroph proliferation. Transgenic mice expressing FGF-2 under the control of the GH and the α -subunit promoters develop hyperplasia of several adenohypophysial cell types but not frank adenomatous transformation. FGFs or homologous family members may, therefore, play an important role in pituitary tumorigenesis.

There are four mammalian FGF receptor (FGFR) genes encoding a complex family of transmembrane receptor tyrosine kinases. Each prototypic receptor is composed of three immunoglobulin-like extracellular domains (two of which are involved in ligand binding), a single transmembrane domain, a split tyrosine kinase, and a COOH-terminal tail with multiple autophosphorylation sites. Multiple forms of cell-bound or secreted receptors are produced by the same gene. Tissue-specific alternative splicing, variable polyadenylation sites, and alternative initiation of translation result in truncated receptor forms. Structural alterations of FGFRs may play a role in human tumorigenesis. Antisense targeted interruption of FGFR1 reduces malignant melanoma cell proliferation and differentiation. The normal pituitary expresses mRNAs for FGFR1, 2, and 3. An interesting finding was the

presence of novel truncated mRNA for a kinase-containing variant of FGFR4 with an alternative initiation site in pituitary adenomas. This tumor-derived kinase encodes a polypeptide receptor that lacks a signal peptide and the first two extracellular immunoglobulin-like domains. *ptd*-FGFR4 has a distinctive cytoplasmic localization and is constitutively phosphorylated. Transfected cells display transforming features *in vitro* in soft agar and develop tumors *in vivo* in nude mice. More importantly, targeted expression of *ptd*-FGFR4 to pituitary lactotrophs, but not wild-type FGFR4, results in hyperprolactinemia and pituitary adenomas that morphologically mimic primary human pituitary adenomas. These findings suggest that dysregulated FGFR4 function plays an important role in pituitary tumorigenesis and that FGFR4 is a candidate tumor-specific kinase.

Loss of Function

p53

This nuclear protein is critical in the control of G₁/S phase progression by regulating the gene expression of p21, the first of the group of cyclin-dependent kinase inhibitors to be identified. Following DNA damage, p53 can induce growth arrest during the G₁ or G₂ phase of the cell cycle or by stimulating apoptosis, thereby protecting the normal cell from replicating damaged DNA. Conversely, p53 mutations render the cell genome more vulnerable to mutations that represent the rate-limiting steps in tumor progression. Indeed, inactivating mutations of p53 have proven to be among the most commonly encountered gene alterations in human malignancies. However, studies have failed to identify p53 mutations at putative "hotspots" in the different types of human pituitary adenomas.

The Retinoblastoma Gene

The retinoblastoma (Rb) gene is another member of the family of tumor suppressor genes that has been implicated in several neoplasms including retinoblastoma and osteosarcoma. Mice heterozygous for an Rb mutation develop pituitary tumors of intermediate lobe corticotroph differentiation. No such mutations have been identified in human pituitary adenomas. Instead, there is loss of heterozygosity (LOH) at sites telomeric and centromeric to the Rb locus in some aggressive pituitary adenomas. These data argue for an independent tumor suppressor gene (TSG) on 13q, which is closely linked with but distinct from Rb. In addition, methylation of the Rb promoter region has been described in association with diminished detectable Rb protein expression.

Cyclins, Cyclin-Dependent Kinases, and Cyclin-Dependent Kinase Inhibitors

A series of cyclins and cyclin-dependent kinases (cdks) plays a central role in the regulation of cell cycle progression. The cyclin D (cdk4) and E (cdk2) complexes are catalytically active during the late G₁ phase and are implicated in the regulation of G₁/S progression. The Rb protein is one of the putative substrates of the cdks. Rb phosphorylation abrogates the ability of these proteins to inhibit transactivation of transcription factors important in cell cycle control. In turn, cdk activity is modulated by cdk inhibitors. These include p27^{kip1}, p57^{kip2}, p16^{ink4A}, p15^{ink4B}, p18^{ink4c}, and p19^{ink4D}.

Prompted by the potentially pivotal role of the Rb protein in regulating pituitary cells and the negative findings involving the *Rb* gene itself, factors governing Rb phosphorylation became obvious candidates. Specifically, cdk inhibitors have received extensive attention. As with the Rb itself, p16 has not been found to be mutated in pituitary adenomas, but is frequently silenced by means of extensive methylation in human pituitary adenomas. These findings suggest an alternative mechanism in modulating Rb-related protein control of the pituitary tumor cell cycle.

Mice lacking p27^{kip1} have an increased propensity for the development of multiorgan neoplasia including pituitary tumors. As with the *Rb* gene, however, mutations of the p27^{kip1} gene do not appear to play a role in human pituitary tumorigenesis.

MEN1

According to the two-hit model of tumorigenesis, both copies of a gene situated on opposite alleles must be inactivated, such as by deletion, rearrangement, or silencing through methylation, to confer a selective growth advantage to a precursor cell, which may subsequently proliferate in a clonal neoplastic fashion. Such genes that require homozygous inactivation of both copies are termed TSGs, anti-oncogenes, or recessive oncogenes. Examples of TSGs include Rb and p53. In the affected tumors, allelic loss of the gene in question is invariably noted.

After a decade of search, the MEN1 gene was identified by positional cloning with germ-line mutations characterized in kindreds with familial MEN1. The gene product was coined menin to describe the 610-amino-acid protein product. Targeted gene inactivation of menin results in prolactinomas characterized by somatic loss of the wild-type allele with remarkable similarity to humans with MEN1. As predicted, mutations in sporadic pituitary tumors have been described.

One copy of the MEN1 gene was found to be deleted in 10% of sporadic tumors examined. Missense mutations have been described throughout the gene of the remaining allele. Thus, as predicted by Knudson's two-hit tumor suppressor gene hypothesis, mutational inactivation of one copy of MEN1 coupled with deletion of the second allele strongly indicates that this gene is involved in the pathogenesis of hereditary (familial) pituitary tumors and in a subset of sporadic pituitary tumors. Up to 20% of sporadic pituitary adenomas exhibit LOH at the 11q13 locus even in the absence of menin mutations, suggesting additional TSG at this locus. The characterization of normal menin function will likely prove to be of evolving significance in pituitary tumorigenesis. Thus far, menin has been shown to modulate a number of growth-regulatory pathways including that of the inhibitory transforming growth factor- β (TGF- β) as a result of interaction with the Smad3 transcription factor.

Loss of Inhibitory Hormones

Dopamine

The role of diminished hypothalamic inhibition was first suggested based on the observation of neovascularization in lactotroph adenomas. It was speculated that neovascularization would allow lactotrophs to escape from tonic dopaminergic inhibition. Dopamine signal transduction is mediated through D1 receptors that stimulate adenylyl cyclase activity and D2 receptors (D2R) that inhibit this enzyme. The family of dopamine receptors is complex in biochemical, physiological, and pharmacological diversity. Nevertheless, it appears that the predominant anterior pituitary dopamine receptor is the D2R. Targeted elimination of D2R activity in D2R knockout mice results in lactotroph hyperplasia and, subsequently, lactotroph adenoma formation in female D2R-deficient mice. Interestingly, these lesions are monohormonal PRL-immunoreactive neoplasms that display a characteristic juxtannuclear Golgi pattern of PRL staining and loss of the reticulin fiber network. Several of these adenomas have been noted to be much larger than normal glands, with marked suprasellar extension and invasion of brain but no gross evidence of distant metastases.

Although some pituitary tumors have been shown to be responsive to dopamine suppression, the dopaminergic resistance that is found in some tumors implicates diminished D2R activity as a putative factor in pituitary tumorigenesis. Thus far, however, investigation of the D2R gene has revealed it to be structurally intact in human lactotroph adenomas.

Prolactin

The autoregulation of PRL secretion in the rat has been demonstrated at the levels of both the hypothalamus and the pituitary. In transfected somatolactotrophs, PRL exerts a strong and specific inhibition of PRL gene transcription. These effects appear to be mediated by intermediate and long forms of the PRL receptor. Deletions of the PRL promoter indicated that the autoregulatory effect of PRL requires the same regulatory domains that have been described for the other PRL gene regulators. These studies support an extra-short loop of PRL transcriptional autoregulation. In the normal human pituitary, PRL and luteinizing hormone cells exhibit the highest levels of PRL receptor (PRL-R) mRNA expression, whereas PRL-producing pituitary adenomas have significantly higher levels of PRL-R mRNA than other types of adenomas. Dopamine agonist treatment decreases the levels of PRL-R mRNA in PRL adenomas.

Somatostatin

GH secretion is under contrasting influence from hypothalamic stimuli including GHRH, which stimulates GH secretion, and somatostatin (SS), which inhibits GH secretion. Specific receptors for SS (SSTRs) are expressed on somatotroph adenomas. Earlier studies suggested a relationship between the density of SS receptors on GH tumors and the secretory response to this analogue both *in vitro* and *in vivo*. Binding sites for SS, however, have been identified by autoradiography in tumors resistant to the GH-lowering effects of octreotide. These findings are consistent with differential adenylyl cyclase coupling by the five known subtypes of SSTRs and their heterogeneous expression in pituitary adenomas. Expression of SS itself in large invasive GH tumors appears to be diminished compared to that in the normal pituitary. These findings suggest multiple paracrine, autocrine, and endocrine mechanisms for SS-mediated control of somatotroph function and proliferation.

Thyroid Hormones

The development of pituitary thyrotroph adenomas in patients with prolonged primary hypothyroidism has provided further evidence supporting the hypothalamic role in pituitary tumorigenesis. Thyroid hormones mediate their actions via nuclear thyroid hormone receptors (TRs) that bind to specific regulatory hormone-response elements. There are two major classes of TRs, designated α and β , each of which undergoes alternative splicing to generate $\alpha 1$ and $\alpha 2$ and $\beta 1$ and $\beta 2$ isoforms. With the exception of the $\beta 2$ form, which is predominantly expressed in the

hypothalamic–pituitary system, these receptor isoforms are ubiquitously expressed. Of interest, in the pituitary, the $\beta 1$ and $\beta 2$ isoforms appear to be expressed to a lesser extent in adenomas than in the normal gland. Screening TR- α mRNA identified three novel missense mutations, two in the common TR- α region and another that was $\alpha 2$ specific. TR- β -response elements failed to show any differences from published sequences.

Mice with targeted disruption of the entire TR- β locus exhibit elevated thyroid hormone levels as a result of abnormal central regulation of thyrotropin but do not develop pituitary tumors. Thus, the putative differential hormone regulatory and mitogenic effects of the different THR isoforms in the pituitary remain unclear.

TGF- β

TGF- β has been implicated in the regulation of normal and neoplastic cell function. TGF- β regulates the expression of various proteins, including the cell cycle inhibitory protein p27Kip1 (p27). TGF- β 1/2/3 isoforms and the TGF- β receptor are expressed in normal and adenomatous pituitaries. Dispersed pituitary adenomas cells show a biphasic response to TGF- β with changes in follicle-stimulating hormone (FSH) secretion. The TGF- β family, however, is represented in at least three different forms in the pituitary. Inhibins and activins consist of two homo- or heterodimeric polypeptide subunits derived from a common precursor; inhibin A (α - β A) and inhibin B (α - β B) selectively inhibit the release of FSH from pituitary gonadotroph cells, whereas activin (β A- β B), activin A (β A- β A), and activin B (β B- β B) stimulate its release. Inhibin subunits are expressed by pituitary gonadotroph adenomas and activin is known to stimulate

hormone secretion by these tumors. Activin, however, inhibits cell proliferation in a variety of cell types including pituitary adenomas. These actions are mediated through type I and type II serine/threonine kinase receptors. The predominant form is type I (ActRIB or Alk4). Truncated forms of the type I receptors expressed by gonadotroph adenomas interfere with wild-type receptor function and block the anti-proliferative effect of activin. These findings suggest an important role for the activin/follistatin/activin receptor balance in modulating pituitary tumor cell replication.

Gonadal Steroids

The development of pituitary gonadotroph adenomas in patients with prolonged primary hypogonadism suggests that the lack of hormone negative feedback may facilitate pituitary tumor development. Again, however, the role of GnRH stimulation cannot be easily distinguished from that of gonadal hormone inhibition in the development of these adenomas.

CONCLUSIONS

Accumulating evidence suggests that the control of pituitary cell multiplication rests on a precarious balance between growth factor stimulation and inhibition with dominant contributions from the FGF/FGFR and TGF- β systems (Fig. 1). The events leading to pituitary tumorigenesis in the vast majority of tumors remain to be validated directly from the human situation in genetic mouse models. Differences between pituitary and other endocrine and nonendocrine neoplasms will likely emerge to explain the remarkably varied spectrum of biologic behavior in terms of tissue

Figure 1 Proposed model of pathophysiology of pituitary tumorigenesis. An integrated approach incorporating the dominant gain and loss of function cascade events is summarized.

invasiveness and metastatic potential, which is unique to pituitary adenomas.

endocrinologically, have aided intraoperative orientation, and have improved intraoperative visualization.

Imaging

The major advance in surgical planning over the past 50 years has been the introduction of sophisticated radiographic imaging techniques. Computerized tomography was introduced in the early 1980s, followed by magnetic resonance imaging (MRI) shortly thereafter. Current MRI scans will delineate all but the smallest microadenomas and demonstrate their proximity to surrounding structures. MRI scanners have been incorporated into the operating room environment and can provide near-real-time MRI for both intraoperative orientation and determination of the adequacy of resection. Whether this expensive technology leads to improvements in patient care and outcome remains to be shown.

Surgical Techniques

Advances in surgical techniques have aided both intraoperative orientation and visualization. Navigational devices that will correlate intraoperative localization with preoperative imaging have become available and may offer some benefits when the traditional anatomical landmarks have been destroyed, as in cases of recurrent tumors. Improved visualization with a wider field of view and less tissue dissection is offered by the use of the endoscope, though traditional operative microscopy offers better optics, depth of field, and binocular vision.

SURGICAL RESULTS

Secretory Tumors

Cushing's Disease

Transsphenoidal surgery remains the primary mode of treatment for Cushing's disease, with cure rates approaching 90% in experienced hands. After surgical cure, patients will demonstrate profound hypoadrenalism for some months postoperatively and require cortisol replacement during this time. Tumors may recur at a rate of 7–10% at 5 years; reoperation for tumor recurrence is less successful, with remission rates of approximately 50%. Here, adjuvant therapy, including radiosurgery, adrenalectomy, or medical therapy with ketoconazole, may play a role. Since MRI is able to detect microadenomas in this disease in at best 60–70% of cases, accurate endocrine diagnosis, including inferior petrosal sinus catheterization, is necessary.

Acromegaly

Patients with acromegaly tend to present with larger, more invasive tumors and here transsphenoidal surgery is less successful. The remission rate is 50–60% in macroadenomas, whereas the remission rate may approach 90% in the less common microadenomas. Newer medical treatments, including the use of somatostatin analogues, are useful in controlling growth hormone levels in those patients not surgically cured and aggressive multimodality therapy (e.g., surgery, somatostatin analogues, radiosurgery) is necessary to control the increased mortality risk associated with the disease. The role of medical pretreatment, or primary medical therapy for acromegaly, remains unclear, but has been suggested for those patients who are not optimal surgical candidates or who have a minimal chance of surgical cure.

Prolactinomas

Women who present with amenorrhea–galactorrhea, mild elevations in prolactin level, and microadenomas on MRI scanning are usually best treated with dopamine agonist therapy. Surgery, though effective in approximately 90% of patients with microadenomas, is reserved for those patients who are unable to tolerate or who fail to respond to medical treatment. With newer, better tolerated dopamine agonists (cabergoline), patients only rarely require surgical treatment. Men with prolactinomas tend to present with either impotence or visual abnormalities and their tumors are more likely to be large and invasive. Dopamine agonist therapy remains effective in these cases, with surgery reserved for those cases that fail to respond. Even patients with bitemporal field defects will often respond dramatically after a few weeks of treatment with a dopamine agonist. It must be remembered that mild elevations in prolactin (less than ≈ 200 ng/ml) may have causes other than prolactin-secreting tumors (e.g., pregnancy, medication effects). A large tumor with a mild increase in prolactin level may represent the so-called “stalk effect” from compression of the pituitary stalk and normal gland, resulting in blockade of intrinsic dopamine inhibition and an elevated prolactin level. This tumor is unlikely to be a prolactinoma and may well require surgical removal. Dopamine agonist therapy in these cases may well normalize the prolactin level, but will do nothing to shrink the tumor.

Nonfunctioning Tumors

The term “non-functioning” may well be a misnomer, as many of these tumors secrete inactive hormone fragments, especially the α -subunit. Because of their

endocrine inactivity, they become large and invasive before being detected. They usually present with signs of mass effect, either with visual abnormalities, especially the classic bitemporal field defect of chiasm compression, or with endocrine abnormalities from destruction of the remaining gland. Surgery is required to decompress the optic apparatus and approximately 70% of patients will regain some degree of peripheral vision. Decompression of the remaining gland results in improvements in hormone function in approximately 50% of these patients. A small amount of residual tumor may be followed with serial MRIs, whereas an extensive amount of residual should be treated with radiotherapy. An incidentally found nonfunctioning tumor (the “incidentaloma”) has been reported in up to 10% of MRI studies. Microadenomas (<1 cm) can usually be followed with serial MRI; macroadenomas (>1 cm) often merit resection, though some would follow for a time with MRI to determine the rate of growth before recommending surgery.

COMPLICATIONS

Transsphenoidal surgery in experienced hands carries a low risk of serious complications. New hormone insufficiency may occur in 5 to 10% of cases, although this may be considerably greater in cases of Cushing’s disease, in which extensive exploration of the gland is sometimes required to find a tiny microadenoma. The incidence of permanent diabetes insipidus is approximately 1–2%. Serious complications are unlikely. Carotid artery injury occurs at a rate of approximately 0.1%, whereas permanent postoperative visual decline occurs at a rate of approximately 0.5%. Postoperative CSF rhinorrhea is seen in approximately 1–2% of cases and may lead to meningitis if

untreated. Approximately 5% of patients report persistent sinus disease postoperatively.

CONCLUSION

Transsphenoidal surgery remains the therapy of choice for nonfunctioning adenomas, especially in cases of optic chiasm compression or hormonal insufficiency. Secretory tumors, except for prolactinomas, require surgical therapy, although the treatment of acromegaly is in flux.

Figure 1 Binding of the five isoforms of PDGF to the three dimeric receptor complexes. The antiparallel arrangement of subunits in PDGFs and the key features of the receptors (i.e., five extracellular Ig-like domains and the split tyrosine kinase domain) are schematically illustrated, together with binding specificities.

Ligand–Receptor Interactions

The signaling ligand–receptor complex is composed of one PDGF dimer and a dimeric receptor complex, and it is stabilized by ligand–receptor and receptor–receptor interactions (Fig. 2). Both subunits of the ligand dimer contribute to the two binding epitopes. Amino acid residues in all three loops participate in receptor interactions. The receptor regions involved in ligand interactions are incompletely defined but appear to predominantly involve Ig domains 2 and 3. In addition to being kept together by the divalent ligand, the receptor dimer is stabilized by homophilic Ig domain 4-mediated receptor–receptor interactions.

PDGF RECEPTOR SIGNALING

PDGF Receptor Activation

In the absence of ligands, PDGF receptors occur as monomeric forms with low basal tyrosine kinase activity, caused by a conformation unfavorable for ATP binding. Ligand binding and subsequent receptor dimerization lead to tyrosine kinase activity by stimulating transphosphorylation of the regulatory tyrosine in the activation loop of the kinase domain (Fig. 2). This is followed by phosphorylation of multiple tyrosine residues in the kinase insert, the juxtamembrane region, and the carboxyl-terminal tail region (Fig. 2).

Intermediate Signaling

Phosphorylated tyrosine residues of PDGF receptors act as docking sites for downstream signaling molecules that, through SH2 domains, bind to PDGF receptors in a site-specific manner (Fig. 2). Signaling proteins that bind to PDGF receptors include signal transduction proteins, docking proteins, and transcription factors.

Well-characterized signal transduction proteins that bind directly to phosphorylated PDGF receptors include the tyrosine kinase c-Src, the protein tyrosine phosphatase SHP-2, phospholipase C- γ (PLC- γ), the Ras activator and exchange factor Grb2/Sos1, and the p85/p110 class I phosphoinositide-3-kinase (PI-3-kinase). Activation of signaling downstream of these enzymes, upon SH2 domain-mediated receptor binding, occurs through different mechanisms, including induction of conformational changes (c-Src), tyrosine phosphorylation (PLC- γ), and translocation (Grb2/Sos1 and PI-3-kinase).

Shc, Nck, Crk, and Grb7 are docking proteins that associate with PDGF receptors. Through SH3 domains or other protein–protein interaction domains, these proteins act as scaffolds for the creation of multiprotein signaling complexes. The composition of these complexes and their role in receptor signaling remain to be fully elucidated.

Figure 2 Schematic illustration of PDGF receptor activation. Ligand binding to Ig-like domains 2 and 3 of the receptors leads to formation of a signaling complex composed of one PDGF molecule and two receptor molecules. The complex is stabilized by ligand–receptor and Ig domain 4-mediated receptor–receptor interactions. Receptor dimerization is associated with phosphorylation of a regulatory tyrosine (asterisks) in the kinase domain and tyrosines outside the kinase domain that act as binding sites for signaling proteins.

Members of the STAT family of transcription factors also bind directly to PDGF receptors. After receptor binding, these factors undergo tyrosine phosphorylation, dimerization, and translocation to the nucleus, where they act as transcriptional regulators.

Ligand-induced receptor activation thus leads to an array of biochemical responses, including the production of various second messengers and concomitant activation of multiple signal transduction pathways. Ultimately, these events are translated into changes in gene expression and cellular responses.

Cellular Responses

PDGFs were originally purified and characterized based on their ability to induce a proliferative response. Subsequent studies have revealed additional cellular responses to PDGF receptor activation, including the ability of PDGF to induce migration toward increasing PDGF concentrations. PDGF receptor activation also confers reduced sensitivity to apoptotic stimuli and thus acts as a survival signal. *In vitro* cellular responses to PDGF, where the physiological counterpart is less understood, include the formation of specific actin microfilament structures (e.g., circular ruffles) and contraction of three-dimensional collagen gels.

Numerous efforts have been made to link individual signaling pathways with different cellular responses. Although this approach initially appeared to be promising, accumulating evidence indicates that extensive cross-talk between different biochemical pathways takes place, which can occur in a cell type-specific manner. Thus, induction of a particular cellular response is dependent on the balance within a network of signaling components rather than activation of a specific biochemical pathway.

DEVELOPMENTAL AND PHYSIOLOGICAL ROLES OF PDGF

Genome sequencing projects have allowed systematic characterization of the PDGF system in model organisms. In *Caenorhabditis elegans*, there are four VEGF receptor/PDGF receptor homologs and one putative ligand. In contrast, the *Drosophila melanogaster* genome encodes only one receptor gene but three ligand genes. Interestingly, many cell types, e.g., glial cells, cells of the gonads, and cells of the gut, which in vertebrate development involve PDGF receptors, appear to be controlled by the VEGF receptor/PDGF receptor in *D. melanogaster*.

PDGF α -Receptor-Dependent Developmental Processes

PDGF α -receptor knockout mice die between E8 and E16 with multiple mesenchymal defects, including abnormal somite patterning, cleft palate, and skeletal malformations. PDGF A-chain knockouts survive until perinatal age but show defects of the development of alveoli, intestinal villi, hair follicles, and the testis, all of which can be explained by defects in epithelial–mesenchymal interactions. Also, hypomyelination, caused by defects in oligodendrocyte development, occurs in PDGF A-chain $-/-$ mice. The milder phenotype of the A-chain knock-out mice, as compared to the α -receptor $-/-$ mice, is probably due to partial rescue of PDGF α -receptor signaling, in these mice, by other PDGF isoforms.

PDGF β -Receptor-Dependent Developmental Processes

The best characterized phenotypes of PDGF-B and PDGF β -receptor knockout mice are defects in kidney development and aberrations in vascular development. The kidney defects consist of incomplete development of capillary tufts in the glomeruli. The mesangial cells, which normally surround the glomerular capillaries, are primarily affected by receptor depletion. The vascular defects, involving dilated, ectopic, and unstable capillaries, are caused by a reduction in pericyte coverage. The defects occur with varying severity in different organ, suggesting tissue-specific PDGF dependence for pericyte recruitment.

Physiological Functions of PDGF

Wound healing involves several steps that are stimulated by PDGF, including recruitment and proliferation of fibroblasts and smooth muscle cells and the production of extracellular matrix components. Topical application of PDGF, or PDGF gene transfer, improves wound healing in animal models. Beneficial effects of recombinant PDGF-BB have also been demonstrated in clinical trials.

PDGFs may also act as autocrine negative regulators of platelet aggregation and thus exert a negative feedback function in thrombosis formation. Additional, less characterized functions of PDGF in the vascular system include the control of vessel tonus, which can involve either relaxation or constriction of blood vessels.

Finally, a novel function of PDGF receptor signaling in the control of tissue homeostasis was revealed

by animal studies showing that local application of PDGF-BB in loose connective tissue increases interstitial fluid pressure (IFP). Liquid transport and convection-driven transport of macromolecules between vessels and extracellular compartments are partially controlled by the pressure difference between capillaries and the interstitial fluid. The effects of PDGF receptor on IFP thus imply a function of PDGF receptor signaling in the control of transvascular flow of water and macromolecules.

Isoform-Specific Functions of PDGF Receptors

The major differences between the phenotypes of PDGF α - and β -receptor knockout mice can largely be explained by differences in the expression patterns of the two proteins. However, intrinsic differences in signaling between the two receptors also occur, as exemplified by isoform-specific differences in the ability to stimulate chemotaxis. *In vivo* support for this notion was also provided by elegant experiments in which two complementary mice strains were generated, in which the intracellular domains of the two PDGF receptors were exchanged. In this setting, the intracellular α -receptor domain failed to fully mediate the vascular development normally executed by the β -receptor.

PDGF AND DISEASE

PDGF Antagonists

As discussed later, PDGF receptor signaling is implied as a causative factor in numerous pathological processes. This has stimulated development of various types of PDGF antagonists that act by interference with ligand binding, receptor dimerization, or tyrosine kinase activity. Prototypic examples of the first type are inhibitory antibodies binding to ligand or receptor. Interference of receptor dimerization has been achieved with soluble Ig domain 4 or antibodies targeting this domain. Finally, low-molecular-weight kinase inhibitors with varying degrees of specificity for PDGF receptors have been developed. STI571/Glivec/Gleevec/Imatinib is the best characterized of this class of compounds. In addition to PDGF receptors, STI571 also inhibits the Abl-kinase and the c-Kit/CSF-1 receptor.

PDGF and Cancer

The discovery in the early 1980s that the transforming protein of the simian sarcoma virus was a homologue

of the PDGF B-chain fuelled studies on the association between PDGF receptor signaling. The association between cancer and PDGF initially focused on PDGF autocrine stimulation of tumor cell growth. PDGF receptor signaling that contributes to the recruitment and function of tumor stroma and to tumor angiogenesis is receiving increased interest.

Different genetic mechanisms for the activation of PDGF receptor signaling, and subsequent autocrine growth stimulation, have been described. In subsets of glioblastoma multiforme, PDGF α -receptors are amplified. Activating point mutations in the same receptor occur in a fraction of gastrointestinal stromal tumors. Translocations leading to novel ligand-independent fusion receptors, involving the α - or β -receptor in idiopathic hypereosinophilic syndrome and chronic myelomonocytic leukemia, respectively, have also been described. Finally, genetic activation of the PDGF B-chain through fusion to the highly transcribed collagen gene is a characteristic feature of dermatofibrosarcoma protuberans. Successful use of PDGF antagonists for treatment of all these diseases, with the exception of glioblastoma multiforme, has been reported. There are also other solid tumors, such as soft tissue sarcomas and most glioblastomas, for which the basis for the aberrant coexpression of PDGF and PDGF receptors is unknown.

Regarding tumor angiogenesis, it is clear that a large majority of solid tumors express PDGF receptors on pericytes. Studies using animal cancer models also indicate that the extent of tumor vessel pericyte

coverage is dependent on paracrine stimulation of PDGF receptors on pericytes by tumor cells or endothelial cells. These findings have potential clinical implications since studies on antiangiogenic agents suggest that depletion of pericytes increases the sensitivity of tumor capillaries to antiendothelial agents such as VEGF antagonists. This led to the notion, which has been experimentally confirmed, that cotreatment with pericyte-targeting PDGF antagonists and antiendothelial agents will exert a more potent antiangiogenic and therapeutic effect.

The tumor stroma, mostly composed of cancer-associated fibroblasts and extracellular matrix, is emerging as a tumor compartment with important functions in tumor growth and tumor physiology. In contrast to most normal connective tissue, tumor stroma is characterized by expression of ligand-activated PDGF receptors. Studies in animal models with PDGF receptor expression restricted to tumor stroma have shown that inhibition of PDGF receptor expression is associated with an increased tumor uptake of systemically delivered standard chemotherapeutic agents (Fig. 3). Interestingly, this increased tumor drug uptake, which is not paralleled by increased uptake in other organs, is associated with an enhanced antitumor effect of standard chemotherapy such as taxol or 5-fluorouracil. The mechanism(s) underlying this effect is not fully understood, but available data indicate a role for the PDGF antagonist-induced reduction in tumor IFP as a causally related effect of PDGF receptor inhibition (Fig. 3).

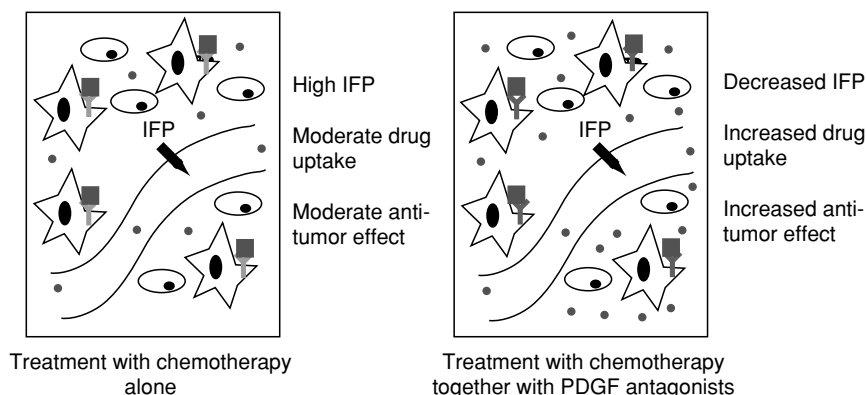

Figure 3 PDGF receptor inhibition in tumor stroma cells of experimental tumors is associated with increased tumor drug uptake and enhanced therapeutic response. In tumor models with expression of ligand-activated PDGF receptors on fibroblasts (stars), cotreatment with PDGF antagonists results in decreased tumor interstitial fluid pressure (IFP), an associated increase in tumor drug uptake, and enhanced antitumor effects of chemotherapy.

PDGF in Atherosclerosis and Restenosis

Smooth muscle cell proliferation and migration are hallmarks of atherosclerosis as well as vessel obstruction following percutaneous transluminal angioplasty, bypass grafting, or transplantation. Up-regulation of PDGF receptors has been demonstrated in association with these pathological processes. Since PDGF is known to stimulate proliferation and chemotaxis of smooth muscle cells, PDGF antagonists have been used in a number of animal models; the results are encouraging.

Moderate inhibitory effects on fibrous cap formation in apolipoprotein E-deficient mice and on atherogenesis in cholesterol-fed rabbits occur after treatment with PDGF antagonists. However, studies with extended follow-up indicate that treatment with PDGF blockers in these models delays rather than prevents lesion formation.

Also, in rabbit, swine, and primate models of restenosis, beneficial effects on intima formation have been demonstrated after PDGF receptor inhibition. These findings have been confirmed in a swine model of stent-induced restenosis. These studies thus provide clear evidence that PDGF receptor stimulation of smooth muscle cells contributes to lesion formation in these models. Caution is warranted since there is also evidence from studies with longer follow-up that the effects are transient, with lesions reoccurring after withdrawal of treatment.

PDGF and Fibrotic Disease

Evidence suggests a causal role of PDGF receptor signaling in proliferative glomerulonephritis. PDGF receptor up-regulation is a histological feature of the disease. Also, forced expression of PDGF by gene transfer, or infusion of PDGF, induces kidney fibrosis in animal models. Finally, using PDGF receptor kinase inhibitors or PDGF neutralizing agents in the Thy-1 model of nephritis, a few studies have provided encouraging results, demonstrating a reduction in mesangial cell proliferation and matrix accumulation.

Lung and liver fibrosis are additional examples of diseases for which several observations indicate a role of PDGF receptor signaling in the fibroproliferative aspects of the disease; up-regulation of PDGF receptors occurs in lesions, forced overexpression of PDGF stimulates disease development, and animal model studies with PDGF inhibitors demonstrate a partial inhibition of the disease process.

PERSPECTIVES

There are a few key issues for future studies on the mechanism of action of PDGF, its role in disease, and its potential as a drug target. More detailed knowledge about the ligand–receptor interactions should assist in understanding ligand–receptor specificity and potentially help in designing isoform-specific antagonists. The determination of the structure of a PDGF ligand–receptor is therefore highly warranted. In the context of signaling mechanisms, the foundation concerning mediators of receptor signaling has been laid. Development of the current models to include spatial and temporal information about pathway activation is likely to increase understanding of how combinations of biochemical signals ultimately lead to changes in gene expression and to different cellular responses.

The role of PDGF in development and physiological processes has been greatly enhanced by studies of knockout phenotypes but has also been hampered by the embryonal or perinatal lethality associated with these genotypes. It can be predicted that analyses of tissue-specific and conditional knockout mice will provide additional information.

Recent clinical results with PDGF antagonists in autocrine malignancies have established PDGF receptors as “druggable” targets for disease management. These studies should stimulate further experimental and clinical use of PDGF antagonists, alone or in combination, in which PDGF receptors on pericytes and cancer-associated fibroblasts act as main targets. Improved methods for monitoring PDGF receptor activation and expression in tissue sections are highly warranted for optimal exploitation of the PDGF system as a cancer drug target. Also, it is likely that the availability of multiple isoform-specific antagonists will aid in reducing side effects and in allowing second-line strategies in case of molecular resistance. Finally, the transfer of the findings in animal models of vasculoproliferative diseases and fibrosis models from experimental to clinical settings is much awaited.

granulosa cells. More granulosa cells with FSH receptors mean further increases in granulosa cell aromatase activity and further amplification of estrogen production, culminating in an LH surge and ovulation.

The polycystic ovary is characterized by increased intraovarian androgen concentrations. The increased androgen content interrupts follicle development through inhibition of FSH receptor recruitment and aromatase activity. Estrogen production is impeded and follicular growth stops before maturity and ovulation can be achieved. A pattern of hyperandrogenism and anovulation is thus established. *In vitro* studies have demonstrated that granulosa cells from PCOS ovaries function normally if adequate FSH levels are supplied and virtually all PCOS patients can be induced to ovulate, if enough exogenous FSH is supplied. The problem thus is one of inadequate FSH action at the level of the follicle and probably represents a deficiency of FSH or a blockade of FSH action by intraovarian regulators.

DIAGNOSIS

Many diagnostic criteria have been developed, but no one item has been shown to be indispensable. Indeed, there is still substantial discussion as to what elements are crucial for the diagnosis. Evidence of peripheral hyperandrogenism (hirsutism), irregular menses, and chronic anovulation in the absence of other causes such as hypothyroidism and hyperprolactinemia constitutes the classic clinical presentation. Some, however, have argued that the appearance of multiple small cysts within the cortex of the ovary (representing incomplete maturation of follicles) is enough to make the diagnosis, even in the presence of normal menstrual function. Most authorities, however, advocate that evidence of menstrual dysfunction and hyperandrogenism should be present. Obesity is common, but in some studies as many as 50% of women with PCOS are not obese.

Biochemical markers include elevated serum LH levels, an elevated LH:FSH ratio (at least 2:1), elevated circulating androgens (total and free testosterone, androstenedione, dehydroepiandrosterone sulfate), decreased sex hormone-binding globulin, and evidence of hyperinsulinemia.

TREATMENT

The initial treatment of Stein and Leventhal, that of bilateral ovarian wedge resection, was the only available treatment for polycystic ovary syndrome until the

1960s. That procedure is theorized to produce a sudden decrease in the concentration of intraovarian androgens through the removal of ovarian stromal tissue. The lower levels of intraovarian androgens release the follicle from interference with FSH action and follicle development and thus ovulation can occur. Due to concerns about postoperative adhesion formation and subsequent impairment of fertility, coupled with the introduction of effective medical treatments, the procedure is rarely performed anymore. Instead, treatment varies considerably depending on the individual patient's desires and most troubling symptoms.

For many years, PCOS was regarded by many as a "nuisance disease" with inconvenient symptoms, but presenting no major health consequences. As a result, treatment was directed at managing the most bothersome symptoms, such as irregular menstrual bleeding, hirsutism, and infertility. In women whose only concern was their irregular menstrual cycles, progestins were supplied to make up their deficiency of the hormone progesterone in the anovulatory state. In those who wished pregnancy, ovulation was induced with medications such as clomiphene citrate or injections of FSH. Those presenting with hirsutism and other signs of peripheral hyperandrogenism, such as acne, were given oral contraceptives and agents that blocked androgen action at the level of the hair follicle. As the relationship between hyperinsulinemia and PCOS began to be noted, a view of PCOS as a systemic disease with long-term health consequences, including increased cardiovascular risk and development of diabetes, emerged. It has become common for women with PCOS to routinely undergo screening for glucose intolerance and insulin resistance. Where these conditions are present, treatment with insulin-sensitizing agents, such as metformin, is often instituted.

NEW DEVELOPMENTS—THE INSULIN CONNECTION

For some time, it has been observed that women with polycystic ovary syndrome have a higher incidence of long-term health problems than do normally menstruating women. The incidence of non-insulin-dependent diabetes mellitus is increased as is cardiovascular disease. Increasing attention has been given to the observation of insulin resistance in a large proportion of women with PCOS (up to 80% by some estimates). The elevated levels of insulin in these women that are necessary to maintain normal serum glucose levels cause direct stimulation of androgen production in the ovary, thus leading to the hyperandrogenism

characteristic of polycystic ovary syndrome. As insulin promotes fat storage and inhibits fat release from adipose tissue, these elevated insulin levels may play a role in promoting obesity, which, in turn, promotes further insulin resistance.

Findings of primary defects in the insulin receptor may explain much of the familial clustering of polycystic ovaries. Observed abnormalities of the insulin receptor in PCOS include excessive autophosphorylation of serine residues rather than threonine residues as is the case with normal insulin receptor function. Excessive serine autophosphorylation inhibits insulin receptor action by interfering with the translocation of intracellular glucose transporters to the cell surface, thus decreasing glucose uptake in those cells. Administration of medications designed to increase insulin sensitivity, such as metformin, have proven very useful in improving the hormonal and metabolic abnormalities of the syndrome and are rapidly becoming a primary treatment modality for PCOS.

to healthy controls. The results of a retrospective cohort follow-up study showed an increased prevalence of hypertension in women with PCOS. Another study of similar design documented an increased prevalence of coronary artery disease. However, the number of patients in both studies was very small (33 and 28 patients with PCOS, respectively).

Pierpoint *et al.* evaluated cardiovascular mortality in women with PCOS. A total of 786 patients diagnosed in the United Kingdom between 1930 and 1979 were traced from hospital records. The standardized mortality ratio was then calculated based on 59 deaths. The study found a higher mortality from diabetes mellitus but no increased average mortality from circulatory disease. However, the patients were included only on the basis of histopathology and surgical records. These criteria cannot be considered sufficient for the diagnosis of PCOS. Moreover, it can be assumed that a successfully performed procedure (wedge ovarian resection) can diminish some of the endocrine and metabolic disturbances and thus also alter the later risks.

In conclusion, there is no doubt that women with PCOS cluster many of the proven risk factors for cardiovascular disease. The syndrome is characterized by an increased prevalence of hyperinsulinemia, dyslipidemia, impaired glucose tolerance, and type 2 DM. In small groups of patients, atherosclerotic changes were found more often. Although evidence of an increased prevalence of coronary artery disease is low, on the basis of available data, women with PCOS should be considered a risk group in the population.

ENDOMETRIAL CANCER

An increased risk of endometrial cancer is often presented as one of the health consequences of PCOS. Epidemiological studies have repeatedly found an increased prevalence of obesity, irregular menstrual cycles, amenorrhea, infertility, or hirsutism in patients with endometrial cancer. In a study evaluating 110 case-control pairs ages 45 years or less, current weight, amenorrhea, and infertility were associated with an increased risk. However, a large case-control Danish study of 237 cases and 538 controls under 50 years of age was not able to confirm BMI or amenorrhea as risk factors after careful adjustment for other confounders.

Evidence regarding the increased risk of endometrial cancer in PCOS patients is still weak. Published papers are mostly case series and include only a small number of cases (8–12). After careful evaluation, it is

found that most patients are obese or even extremely obese. One of the main arguments is the study by Coulam *et al.* in 1983, which evaluated the prevalence of neoplasia in 1270 women with chronic anovulation syndrome. An increased risk was found only for endometrial cancer; however, the relative risk reached only 3.1 (95% CI 1.1–7.3). It must be emphasized that this was not a case-control study, but the results were compared to the expected numbers based on an age-specific database from a certain region. Moreover, the calculation was made on the basis of only 5 observed and 1.59 expected cases. No prospective study has been published yet.

Unopposed estrogens due to long-term anovulation are presented as a principal mechanism of development of endometrial cancer in PCOS patients. However, it does not correspond to the finding of a thin endometrium in the majority of patients or the low incidence of dysfunctional uterine bleeding, which should be the result of endometrial hyperproliferation. It is also improbable that hyperandrogenemia would play an important role. A dose-dependent anti-estrogenic effect of androgens on the endometrium has been found in animals. It is thus likely that other mechanisms are involved. It has been demonstrated *in vitro*, on long-term cultures of human endometrial cells, that insulin, insulin-like growth factor-I (IGF-I), and IGF-binding proteins influence endometrial differentiation. Moreover, a greater number of binding sites for IGF-I were identified in cell cultures of endometrial cancer. If hyperinsulinemia is the main mechanism increasing the risk of endometrial cancer in PCOS patients, primarily obese women and women with insulin resistance would be at risk.

PCOS women cluster many of the risk factors for endometrial cancer. Although evidence is weak, it can be assumed that those patients will have an increased risk. However, it is not certain whether this risk applies only to certain subgroups of patients (obese women, patients with insulin resistance) or whether PCOS presents an independent risk. Hyperinsulinemia could play a significant role.

BREAST CANCER

In comparison to the normal population, women with PCOS have a lower number of full-term pregnancies and a higher age at first pregnancy. Both of these parameters are known risk factors for the development of breast cancer. In addition to the consequences of infertility, other mechanisms may play a role. A common finding in obese and lean women with PCOS is hyperinsulinemia. Some experimental data

prove the important role of insulin and insulin-like growth factor in the development and proliferation of breast cancer.

Only a small number of authors have evaluated the risk of breast cancer in women with PCOS. Unfortunately, none of the published studies have fulfilled the criteria of level of evidence I or II. In addition, their inadequacy lies either in the small number of identified cases or in the insufficient diagnosis of PCOS based on self-reports by the patients.

In 1983, Coulam *et al.* evaluated the medical records of 1270 patients, in whom chronic anovulation was diagnosed between 1935 and 1980 at the Mayo Clinic. An increased risk of breast cancer was found only in postmenopausal women [relative risk (RR) 3.6; 95% confidence interval (CI) 1.2–8.3], whereas the total relative risk was not increased (RR 1.5; 95% CI 0.8–2.6). However, these results were based on only 12 identified cases. Furthermore, the observed cases were compared to the expected numbers using age-specific incidence rates for 1967 in Connecticut. Seven years later, Gammon and Thompson published the results of a case-control study analyzing the association between infertility and breast cancer in 4730 cases and 4688 controls. The authors did not find an increased risk in infertile women [odds ratio (OR) 1.01; 95% CI 0.89–1.15] or in the subgroup of infertile women with ovarian pathology (OR 0.75; 95% CI 0.48–1.24), after controlling for age, age at first delivery, and parity. In addition, 1 year later, on the basis of the same results, the authors reported a breast cancer age-adjusted odds ratio of 0.52 (95% CI 0.32–0.87) in women with PCOS. The main drawback of the study is the identification of PCOS on the basis of a self-reported history of physician-diagnosed polycystic ovaries. This also corresponds to the unexpected low prevalence of PCOS between cases and controls (0.49% versus 0.94%). Another prospective study of a cohort of 34,835 women followed for over a 6-year period was also based on self-reports of PCOS cases. In this series, no increased risk of breast cancer was documented (RR 1.3; 95% CI 0.7–2). Contributing to the discussion are the results of the above-mentioned study published by Pierpoint *et al.*, which focused on mortality in women with PCOS. No significant increase in standardized mortality ratio (SMR) for breast cancer was found (SMR 1.48; 95% CI 0.79–2.54).

If the known risk factors for breast cancer, such as the number of full-term pregnancies and age at first pregnancy, are evaluated separately, on the basis of available data PCOS should not be considered an independent significant risk factor for breast cancer.

| Partington's syndrome |

NORMAL VARIANTS

Familial or Genetic Tall Stature

This includes tall, otherwise normal children, who mature at the normal rate and attain puberty and a tall adult height at the usual age.

Tall Normal Girls

There is usually no difficulty in establishing the diagnosis of a tall, normal girl, by the normal history and physical findings, the normal pubertal development, the lack of dysmorphic features, and the family history of tall stature.

One or both of the parents and other members of the family are often tall. Genetic tall stature is believed to be determined by multiple genes, but the manner whereby these genes result in tall stature has not been determined. Patients with tall stature are normal at birth; an increased rate of linear growth is usually evident during the first 2 years and tall stature is obvious by the age of 3 or 4 years. Subsequently, growth continues at a rate slightly greater than normal and the child remains between 2 and 4 SD above the mean for height for age. Timing of puberty is normal, as is the time of attainment of the tall adult

Table III Molecular Basis and Etiopathogenesis of Overgrowth (Established or Suggested)

| Disorder | Cause | Molecular basis |
|--|--|---|
| Extra growth genes | | |
| Klinefelter's syndrome (47,XXY) | Extra growth gene SHOX | Extra X |
| Trisomy X (47,XXX) | Extra growth gene SHOX | Extra X |
| Males 47,XYY | Extra Y-specific growth control gene | Extra Y |
| Excessive GH secretion (pituitary tumors) | | |
| Sporadic | | |
| Gigantism/acromegaly | Mutations in $G_{\alpha s}$ protein gene | 20q12–q13.2 |
| | LOH (allelic loss) of 11q.13 (no mutations of MEN1 gene) | 11q13 |
| | Overexpression of PTTG | |
| McCune-Albright syndrome | Mutations in $G_{\alpha s}$ protein gene | 20q12–q13.2 |
| Familial | | |
| MEN1 | MEN1 gene mutations and LOH of 11q.13 | 11q13 |
| Acromegaly/gigantism | LOH (allelic loss) of 11q.13 (no mutations of MEN1 gene) | 11q13 |
| Extra growth factors | | |
| IGF-II | | |
| Beckwith-Wiedemann syndrome | Overexpression of IGF-II | 11p15.5 |
| H19 silencing | Overexpression of IGF-II | 11p15.5 |
| Simpson-Golabi-Behmel syndrome | Modulation of IGF-II | Mutations |
| | Deficiency of glypican 3 | GPC-3 gene |
| | | Xq26 |
| IGF-I–insulin | | |
| Obesity | Hyperinsulinism—free IGF-I | |
| Lipodystrophy | Hyperinsulinism | |
| Infant of diabetic mother | Hyperinsulinism | |
| Infant giants with neonatal hypoglycemia | Hyperinsulinism | Various |
| Extra growth factors—receptors | | |
| Partington's syndrome | Extra FGFR3 gene (?) | Duplication, 4p16.3 |
| Deficiency of factors needed to arrest growth | | |
| Aromatase deficiency | Estrogen deficiency | Mutations in Cyp19 gene, 15q21.1 |
| Estrogen receptor deficiency | Estrogen deficiency | Mutations of estrogen receptor gene, 6q25.1 |
| Hypogonadism | Estrogen deficiency (secondary) | Primary—various |
| Deficiency of factors needed to prevent elongation of bones | | |
| Marfan's syndrome | Mutation of fibrillin gene | FBN1, 15q21.1 |
| Beals' syndrome (CCA) | Mutation of fibrillin gene | FBN2, chromosome 5 |
| Homocystinuria | Abnormal collagen | |
| | Mutations of CBS gene | 21q21 |
| Alterations of genes—involved in regulation of cell cycle, growth, and tumor suppression | | |
| Bannayan-Riley-Ruvalcaba syndrome | PTEN gene mutations | 10q23 |
| Cowden's syndrome | PTEN gene mutations | 10q23 |
| Sotos' syndrome | NSD1 gene mutations | 5q35 |
| Weaver's syndrome | NSD1 gene mutations | 5q35 |

Note. CBS, cystathionine β -synthase; CCA congenital contractural arachnodactyly; Cyp19, cytochrome P450 19-aromatase; FBN1 or 2, fibrillin gene 1 or 2; FGFR3, fibroblast growth factor receptor 3; GPC-3, glypican 3; $G_{\alpha s}$, guanine nucleotide-binding protein 1 stimulatory α -chain; IGF-I or -II, insulin-like growth factor-I or -II; LOH, loss of heterozygosity; MEN1, multiple endocrine neoplasia type 1; PTTG, pituitary tumor-transforming gene; NSD1, nuclear receptor-binding SET [where SET denotes SU(VAR)3-9,E(Z)trithorax] domain protein 1; PTEN, phosphatase and tensin homologue in chromosome 10; SHOX, short stature homeobox-containing gene.

height. The prediction of adult height is based on the bone age and height at the time.

Tall stature has become more acceptable in women than it was previously and consultation to curtail adult height has become much less frequent than in the past. Estrogens in large amounts, 3 to 10 times the replacement dose, have been proven effective in curtailing adult height. Bromocriptine does not appear to be effective. Octreotide, the long-acting somatostatin analogue (SMS-201-995), may be an alternative, but experience with this drug is limited.

The estrogen preparations most frequently used have been conjugated estrogens (7.5 to 10 mg) and ethinyl estradiol (0.1 to 0.3 mg) daily, without interruption. A progesterone-like compound should be given in cycles for 10 days every month, to induce menstrual periods and prevent metrorrhagia hemorhagica. Estrogen treatment increases GH secretion, but sharply decreases the rate of growth, partly as a result of a decrease in IGF-I levels. In addition, the bone age accelerates at an average of 1.8 years per year of treatment, with a range from 1.0 to 2.5 years. Treatment is usually begun after the age of 11 years and after the spontaneous onset of puberty.

The authors of this article have offered treatment to girls with a predicted adult height in excess of 178 or 180 cm. Treatment is also given to girls who are taller than 178 cm, when first seen, with a growth potential of another 2.5 cm or more, regardless whether they are pre- or postmenarcheal.

Duration of treatment has ranged from 8 months to 3 years.

The height reduction depends on the bone age and potential growth at the onset of treatment and may range from 2.5 cm in a girl with a bone age of 14 years to 14.0 cm in a girl with a bone age of 10½ or 11 years.

Grave side effects are quite rare. The main concern is the potential risk of thrombosis. In a survey of 904 cases, there was only one thromboembolic episode in a girl on treatment, after a crushing foot injury. Two others cases of thrombosis of the femoral vein have been reported: one occurred after a febrile viral disease, requiring bed rest for 4 days, and another occurred after arthroscopy of the knee with immobilization.

There is no evidence for an increased risk of endometrial, cervical, ovarian, or breast cancer with contraceptives in young women. There is no evidence that fertility is affected.

Because of the potential risk of thrombosis, it is not a treatment to be promoted, but it should be offered, when justified, because of the great benefit for some girls. This treatment is applicable and could

be helpful to other patients with overgrowth disorders (i.e., Marfan's syndrome, Sotos' syndrome, trisomy X, androgen resistance). It is contraindicated in patients with homocystinuria.

Tall Normal Boys

Tallness in boys is better accepted by society and by the individual than it is in girls and rarely is medical attention sought. The pattern of growth and development of tall normal boys is similar to that mentioned for tall normal girls, as is the family history.

There is usually no difficulty in establishing the diagnosis of a tall normal boy by the normal history and physical findings, the normal pubertal development, the lack of dysmorphic features, and the family history of tall stature. A bone age and a prediction of adult height should be obtained.

Treatment with long-acting testosterone esters can reduce the adult height. Experience with such treatment is limited and the need to treat normal tall boys is rare. Treatment has been given to tall normal boys with a predicted adult height usually in excess of 198 cm. The preparations most frequently used have been testosterone enanthate or cypionate at a dose of 200 mg every 2 weeks for young adolescents and 500 mg every 2 weeks for older adolescents. The growth velocity increases, particularly in the first 6 months, but the bone age advances faster than the height, at an average of 1.8 years per year of chronological age, and as a result, adult height is reduced. The reduction in height depends on the bone age at the onset of treatment and ranges from 3.0 ± 2.29 cm in those with a bone age higher than 15 years at the beginning of treatment to 8.0 ± 5.4 cm in boys with a bone age of 12 to 14 years. It could be more, however. In a 12-year-old boy with a predicted height of 203 cm and a bone age of 9½ years, treated with testosterone enanthate (200 mg every 2 weeks) for 1½ years, the bone age advanced 6 years (4 years per year of chronological age) and the reduction of height was 21.5 cm. The mechanism of action is related to the anabolic and androgenic effects of testosterone, particularly in hastening bone maturation. This latter effect is probably the result of estrogen derived from testosterone. The side effects include weight gain, partly as a result of sodium retention at the initiation of treatment and partly from the protein anabolic effect. Gynecomastia occurs in some patients. During treatment, the testes do not grow in the youngest boys and decrease in volume in the older boys, from volumes of 10–12 to 8 cc, on average, at the end of treatment. There is oligo- and azoospermia. After treatment, the testicular volumes return to normal in the course of 1 to 2 years. Testicular function

is reversible by 1 year in the majority of patients, but recovery is slow in some patients, lasting 3 to 5 years. Aggravation of acne is a side effect reported in 30 to 60% of boys. Studies of subjects 10 years after termination of treatment showed normal testicular function. This treatment could also be offered to patients with other overgrowth conditions, such as Klinefelter's syndrome (XXY), XYY males, eunuchoidism (for virilization as well as for curtailment of height), and Marfan's syndrome, if they so desire.

Bromocriptine decreases the rate of growth somewhat, but does not advance the bone age and it is uncertain whether adult height will be reduced significantly.

Octreotide has also been used for treatment of tall boys and appears to be effective. The concerns are the cost, the need for two to three injections a day, and the risk of gallstone formation in 27% and bile sludge without stones in 22% of the patients receiving octreotide for 12 months or longer.

Familial Rapid Maturation

These are normal children who may be tall in childhood, who have an advanced bone age corresponding to their height age, and who attain pubertal development and cessation of growth earlier than the usual age. The adult height is within the normal range. Family history usually reveals a similar growth pattern in one of the parents or in other members of the family. There is no need for treatment.

OVERNUTRITION (OBESITY)

Obese children tend to be taller and grow faster than their lean peers during childhood and early adolescence. They do have advanced skeletal maturation, a blunted pubertal growth spurt, when compared with lean subjects, and normal adult heights. Longitudinal growth data on children who develop obesity during childhood showed a distinct tendency for height gain to accelerate coincident with or after the onset of excessive weight gain. Many of the tall obese children follow normal percentile lines for height, but some have excessive growth rates during infancy or childhood, reaching heights of 3 or 4 SDS, and other possibilities associated with abnormal excessive growth need to be considered. The diagnosis is based on clinical grounds and on the exclusion of other possible causes of overgrowth.

The tall stature and increased growth velocity associated with obesity are probably mediated by insulin and IGF-I. Growth hormone secretion is low.

Studies of patients with moderate and severe obesity and controls clearly showed an increase in serum insulin in males and females, a decrease in insulin-like growth factor-binding protein-1, and an increase in the free IGF-I. Thus, the increased growth velocity of obese children is most likely the result of the effect of hyperinsulinemia and increased free IGF-I on the insulin and IGF-I receptors.

The advisable treatment is to place the patient on a moderate calorie-restriction diet, until he or she reaches an ideal body weight, and then liberalize the caloric intake to resume normal growth velocity and weight gain.

CHROMOSOMAL ABNORMALITIES

Trisomy X (47,XXX Females)

Trisomy X should be included in the differential diagnosis of tall girls. Patients with trisomy X tend to be tall. Forty-two percent of the girls with trisomy X between the ages of 6 and 13 years are over the 90th percentile for height. Adolescent and adult 47,XXX females are tall, with heights generally at or above the 90th percentile (171 cm (67.32 in.)). They have long legs. Most of the patients have a normal phenotype, affected children are not recognized, and the condition is underdiagnosed. Trisomy X is the most frequent X chromosomal abnormality, occurring in 1 of 1000 newborn females; it is two to three times more frequent than Turner's syndrome. Some patients may have minimal dysmorphic features (clinodactyly, syndactyly). Most of the patients have normal sexual development, menarche, and ovarian function, but some may have secondary amenorrhea and premature ovarian failure. Primary amenorrhea and ovarian dysgenesis have been reported. The IQ may range from 55 to 115 and approximately one-half to two-thirds of patients may have an IQ that is slightly below normal.

The cause for the tendency to tall stature is probably the extra X chromosome. Many observations have clearly indicated that Xp deletions, particularly the lack of the tip of Xp, leads to short stature and that additional X chromosomes can compensate for that loss. In 1997, Rao *et al.* isolated a homeobox-containing gene from PAR1 that they named SHOX (for short stature homeobox-containing gene). The evidence suggests that deletions of the tip of Xp with the absence of SHOX could result in short stature and that additional inactivated X chromosomes, with active growth genes (SHOX) escaping inactivation, could cause tall stature, such as in Klinefelter's syndrome and trisomy X.

The presence of long legs in trisomy X as well as in Klinefelter's syndrome suggests that the characteristic is related to the extra X chromosome and to the extra growth gene SHOX, with the effect on bone growth. Large-scale deletions of SHOX in several families, and a nonsense mutation in one family, were reported in patients with dyschondrosteosis (Leri-Weill syndrome). This is an autosomal-dominant form of mesomelic dysplasia with deformity of the forearm (Madelung deformity), metaphysical changes, severe short stature, short arms, and short legs.

The possibility of 47,XXX should be suspected in girls of normal or tall stature with secondary amenorrhea, premature ovarian failure, or learning difficulties. A karyotype would seem advisable in the evaluation of tall girls.

Many of the patients are normal and need no treatment. For patients with excessive tall stature, treatment similar to that described for tall girls could be provided.

Klinefelter's Syndrome XXY

This syndrome was first described by Klinefelter and co-workers in 1942 with the characteristic features, which become evident at adolescence, of gynecomastia, tallness, variable degree of eunuchoidism, imperfect virilization, small firm testes with hyalinization of the seminiferous tubules and aggregation or clumping of the Leydig cells, small penis, tendency to dull mentality, and increased urinary excretion of gonadotropins (Fig. 1). In 1959, a 47,XXY sex chromosome constitution in patients with this disorder was first reported. All the variants have in common the presence of at least two X chromosomes and a Y chromosome, except for rare patients who have only a 46,XX complement (XX males).

Patients are on average 10 cm (3.9 in.) taller than XY males. Tall stature is usually present before puberty, as is the disproportionate leg length, which suggests that this feature is not related to androgen deficiency and may be determined by the extra X chromosome, as discussed for trisomy X. The arm span is not increased and is equal to or less than the height. Affected children may be immature, excessively shy, anxious, and aggressive and may engage in antisocial acts, such as fire setting, theft, and cruelty to animals. There is a higher than average incidence of problems with speech development, with learning, and with social adjustment. The full-scale IQ is usually normal. Severe retardation is uncommon. Gynecomastia usually persists, contrary to adolescent

Figure 1 A tall boy, age 15 years, 10 months, with Klinefelter's syndrome: karyotype XXY, small firm testes, gynecomastia, and long legs. Height is 185 cm (6 ft $\frac{3}{4}$ in.).

gynecomastia that usually subsides after 2 to 3 years. Breast cancer occurs in approximately 4% of the patients, with an incidence 18 times higher than in normal males. Germ cell tumors, particularly in the mediastinum, that secrete human chorionic gonadotropin and cause luteinizing hormone-releasing hormone-independent sexual precocity, occur in 1.5 per 1000 patients.

Chromosome surveys at birth show an incidence of approximately 1 in 500 to 1 in 1000. As discussed in relation to trisomy X, the active genes (escaping inactivation) in the inactivated X chromosome may be responsible for the abnormalities found in Klinefelter's syndrome and, particularly, the extra growth gene, SHOX, may be responsible for the tall stature. Patients with Klinefelter's syndrome with an isochromosome Xq (47,XiXqY), lacking the extra short arm

of the second X chromosome and consequently the extra SHOX gene, show all the typical manifestations of Klinefelter's syndrome except tall stature.

Less than 10% of the estimated number of affected fetuses are detected prenatally and 75% of patients go through life undetected. Diagnosis of the syndrome in patients after puberty is not difficult, by the findings of the typical phenotype of tall stature, incomplete virilization, small firm testes, and elevated serum gonadotropin levels. The diagnosis can be confirmed by the karyotype.

With the onset of puberty, testosterone synthesis is impaired and gonadotropin levels are elevated. Many of the patients have low testosterone levels during adolescence and as a result have incomplete virilization, small penis, poor muscular development, and eunuchoid proportions. Osteoporosis occurs in 25% of the patients. To prevent the physical and psychological complications of hypogonadism, testosterone treatment is recommended. Treatment could be started, if needed, with 50 mg of testosterone enanthate (or cypionate) in oil, intramuscularly (im), monthly when the bone age is 12 to 13 years, increasing to 100 mg monthly when the bone age is 14 years, and increasing to 200 mg every 3 or 4 weeks when full virilization is desired or when growth is ending. At the same time, this could prevent excessive adult height. The adult replacement dose is 300 mg every 3 weeks or 200 mg im every 2 weeks.

Psychologically disturbing or persisting gynecostasia should be corrected by reduction mammoplasty. Early intervention for learning and behavioral disorders may be beneficial.

47,XYY Males

47,XYY males are known to have excessive height. The first report of an XYY male was made in 1961, when an essentially normal, fertile male of average intelligence was studied because he had a daughter with Down's syndrome. Subsequently, an increased prevalence of the XYY karyotype was found among tall, mentally retarded incarcerated males and created a stereotype of affected individuals as having deviant behavior, marked by physical aggressiveness and violence. This impression is not applicable to all patients. The only consistent physical feature of the syndrome is excessive height, with 50% of patients being above the 90th percentile of normal. Forty to 50% have learning difficulties. Adults with this syndrome are tall and have nodular cystic acne, large deciduous and permanent teeth, and some neurological abnormalities, such as

intention tremor, incoordination, and, frequently, radio-ulnar synostosis.

There is no evidence of any endocrine abnormality. The tall stature is probably determined by the additional Y chromosome. A region that has a great influence on growth and on tooth size was mapped by different investigators to the most proximal portion of the long arm of the Y chromosome, close to the centromere, and is called growth control in the Y (GCY) or Y-specific growth gene. GCY may be the gene responsible for the difference in height and tooth size between males and females. The observations suggest that tall stature in 47,XYY males is related to extra growth genes in the additional Y chromosome: SHOX and GCY or Y-specific growth gene.

As with trisomy X and Klinefelter's syndrome, XYY males go unrecognized, because of the lack of marked phenotypic changes. To detect such patients, a karyotype needs to be obtained in any patient with tall stature whose cause is unknown. The disorder should be suspected in tall males with nodular cystic acne, who exhibit antisocial behavior.

No treatment for the tall stature is needed, unless patients are affected psychologically and would so desire treatment. In that case, treatment will be the same as for tall normal boys.

Fragile X Syndrome

In a report of seven young fragile X-positive girls, the two most common and most important findings were the overgrowth, present from birth onward, and behavioral features, including severe attention problems and extreme shyness and anxiety. The fragile X syndrome is the most common form of inherited mental retardation with a prevalence estimated to be 1 in 1250 males and 1 in 2500 females. In 1991, the gene, which when disrupted results in the fragile X site at Xq27.3, was isolated and characterized. The DNA segment shows a peculiar stretch of trinucleotide repeats (cytidine, guanosine, guanosine) in the fragile X mental retardation gene 1 (FMR-1) that increases the size of the specific DNA fragment of the X chromosome at Xq27.3.

In males, the most typical features are large ears and macro-orchidism, with approximately half of the patients having an ear length above the 90th percentile for normal (Fig. 2). Testicular volumes after puberty in normal males range from 10 to 25 ml and those in fragile X-positive patients range from 25 to 70 ml. Overgrowth and macrocephaly are seen in females. Females function in the borderline to mildly

Figure 2 A 20-year-old mentally retarded young man with fragile X syndrome, prominent forehead and chin, and large ears. Height is 183 cm. Photograph courtesy of Dr. A. Sommer, Department of Genetics, Children's Hospital, Columbus, Ohio.

retarded range. Intelligence assessment showed an IQ of less than 70 in 25% and of less than 85 in 53% of the girls with a positive fragile X chromosome, by cytogenetic studies.

The possibility of fragile X syndrome should be suspected in males and females with mental retardation and the phenotypic changes and the diagnosis should be confirmed by DNA testing. No treatment is known except for supportive measures for the psychological and behavioral disorders. No treatment is usually needed for the overgrowth.

SYNDROMES AND OTHER DISORDERS

Marfan's Syndrome

Marfan's syndrome is an inherited disorder of connective tissue affecting the skeletal system, with elongation of the tubular bones (dolichomorphism), the cardiovascular system, and the ocular system. It is estimated to affect 1 in 20,000 people. The natural history of the syndrome, the autosomal-dominant inheritance, and the variability of the manifestations were pointed out by McKusick in 1955.

The clinical manifestations relating to the skeleton include tall stature, long and thin arms and legs (dolichostenomelia) (Fig. 3), arachnodactyly (spidery fingers), pectus excavatum (hollow chest) or

Figure 3 A boy, age 14 years, 2 months, with Marfan's syndrome, showing dolichomorphism, slender extremities, and long limbs; arm span is 10 cm more than height. He has cardiovascular changes with dilation of the aortic root.

carinatum (pigeon breast), narrow facies with narrow palate, and scoliosis and kyphosis in 60 to 100% of the patients. Joint laxity and inguinal, femoral, and diaphragmatic hernias are other consequences of the abnormal connective tissue. The ocular manifestations include upward subluxation of the lenses, as a result of the defect of the suspensory ligament, increased axial globe length with myopia, and retinal detachment. The most life-threatening complications are those of the cardiovascular system, with dilation of the ascending aorta with or without a dissecting aneurysm and less commonly of the thoracic or abdominal aorta or pulmonary artery. As a consequence of the dilation of the aorta, there is secondary aortic regurgitation. Mitral valve prolapse is very common also. Without treatment for the cardiovascular complications, particularly the aortic dilation, the mean age of death is in the midforties, from aortic dissection and rupture.

Patients with Marfan's syndrome are mentally normal, but neuropsychologic impairment, including learning disability and attention deficit disorder, occurs in approximately 40% of patients.

This is an inherited disorder, transmitted in an autosomal-dominant fashion. Approximately 85% of patients have a positive family history and 15% of patients have a sporadic presentation. The basic defect in Marfan's syndrome has been traced to a defective fibrillin gene (FBN1) mapped to chromosome 15 (15q21.1). Fibrillin is a connective tissue protein found in microfibrils, a constituent of elastic tissue and abundant in tissues affected in Marfan's syndrome, including the aorta, the suspensory ligament of the lens, and the periosteum.

For the clinical diagnosis, the revised criteria of 1996 (Ghent Nosology) are followed. These criteria are based on four major diagnostic findings: (1) a positive family history and involvement of (2) the skeletal, (3) the ocular, and (4) the cardiovascular systems.

The diagnosis of Marfan's syndrome can be made in an index case, when there is a major involvement in two different organ systems and a minor involvement in a third system or when there is a mutation in the FBN1 gene, a major involvement of one system, and a minor involvement of a second system.

For a relative of an index case, the diagnosis can be made when there is a major criterion provided by family history, one major criterion in an organ system, and involvement of a second organ system.

Female and male patients with Marfan's syndrome may attain an excessively tall height. Treatment to curtail final height may be indicated, particularly for females, for the same reasons that one treats tall normal girls. In addition, since scoliosis and kyphosis might develop in 60 to 100% of patients with Marfan's syndrome, the arrest of growth may be beneficial. Estrogen treatment is effective. For boys, the indication for treatment would also be excessive height and scoliosis. The treatment is injection of testosterone esters, as indicated for tall normal boys. It is crucial that attention be paid to the possible development, prevention, and treatment of life-threatening cardiovascular abnormalities. Propranolol, which reduces the pounding of the ventricular ejection on the ascending aorta, is routinely used in patients who are beginning to have dilation of the aortic root. A composite graft operation to replace the ascending aorta and aortic valve has been highly successful.

Beals' Syndrome (Congenital Contractural Arachnodactyly)

Although there were previous reports consistent with this disorder, Beals and Hecht delineated this syndrome in 1971 and it is known as Beals' syndrome. It is also known as congenital contractural arachnodactyly (CCA; joint contractures and arachnodactyly).

The skeletal features are similar to those for Marfan's syndrome, with long slender limbs (dolichostenomelia) and arachnodactyly. There is camptodactyly of the fingers. The difference between Beals' syndrome and Marfan's syndrome is that there are joint contractures, rather than looseness of the joints, and the eye and aorta are not affected. The helixes of the ears are folded and the ears have a wrinkled appearance. Kyphosis, scoliosis, or kyphoscoliosis occurs in 50% of the patients who are more severely affected.

This is an inherited disorder segregating in an autosomal-dominant fashion. It has been demonstrated that CCA is caused by a mutation in a second fibrillin gene (FBN2), which is mapped to chromosome 5q23-q31.

Diagnosis is based on clinical grounds. Although rare, at least 33 pedigrees with CCA have been described.

Homocystinuria

Homocystinuria is an inherited inborn error of metabolism of methionine, due to a deficiency of the enzyme cystathionine β -synthase (CBS), originally reported by Carson *et al.* and Gerritsen and Waisman in 1963. CBS converts homocysteine to cystathionine, a reaction requiring pyridoxal phosphate (vitamin B6) as a cofactor. The prevalence is estimated at 1 in 200,000 live births. In Ireland, it is more frequent, occurring in 1 in 40,000 live births. Approximately 40% of patients respond to high doses of vitamin B6 (pyridoxine) and usually have milder clinical manifestations: a delay in the onset or a lower rate of complications than those who do not respond to vitamin B6 therapy.

Cystathionine β -synthase deficiency is inherited as a recessive trait, but there is considerable genetic heterogeneity in known patients. The gene for CBS has been mapped to the q21 region of chromosome 21.

The clinical manifestations are similar to those for Marfan's syndrome, but there are some differences. Major involvement relates to four different organ systems: the ocular system, the skeletal system, the vascular system, and the central nervous system

(CNS). Ectopia lentis or subluxation of the lens downward, contrary to the upward dislocation in Marfan's syndrome, is the most consistent finding. The skeletal abnormalities impart a phenotype that is similar to that in Marfan's syndrome, with dolichostenomelia (elongated and thin arms and legs), arachnodactyly, and tall stature (Fig. 4,) often with eunuchoid proportions. Among the most consistent skeletal abnormalities is osteoporosis. Scoliosis and kyphosis occur frequently. Other abnormalities include genu valgum and pectus carinatum or excavatum. The most frequent central nervous system manifestation is mental retardation, which may occur in as many as 50% of patients, with an IQ ranging from 30 to 75. Thromboembolic episodes involving the large and small vessels are life-threatening, particularly those in the brain; they are common and may occur at any age. The sulfhydryl groups of homocysteine interfere with collagen cross-linking and cause collagen abnormalities. In view of the similarities of many of the clinical features of homocystinuria and Marfan's syndrome, it is likely that many of the manifestations are related to qualitative changes in fibrillin. Sulfhydryl groups may also contribute to the disruption of the vascular endothelium and as a result contribute to thrombosis.

The most consistent biochemical finding has been homocystinuria. There is an increase in serum homocysteine and a reduced concentration or absence

Figure 4 Growth chart of a female patient with homocystinuria.

of cysteine and cystathionine. In addition, serum methionine is increased in most patients.

Some patients may respond to 25 mg of vitamin B6 daily, but usually higher doses are needed. Treatment with high doses of vitamin B6, 200 to 1000 mg per 24 h, causes marked improvement in patients responsive to this therapy. Some patients may not respond because of folate depletion. Thus, folic acid at 1 to 5 mg per 24h should be added to the regimen. In patients who are unresponsive to vitamin B6, restriction of methionine intake, in conjunction with supplementation of cysteine, is recommended. Surgery should be avoided in these patients whenever possible. Should surgery be necessary, hydration pre- and postoperatively may lessen the risk of thrombosis.

Beckwith-Wiedemann Syndrome

This syndrome was initially described independently by Beckwith and Wiedemann in 1963. It is associated with prenatal and postnatal overgrowth, with the most characteristic features occurring at birth: omphalocele or umbilical defects, macroglossia, and gigantism (Fig. 5). Thirty to 50% of affected children may have severe, persistent hypoglycemia beginning in the first days of life from hyperinsulinism, as a result of pancreatic islet cell hyperplasia. The hypoglycemia usually subsides by 4 months of age. There is visceromegaly with enlargement of the liver, kidneys, pancreas, and occasionally the heart; renal medullary dysplasia; fetal adrenal cortical cytomegaly; and interstitial cell hypoplasia of the gonads. Hemihypertrophy is present in 12.5% of cases.

Figure 5 A 4½ month old infant with Beckwith-Wiedemann syndrome, showing macroglossia, umbilical hernia, prominent calf muscles, and overgrowth. Length is 67.3 cm (26½ in.) and weight is 7.7 kg (both >75th percentile).

There is an increased incidence of malignant tumors (7.4 to 10%), the most frequent being Wilms' tumors and adrenal cortical carcinoma. Other tumors could be nephroblastoma, hepatoblastoma, and rhabdomyosarcoma.

Children with Beckwith-Wiedemann syndrome (BWS) are large at birth. Growth velocity is usually above the 90th percentile until 4 to 6 years of age and is normal thereafter. Patients reach an average height of 2.5 SDS at or after puberty with weights between the 75th and 95th percentiles.

Several hundred cases have been reported. The prevalence is not known, but is estimated to be 1 in 14,000 persons. Approximately 85% of cases are sporadic and 15% are inherited, suggesting autosomal-dominant inheritance with incomplete penetrance.

BWS is a complex and heterogeneous genetic disorder resulting from alterations of the expression of imprinted genes, involved in growth and cell cycle control, in the 11p15 chromosomal region. The 11p15 region harbors a cluster of imprinted genes. IGF-II, insulin (Ins), and LIT1 (loss of intestine 1) normally show paternal expression, whereas H19, p57KIP-2, and KvLQT1, except for some tissue variation, are predominantly maternally expressed. The loss of imprinting of the maternal IGF-II gene, with resulting biallelic expression, is one of the most common molecular defects found in patients with Beckwith-Wiedemann syndrome without chromosomal abnormalities. In other patients, loss of maternal IGF-II imprinting is associated with complete suppression of maternal H19 expression. Overexpression of IGF-II can also result from paternal uniparental disomy of chromosome 11 or from duplications of the paternal 11p15 region associated with trisomy of 11p. The contribution or role of the loss of function of maternally expressed genes that act as growth or tumor suppressors is difficult to assess. Alterations in any of these suppressors could cause BWS and the phenotypic spectrum might depend on which maternally expressed gene is mutated. Loss of imprinting of the maternal LIT1 gene with biallelic expression of LIT1 is the other most frequent abnormality in BWS, accounting for 40 to 50% of patients, and is not linked to loss of imprinting of IGF-II.

The diagnosis is based on the clinical manifestations that have been described. Some of the phenotypic changes are somewhat similar to those of infants of diabetic mothers. Patients with Beckwith-Wiedemann syndrome may be difficult to distinguish from patients with Simpson-Golabi-Behmel syndrome (SGBS). Patients with the latter syndrome have some features similar to Beckwith-Wiedemann

syndrome. Distinguishing characteristics of SGBS are a cleft lip and palate, cardiac defects, polydactyly, vertebral and rib anomalies, hypoplastic or absent index fingernails, and X-linked recessive transmission.

Detection and treatment of hypoglycemia are most important for survival and to prevent neurological damage. The excessive rate of growth for the first few years and the tall stature during childhood and adolescence require no treatment, unless an excessive adult height is predicted, particularly in females. Regular follow-up for possible tumor development is needed and routine ultrasonography of the kidneys is mandatory (every 3 months for the first 6 years is recommended), because Wilms' tumor and adrenocortical carcinoma are the most frequent neoplasms.

Somatic Overgrowth (H19 Methylation and Silencing)

As discussed in relation to Beckwith-Wiedemann syndrome, the H19 gene locus is in the chromosome 11p15 region and may function as a tumor suppressor. H19 is closely related to IGF-II and is paternally imprinted and maternally expressed in most tissues. Biallelic expression of IGF-II by disruption of maternal IGF-II imprinting has been shown in mice, as a result of a maternally inherited targeted H19 gene. Also, biallelic expression of IGF-II, associated with methylation and silencing of the maternal normally expressed H19 gene, has been found in BWS and Wilms' tumors.

Morison *et al.* examined H19 methylation and IGF-II expression in children with overgrowth, without diagnostic features of BWS or abnormalities suggesting any particular syndrome.

In three of the six children with somatic overgrowth, without features of BWS, the overexpression of IGF-II was attributable to abnormal methylation and silencing of H19. This observation has important implications for the evaluation of children with overgrowth without other manifestations suggestive of a syndrome.

Simpson-Golabi-Behmel Syndrome

This syndrome was originally described by Simpson in 1975 and by Golabi and Behmel, independently, in 1984.

This syndrome is an X-linked recessive disorder characterized by prenatal and postnatal overgrowth, unusual facial appearance (described in the past as bulldog syndrome), and digital and other anomalies

(Fig. 6). Female carriers sometimes can have some facial changes. Affected male patients may attain adult heights of 192 to 210 cm (6 ft 4 in. to 6 ft 11 in.).

Patients have macrosomia, macroglossia, visceromegaly, omphalocele, renal dysplasia, earlobe creases, neonatal hypoglycemia as a result of islet cell hyperplasia, and a risk of embryonal tumors, including Wilms' tumor, neuroblastoma, and hepatocellular carcinoma during early childhood, features similar to those in BWS.

The most prominent features of the disorder consist of overgrowth, characteristic facial changes (large protruding jaw, widened nasal bridge, upturned nasal tip, broad nose, wide mouth, large tongue, thick lips), high arched or cleft palate, large head, hypoplastic or absent index fingernails, and inguinal hernia. The bone age is advanced. Intelligence is usually normal or only mildly retarded in some cases. Hypotonia is common.

The gene for this syndrome has been identified by Pilia *et al.* This syndrome results from different microdeletions of the glypican-3 (GPC-3) gene in Xq26. Mutations or deletions were identified subsequently, suggesting that SGBS is caused by a nonfunctional GPC-3 protein. GPC-3 membrane-bound protein interacts with and binds IGF-II and may be important in the modulation of IGF-II. Theoretically, glypican-3 could complex with and sequester IGF-II or facilitate degradation of IGF-II through a further interaction with the IGF-II receptor. The loss of function of glypican-3 and decreased IGF-II binding would lead to an increase in the level of IGF-II that could activate the IGF-I receptor.

Patients with SGBS have many overlapping features with patients affected with Beckwith-Wiedemann syndrome and in some cases molecular studies will be needed to assign a proper diagnosis. SGBS does not overlap genetically but does overlap clinically with

Figure 6 An 18-year-old with Simpson-Golabi-Behmel syndrome, illustrating the (A) broad stocky appearance, (B) unusual facial features, and (C) malformed nails. Reprinted from Simpson, J. L., *et al.* (1975). *Malformation Syndromes of the Birth Defects: Original Article Series* 11(2), 22, with permission from the March of Dimes Birth Defects Foundation.

BWS, which may be related to overexpression of IGF-II.

Sotos' Syndrome

This syndrome was described in 1964. The major diagnostic features are excessive growth, large dolichocephalic head, distinctive facial configuration, advanced bone age, and a nonprogressive neurological disorder with mental retardation. More than 300 cases have been reported and many more are known. The prevalence is not known, but it is probably one of the most frequent overgrowth syndromes after BWS and Marfan's syndrome. Males and females are affected equally. It occurs in all ethnic groups and has been detected throughout the world.

The main clinical finding is prenatal and postnatal overgrowth. The growth velocity is particularly excessive in the first 3 to 4 years of life and subsequently proceeds at the normal rate, but in the high percentiles. The mean height increases from 2.2 SDS at birth to 2.8 SDS at 1 year of age and to mean values of 3 SDS during childhood. The weight is usually appropriate for the height and the bone age is advanced by 2 to 4 years over chronological age, during childhood. Adult height usually exceeds the 50th percentile of normal. Some individuals may reach excessive adult heights: males of 193 to 203 cm (6 ft 4 in. to 6 ft 8 in.) and females up to 188 cm (6 ft 2 in.) are known.

The craniofacial configuration is most characteristic, with a prominent forehead and receding frontoparietal hairline in 96% of the cases, dolichocephalic large head, hypertelorism, down-slanting of the palpebral features, high narrow palate, prominent palatine ridges, and pointed chin (Fig. 7). Premature eruption of teeth occurs in 60 to 80% of patients. CNS manifestations are frequent. Delay in the attainment of milestones of development, walking and in particular talking, is almost always present and clumsiness is frequent (60 to 80%), as are hypotonia and lax joints. Mental deficiency is present in 80 to 85% of the patients, with an average IQ of 72 and a range from 40 to borderline mildly retarded. Fifteen to 20% may be normal mentally and may have IQs of up to 129. Seizures may occur in 30% of the cases. Mildly enlarged ventricles and increased subarachnoid spaces may be present in some patients.

No endocrine abnormalities have been found to explain the rapid growth.

A genetic cause was suspected for a long time. Several families with members affected in two or three generations have been reported, suggesting autosomal-dominant inheritance. Most of the cases are

Figure 7 A girl, age 4 years, 8 months, with Sotos' syndrome. Height was 124 cm (4 ft 7/8 in.; height age 7 years, 7 months) and weight was 35.2 kg (weight age 7 years, 9 months). Bone age was 4 years, 10 months. Her father (198 cm, or 6 ft 6 in.) and her half-sister from a different mother are also affected. Note the characteristic features: large head, frontal bossing, hypertelorism, down-slanting of palpebral fissures, pointed chin, and large ears.

sporadic, but could be due to new mutations. Deletions or point mutations of a single gene, nuclear receptor-binding SET (where SET denotes SU(VAR)3-9, E(Z)trithorax) domain protein 1 (NSD1), located at chromosome 5q35 were identified in 65-75% of the sporadic cases, indicating that haploinsufficiency of NSD1 is the major cause of Sotos' syndrome. Other genetic abnormalities are possible. The finding that all the NSD1 mutations identified were either heterozygous or hemizygous is consistent with an autosomal-dominant condition in the majority of cases of Sotos' syndrome.

The human NSD1 gene consists of 23 exons, encodes a protein of 2696 amino acids, and is expressed in the human fetal and adult brain, which could explain the findings of large brain and mental deficiency. It is also expressed in skeletal muscle, kidney, spleen, and thymus. The NSD1 protein interacts with the

ligand-binding domain of nuclear hormone receptors and may act as a corepressor or coactivator. The finding that haploinsufficiency of NSD1 induces overgrowth in Sotos' syndrome indicates that NSD1 acts as a corepressor of genes that promote growth.

There is no biochemical marker for the disease. The diagnosis is based on clinical grounds. The most characteristic manifestations are excessive growth and the craniofacial configuration. Without these signs, the diagnosis cannot be made. It is anticipated that future DNA studies of patients would permit a more certain diagnosis and delineation of the spectrum of the condition. The diagnostic tests are carried out mainly to exclude other possibilities, such as fragile X, Klinefelter's, and excessive growth hormone secretion. Magnetic resonance imaging of the brain, showing mildly enlarged ventricles and increased subarachnoid spaces in some patients, is helpful, but not diagnostic.

The management of the mental retardation is no different than for any child with a mental deficiency. The excessive height is usually not a handicap for males. Girls with a predicted ultimate height in excess of 178 cm (5 ft 10 in.) may benefit from treatment with high doses of estrogen to curtail linear growth, as for tall normal girls. Social and behavioral problems during childhood and immaturity in adulthood may improve with psychological counseling. Other important concerns are the possibility of tumor development (~3.0%) and the risk of transmission. Because the evidence suggests that this is an autosomal-dominant disorder affecting males and females, the affected individual has a 50% risk of having affected children. Affected individuals are fertile. There is no evidence that life span is shortened.

Weaver's Syndrome

Weaver's syndrome was described in 1974. It is characterized by excessive growth prenatally or postnatally, unusual facies, advanced skeletal maturation, and camptodactyly. At least 37 cases have been reported: 21 males and 16 females.

Some males have attained an adult height of 194.2 cm (6 ft 4½ in.), a weight of 102.2 kg (225 lbs), and a head circumference of 61 cm (24 in.) and some females have attained an adult height of 176.3 cm (5 ft 9 in.), a weight of 87.6 kg (193 lbs), and a head circumference of 59.5 cm (23.43 in.).

The excessive growth is present at birth or has its onset during infancy. Eighty percent of patients are developmentally delayed or have mental retardation. Mental retardation can range from mild to severe.

Many of the features resemble those found in Sotos' syndrome. The craniofacial characteristics, although somewhat similar, are in some points different. Patients with Weaver's syndrome have hypertelorism, large ears, depressed nasal bridge, and down-slanting palpebral features, but the skull, in many cases, is not dolichocephalic, the occiput is often flat, patients do not have a prominent chin, and the face is broad. Another distinctive finding is that in many cases there is hypertonia rather than hypotonia. No consistent endocrinological abnormality has been found. The advanced skeletal maturation is striking, with the carpal age much higher than the maturation of the hand.

Most of the cases have been sporadic. Parent to child transmission has been reported five times, suggesting autosomal-dominant inheritance. NSD1 mutations have been described in three of seven patients with Weaver's syndrome, suggesting that Sotos' and Weaver's syndromes are allelic. Additional observations would be helpful to confirm these findings.

Bannayan-Riley-Ruvalcaba Syndrome and Cowden's Disease

Bannayan-Riley-Ruvalcaba syndrome (BRRS) is an autosomal-dominant disorder characterized by macrocephaly, multiple hamartomas (lipomas, hemangiomas, lymphangiomas, intestinal polyps) and other tumors (seminoma, germinoma), macrosomia at birth, pigmented spots in the glans and shaft of the penis (Fig. 8), and pseudo-papilledema. Originally, it was described as three different syndromes: Bannayan-Zonana syndrome, Riley-Smith syndrome, and Ruvalcaba-Myhre-Smith syndrome. As more cases were described, it became evident that patients with the different syndromes shared similar manifestations and the unification of the three disorders into the Bannayan-Riley-Ruvalcaba syndrome was suggested.

The gene for BRRS has been localized to chromosome 10q23, overlapping the region for Cowden's disease. Marsh *et al.*, in 1997, demonstrated germline mutations in the PTEN gene (for phosphatase and tensin homologue deleted on chromosome 10) in patients with Bannayan-Zonana syndrome. Some of the mutations in the PTEN gene found in Bannayan-Zonana syndrome were the same as those previously reported in Cowden's disease. Because of the considerable phenotypic overlap between BRRS and Cowden's disease and because of the demonstration that in their patient the PTEN gene was deleted on chromosome 10, by an interstitial deletion of

Figure 8 A 15-year-old with Bannayan-Riley-Ruvalcaba syndrome. Note pigmented spots on the glans and shaft of the penis. Reprinted from Ruvalcaba, R. H. A., Myhre, S., and Smith, D. W. (1980). *Clinical Genetics* 18, 413–416, with permission. Copyright 1980, Munksgaard International Publishers Ltd., Copenhagen, Denmark.

10q23.2–q24.1, Arch *et al.*, in 1997, suggested that BRRS and Cowden's disease are allelic disorders. In 1998, Zori *et al.* reported a mother with Cowden's syndrome whose son had BRRS; both were heterozygous for the same mutation of the PTEN gene.

Cowden's disease has been described mainly in adults. It is an autosomal-dominant condition characterized by macrocephaly, multiple hamartomatous lesions, especially of the skin and mucous membranes, verrucous skin lesions of the face and limbs, and cobblestone-like papules of the gingiva and buccal mucosa, but also involving hamartomas and neoplasms of internal organs, most commonly in the thyroid, breast, and ovary.

Progressive macrocephaly, scrotal tongue, and mild to moderate mental retardation are important signs of Cowden's syndrome in young children. Trichilemmomas in the nasolabial folds and palmar and plantar hyperkeratotic pits usually become evident later in childhood. They are often accompanied by the appearance of subcutaneous lipomas and cutaneous hemangiomas.

PTEN has been shown to play a large role in human malignancy. Somatic PTEN deletions and mutations have been observed in sporadic breast, brain, prostate, and kidney cancer cell lines and in several primary tumors, such as endometrial carcinomas, malignant melanoma, and thyroid tumors. The spectrum and genotype–phenotype analyses in Cowden's disease and Bannayan-Riley-Ruvalcaba syndrome were studied by Marsh *et al.* Some patients with BRRS and Cowden's

disease have similar manifestations. The difference in the manifestations in the two disorders may be related to different mutations, which needs to be further clarified by genotype–phenotype correlations in the future.

Because of a variety of hamartomas and tumors that could occur in patients with BRRS and Cowden's disease, long-term follow-up of these patients is needed. The treatment depends on the type of hamartoma or tumor.

Partington's Syndrome

In 1997, Partington *et al.* reported three families with 11 members, male and female, showing a new overgrowth syndrome. The syndrome is characterized by generalized overgrowth, mild to moderate mental handicap, and duplication of 4p16.3. The soft tissues are involved, with thickening and coarsening of the face. The hair on the head is abundant and the eyebrows are bushy. Bony overgrowth leads primarily to a heavy body frame with a large head circumference, prominent supraorbital ridges, and a square jaw, but a rather small, upturned nose (Fig. 9). The hands and feet are large. The degree of mental handicap varies from moderate to mild with no specific behavioral characteristics. Considerable variation is seen in the manifestations of this syndrome between various members of the same family.

The height was well above average. Although physical overgrowth was detectable in childhood, it became most obvious in late adolescence and early adult life. Of the 10 subjects with overgrowth, all of whom were over the age of 15 years, all the heights were at or above the 75th percentile and 5 of them were above the 90th percentile. Some subjects experienced late growth. One patient between the age of 18 and 28½ years grew 15 cm (5.9 in.) and another patient between the age of 17½ years and 28 years grew 26 cm (10.2 in.), growth patterns that are quite abnormal. The patients are large people with large body frames.

The 4p16 region contains many genes, some of them responsible for well-known disorders such as Huntington's disease, achondroplasia, thanatophoric dysplasia, and hypochondroplasia. The last three result from mutations in the fibroblast growth factor receptor 3 (FGFR3) gene. In addition, deletions of this region result in Wolf-Hirschhorn syndrome and Pitt-Rogers-Danks syndrome.

The three families reported by Partington *et al.* had different translocations: translocation of 4p16.3 and 1q44 in family 1, translocation of 4p16.2 and 8p23.1 in family 2, and translocation of 4p16.3 and 21q22.3

Figure 9 The two women, shown standing, are sisters and both have a translocation of 4p16.2 and 8p23.1: t(4;8) (16.2;p23.1). The two patients seated on the left (male, age 18 years, and female, age 16 years), affected with overgrowth disorder, are the children of the woman on the left. The two patients seated on the right are the children of the woman on the right. One is affected with overgrowth (female, age 15 years) and the other has Pitt-Rogers-Danks (PRD) syndrome (male, age 13 years). The children with overgrowth (two were tested) showed an unbalanced translocation with three doses of 4p16.3 (duplication of 4p16.3 and monosomy of 8p23.1). The patient with PRD syndrome showed one dose of 4p16.3 (deletion of 4p16.3 and duplication of 8p23.1). Reprinted from Partington, M. W., *et al.* (1997). *Journal of Medical Genetics* **34**, 719–728, with permission. Copyright 1997, BMJ Publishing Group, London, UK.

in family 3. One of the parents of the patients carried the balanced translocation. As a consequence, the progeny may receive one, two, or three copies of 4p16.3. All four subjects with overgrowth who were studied had an unbalanced translocation with three copies of 4p16.3. Partington *et al.* suggested that FGFR3 could be a candidate gene for growth abnormalities, with three doses leading to the overgrowth syndrome and one dose leading to growth failure (Pitt-Rogers-Danks syndrome).

The suggestion that additional doses of FGFR3 are responsible for the overgrowth has been questioned, because evidence suggests that FGFR3 is a negative regulator of bone growth. Known mutations of FGFR3 are activating mutations and lead to short-limb skeletal dysplasias (achondroplasia, thanatophoric dysplasia, and hypochondroplasia). Whether the overgrowth syndrome described by Partington *et al.*

is the result of overdosage of the FGFR3 gene, inactivating mutations of the gene, or other genes in 4p16.3 remains to be determined by further studies.

Figure 1 Reference curves (in girls): height and weight for age are presented as the mean (M) \pm 2 SD (standard deviations).

until cessation of growth. They have been analyzed in a normal population and standardized as a reference. For practical purpose, sequential X-rays of the left-hand wrist were selected and presented in an atlas by Greulich and Pyle, which is the internationally accepted reference for bone age assessment. Ideally, chronological and bone ages progress in parallel with little difference. Although the concept of bone age reflecting skeletal maturation, and possibly body maturation, has been a valuable tool in assessing abnormal growth, a number of caveats must be considered when applied to pathological conditions.

Prediction of Adult Height

The ultimate and often important information is the predicted adult height. Methods have been developed based on bone age, height, and eventually chronological age for such a prediction. In addition, in some genetic diseases, such as Turner's syndrome or achondroplasia, disease-specific growth curves have been developed, which may also be helpful in the evaluation of therapeutic interventions. In normally growing children, because height remains canalized along a given

centile or SD value, adult height can be fairly well predicted by extrapolating within the adult height distribution; it can also be calculated as the mean parental height with the addition or subtraction of 6.5 cm for boys and girls, respectively. This value is only approximate. In addition, the parental genetic background can be accounted for by calculating "the parental target height." These predicted values, because they are derived from statistical calculations, remain approximate, but quite useful.

Catch-Up Growth

The term "catch-up growth" was introduced to describe the phase of rapid growth that allows a child to accelerate growth until he has fully recovered his genetic pace of growth after a prolonged illness with inhibition of growth. The child would return to his original pre-retardation growth curve. It is a compensation phenomenon for the potential loss of growth. This is a reliable indicator of recovery and suppression of the growth-retarding agent. It is observed when growth retardation is secondary to malnutrition or failure to thrive or when replacement therapy is given in appropriate dosage in conditions such as hypothyroidism, complete GH deficiency, or delayed puberty. The mechanisms regulating catch-up growth are still unknown. One hypothesis suggests a cellular phenomenon in which the cell, which eventually becomes the chondrocyte, has a program and a stabilizing mechanism to recognize where it is in that program. Hormones would act as permissive agents to adjust at the program level.

ENDOCRINE REGULATION OF GROWTH

The Epiphyseal Growth Plate and Skeletal Growth

Body height depends on the growth of long bones and the spine. It originates from independent ossification centers: the growth plate cartilage separates the epiphysis (distal centers) and the metaphysis of long bones (Fig. 2). This plate is a distinct organ. It is the site of ossification forming the endochondral bone during growth. It is therefore the main target of hormones controlling skeletal growth. Normal growth is only possible if the growth plate is genetically normal and able to respond to endogenous hormonal stimulation. Cessation of growth is due to fusion of epiphyseal and metaphyseal bones with disappearance of the cartilage growth plate.

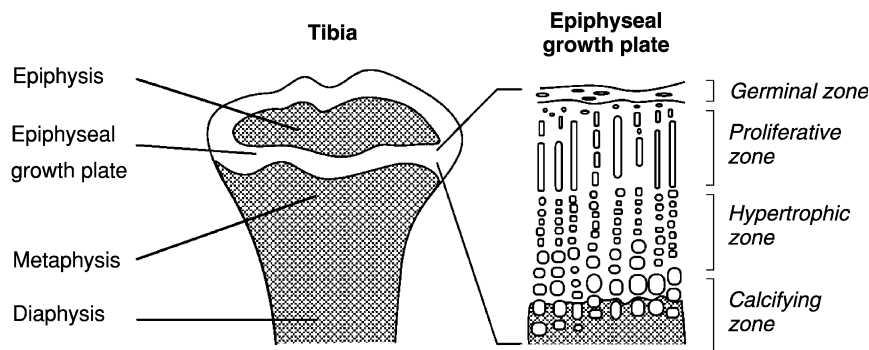

Figure 2 Cartilage growth plate, such as that located at the upper end of the tibial bone. The microscopic structure shows the maturation of the chondrocytes from the germinal zone down to the calcifying zone, where bone formation is initiated.

The mechanisms that affect stature are complex: (1) some are intrinsic to the growth plate with local intracellular and intercellular factors controlling chondrocyte multiplication and maturation and (2) others are extrinsic, such as the hormones that promote these changes by acting directly at the cellular level or by interfering with locally produced growth factors. This endocrine control of growth also depends on local receptors specific to each hormone. A state of resistance to a given hormone would occur if its receptor is knocked out by a mutation of the gene encoding it. It would lead to disease, providing a model for the understanding of endocrine control of skeletal growth. This was typically observed in patients resistant to estrogens with inactivating mutations in the estrogen's receptor.

The GH–Insulin-like Growth Factor-I Axis

By secreting GH, the pituitary gland plays the central role in the regulation of growth (Fig. 3). It is controlled by the hypothalamus, with which it has a close anatomical connection. As a matter of fact, GH secretion results from an interplay of two main hypothalamic factors: a positive factor, GH-releasing hormone (GHRH), and a negative factor, somatostatin- or somatotropin-release inhibiting factor. GHRH is required for GH stimulation as it controls the episodic release of GH. Somatostatin affects the timing and amplitude of GH secretion. The final pattern and amplitude are defined by this reciprocal interaction. A newly identified secretagogue is ghrelin, a GHRH-like peptide produced largely by the stomach, allowing a tight link with nutrition.

Stimulation of GH secretion occurs during sleep, fasting, hypoglycemia, and stress. GH production decreases after birth and remains unchanged during childhood. Its production is enhanced by sex steroids,

essentially estrogens, during puberty in both sexes. Importantly, GH acts through a specific receptor in target cells, principally in the liver, where most of the circulating insulin-like growth factor (IGF-I) is synthesized, but also in the hypothalamus, where IGF-I controls the GHRH–somatostatin system, and in the early differentiating chondrocyte in the growth plate. Mutations in the GH receptor cause a severe dwarfism, which was described by Laron, with high GH levels but low IGF-I levels and including the full clinical picture of GH deficiency.

A critical finding in the early 1950s showed that the action of GH was mediated by a factor that was later named IGF-I. Plasma IGF-I values are stable, in contrast with pulsatile GH concentrations. It is therefore accepted that IGF-I levels reflect the status of GH secretion in normal individuals. Variations are related to age and puberty. As a consequence of these findings, GH deficiency can be treated with recombinant GH, allowing the stimulation of IGF-I production and bone growth.

The predominant action of GH is mediated by liver-secreted IGF-I, which is delivered to the growth plate. However, there is an additional mechanism with local production of IGF-I that is also controlled by GH, promoting the proliferation of chondrocytes. The crucial role of IGF-I at that level is supported by the severe growth retardation induced by deletions in the gene coding for the GH receptor that abolish the production of IGF-I by the liver and dramatically reduce the circulating level of IGF-I.

Thyroid Hormones

Hypothyroidism (decreased thyroid hormone activity) is a major treatable cause of linear growth and bone maturation retardation in children. Congenital forms of hypothyroidism can be prevented by neonatal

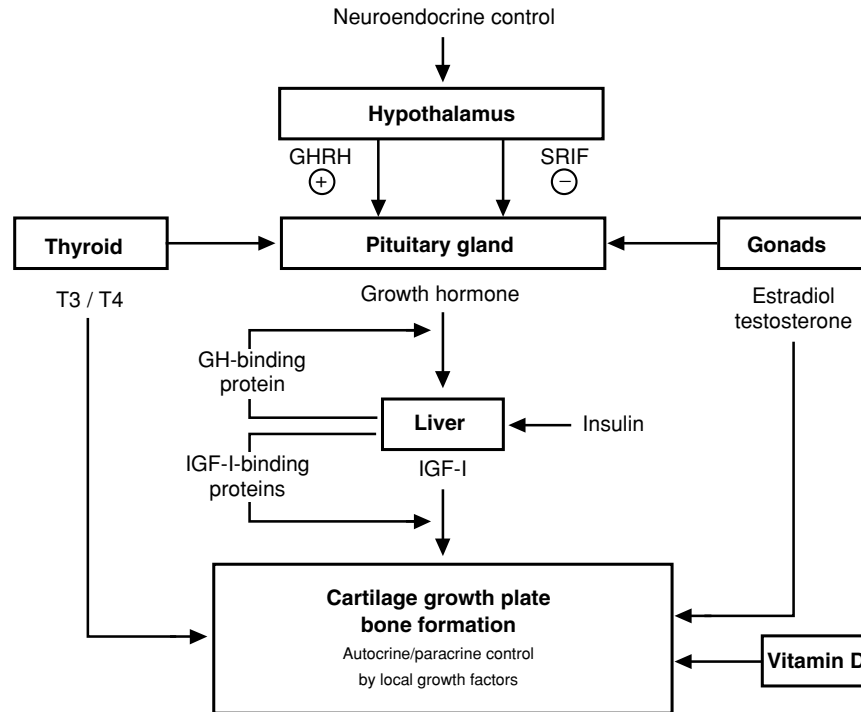

Figure 3 The endocrine control of growth with the central role of the growth hormone–IGF-I axis. Hormones also have a direct effect on the growth plate.

screening, but hypothyroidism may also occur at any postnatal age. The active thyroid hormone is T3 (triiodothyronine), which is produced by conversion from thyroxine or directly by the thyroid gland. This hormone is necessary for appropriate chondrocyte differentiation in the growth plate. It acts directly through specific receptors and also regulates the local production of IGF-I and GH responsiveness. In addition to its direct effects on the growth plate, T3 controls the secretion of GH by the pituitary: in hypothyroidism, decreased GH secretion contributes to growth retardation. It is corrected by thyroid hormone replacement therapy. An opposite model of T3 action is observed in children with hyperthyroidism, as they show accelerated growth and bone maturation, leading to premature growth plate closure.

Pubertal Growth and Sex Steroids

Until puberty, there is a slow but continuous bone growth essentially dependent on the activity of the GH–IGF-I axis and the thyroid hormones. At puberty, estrogens and androgens are secreted in both sexes. The major contribution to growth stimulation is made by estrogens, part of which are derived from testosterone. The increase in serum estradiol concentration occurring in both sexes enhances pulsatile GH

secretion and circulating IGF-I, supporting the pubertal growth spurt, which will contribute up to 20% of the final adult height. The high pubertal levels of GH and IGF-I are maintained during several years of rapid growth. There is debate about the respective role of estrogens and androgens during pubertal growth. It is accepted that estradiol secreted by the ovary in girls or derived by aromatization from testosterone in boys is the main factor; the secretion of estradiol is responsible for the growth spurt and its continuous increase is the cause of bone maturation until epiphyseal closure and cessation of growth in both sexes. Numerous genetic diseases, which involve sex steroid secretion or action, provide pathological models of pubertal growth, supporting the view of the prominent role of estrogens.

In addition, androgens may play a role as shown by the growth stimulation obtained with some synthetic androgens that cannot be converted to estrogens. Animal studies have shown that androgens do have direct effects independent of those of estrogens. They promote chondrocyte maturation and bone growth. How these local actions, which are probably similar for estrogens, are integrated with the action of the GH–IGF-I system remains unclear.

In addition to their effect on growth, sex steroids are responsible for the pubertal increase in mineral

bone mass (essentially calcium content) up to the adult level, which is attained in the early twenties. Estrogens contribute substantially, probably up to 25%, to volumetric bone mineral density. However, the 25% greater bone mass in postpubertal boys than in girls is likely due mainly to the pubertal testosterone secretion. Therefore, it is not surprising that the absence or severe delay in puberty in both sexes will lead to persisting growth but insufficient bone mineralization. The opposite occurs if puberty is precocious.

Cortisol and Glucocorticoids

Cortisol produced by the adrenal gland has little influence on growth under physiological conditions and cortisol deficiency does not impair growth. However, this is finely tuned as demonstrated by the following clinical conditions: (1) when a cortisol-deficient patient requires replacement therapy, adjustment of the dosage will be monitored partly for its effects on growth, with reduced growth velocity induced by a minor overdose, and (2) growth retardation may be the sole symptom, or the first symptom, of chronic hypersecretion of cortisol, as seen in children with Cushing's syndrome. Corticoids have a direct effect on the growth plate and may reduce GH secretion. In addition, they induce a state of IGF-I resistance.

Vitamin D

Vitamin D is a hormone that is ingested in the diet (as vitamin D) or produced by the skin (as vitamin D₃). It is transformed into its active biological form by the liver and the kidney. It is a critical regulator of calcium absorption and metabolism and hence of bone

mineralization at all ages. In infants and young children, vitamin D deficiency can impair growth by disrupting chondrocyte maturation and inhibiting mineralization, causing widening of the epiphyseal growth plate with specific changes in bone formation, as can be seen on X-rays of the distal part of long bones. These changes are known as vitamin D-deficiency rickets. This condition may be part of a more severe and complex nutritional disorder, which contributes to the growth impairment in these young children.

changes in extracellular potassium concentration can be life-threatening. Therefore, plasma potassium concentration must be maintained close to its setpoint. Cells act as an important storage pool for potassium, alternatively taking up excess potassium or releasing potassium, and operate to maintain its plasma concentration within the narrow limits allowed for physiologic function.

EXTRARENAL REGULATION OF POTASSIUM BALANCE

Potassium can be actively transported into and can diffuse out of all cells. Extracellular potassium concentration is therefore regulated by cell membranes that act as effector organs by buffering rapid changes in plasma potassium concentration, such those occurring during the absorptive period. This system is highly effective, particularly in protecting against sudden changes in potassium concentration. For instance, after an intravenous bolus injection of KCl that raises the plasma potassium concentration by 1.1 mmol/liter (a 25% increase), the system is able to return to the setpoint within approximately 7 min of the start of the bolus injection.

The maintenance of distribution of potassium across cells is largely dependent on the activity of the Na^+/K^+ -ATPase, which expends energy to pump sodium out of the cell and potassium into the cell. Virtually every cell in the body uses this mechanism to maintain a high intracellular potassium concentration and a low extracellular potassium concentration.

There are several regulatory factors that control the distribution of potassium within body fluid compartments (Table I). Among them, hormones play a prominent role. Insulin drives potassium into cells independent of its hypoglycemic effect, possibly increasing Na^+/K^+ -ATPase activity. Also, β -agonists, such as epinephrine, promote rapid and profuse potassium movement from the extracellular to the intracellular fluid by cyclic AMP-dependent activation of the Na^+/K^+ -ATPase. Both insulin release and epinephrine release increase after meals, thus facilitating the movement of the ingested potassium to the intracellular space. Hyperkalemia stimulates adrenal aldosterone secretion, which not only affects the renal excretion but also favors a shift of potassium to the intracellular space. Apart from hormonal factors, there are other extrarenal mechanisms that control the distribution of potassium within the body compartments. Changes in the acid-base status can lead to changes in plasma potassium concentration. In particular, a

decrease in blood pH causes hydrogen ions to enter cells. Consequently, potassium exits cells in exchange for hydrogen entering. Alkalemia generally induces the opposite response. An acute rise in plasma osmolality causes an abrupt increase in plasma potassium, most likely due to the rapid exit of water from the cells, accompanied by an increased amount of potassium leaving the cell. Finally, several drugs (Table I) could significantly affect extrarenal potassium homeostasis.

RENAL REGULATION OF POTASSIUM BALANCE

Long-term potassium homeostasis is regulated mainly by the kidney, which ultimately controls plasma potassium concentration as well as total body potassium. The balance of potassium intake and potassium excretion depends on the rate of renal excretion, which can range from less than 10 to over 400 mmol per day, accounting for 90–95% of potassium excretion in the body; the remainder is eliminated by the gastrointestinal tract and sweat glands.

Potassium is freely filtered across the glomerular membrane. Although there is a complex process of potassium reabsorption and secretion by the nephron from the proximal tubule through the loop of Henle, the bulk of filtered potassium load is reclaimed in the proximal nephron, mostly in the proximal tubule.

Beyond the early distal tubule, the tubule may modulate potassium delivery by either reabsorbing or secreting it. Hence, urinary potassium excretion is ultimately regulated by changes in potassium secretion at the distal tubule and the collecting duct under the influence of a number of modulators (Table II).

It should be considered that under most circumstances the kidney primarily works to excrete (rather than to reabsorb) potassium to maintain potassium balance against variation in potassium intake from dietary or other sources. Under normal conditions, when ample potassium is consumed in the diet, there is an addition of potassium along the distal nephron; in the presence of a very high potassium intake, the distal nephron effects net secretion, whereas it effects net potassium reabsorption only in the presence of potassium restriction. Cells in the connecting and collecting tubules respond to a number of signals by modulating their rate of potassium secretion over a wide range of values. The Na^+/K^+ -ATPase located in the basolateral membranes of the tubules provides the driving force for potassium secretion by pumping potassium into the cells. This enzyme system

responds to changes in extracellular potassium concentration, changes in extracellular pH, and changes in mineralocorticoid hormone secretion.

First, intake of potassium is the most important determinant of potassium secretion, by affecting the tubular excretion rate, probably as a function of intracellular potassium concentration. Second, the feedback control of aldosterone secretion by the zona glomerulosa of the adrenal cortex is needed for regulation of potassium excretion. Aldosterone secretion is under the strict control of two stimuli, i.e., the plasma concentration of angiotensin II and the plasma concentration of potassium itself. Aldosterone, which stimulates Na^+/K^+ -ATPase, promotes potassium secretion by increasing basolateral potassium entry into the cells and intracellular potassium concentration. This in turn will favor the delivery of potassium into the renal tubule lumen down its concentration gradient, thereby stimulating potassium secretion. Glucocorticoids also affect potassium secretion primarily by increasing tubule fluid flow rate. Acid-base changes acutely affect secretion. Alkalosis induces greater potassium secretion at the distal tubule by moving potassium into the cells and acidosis moves potassium out of cells as hydrogen ions move in. The urine flow rate itself affects potassium secretion; with diuresis, increased amounts of fluid and salts move to the distal tubule, enhancing potassium excretion. Thus, pharmacological agents, particularly diuretics, may alter potassium excretion. For instance, loop diuretics, such as furosemide, in addition to increasing flow rate to the distal nephron, inhibit potassium reabsorption by the thick ascending limb of the loop of Henle. In contrast, the so-called potassium-sparing diuretics amiloride and triamterene block the apical sodium channel in the late distal tubule and collecting duct. The blockade of the apical sodium channel increases sodium excretion without affecting potassium secretion. Finally, aldosterone antagonists (e.g., spironolactone) also increase sodium excretion without an increase in potassium excretion.

Table II Determinants of Renal Potassium Excretion

Lower potassium excretion

- Decreased intracellular potassium concentration
 - Decreased dietary intake
 - Acidosis
- Unfavorable electrical or chemical profile
 - Reduction of luminal electronegativity
 - Reduction of distal urine flow
 - Reduction of distal sodium delivery or reabsorption
- Kidney function
 - Decreased tubular filtration rate
 - Tubular damage
- Diuretics
 - Inhibitors of the apical sodium channel (amiloride, triamterene)
 - Inhibitors of aldosterone

Increase potassium excretion

- Increased intracellular potassium concentration
 - Increased dietary intake
 - Alkalosis
 - Aldosterone
- Favorable electrical or chemical profile
 - Increase in luminal electronegativity
 - Increase in distal urine flow
 - Increase in distal sodium delivery
 - Low luminal chloride concentration
- Loop diuretics (furosemide)

NUTRITIONAL AND METABOLIC ASPECTS

Potassium is largely present in fruit, vegetables, legumes, and nuts, in the form of inorganic (bicarbonate and phosphate) or organic (gluconate and citrate) salts. Potassium is also found in milk and dairy products and in some types of meat (see Table III).

The total, nondiscretionary intake of potassium varies among different populations. In the

^amg/100g (mmol/100 g).

International Collaborative Survey of Electrolyte Excretion and Blood Pressure, which analyzed 24h sodium and potassium urinary excretion in over 10,000 individuals from 32 countries, the average potassium intake ranged from 25 mmol/day (American

blacks in Goodman, Wisconsin, United States) to 87 mmol/day (Xingu Indians, Brazil). A few isolated populations participating in this worldwide survey were found to consume much greater amounts of potassium and smaller amounts of sodium than people living in industrialized countries, their sodium/potassium ratio being similar to that estimated by anthropologists for our hunter-gatherer ancestors. As discussed above, major sustained increases in plasma potassium concentration are almost never caused by dietary changes, because the homeostatic mechanisms are highly efficient in healthy individuals. In response to a large oral potassium load, the excess potassium is partly stored in the large cellular compartment and partly excreted in the urine in a matter of a few hours. Thus, hyperkalemia may develop only in the presence of severe pathological conditions that impair the activity of these defense mechanisms (e.g., renal failure, adrenal insufficiency). On the other hand, the control of potassium homeostasis is less effective in preventing the hypokalemia caused by a subnormal potassium intake, particularly in the presence of a concomitant high-sodium diet, which induces an obligatory potassium loss. In fact, severe potassium depletion may occur when habitual potassium intake is less than 25 mmol/day. In particular, two conditions may often lead to potassium depletion. One is the "protein-modified fast," which may be adopted by severely obese patients in the early phase of a weight-reducing program; the other is chronic alcoholism, due to the large amount of "empty calories" ingested from alcohol.

For the reasons just discussed, the collection of accurate information about dietary potassium intake is of primary importance. As powerful homeostatic mechanisms act to minimize changes in plasma potassium, the measurement of plasma potassium concentration is of limited value in estimating the adequacy of potassium intake. Several approaches based on dietary assessment methods have been proposed. The personal recall of food consumption is the least reliable method; history records are slightly better, although their accuracy may be hampered by incomplete record-keeping, variability in the potassium content of foods, and errors in estimation of quantity. The most accurate single technique for estimation of dietary intake of nutrients, including potassium, is the collection and analysis of duplicate food samples; unfortunately, this method is expensive and not applicable to population studies. For everyday purposes, the measurement of urinary potassium excretion provides a reasonably good estimate of dietary intake. Its use is based on the assumption that at least 90% of the potassium ingested is eliminated through

the renal route. Well-recognized limitations of this method include the relatively high day-to-day intra-individual variability in potassium intake (and thus potassium excretion) and also the concomitant variability in sodium intake, which in turn influences potassium excretion. To overcome this problem, a certain number of 24 h urine collections are requested if a reasonably good estimate of an individual's habitual potassium intake is to be obtained. Despite these limitations, the measurement of urinary excretion is as yet the simplest and least expensive way to assess dietary sodium and potassium intakes in population studies as well as in clinical studies.

average of 145 to 150 cm. In some individuals, scoliosis, as well as osteopenia and osteoporosis, may be present.

Hypogonadism

Genital hypoplasia (particularly in boys, who present with a small penis), cryptorchidism, and a bifid or

Figure 2 Severe muscle hypotonia in an infant with PWS.

hypoplastic scrotum are common features. In most cases, puberty remains incomplete, more so in boys than in girls, as a consequence of hypothalamic dysfunction. Although precocious development of pubic and axillary hair is a frequent finding, it is the consequence of premature secretion of adrenal androgens, but the pubertal development of the gonadal axis is delayed, insufficient, or absent. Single cases with complete precocious puberty are reported in boys with adult testicular volumes and in girls with menarche. Two women with PWS have become pregnant. In one case, a woman with maternal disomy gave birth to a healthy girl, whereas the other woman, who had a deletion of 15q11–q13, gave birth to a child with Angelman's syndrome.

Developmental Delay and Mental Retardation

Developmental delay is a major concern in most cases. In particular, speech and motor development are retarded. Speech and language difficulties become apparent from an early age on. Children with PWS

usually are able to sit up at 12 months, walk between the ages of 28 and 32 months, and talk in short sentences as late as at 42 months. Most individuals with PWS present mild to moderate mental retardation and IQ testing indicates an average IQ of approximately 60 to 70.

Behavioral Problems

During early childhood, a characteristic behavioral profile emerges. Even at this early stage, young children typically stick to an activity with more persistence than other children and have difficulty with changes in routine. Nevertheless, younger children are happy, affectionate, and cooperative. After the age of 2 years, children with PWS may become obsessed with food and later develop all kinds of food-seeking strategies and atypical behavior, such as gorging on available food, breaking into locked food storage areas, and getting up at night to forage for food. By the time they reach school age, the compulsiveness and obsession of their behavior become more evident. Typical temper tantrums are often observed. Stubbornness and intolerance of frustration relates in the beginning primarily to withholding of food, but may occur also in other situations at a later stage. Adolescents are almost always described as extraordinarily stubborn, clever, manipulative, moody, and prone to temper outbursts. The incidence of psychological disorders is increased in PWS and genuine psychosis occurs in approximately 5 to 10% of patients.

Respiratory Abnormalities

Respiratory abnormalities in PWS are well known. An increased incidence of sleep-related breathing disorders has been reported in obese adults with PWS and a primary disturbance of central respiratory control has been demonstrated in young, not yet obese children with PWS. The pathogenesis of respiratory problems seems to be multifactorial in origin, including peripheral and central mechanisms, such as muscular hypotonia and facial dysmorphism as well as hypothalamic and chemoreceptor dysfunction.

Miscellaneous Characteristics

Individuals with PWS have a characteristic face with a narrow bifrontal diameter, almond-shaped eyes, strabismus, and a triangular mouth. Many individuals are hypopigmented with fair hair and blue eyes. Oral

characteristics include thick saliva, hypoplastic enamel, and caries. Pain sensitivity is reduced and a tendency to self-injury is observed, especially skin-picking on arms, hands, and feet.

Life Expectancy

Life expectancy has been prolonged well into adulthood. Whereas complications of morbid obesity, such as type 2 diabetes and cardiac or respiratory deficiencies have previously doomed affected individuals to an early death, increased awareness of the syndrome and more attention to its management have significantly reduced their likelihood.

DIAGNOSTIC CRITERIA

Diagnostic criteria for PWS were first proposed by Holm in 1981 and were further developed through a consensus process in 1993. At that time, sophisticated genetic analyses were not yet widely available. Because diagnosis of PWS can be confirmed by genetic testing, clinical diagnostic criteria should be used more often to raise diagnostic suspicion and prompt testing. Therefore, the purpose of clinical diagnostic criteria has shifted from assisting in confirming the diagnosis to raising diagnostic suspicion, thereby prompting testing. Accordingly, revised clinical criteria to help identify appropriate patients for DNA testing for PWS have been suggested by Gunay-Algun *et al.*

METABOLISM IN PWS

Carbohydrate Metabolism

Diabetes mellitus is a common complication, occurring in 7 to 9% of adolescents and 17 to 40% of adults with PWS as a consequence of severe obesity. The variance in the reported prevalence depends mainly on differences in age and the degree of obesity, but also on the ethnicity of the various study groups.

The specific etiology of the type 2-like diabetes in PWS remains unknown. Children and adolescents generally present with decreased fasting insulin levels and a normal insulin sensitivity, but a reduced and delayed insulin response of beta cells in oral glucose tolerance tests. Normal insulin sensitivity seems to be related to the relatively low degree of visceral fat accumulation. Later, the manifestation of a type 2-like diabetes in PWS is assumed to be precipitated by the addition of excessive obesity to impaired insulin

secretion. In fact, also in PWS, insulin sensitivity can be impaired above a critical increase in fat mass.

Energy Balance

The enormous fat accumulation in PWS is caused by an imbalance of energy intake and energy expenditure, which results in an increase in energy storage. Basal metabolic rate—largely identical with the resting energy expenditure—was found to be decreased by 20 to 50% in PWS, when related to weight or height, reflecting the decrease in lean mass in this syndrome. Activity-related energy expenditure, assessed by deuterium dilution, is also decreased in PWS. The reason that PWS children and adolescents engage less in physical activity has been ascribed to hypothalamic dysfunction.

Lipid Metabolism

Certain aspects of lipid metabolism in PWS differ from nonsyndromal obesity. In PWS, triglyceride levels are normal, though still correlated with abdominal obesity. Low-density lipoprotein cholesterol levels, however, are elevated and high-density lipoprotein cholesterol levels are decreased, as is found in GH deficiency.

HYPOTHALAMIC DYSFUNCTION

Despite in-depth knowledge of the genetic condition in PWS, the final link between the chromosomal disorder and the clinical symptoms remains unclear. Hypothalamic dysfunction, as already originally presumed by Prader *et al.*, appears to underlie many of the features of PWS, including hypogonadism, disturbed energy balance, high pain threshold, and sleep disorders, but no overt structural abnormalities of the hypothalamus have been found yet. It has been shown that growth hormone deficiency due to hypothalamic dysregulation contributes not only to the abnormal growth pattern and osteopenia, but also to the excess of body fat and to the deficit of lean body mass, with reduced energy expenditure as a consequence. The decreased growth hormone (GH) secretion in PWS differs from that seen in simple obesity, where GH secretion is not disturbed, but rather is down-regulated and fully reversible by weight loss.

In view of the intriguing similarity of PWS to leptin deficiency, as shown by the ob/ob mouse with decreased satiation, hypoactivity, and obesity as well as short stature with decreased GH secretion and

infertility, some studies have investigated leptin levels in individuals with PWS, but found normal plasma leptin levels for body fat. Therefore, it is tempting to speculate that a disorder further down the cascade of the weight-regulating system may be responsible for the dysfunctional hormonal regulation in the hypothalamus as well as for decreased satiation and hypoactivity.

THERAPY

Comprehensive Team Approach

Individuals with PWS need a variety of interventions to optimize their growth and development. These physical and occupational therapies include dietary management, GH and sex steroid substitution, speech, language and learning disability services, behavior and family interaction management, support, and care. Successful patient management therefore requires a multidisciplinary team, consisting of a PWS specialist, an endocrinologist, a geneticist, a psychologist, a dietician, a physiotherapist, and a coordinating nurse.

Growth Hormone Treatment

In prepubertal obese children with PWS, administration of GH has a remarkable impact on growth and, in combination with restriction of food intake, also on body composition, resulting in a dramatic change in the phenotype. GH treatment continuously increases height velocity and normalizes growth and body proportions (Fig. 3). If treatment is instituted early enough, final height prediction will reach the parental target height range after 3 years and short stature as well as small hands and feet will no longer be present. GH has a sustained impact on the net loss of body fat, which nevertheless remains elevated and improves the pattern of serum lipids. In addition to the medical benefits, the disappearance of the obese phenotype of prepubertally GH-treated PWS children relieves the patients and their families of stigmatization. A further benefit of GH treatment in PWS is the increase in lean body mass and, subsequently, resting energy expenditure. This leads to a reduction of energy stores, mainly of body fat, if energy intake is not increased. However, the initial deficit in lean body mass is counteracted by GH only during the first year of therapy. In the long term, GH therapy does not further compensate for this deficit. Further favorable effects of GH treatment in PWS were reported on respiratory muscle function, physical capacity,

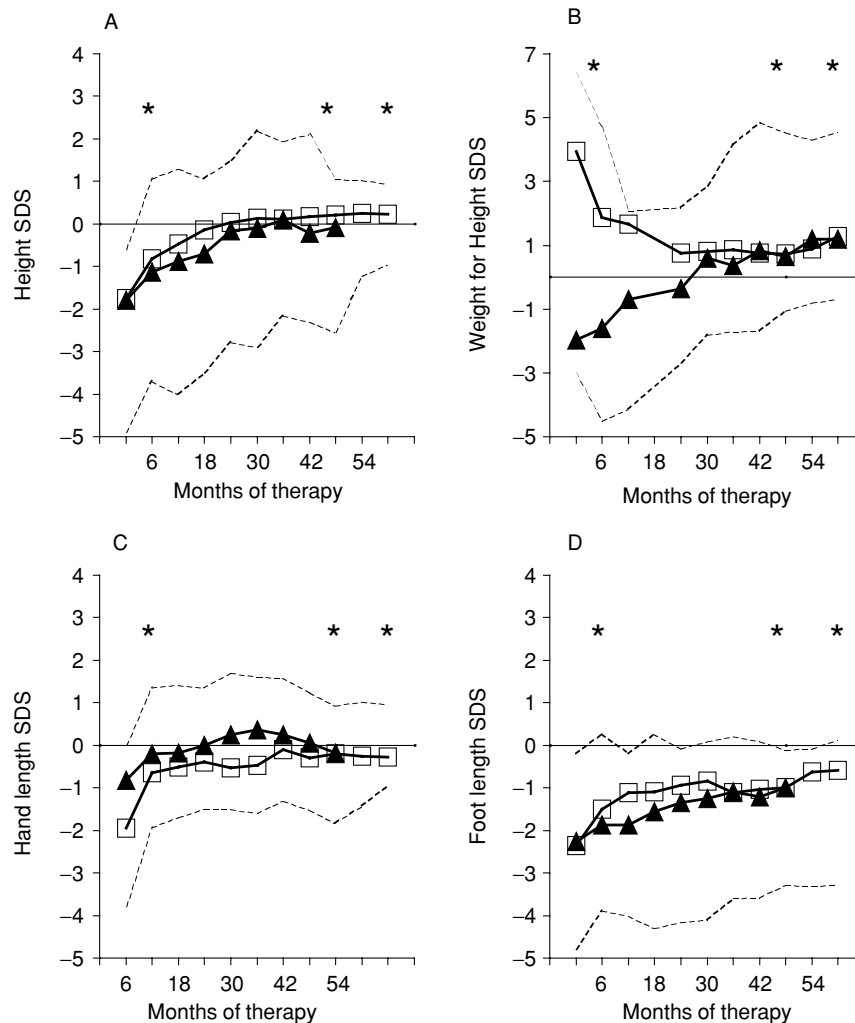

Figure 3 Height standard deviation score (SDS) (A), weight for height SDS (B), hand length SDS (C), and foot length SDS (D) of children with PWS, referring to normative data of the Zurich Longitudinal Study, before and during up to 5.5 years of GH therapy. Values are shown for young, initially underweight children (black triangles, $n = 10$) and overweight prepubertal children (open squares, $n = 8$). Medians are shown as solid lines and the minimum and maximum of the combined groups are shown as broken lines. Significant differences, tested at 6, 48, and 60 months by Wilcoxon test, in each group versus the value before therapy are indicated by asterisks ($*P < 0.05$). Reprinted with permission from Eiholzer, U., *et al.* (2000). *Horm. Res.* 53, 44–53. Karger, Basel.

strength, agility, and activity. However, the benefits of GH treatment also need to be weighed against the risks related to diagnostic procedures or treatment; during narcosis and sedation, the specific risk due to central hypoventilation must be considered. Hypothalamic hypothyroidism may be uncovered during GH therapy and needs adequate substitution. Scoliosis or kyphosis can be aggravated by GH-induced catch-up growth and requires careful orthopedic management. Furthermore, another study has warned that GH treatment may accelerate the manifestation of diabetes in PWS, particularly in children who become extremely obese during therapy.

Regardless of GH treatment, carbohydrate metabolism in PWS needs to be closely and permanently monitored. GH treatment in PWS is a rather new therapeutic option and therefore only a little experience has been gained in controlled studies thus far. Many questions concerning appropriate age at initiation of treatment, optimum dosage, long-term safety, and long-term effects remain unanswered.

Sex Hormone Substitution

Although hypogonadism is clearly documented in PWS, the substitution of sex hormones in puberty

remains controversial. Most authors recommend androgen substitution in males because of its beneficial effects, such as complete virilization, change in voice, prevention of osteoporosis, and increasing muscle mass as well as activity level, but some authors believe that it may lead to a more aggressive behavior and aggravate temper tantrums. However, there are no studies examining behavior during sex steroid substitution. In young women with PWS, estrogen substitution may prevent osteoporosis and although an increase in obesity is feared, it has not yet been scientifically assessed in these patients.

Physical Therapy and Exercise

Physical therapy should aim to prevent scoliosis and to improve muscle strength and physical activity. Increased physical activity may lead to increased energy expenditure; it promotes a negative energy balance, raises the postexercise metabolic rate, builds muscle mass, and enhances the overall sense of well-being. Therefore, the crucial importance of regular physical activity should be clearly communicated to patients, parents, and caregivers.

Dietary Restriction and Psychological Counseling

Even though height and weight are normalized during GH treatment, children with PWS must stick to a strict diet with a reduced energy intake of 75% of that for healthy children to stabilize the weight balance. A food intake restriction of this extent is possible only with close and strict supervision by parents and caregivers. Consequently, there is a lifelong need for environmental modifications to restrain food intake in PWS. This enormous task not only challenges

all caregivers, but may also exacerbate behavioral problems in patients. Therefore, there is no doubt about the need for psychological counseling and a comprehensive care team approach.

idiopathic or organic. In general, the majority of girls with CPP have the idiopathic form. The incidence of CPP in boys is much lower than in girls, and more frequently the cause is organic.

It has been shown that 70–90% of girls with CPP are idiopathic. The number of organic causes will likely increase with the refinement of central nervous system imaging by magnetic resonance imaging (MRI), revealing, for example, hypothalamic hamartoma in children formerly diagnosed with idiopathic CPP. In young girls, CPP must be differentiated from premature thelarche without central activation.

In idiopathic CPP, no organic cause for the precocious onset of puberty is found. In general, the younger the girl at the onset of CPP, the higher the chance of organic pathology.

In organic CPP, a cerebral organic lesion causes the premature onset of puberty. Local pressure on GnRH neurons or disruption of inhibitory fibers may cause GnRH release. [Table I](#) lists the causes of organic CPP. Treatment of CPP in children with organic lesions is primarily aimed at the underlying pathology. However, the progression of puberty is not always halted by this treatment.

DIAGNOSIS AND CLINICAL PRESENTATION

Girls with CPP usually present with breast development as the initial sign of puberty ([Fig. 2](#)). Frequently, this is accompanied by acceleration of growth, occurrence of pubic hair, and, sometimes, behavioral changes. In some girls, menarche occurs soon after the onset of breast development due to rapid progression of puberty.

Less visible changes occur in bones and internal genitalia. The progression of bone age accelerates as a result of estrogenic stimulation and may cause premature closure of the growth plate, resulting in compromised final height. The method of bone age assessment in CPP is not uniform. In most studies, the Greulich–Pyle method is used. It has been shown that final height predictions for CPP using the tables of Bayley and Pinneau for accelerated bone age significantly overestimate the achieved final height, and it is more appropriate to use the “average” tables for prediction.

Figure 2 A 7-year-old girl with clinical presentation of CPP.

Pelvic ultrasonography reveals the changes in aspect and volume of the ovaries and uterus. The ovaries increase in volume, and the number of follicles as well as the diameter of the ovaries increase. Uterine findings include changes in shape and the presence of endometrium.

In young girls presenting with CPP, MRI of the brain (especially the pituitary region) is mandatory to exclude central nervous system (CNS) abnormalities. The role of MRI in girls with signs of puberty at age 6 or 7 is under discussion. Some studies indicate that in these cases the search for pathology should not be performed. On the other hand, MRI in girls with CPP at age 6 or 7 has shown CNS abnormalities. A decision tree is being developed to rationalize the decision process.

An essential part of the diagnosis of CPP is the biochemical confirmation of the central (hypothalamopituitary) stimulation of the gonads by gonadotropins. In premature thelarche, for example, no central activation is present. The demonstration of central activation is a prerequisite for treatment with GnRH agonists. Basal values of LH or follicle-stimulation hormone (FSH) have limited value. Therefore, stimulation tests with native GnRH or a short-acting GnRH agonist (GnRHa) should be used in the diagnostic workup.

The increasing sensitivity of the pituitary for GnRH stimulation in normal puberty is the basis of the test. Depending on the assay, the peak value of serum LH should exceed a particular threshold. Early studies used thresholds >10 IU/liter using radioimmunoassay methods, whereas the use of the more sensitive immunofluorometric assay allows cutoff values of approximately 6 IU/liter. A prepubertal response in a GnRH stimulation test does not completely rule out the presence of CPP since it has been demonstrated that the more potent GnRH agonists, when used in a stimulation test, are able to produce pubertal LH peaks in children with prepubertal LH peaks in the standard GnRH stimulation test. Mainly children with recent onset of puberty demonstrate these varying results in the different stimulation tests.

Some authors have emphasized that a predominant response of LH over FSH should be used in the diagnosis of puberty. However, there is no absolute value for the LH:FSH ratio.

The use of sex steroid serum levels in the diagnosis of CPP is limited as well because of the circadian variation of these levels. However, they may be used in the evaluation of pubertal suppression during treatment. Table II provides a summary of the diagnostics in CPP.

TREATMENT

Gonadotropin-Releasing Hormone Agonists

Synthetic agonists of GnRH in depot form are the treatment of choice for CPP. Basically, the native GnRH molecule is modified at least at the glycine 6 position, where it is substituted by another amino acid resulting in a superagonistic effect. Prolonged exposure of the pituitary to a GnRHa paradoxically results in inhibition of gonadotropin secretion (Fig. 3).

The mechanism of this inhibitory effect is not completely clear. For example, it seems that the frequency

Figure 3 Schematic representation of the inhibiting effect of gonadotropin-releasing hormone agonist (GnRHa) exposure. I, GnRH stimulation before GnRHa treatment. Luteinizing hormone (LH) increases considerably in reaction to GnRH stimulus. II, GnRH stimulation during GnRHa treatment. There is no increase in LH after GnRH stimulus due to the inhibitory effect of prolonged GnRHa exposure.

of the GnRH pulses is not altered after GnRHa exposure and that down-regulation of GnRH receptors occurs to only a limited extent. The depot formulations of GnRHa have been shown to be able to effectively suppress the endogenous pubertal activity in CPP. The clinical representation of this inhibition is arrest of pubertal development, sometimes even regression of physical signs of puberty, decreasing volume of ovaries, and deceleration of bone age maturation.

In Europe, triptorelin and leuprolide acetate are most frequently used as GnRHa depot preparations. The recommended monthly dose is 3.75 mg intramuscularly or subcutaneously. In general, in the United States 7.5 mg is the recommended dose. The optimal dose should be the lowest with which optimal suppression can be achieved. Only a few side effects have been described, mainly sterile abscesses at the injection sites.

Indications

In the literature, no general view has been presented as to when to start treatment in CPP. Indications for treatment are either auxological or psychological. The aim of treatment concerning growth is to attain a final height in accordance with parental height and thus to prevent height loss due to the early onset of puberty. Psychological issues include reduction of psychological stress resulting from development of puberty inappropriately early for age. Sexual abuse and early pregnancy appear to be rare. However, for patients with mental retardation, early sexual activity and early menarche require special concern of families and peer groups (school). In these patients, GnRHa treatment may be indicated. Before initiation of treatment, central activation of the pituitary has to be demonstrated.

Monitoring

Several parameters should be used to monitor the suppressive effect of treatment. As mentioned previously, clinical progression of puberty must stop or even regress, and menstrual bleeding should not occur. However, withdrawal bleeding soon after the initiation of treatment is frequently observed. Furthermore, the pubertal growth velocity should decrease to normal prepubertal values. Bone age progression will slow, especially after 6 months of treatment. On ultrasound, ovarian volume decreases to prepubertal values. Biochemically, baseline sex steroid levels will become prepubertal in effectively suppressed patients. Suppression of hypothalamic–pituitary–gonadal axis activity is determined during treatment by intravenously GnRH testing. Alternative methods include

taking a blood sample after subcutaneous GnRHa or after injection of the GnRHa depot. Some children show behavioral changes after the injection interval, which may indicate ineffective suppression during the final days of the injection interval.

Results of Treatment

Numerous studies have addressed the effect of GnRHa treatment for CPP, and final height data have become available. However, none of these studies used randomized controlled study designs; thus, all need critical review. Most studies have used the difference between height prediction at the start of treatment and attained final height as the most important outcome parameter. It is well-known that there is a wide variation in bone age assessment between observers; thus, height predictions may lack reliability. Study designs should include an assessment of bone age by only one observer. Furthermore, as noted previously, height predictions vary depending on the method and the prediction tables used. Another way to evaluate the effect of treatment is to compare attained final height with midparental height or genetic target height.

Table III presents some of the major studies on final height after GnRHa treatment in girls with CPP. It can be concluded from the table that final height in girls with CPP after GnRHa treatment results in final height gain of approximately 6 or 7 cm. When compared to parental height, final height is 0.5–1.0 SD below target height or midparental height. Many factors influence the results of treatment, but no clear conclusion can be drawn from the different studies about the relative importance of

Table IV Factors That Influence Final Height after GnRHa Treatment

| |
|--|
| At start of treatment: |
| Bone age at start of treatment: |
| higher bone age → better final height. |
| Chronological age at start of treatment: |
| lower chronological age → better final height. |
| At discontinuation of treatment: |
| Bone age at end of treatment: the higher the age, the less positive effect on final height. |
| Chronological age at end of treatment: the higher the age, the less positive effect on final height. |
| Bone age advance at discontinuation of treatment: |
| The more advanced over chronological age, the less positive effect on final height. |

each, mainly due to the complex interaction of the variables included.

Multivariate analyses of the results of treatment are probably most appropriate for the development of guidelines. The factors shown in [Table IV](#) have been shown to influence the results of treatment (height gain) in multivariate analysis. Several studies show better results in girls with CPP when treatment is initiated before age 6. In contrast, in univariate analysis, chronological age at the start of treatment is negatively correlated with height gain. These contradictory results emphasize the need for proper analysis of the results of treatment.

The optimal timing with respect to chronological age and bone age for discontinuation of treatment cannot be determined from the literature. Possibly the best indication to discontinue treatment is a decrease of height velocity below prepubertal values during GnRHa treatment. Alternatively, one may assess height prognosis every 6 months and discontinue treatment after a decrease in height prognosis.

Concerning other outcome variables after GnRHa treatment in CPP, endocrine investigation after discontinuation of treatment showed complete reversibility of gonadal suppression. Menarche occurred within 1 year after discontinuation of treatment. The scant data on fertility showed no adverse outcome.

Studies on bone mineral density (BMD) during GnRHa treatment in girls showed normal BMD for chronological age and low BMD when corrected for bone age. At final height, BMD appeared to be normal.

In some children, body mass index (BMI) increases during GnRHa treatment. Pretreatment BMI SD is the strongest predictor of increased BMI SD at final height. GnRHa treatment does not lead to obesity.

GnRHa and Growth Hormone

During treatment with GnRHa, it is frequently observed that height velocity decreases, even below prepubertal levels. The effects of GnRHa treatment on the growth hormone (GH)–IGF axis remain controversial. However, several groups have studied the effect of the addition of GH to GnRHa in children with precocious puberty. Results suggest the importance of maintaining adequate height velocity during treatment to achieve height gain. In short-term studies, the addition of GH resulted in increased predicted adult height compared to treatment with GnRHa alone. Only one study provides data for final height, confirming the results of the short-term studies.

Other Treatment Options

Progestational agents (e.g., cyproterone acetate or medroxy progesterone acetate) no longer play a role in CPP treatment. Hormonal suppression has been shown to be inadequate, thus compromising final outcome. Daily administered preparations of GnRHa (e.g., nasally) should not be used since they have been shown to be inferior to depot preparations.

Depot preparations that allow children to receive an injection once every 3 months instead of monthly are being studied. The difference in efficacy between intramuscularly and subcutaneously administered depot preparations is not known.

Aromatase inhibitors may become important in the treatment of CPP. However, no data in children are available.

CONCLUSION

Effective suppression of pituitary gonadal function is achieved with depot GnRHa treatment in girls with CPP. Hormonal suppression is fully reversed after treatment is discontinued. Further studies should be performed to determine the final indications of treatment.

Table I Differential Diagnosis of Central Precocious Puberty in Males

| |
|--|
| Idiopathic: Sporadic |
| CNS lesions |
| Hypothalamic hamartoma |
| Malignancies: Astrocytoma, ependymoma, glioma |
| Optic glioma |
| CNS infections |
| Head trauma |
| CNS irradiation |
| Congenital malformations: Arachnoid/suprasellar cyst, hydrocephalus, septo-optic dysplasia |
| Secondary central precocious puberty |
| Congenital adrenal hyperplasia |
| Hypothyroidism |

HORMONAL STUDIES

Diagnostic tests include assays of serum testosterone (T), LH, and follicle-stimulating hormone (FSH), preferably by the most sensitive methods available. Depending on method sensitivity, levels higher than 10–20 ng/dl of total T are in the pubertal range. Although in the early stages of puberty T and LH levels are highest during sleep, early morning T may be of diagnostic value. Basal LH levels can be misleading because of the episodic nature of LH secretion and the lack of sufficient sensitivity of most commercial assays. Unless third-generation sensitive methods are employed, a random LH level may not be distinguishable from the prepubertal range. Therefore, in order to adequately assess gonadotropin secretion, dynamic studies should be performed using a GnRH stimulation test. The characteristic pubertal pattern is that of a significant and incrementally dominant LH response compared to FSH response. The reverse is true of the prepubescent pattern, typically illustrated by a relatively blunted LH response and a predominant FSH response to stimulation.

IMAGING STUDIES

Skeletal Age

To determine the biological age of the child, an X ray of the nondominant (left) hand and wrist is taken. If the bone age (BA) is advanced by more than 2 standard deviations for chronological age, it is unlikely that the child has a normal variant of pubertal development. BA is also important for estimating the child's final adult height; thus, it is of value in determining if and when therapeutic intervention is indicated.

Magnetic Resonance Imaging

It is imperative to perform magnetic resonance imaging (MRI) of the brain in every child with CPP in order to exclude a CNS lesion as the cause (Table I). Studies have shown that CPP may be the only presenting sign of an intracranial tumor or malformation.

DIFFERENTIAL DIAGNOSIS

Table I lists the main causes of CPP. Idiopathic CPP accounts for up to 50% of cases of CPP in boys, and it is usually a sporadic occurrence. Because of the relatively high incidence of underlying organic lesions, idiopathic CPP should be considered a diagnosis of exclusion in boys. Among the organic causes, CNS pathology should be a foremost consideration in the differential diagnosis.

Organic Causes

CNS Tumors

CNS tumors are the most important lesions and they can be occult, sometimes necessitating serial MRIs for detection. The most common ones are hamartomas of the tuber cinereum, optic gliomas, and astrocytomas. Hypothalamic hamartomas are congenital, nonneoplastic, tumor-like lesions formed by heterotrophic gray matter, neurons, glial cells, and fiber bundles in the hypothalamus. They tend to grow slowly and are manifested by puberty occurring at an early age. Some hypothalamic hamartomas are associated with gelastic seizures, also called laughing seizures, which are often resistant to anticonvulsive treatment. Optic gliomas may be associated with neurofibromatosis. Although CNS neoplasms eventually manifest localizing signs (e.g., visual impairment and diabetes insipidus), precocious sexual development may be the earliest manifestation. Other CNS lesions, including congenital malformations, head trauma, or infection, may be causes of sexual precocity.

CNS Radiation

The incidence of precocious puberty following radiation to the brain is related to the radiation dosage. A relatively high dose is likely to cause gonadotropin deficiency, whereas low doses induce precocious sexual development. In contrast, chemotherapy alone is not a causative factor in sexual precocity.

Secondary CPP

Long-term exposure to endogenous sex steroids (e.g., for inadequately treated congenital adrenal hyperplasia) leads to an accelerated linear growth and BA and

early initiation of puberty. An intriguing observation with respect to environment is the high incidence of CPP in children adopted from developing countries. Primary hypothyroidism may also cause CPP, which is reversible after thyroid hormone treatment.

NATURAL HISTORY

The natural history of children with CPP is varied. Frequently, the progression of pubertal development is more rapid than that of the normal pattern of maturation (especially in the case of brain tumors), with accelerated growth and skeletal age. This continuous exposure to sex steroids eventually causes premature fusion of the epiphyseal growth plates, leading to an overall decreased adult height. However, often in idiopathic CPP, secondary sexual characteristics progress either very slowly or in short bursts followed by quiescent periods during which growth velocity returns to normal and BA acceleration is halted. In such cases, the final height may not be compromised, and therapy is not required.

MANAGEMENT

Indications for Treatment

The principal objective is the attainment of a normal adult target height as genetically determined. A rapidly advancing BA will result in tall stature during childhood but eventually premature epiphyseal fusion leading to short adult stature. Treatment is clearly indicated in such cases. Other indications include psychosocial/behavioral aspects of precocious puberty. Surprisingly, however, only a few serious psychological problems and long-term sequelae have been described. There is a consensus that not all patients with CPP need medical intervention, such as in cases in which pubertal development is slow and the potential for attaining a normal adult height is preserved.

Treatment Options

GnRH Agonists

The optimal therapy of CPP is the administration of GnRH agonists. These agents are potent derivatives of the natural decapeptide GnRH, and they are structurally similar. They are available in either aqueous forms given by daily injections or as depot (long-acting) formulations. By binding to the pituitary GnRH receptor, the agonist initially causes a stimulatory effect of short duration. It subsequently induces

suppression of gonadotropin secretion through sustained occupancy of GnRH receptors and desensitization to endogenous GnRH. For patient convenience and compliance, the trend has been to use depot preparations. One commonly used agonist is leuprolide acetate given in monthly doses of 7.5–11.25 mg. To ensure adequate LH suppression, a short GnRH stimulation test should be performed after the first 2 months of therapy.

Combined GnRH Agonist and Growth Hormone Therapy

An exaggerated deceleration of the growth rate can be observed during GnRH agonist therapy caused by the excessive suppression of the growth-promoting effects of sex steroids and, indirectly, growth hormone secretion. Some authors have advocated the combined use of growth hormone and GnRH agonist therapy in these instances. This is also necessary in cases of brain tumors or postirradiation when growth hormone deficiency coexists with CPP.

Treatment Effects

Treatment with GnRH agonist may lead to a decrease in testicular volume, and penile erections become less frequent. When present, aggressive behavior may decrease in frequency and severity. Linear growth velocity is decreased, as is the rate of bone maturation, resulting in improvement of adult height potential.

Monitoring of Treatment

Periodic evaluation of the child's growth, hormone levels, including serum T and LH, ensures that adequate hormone suppression is maintained. An annual assessment of BA is generally sufficient. The aim should be to achieve normalization of the growth rate proportionate to the BA advance, such that the predicted adult height improves progressively. Family counseling is important during this generally long-term therapy.

Post-Therapy Physiologic State

Complete reversibility of the hypothalamic–pituitary–gonadal axis suppression occurs after GnRH agonist therapy is discontinued. Puberty resumes in the majority of cases within 3–6 months, and testicular growth becomes age appropriate. No cases of infertility have been reported. Treatment with GnRH agonists, particularly when administered as depot preparations, generally preserves a satisfactory adult

height potential, more favorably in idiopathic CPP than in cases in which there is an organic cause.

Complications

Side effects are usually mild. Sterile abscesses at the injection site have been reported due to an idiosyncratic reaction to the injection vehicle.

Peak bone mass is accrued during the pubertal years. Bone mineral density (BMD) is often increased for age at the time of diagnosis of CPP and declines during agonist treatment. Also of concern is whether defective bone mineralization could occur after several years of suppression of gonadal steroids. Most studies have not shown such a negative outcome. Nonetheless, the effects on ultimate BMD deserve further study. Optimizing calcium and vitamin D intake during therapy is recommended.

FUTURE DIRECTIONS

Since estrogen is the primary stimulus for skeletal maturation and fusion of the epiphyseal growth plates, the use of aromatase inhibitors for the enhancement of growth potential has been reported in preliminary studies. This may offer a promising therapeutic modality for boys with CPP whose height potential is seriously compromised.

Table 1 Causes of Gonadotropin-Independent Precocious Puberty

| |
|--|
| Latrogenic or exogenous sexual precocity |
| Human chorionic gonadotropin-secreting tumors |
| Hypothyroidism |
| Gonadal origin |
| <i>Females:</i> Hormone-secreting ovarian tumor, McCune–Albright syndrome |
| <i>Males:</i> Testotoxicosis, Leydig cell adenoma, aromatase excess syndrome |
| Adrenal origin |
| Congenital adrenal hyperplasia |
| Virilizing adrenal neoplasm |
| Cortisol resistance syndrome |

retroperitoneum and certain hypothalamic pineal tumors cause sexual precocity in boys by secreting hCG rather than activating the hypothalamic GnRH pulse generator. Hepatomas and hepatoblastomas can also secrete hCG, leading to sexual precocity in boys.

Familial Male-Limited Precocious Puberty

Normally, testicular Leydig cells produce testosterone after LH binds to its receptor, with subsequent signaling through G proteins and the adenylyl cyclase pathway of signal transduction. Genetic mutations may prematurely activate this cascade either at the level of the LH receptor (testotoxicosis) or downstream, at the level of the stimulatory G proteins (McCune–Albright syndrome).

Familial male-limited precocious puberty, also known as testotoxicosis, is an autosomal dominant form of gonadotropin-independent precocious puberty caused by constitutively activating mutations of the human LH receptor gene. Affected boys develop rapid virilization, growth acceleration, and skeletal advancement between 2 and 4 years of age, with elevated levels of testosterone despite prepubertal levels of LH. Testicular biopsy specimens show premature Leydig cell maturation.

FEMALE GONADOTROPIN-INDEPENDENT PRECOCIOUS PUBERTY

McCune–Albright Syndrome

The McCune–Albright syndrome is a sporadic disease characterized by polyostotic fibrous dysplasia, café

au lait pigmentation of the skin, gonadotropin-independent sexual precocity, and multiple endocrinopathies, including hyperthyroidism, pituitary adenomas secreting growth hormone, and autonomous adrenal hyperplasia.

The sexual precocity in girls is frequently heralded by menstrual bleeding in the first 2 years of life. The ovaries contain multiple follicular cysts and commonly exhibit asymmetrical enlargement. Serum estradiol is elevated; in contrast, the LH response to GnRH is prepubertal.

Somatic activating mutations of the stimulatory G protein are found in mosaic form in the affected organs in this disorder. These mutations occur early in embryogenesis, resulting in a widespread mosaic of normal and mutant-bearing cells. The constellation of abnormalities is dependent on the specific distribution of mutant-bearing cells.

dehydroepiandrosterone sulfate (DHAS) as precursor for placental production of estrone (E_1) and estradiol (E_2). The placenta, which lacks 16α -hydroxylation ability, also uses 16α -DHAS produced in the fetal liver as precursor for estriol (E_3), but 90% of estriol production results from fetal adrenal DHAS production. E_3 is the E produced in greatest quantity during pregnancy; E_1 and E_2 are derived equally from fetal and maternal precursors.

E_1 in the maternal plasma rises from 6 to 10 weeks and reaches 2–30 ng/ml at term. E_2 rises from 6 to 8 weeks and reaches 6–40 ng/ml at term. During pregnancy, E_1 and E_2 excretion is increased approximately 100-fold compared to nonpregnant levels, whereas E_3 excretion increases 1000-fold. The maternal level of E_2 is higher than in the fetus, whereas the level of E_3 is lower.

The maternal cardiovascular adaptations to pregnancy are also regulated by E. Blood volume is increased by E stimulation of the maternal and trophoblastic renin–angiotensin systems and uteroplacental blood flow is influenced by the vasodilatory effects of E. Placental aromatization is so efficient that no androgens from the maternal side reach the fetuses, protecting it from masculinization. The Es presented to the maternal bloodstream are rapidly metabolized by the maternal liver prior to excretion into the maternal urine. Only approximately 8–10% of the maternal blood E_3 is unconjugated.

THE FETAL ADRENAL CORTEX

By gestational weeks 8–9, the fetal adrenal cortex is differentiated into a thick inner fetal zone and a thin definitive outer zone, the forerunner of the adult cortex. By the end of the first trimester, the gland reaches a size equal to or larger than that of the adjacent kidney. After the 20th to the 24th week, the adrenal glands slowly decrease in size until a second growth spurt at approximately 34–35 weeks. After delivery, the fetal zone (approximately 80% of the bulk of the gland) rapidly involutes to be replaced by simultaneous expansion of the adult adrenal cortex.

The expression and the isomerase activity of 3β -hydroxysteroid dehydrogenase are low in the fetal adrenal and therefore dehydroepiandrosterone (DHA) and DHAS are its major products. Fetal DHA and DHAS production rises steadily, concomitant with the increase in the size of the fetal zone and increase in adrenal weight. Maternal E levels follow the increased availability of the fetal DHAS as a precursor. Early in pregnancy, the gland grows and functions without

adrenocorticotrophic hormone (ACTH), perhaps in response to hCG. After 15–20 weeks, fetal ACTH is required. Paradoxically, during the last 12–14 weeks of pregnancy when fetal ACTH levels are declining, the adrenal gland quadruples in size. Because prolactin is the only fetal pituitary hormone to increase throughout pregnancy, paralleling changes in the size of the fetal adrenal, it was proposed as the critical tropic substance. Nevertheless, only ACTH exerts adrenal steroidogenesis. It activates adenylate cyclase, increases LDL receptors, and increases the expression of its own receptors. These cause increased uptake of circulating LDL-cholesterol, largely derived from the fetal liver, and *de novo* synthesis of cholesterol in the adrenals to sustain the high rates of DHAS and E formation. The tropic support of the fetal adrenal gland by ACTH from the fetal pituitary is protected by the placental conversion of cortisol to cortisone by 11β -hydroxysteroid dehydrogenase. In late gestation, when E levels are high, less cortisol is transferred to the fetus, fetal ACTH secretion increases, the fetal adrenal gland undergoes greater maturation, and fetal cortisol synthesis from endogenous cholesterol increases.

Corticotropin-releasing hormone (CRH) production and the size of the fetal adrenal gland are closely correlated. CRH augments fetal ACTH secretion in a positive feedback mechanism, producing adrenal growth and cortisol and DHAS secretion. CRH may also directly stimulate DHAS production.

Adrenal steroidogenesis is subject to autocrine and paracrine regulation by various growth factors, such as inhibin A, activin A, transforming growth factor- α , basic fibroblast growth factor, and insulin-like growth factor-I (IGF-I) and IGF-II. The exact nature of these effects is beyond the scope of this article.

POLYPEPTIDE HORMONES

The placental villus exterior has cytotrophoblasts (CT), separate mononuclear cells that are prominent early in pregnancy and sparse late in pregnancy, and syncytiotrophoblasts (ST), cells that form a continuous multinuclear layer on the surface. CT is the basic placental stem cell from which the ST arise by differentiation. ST is the functional cell type of the placenta. Trophoblast differentiation is influenced by hCG and several other growth factors. Since the surface of the ST is in direct contact with the maternal blood, placental proteins are secreted directly and preferentially to the mother. Several hypothalamic-like peptides originate in the CT and influence the ST to secrete

pituitary-like hormones. In addition, locally produced hormones, growth factors, and peptides work together to regulate placental function.

Hypothalamic-like Releasing Hormones

Placental gonadotropin-releasing hormone (GnRH) regulates placental steroidogenesis and release of prostaglandins (PGs) as well as hCG. The placental receptors for GnRH have lower affinity than that of GnRH receptors in the pituitary, ovary, and testis. GnRH receptors are present in both CT and ST in a pattern that parallels hCG secretion, suggesting that GnRH regulates hCG secretion. GnRH release is increased by E, activin A, insulin, and PGs and inhibited by P, endogenous opiates, inhibin, and follistatin.

CRH is produced in the trophoblast, fetal membranes, and decidua. Its production is decreased by P and increased by glucocorticoids, which are responsible for the rise in ACTH and cortisol during the last weeks of pregnancy and during labor. The progressive increase in maternal CRH levels during pregnancy is due to the secretion of intrauterine CRH into the maternal circulation.

Human Chorionic Gonadotropin

hCG is a glycoprotein $\alpha\beta$ -dimer. A high content of sialic acid prolongs its half-life compared to its analogue, luteinizing hormone (LH). The α -subunit is identical in hCG, LH, follicle-stimulating hormone, and thyroid-stimulating hormone. The biological activity is specific to the β -subunit. hCG production and secretion are stimulated by GnRH, interleukin-1 β , activin, and E and inhibited by endorphins, inhibin, P, and follistatin. The only definitely known function for hCG is support of the corpus luteum, taking over for LH on approximately the eighth day after ovulation. P production and survival of the corpus luteum are dependent on hCG, in turn supporting the implanting conceptus until the seventh week.

It is likely that hCG stimulates steroidogenesis in the early fetal testes, so that androgen production will ensue and masculine differentiation can be accomplished. It is also possible that the function of the inner fetal zone of the adrenal cortex depends on hCG in early pregnancy. The β -hCG gene is expressed in fetal kidney and adrenal gland, suggesting that hCG may affect the development and function of these organs.

hCG is synthesized mainly in the ST. A maternal serum level of approximately 100,000 IU/liter is

reached at 8–10 weeks of gestation and the corpus luteum begins to involute at this time. hCG levels decrease to approximately 10,000–20,000 IU/liter by 18–20 weeks and remain at that level until term. Clearance of hCG is carried out mainly by renal metabolism.

Human Placental Lactogen

Human placental lactogen (hPL) is a single-chain polypeptide of 191 amino acids. hPL is very similar to human growth hormone (GH) but has only 3% of its activity. Its lactogenic contribution in human pregnancy is uncertain. Its half-life is approximately 15 min. The hPL level in the maternal circulation is correlated with fetal and placental weight, steadily increasing until it plateaus in the last month of pregnancy (5–7 mg/ml). There is no circadian variation and only minute amounts enter the fetal circulation.

hPL's metabolic role is to mobilize free fatty acids from lipids. Relative hypoglycemia in fasting pregnant women ("accelerated starvation") is due to the transfer of glucose to the fetus by facilitated diffusion and due to the diabetogenic effect of placental hormones (E, P, and especially hPL) causing peripheral insulin resistance and hyperinsulinism. As the fasting glucose level decreases, hPL levels rise to stimulate lipolysis and increase free fatty acids, which are an alternative fuel for the mother, sparing glucose and amino acids for the fetus. With sustained fasting, maternal serum ketone levels rise. Due to limited transport of free fatty acids across the placenta, fetal tissues then utilize these ketones, which do cross the placenta. hPL also enhances the fetal uptake of ketones and amino acids. Insulin antagonism by hPL is mediated by the increase in free fatty acid levels, which, in turn, directly interfere with insulin-directed entry of glucose into cells. With a sustained state of inadequate glucose intake, maternal ketosis may impair fetal brain development and function.

hPL, despite its lower levels in the fetus, directly affects fetal tissue metabolism, including synergistic actions with insulin, especially actions on glycogen synthesis in the liver. The failure of fetal growth hormone to affect fetal growth suggests that hPL may be the fetal growth hormone.

Human Chorionic Adrenocorticotrophic Hormone

The rise in maternal free cortisol, cholesterol, and pregnenolone is due to secretion of placental ACTH and CRH, which are not suppressible by glucocorticoids. ACTH production in the ST is stimulated by CRH

from the CT. CRH levels in maternal plasma rise in the second trimester, increasing to peak values at term. Oxytocin is a potent stimulator of CRH and ACTH placental production. A decrease in CRH-binding protein near term further increases the cortisol availability during labor and delivery.

Growth Hormone, Growth Hormone-Releasing Hormone, and Somatostatin

Growth hormone-releasing hormone (GHRH) and somatostatin are found in the placenta and somatostatin is present in the decidua. Somatostatin decreases with advancing gestation. Placental GHRH and somatostatin do not contribute to maternal circulating levels. During the second half of gestation, placental GH gradually replaces pituitary GH in the maternal circulation. Placental GH is not present in fetal blood. Maternal IGF-I levels increase during pregnancy in parallel with GH. Placental GH is not regulated by placental GHRH, but responds inversely to maternal glucose levels, securing glucose availability for the fetus. It also stimulates gluconeogenesis and lipolysis in the mother.

α -Fetoprotein

α -Fetoprotein (AFP) is a glycoprotein derived mainly from fetal liver and partially from the yolk sac, before this degenerates at approximately 12 weeks. It is comparable in size to albumin and may serve as a protein carrier of steroid hormones in fetal blood. AFP may also be a modulator of cell proliferation, synergizing with various growth factors.

Peak values of AFP in the fetal blood are reached at the end of the first trimester; thereafter, levels decrease gradually until a rapid decrease begins at 32 weeks. Maternal blood levels are much lower than fetal levels, rising until week 32 and then declining. Elevated maternal levels of AFP are associated with a variety of fetal anomalies, multiple pregnancies, and increased risk of spontaneous miscarriage, stillbirth, preterm birth, preeclampsia, neonatal death, and low birth weight. Low maternal levels of AFP are associated with trisomies 21 and 18.

Relaxin

Relaxin is a peptide hormone produced by the corpus luteum of pregnancy and by the placenta, decidua, and chorion. It rises during the first trimester and declines in the second. It may have a role in maintaining early

pregnancy, ripening the cervix, inhibiting uterine contractions, and relaxing the pubic symphysis.

Prolactin

Following ovulation, the endometrium becomes a secretory organ and remains so throughout pregnancy. It secretes renin, relaxin, and prolactin. Prolactin production requires the combined effect of P and E plus the presence of other placental and decidual factors, including relaxin, IGF-I, and specific stimulatory and inhibitory proteins. Prolactin derived from the decidua is the source of that found in the amniotic fluid. The prolactin in the fetal circulation is derived from the fetal pituitary. Beginning at 8 weeks, prolactin levels rise from the normal level of 10–25 ng/ml to a peak of 200–400 ng/ml at term. There is marked maternal variability and a diurnal variation as in the nonpregnant state.

Amniotic fluid concentrations parallel maternal serum levels until week 10, rise markedly until week 20, and then decrease until delivery. Prolactin reduces the amnion permeability from fetus to mother and contributes to the regulation of fetal water and electrolyte balance by acting as an anti-diuretic hormone. The increase in maternal levels represents pituitary secretion in response to E.

Cytokines and Growth Factors

Local placental cytokine production is believed to be important for embryonic growth and in the maternal immune response essential for the survival of the pregnancy. A system of communication is present between maternal decidual and fetal tissue to provide growth factor (GF) support for the placenta, which would include fetal hematopoiesis, a known response to colony-stimulating factor-1. Decidual interleukin-1 β and placental tumor necrosis factor- α synergistically release placental interleukin-6 to secrete hCG.

IGF-I and IGF-II are involved in placental, fetal, and postnatal growth. IGFs do not cross the placenta. The fetus can influence maternal IGF-I levels by placental secretion of hPL. During pregnancy, IGF-binding proteins (IGFBP)-2 and -3 decrease, thereby promoting the bioavailability of IGF-I in maternal tissues and enhancing nutrient transfer to the fetus. Placental IGF-I production further enhances transfer of nutrients across the placenta. On the other hand, IGFBP-1 produced in the decidua rises during pregnancy, interferes with IGF-I action, and inhibits fetal growth. Other GFs, such as epidermal GF,

platelet-derived GF, nerve GF, fibroblast GF, and transforming GFs, are involved in differentiation, proliferation, and growth associated with pregnancy.

Inhibin, Activin, and Follistatin

Placental inhibin A rises in the maternal circulation, peaking at 8 weeks and at term. Activin A produced by the placenta also increases. Activin stimulates and inhibin inhibits placental production of hCG, GnRH, and steroids. Follistatin is an activin-binding protein expressed in the placenta, membranes, and decidua. It antagonizes the stimulatory effects of activin.

Endogenous Opiates

Fetal and maternal endogenous opiates originating from the pituitary glands are secreted in parallel with ACTH, in response to CRH, which is, in part, derived from the placenta. Endorphins, enkephalins, and dynorphins are produced also by the ST in response to CRH. They inhibit oxytocin, vasopressin, and gonadotropins and increase prolactin secretion.

The Renin–Angiotensin System

During early pregnancy, maternal prorenin is increased as a result of ovarian stimulation by hCG. The possible roles of the ovarian prorenin–renin–angiotensin system are stimulation of androgen production for E synthesis, regulation of calcium and PG metabolism, and stimulation of angiogenesis. Renin and angiotensinogen are expressed by the membranes and the placenta. Increased maternal renin activity is the result of an E-induced increase in angiotensinogen and a compensatory response to maintain blood pressure in the presence of vasodilation.

Atrial Natriuretic Peptide

Atrial natriuretic peptide is produced in the heart atrium and in the placenta. It is a potent natriuretic, diuretic, and smooth muscle-relaxant peptide that contributes to the regulation of volume and electrolyte changes associated with pregnancy and delivery.

PROSTAGLANDINS IN PREGNANCY

Thromboxane and Prostacyclin

Thromboxane (TXA₂) is the most powerful vasoconstrictor known, whereas prostacyclin (PGI₂) is a

potent vasodilator. Platelets predominantly synthesize TXA₂ whereas PGI₂ is derived mainly from the endothelium. The endothelial production of PGI₂ plays an important role in the marked vasodilation that occurs during pregnancy. The placenta is a major source of TXA₂.

Prostaglandin and the Fetal Circulation

The predominant effect of PGs in the fetal and maternal cardiovascular system is to maintain the ductus arteriosus, the renal, mesenteric, uterine, and placental arteries, and probably the cerebral and coronary arteries in a dilated state. Control of ductus arteriosus patency and closure is mediated through PGs. The arterial concentration of oxygen is the key regulator of the ductus caliber. With increasing gestational age, the ductus becomes increasingly responsive to increased oxygen. Prostaglandin E₂ (PGE₂) is the most important functional PG in the ductus, whereas PGI₂, the major product in the main pulmonary artery, is the major factor in maintaining vasodilation in the pulmonary bed. With increasing maturation, the lung shifts to TXA₂ formation. With the onset of pulmonary ventilation at birth, leading to vascular changes that deliver blood to the duct directly from the lungs, TXA₂ serves as vasoconstrictor to the ductus.

Prostaglandin and Fetal Breathing

Prior to parturition, fetal breathing is very shallow. Placental PGE₂ may suppress breathing by acting in the fetal brain. Occlusion of the umbilical cord is rapidly followed by a loss of this PGE₂ influence and the onset of air breathing.

First, studying these genes helps elucidate the normal aging process, a subject that has fascinated humans in their continuous quest for the fountain of youth. Second, mutations in genes involved in premature aging frequently lead to an early onset of cancer (a disease of cellular aging). As the average life expectancy of the general population in the developed world has increased from 49 years in 1900 to 77 years in 2003, diseases associated with old age, such as cancer, Parkinson's disease, and Alzheimer's disease, have become more common. Approximately 30% of people in the developed world will have cancer at some stage during their lifetime; this likelihood increases exponentially with advancing age. It is therefore no surprise that one of the main phenotypes of premature aging syndromes is the development of a broad range of tumors. There are a number of genetic changes required before tumors can develop. These genetic changes vary in each type of cancer and so give each tumor type a specific "genetic profile" at each stage of its development. However, there are also a number of key common factors among different tumor types and these represent the defining features of cancer. One of the main defining characteristics of cancer cells is the failure to maintain "genomic integrity" (i.e., the ability to faithfully replicate DNA); interestingly, this characteristic may also be used in defining PMAS. Genomic instability may be detected as an abnormal chromosome number and/or structure (such as translocations and breaks). In the case of PMAS, mutations occur in individual genes essential for replication, repair, and transcription, i.e., the processes required to maintain genomic integrity.

Here, the following eight PMAS are discussed: ataxia-telangiectasia (AT), Werner's syndrome (WS), Bloom's syndrome (BS), Rothmund-Thomson syndrome (RTS), xeroderma pigmentosum (XP), Cockayne's syndrome (CS), Hutchinson-Gilford Progeria syndromes, and trichothiodystrophy (TTD).

CLINICAL FEATURES OF PREMATURE AGING SYNDROMES

Table I summarizes the phenotype of PMAS.

Ataxia-Telangiectasia

AT patients show progressive cerebellar ataxia, which is a lack of coordination and balance. Ataxia begins to manifest at the end of the first year of life and patients may be wheelchair-bound by their teens. Ocular and skin telangiectasias (dilated blood vessels) become manifest between 2 and 8 years of age. There is also a

250-fold increased risk of lymphomas and a 70-fold increase in T cell leukemias, hypersensitivity to ionizing radiation, and premature aging, including progeric skin changes, progeric hair changes, and diabetes mellitus. AT cells show chromosomal instability; e.g., rearrangement of chromosome 14 is often involved in AT.

The causative gene for AT is *ATM* (ataxia-telangiectasia mutated), which maps to 11q22.3. *ATM* is a member of the phosphatidylinositol kinase family and becomes activated after induction of DNA double-stranded breaks, e.g., exposure to ionizing radiation. *ATM* has a role in the induction of cell cycle checkpoints, which allow cells to decide whether to repair DNA damage or commit to apoptosis. Mutant *ATM* results in defects in G1, intra-S, and G2 checkpoints. The involvement of *ATM* in DNA damage checkpoints is further emphasized by the identification of *ATM* as part of the BRCA1-associated genome surveillance complex (BASC); this links *ATM* with a number of tumor suppressor and DNA damage repair proteins. BRCA1 is the protein defective in some cases of hereditary breast cancer. The BASC complex includes *MSH2*, *MHS6*, *MLH1*, *ATM*, *BLM*, the *RAD50-MRE11-NBS1* complex, and DNA replication factor C. Many components of this complex have roles in the recognition of DNA damage or unusual DNA structures, suggesting that this complex performs some kind of "sensor" role. *ATM*'s ability as a sensor was further demonstrated in a study by Bakkenist and Kastan, who showed that DNA damage activates *ATM* via intermolecular autophosphorylation of Ser-1981 and dissociation of dimers. *ATM* is inactive in normal cells as a dimer (or multimers) and irradiation causes rapid intermolecular autophosphorylation, leading to dimer dissociation, which initiates cellular kinase activity. Bakkenist and Kastan proposed that rapid *ATM* activation could be due to DNA double-stranded breaks (caused by irradiation), resulting in the rapid change in some aspect of chromatin structure and subsequent *ATM* activation.

There is functional interaction between some of the genes of PMAS, e.g., *ATM* and *BLM* (mutated in BS). *BLM* interacts directly with *ATM*, BS cells exhibit radiosensitivity, and mitotic phosphorylation of *BLM* is partially dependent on *ATM*. *ATM* is also able to phosphorylate *BLM* in a γ -irradiation dose-dependent manner.

Bloom's Syndrome

BS is a very rare autosomal-recessive disorder. The majority of patients that have been identified are of

Table I Summary of Premature Aging Syndrome Phenotypes

| Syndrome | Phenotype | Mode of inheritance | Frequency | Average age of death |
|---------------------------------------|--|---------------------|--|-------------------------------------|
| Ataxia-telangiectasia | Progressive cerebellar ataxia; ocular and skin telangiectasia; small stature; hypogonadism; lymphomas; T cell leukemias; reduced immunoglobulin A (IgA), IgE, and IgG levels; increased α -fetoprotein; progeric skin changes; progeric hair changes; diabetes mellitus | Autosomal recessive | 1/40,000 | ~30 |
| Bloom's syndrome | Growth deficiency (proportional dwarfism); sun-induced facial rash; keel-shaped face; areas of abnormal skin pigmentation; infertility in males and subfertility in females; high incidence (12% of cases) of type II diabetes; decreased levels of IgA and/ or IgM; enormous predisposition to cancer | Autosomal recessive | Very rare overall; 2/100,000 in Ashkenazi Jews | ~24 |
| Werner's syndrome | Graying and thinning of the hair; bilateral cataract formation; type II diabetes mellitus; hypogonadism; loss of skin elasticity; osteoporosis; atherosclerosis; soft tissue sarcomas; thyroid cancers; osteosarcomas; unusual pattern of loss of subcutaneous fat and skin ulceration | Autosomal recessive | < 1/100,000 | ~47 |
| Rothmund-Thomson syndrome | Growth deficiency; sunlight sensitivity with accompanying skin atrophy; cataracts; early graying and loss of hair; some increase in cancer incidence (mainly osteogenic sarcomas) | Autosomal recessive | < 1/100,000 | Not known |
| Xeroderma pigmentosum | Highly photosensitive; 1000-fold increase in frequency of cutaneous basal and squamous cell carcinoma and melanomas; progressive neurodegenerative disease | Autosomal recessive | 1/250,000 | Life expectancy reduced by 30 years |
| Cockayne's syndrome | Cachectic dwarfism; senile appearance; mental retardation; cataracts; optic atrophy; deafness; skeletal abnormalities; photosensitivity; neurodegeneration | Autosomal recessive | ~1/100,000 | ~20 |
| Trichothiodystrophy | Photosensitive; brittle hair and nails; cataracts; faces have an aged appearance | Autosomal recessive | < 1/100,000 | ~10 |
| Hutchinson-Gilford progeria syndromes | Much more rapid overall organ aging; midface hypoplasia; premature atherosclerosis; premature coronary artery disease; parental age effect | Undecided | ~1/6,000,000 | ~13.4 |

Ashkenazi Jewish origin. The gene defective in BS is *BLM*, which maps to chromosome 15q26.1 in humans (Fig. 1). The *BLM* gene encodes a protein of 1417 amino acids that includes 7 conserved amino acid motifs found in many DNA and RNA helicases, including the RecQ family of helicases of which *BLM* is a member. The BS phenotype includes an enormous predisposition to cancer, with a mean age at cancer diagnosis of approximately 24 years. BS patients succumb early in life to the common range of carcinomas associated with the elderly in the general population. Therefore, it may be possible through the study of BS to shed light on at least one crucial aspect of tumorigenesis. BS cells show a 10-fold elevated frequency of homologous recombination events, i.e., an exchange of genetic information between regions of identical or very similar sequence. In BS, this so-called hyper-recombination occurs between both sister chromatids and homologous chromosomes.

The elevated rate of sister chromatid exchange (SCE) is a diagnostic feature of BS. The increased level of interchromosomal recombination may lead to an increase in the rate of somatic loss of heterozygosity, which in turn leads to inactivation of tumor suppressor genes and hence to cancer predisposition in BS.

BLM is also part of BASC and works closely with *ATM*. To examine the role of *BLM* within BASC, the subcellular localization of *BLM* and *BRCA1* was analyzed before and after exposure to DNA-damaging agents. In untreated cells, *BLM* and *BRCA1* colocalization was limited to a few bright nuclear foci. However, after treatment with hydroxyurea or ionizing radiation, colocalization was greatly enhanced in those cells that were in mid to late S phase or in G2. This could be indicative of a specific requirement for *BLM/BRCA1* in replication and/or repair of late replicating DNA.

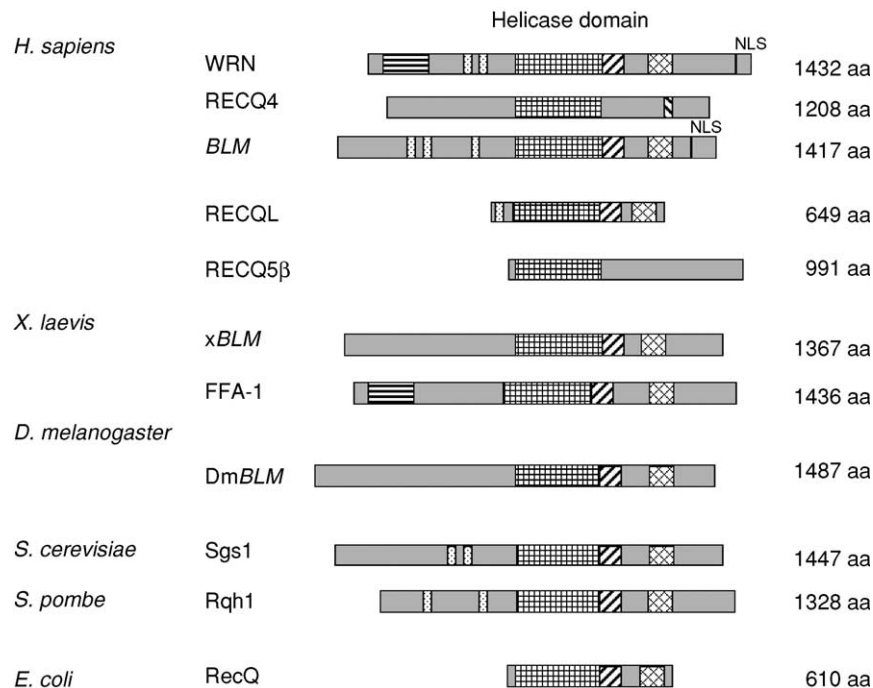

Figure 1 Schematic representation of the RecQ family of DNA helicases. Members of this family have been identified in bacteria (*Escherichia coli*: RecQ), yeasts (*Saccharomyces cerevisiae*: Sgs1; *Schizosaccharomyces pombe*: Rqh1), fruit fly (*Drosophila melanogaster*: DmBLM), frog (*Xenopus laevis*: the *BLM* orthologue, *xBLM*, and the *WRN* orthologue, FFA-1), and mammals (only information for human is shown) (*Homo sapiens*: *BLM*, *WRN*, RECQ4, RECQL, and RECQ5). The central conserved helicase domain is shown as a grid-filled box. The exonuclease domain of *WRN* and FFA-1 (which is not found in other RecQ helicases) is shown as a box with horizontal lines. The boxes with diagonal lines denote a region of conservation that is C-terminal to the helicase domain. This region is apparently unique to RecQ helicases. The boxes with outlined diamond shapes show the so-called HRDC domain, which is also found in certain enzymes that degrade RNA, and the boxes with dots show highly acidic regions. The gray boxes denote domains with little or no sequence similarity among family members. The nuclear localization signal sequences (NLS) in *BLM* and *WRN* are shown in black. Three variants of the RECQ5 protein may exist, but only the β isoform is indicated. The size of each protein (given as the number of amino acid residues) is shown on the right.

Werner's Syndrome

WS is caused by mutations in the *WRN* gene, another member of RecQ family of DNA helicases (Fig. 1). WS is a premature aging condition and has a broad phenotype that includes many age-related disorders that develop from puberty onward. Moreover, WS individuals are also cancer-prone, but display a narrower range of tumor types than is seen in BS. Soft tissue sarcomas, thyroid cancers, and osteosarcomas are characteristic of WS. The average age of death for WS patients is 47 years, mainly due to cancer or cardiovascular disease. Some *WRN* features are not seen in normal aging, e.g., an unusual pattern of loss of subcutaneous fat and skin ulceration. WS cells display increased illegitimate recombination and a high frequency of large chromosomal deletions.

Rothmund-Thomson Syndrome

There has been only limited study of this rare disorder; nevertheless, the gene responsible for RTS has been identified. RTS is caused by mutations in the *RECQ4* gene, another member of the RecQ family of DNA helicases (Fig. 1). In this disorder, affected individuals show growth deficiency, progeroid features, and an increase in cancer incidence. The cancer predisposition in RTS individuals is restricted mainly to osteogenic sarcomas. RTS cells show trisomerization (having three instead of the usual two copies of each chromosome) and an increased frequency of chromosomal aberrations.

Xeroderma Pigmentosum

XP is an autosomal-recessive disorder, consisting of seven complementation groups (*XPA-G*). The *XPD* and *XPB* proteins are involved in nucleotide excision repair (NER) and transcription initiation by RNA polymerase II. Depending on the type of mutation, different pathways could be impaired, resulting in distinct phenotypes. Mutations destroying *XPD* transcription ability lead to TTD. Some mutations in *XPB* and *XPD* also cause CS and trichothiodystrophy, respectively; hence, xeroderma pigmentosum group D (*XPD*) has been described as one gene, two functions, and three diseases. XP patients are highly photosensitive and have a 1000-fold increase in the frequency of cutaneous basal and squamous cell carcinomas and melanomas. Furthermore, 20% of XP patients (complementation groups A, C, and D) also develop a progressive neurodegenerative disease.

Cockayne's Syndrome

CS is a rare disorder with two complementation groups; the two causative genes are CSA and CSB. Cells from CS patients are defective in transcription-coupled repair in both the NER and the base excision repair pathways.

Trichothiodystrophy

There are three complementation groups for this very rare disorder: *XPD*, *XPB*, and TTD-A. *XPD* and *XPB* are helicases of the transcription/repair factor TFIIH (transcription factor IIH). Patients with mutations in *XPD* and *XPB* are defective in NER due to the loss of transcription. *XPD* is a DNA helicase protein involved in repair and transcription and is mutated in some cases of TTD. However, in the TTD-A complementation group, TFIIH is intact and active in transcription and repair, but the levels of TFIIH have decreased. Therefore, TTD can be caused by both a decrease in the level of TFIIH (dose reduction) and a total loss of TFIIH (loss of function).

Hutchinson-Gilford Progeria Syndrome

This is a rare (approximately 1 in 6 million) developmental disease that affects most of the organs in a manner similar to that which occurs in normal aging, except in these patients, overall organ aging takes place much more rapidly. The mode of inheritance is still unclear, but there are suggestions of both recessive and dominant forms; the causative genes have not been identified.

MOUSE MODELS OF PMAS

Genetic studies in mice have revealed significant phenotypic differences in PMAS-deficient mutants from those seen in humans. Deletion of *BLM* in the mouse leads to embryonic lethality, deletion of *WRN* does not lead to obvious premature aging, and *ATM* mutants show only modest growth retardation, neuronal damage, and premature aging. One of the major obstacles in creating mouse models of PMAS has been the fact that mice have very long telomeres, a potential reason that many mouse models do not mimic the clinical situation for PMAS. One of the factors that is observed during the aging process in humans is the shortening of telomeres. However, this problem has been circumvented in a number of studies by creating a double knockout (KO) of two PMAS genes. The use

of these double KO mice has yielded mouse models for most human PMAS.

Studies using double-null mice for *ATM* and the telomerase RNA component (*Terc*) have shown that telomere deficiency and *ATM* deficiency compromise organ homeostasis and accelerate aging. These double KO mice show increased telomere erosion and genomic instability, leading to a global proliferation defect seen in all cell types and tissues. The accelerated telomere erosion could form the basis of premature aging seen in these mice. These mice showed increased hair graying, alopecia, and delay in hair regrowth, clot formation, and wound healing.

The *XP* DNA family has some mutations in *XPB* and *XPD* that cause CS and TTD, respectively. Mice with mutations in *XPD*, a DNA helicase protein that is involved in repair and transcription and is mutated in the human disorder TTD, showed an accumulation of DNA damage and symptoms of premature aging. Double mutants of *XPD* and *XPA* (also involved in DNA repair) show an even faster aging process. When accelerated aging in TTD patients occurs, it does so earlier than in WS or BS individuals.

BLM mouse models have been generated and the cells from *BLM*^{-/-} mice show inherent genomic instability. Although viable animals were recovered in only one case, these mice were cancer-prone. Moreover, embryonic stem cells lacking *BLM* showed an increased frequency of gene targeting, indicative of an increase in homologous recombination (HR). This is consistent with the fact that HR mediates SCEs in vertebrates and that elevated SCEs are seen in BS cells. *WRN*-defective mice have also been generated and crossed with p21 or p53 null mice to generate double mutants. In the first few generations, these

mice did not display premature aging. The p21-*WRN* double mutants also showed no increase in the rate of tumorigenesis. In contrast, the p53-*WRN* double mutants showed an accelerated rate of tumorigenesis associated with the development of a wide variety of tumors not detected in either type of single mutant mice. In a separate study, transgenic mice expressing a mutant *WRN* gene encoding a defective helicase showed none of the premature aging phenotypes characteristic of WS. However, primary cell cultures from these mice did show two of the known characteristics of WS cells: reduced replicative potential and hypersensitivity to 4-nitroquinoline-1-oxide. The expression of the mutant *WRN* also had a dominant-negative effect, resulting in reduced function of the endogenous *WRN* protein.

Studies of *WRN* function in mice and yeast have been very informative regarding the role of telomere maintenance and aging (Table II). The role of Sgs1p in telomeric function (Table II) is apparently conserved in evolution, since mouse *WRN* can partially substitute for yeast *SGS1*. This suggests that in humans *WRN* may play a role similar to that played by Sgs1p in yeast. There are several other lines of evidence suggesting a close link between *BLM* and *WRN* proteins in telomere biology. Both *BLM* and *WRN* interact with telomere repeat-binding protein, TRF2. This *BLM/WRN* interaction with TRF2 occurs via the C-terminal domain in each case and they co-immunoprecipitate and colocalize to alternative lengthening of telomeres-associated PML bodies. This interaction is a functional one, as TRF2 binds and stimulates the catalytic activity of *WRN* and *BLM* helicases.

It is also worth noting that the insulin-like growth factor receptor (IGF-IR) regulates lifespan

Table II Telomere Maintenance and Aging

| Yeast | Mammals |
|---|---|
| <ul style="list-style-type: none"> • The <i>WRN</i> homologue in <i>Saccharomyces cerevisiae</i>, <i>SGS1</i>, is also involved in telomere maintenance, at least in strains lacking telomerase. • Deletion of <i>EST2</i>, part of the catalytic subunit of telomerase in yeast, leads to premature replicative senescence and a progressive erosion of telomeres. • Yeast cells surviving lack of <i>EST2</i> have either amplification of subtelomeric DNA or long and variable telomeric DNA structures reminiscent of human ALT cells. • Deletion of <i>SGS1</i> in <i>est2</i> strains leads to accelerated senescence. <i>est2 sgs1</i> strains do not generate "ALT-like" survivors, suggesting that Sgs1p is needed for telomere lengthening in the absence of telomerase. | <ul style="list-style-type: none"> • WS patients' fibroblasts show an accelerated rate of replicative senescence; however, the forced overexpression of telomerase in these cells stops their senescence. • The <i>WRN</i> protein colocalizes with telomeric factors in telomerase-independent immortalized (ALT) cell lines. • In most tumors, the telomerase gene <i>EST2</i> is reactivated. In ~10% of tumors, instead of telomerase, telomere-stabilizing protein <i>WRN</i> is involved. • Sgs1p telomeric function is conserved in evolution, as mouse <i>WRN</i> can partially substitute for yeast <i>SGS1</i>. |

Note. ALT, alternative lengthening of telomeres.

and resistance to oxidative stress in mice, as it does in lower eukaryotes, such as *Caenorhabditis elegans*. IGF-IR KO mice are not viable, but heterozygous mice (*igfr*-/+) are viable and live an average of 26% longer than wild types. Extended longevity is also seen in mice lacking the insulin receptor in adipose tissue, suggesting that a reduction in fat mass without caloric restriction may be associated with increased longevity, possibly via effects on insulin signaling. It has been proposed that the IGF-IR may be a central regulator of mammalian life span. IGF-IR is, in turn, also a regulator of *ATM*, which when mutated leads to AT, one of the main types of PMAS. Studying the nature of the IGF-IR and *ATM* interaction could hold a key to understanding PMAS as well as the process of tumorigenesis.

In summary, model systems are shedding light on the pathogenesis of PMAS, which in turn enhances the understanding of the processes that regulate normal aging and cancer predisposition.

of the actin cytoskeleton are involved in this follicular rescue. Conversely, androgens, tumor necrosis factor α , IL-6, and Fas ligand all stimulate oocyte apoptosis and follicular atresia. Any alteration in the gene or gene product of these regulators of apoptosis could lead to an inappropriate rate of cell death or cellular dysfunction, premature depletion of oocytes or dysfunctional oocytes, and premature ovarian failure.

Ovarian Compartments

The ovary can be divided into two functional compartments, the follicle and the stroma. Despite a basement membrane separating the two compartments, the ovary is not an immunologically privileged site, in contrast to the testis. This fact is important to the possible pathogenesis of POF. Resident ovarian lymphocytes and polymorphonuclear granulocytes, macrophages, mast cells, and eosinophils appear to be involved in folliculogenesis and corpus luteum function. Alterations in cellular or humoral immune activity or function have the potential to therefore affect ovarian function. As can be appreciated, the participation of the immune system in ovarian function allows for perturbations that could cause clinical POF.

Stages of Ovarian Function

Throughout a woman's life cycle, one can discern five stages of ovarian function: (1) ovulatory and fertile, (2) ovulatory and infertile, (3) anovulatory and estrogen producing, (4) anovulatory and androgen producing, and (5) absent hormonal function. These represent a functional continuum, with normal fertility on one end, through seemingly normal function but diminished fertility, through anovulatory states with only estrogen and then only androgen production, to the quiescent, postclimacteric ovary on the other end of the continuum. The stages and transitions may be clinically obvious or they may be subtle. Indeed, clinical reproductive endocrinologists still struggle to differentiate a fertile, ovulatory woman from an infertile, but ovulatory woman. The passage through these stages or levels of function is predictable, but the onset and timing of the transitions are highly variable.

First, as puberty begins, androgen and estrogen are secreted by the ovary as secondary sexual characteristics develop. Soon thereafter, ovulation begins and fertility is established, continuing usually into the fourth decade of life. Metabolic and central nervous

system conditions, such as polycystic ovarian syndrome and hypothalamic amenorrhea, can disrupt this normal state even in the prime fertile years. As women age, the number of oocytes continues to diminish as a result of atresia and ovulation. Due to this ongoing recruitment, selection, and loss of follicles, the quality of the remaining oocytes declines. At this point, the woman is ovulatory, but infertile.

This subfertility generally becomes evident in the population at approximately 35–38 years of age, with 50% of women in this age group being infertile. After 40 years of age, 90% of women are infertile. Despite regular cycles and apparent ovulation, fertility is rare beyond 42 years of age. Further decline in follicle/oocyte number and function results first in oligo-ovulation (with consequent estrogen but not progesterone secretion from the ovary) and then complete anovulation. Once irreversible anovulation is established, it is only a matter of time until estrogen levels decline sufficiently that menopause is noted.

At the final stages of the ovarian life cycle, the ovary continues to produce normal levels of androgens during the first 5 to 7 postmenopausal years of the climacteric. These play a role in maintaining metabolism, libido, and energy, but they may also cause a relative hyperandrogenic effect resulting in hair loss, hirsutism, and metabolic abnormalities such as an atherogenic lipid profile. Thereafter, the androgen levels also decline until the ovary is steroidogenically quiescent.

This is the natural history of the decline in ovarian function and in women with POF it is a process that occurs significantly earlier than the expected age.

ETIOLOGIES OF PREMATURE OVARIAN FAILURE

Several schemes have been used in the past to classify the etiology of POF. A useful classification advanced by Anasti, Nelson, and Flack recognizes the enhanced understanding of ovarian regulation at the molecular and cellular level, along with the importance of the immune system to normal ovarian function. This classification differentiates those conditions that result in premature or accelerated follicle depletion from those with follicle dysfunction.

FOLLICLE DEPLETION SYNDROMES

Any inherited or acquired defect that disturbs the process of germ cell migration, oogonial proliferation, or initiation of meiosis to form primordial follicles can

result in an insufficient initial complement of follicles. Similarly, any abnormality in the genes that regulate the rate of early atresia could result in early exhaustion of the oocyte pool.

Deficient Initial Number

Deficient initial follicle numbers are seen in patients with gonadal dysgenesis and thymic aplasia/hypoplasia. Any mutation of the genes responsible for germ cell migration or mitotic oogonial proliferation may result in an inadequate initial follicle number. Examples of such mutations causing a deficient initial oocyte population of the ovary have been described in mice, such as the *c-Kit* gene at the *W* locus and an insertional transgenic mutation of chromosome 11 A2-3; germ cell deficiency in women with 46,XX gonadal dysgenesis could be the result of autosomal mutations similar to these examples. Thymic hypoplasia or aplasia has also been associated with POF. Both in the thymectomized neonatal mice model and in humans with thymic disorders (thymic aplasia and myasthenia gravis), there are decreased numbers of natural killer and suppressor T cells, leading to cell-mediated autoimmune destruction of the ovarian follicles. In these women, ovarian failure is typically only one feature of their autoimmune polyglandular dysfunction.

Accelerated Follicle Atresia

Accelerated follicular atresia due to an alteration in the genome is thought to be the basis for one-third to one-half of all POF cases, although only the minority of these cases are identifiable with available molecular techniques. Usually, these alterations involve large chromosomal defects such as 45,X or fragile X (FRAXA) syndromes, although autosomal recessive and autosomal dominant single gene defects such as POF-1, POF-2, and blepharophimosis-associated POF have also been described.

Two competent X chromosomes are required for the proper control and timing of oocyte apoptosis/atresia and follicular depletion. Aberrant control of oocyte atresia may occur when there is an absent X chromosome, a translocation involving the X chromosome, or deletions of portions of the X chromosome. Examples include the ovaries of 45, X stillborn infants in whom germ cells migrate normally to the gonadal ridge with accelerated atresia of the primary oocytes later in fetal life and cohorts of fragile X syndrome patients who have an increased incidence of ovarian dysfunction. Cytogenetic studies of patients with POF that possess

X chromosome deletions have revealed detailed regions of the X chromosome responsible for ovarian function, including the genes POF1 (localized to Xq21.3-q27 or Xq26.1-q27) and POF2 (within Xq13.3-q21.1). Clinically, patients with the POF2 gene deletion have younger onset of ovarian dysfunction than those with the POF1 gene deletion. As molecular genetic studies advance, the exact nature of these genes and their proteins functions will be uncovered.

Specific genes appear to also influence ovarian follicle number, atresia, and the timing of ovarian failure, given the large number of POF patients and families with apparently normal karyotypes. An example is galactosemia, an autosomal recessive condition resulting from deficiency of the enzyme galactose-1-phosphate uridylyltransferase. Most patients with galactosemia eventually develop premature ovarian failure. The premature destruction of primordial follicles seen in these patients is thought to be due to the toxic effects of galactose or one of its metabolites or a deficiency of uridine diphosphate galactose. However, the POF seen in galactosemics could also be the result of a deficient initial follicle number, follicle dysfunction, or abnormal gonadotropins.

Iatrogenic follicle depletion can occur because of ovarian surgery, radiation therapy, or chemotherapy. In a patient over the age of 40, a radiation dose of only 600 cGy results in loss of ovarian function, although younger women have been reported to have a return of ovarian function after higher levels of exposure; a pregnancy has been reported in a 20-year-old woman who had previously received 3000 cGy to the pelvis. Surgical transposition of the ovaries out of the irradiated field has been somewhat successful in preserving fertility, although follicular suppression with gonadotropin-releasing hormone (GnRH) agonists has not.

Chemotherapeutics are designed to destroy rapidly dividing cells, which explains the sensitivity of proliferating granulosa and theca cells of active follicles to these agents. Alkylating agents are non-cell-cycle-specific drugs that result in cross-linking of DNA strands even in nondividing cells and as a result they have been observed to be the most toxic to oocytes. The experience thus far in women treated with chemotherapy has shown that younger women are more likely to regain ovarian function. However, the doses and classes of agents used are also important factors. Based on the observation that prepubertal girls treated with alkylating agents were relatively resistant to oocyte destruction, some work has been performed using GnRH agonists and oral contraceptive pills in an attempt to mimic this prepubertal state

and provide ovarian protection. Data by Blumenfeld demonstrating a protective effect by GnRH agonist in human patients undergoing chemotherapy for lymphoma or autoimmune diseases are encouraging.

Environmental toxicants that affect gonadal function have also been identified. Smoking is a known ovarian toxicant that has been associated with accelerated ovarian atresia. It is well documented that smokers have lower estradiol levels and begin menopause on average 2 years earlier than nonsmokers. In women who are otherwise predisposed to earlier cessation of ovarian function, smoking could accelerate the process such that clinical POF is diagnosed.

Autoimmune disorders have been strongly associated with POF, with up to 60% of POF patients having an associated autoimmune disorder. The most common autoimmune conditions associated with POF are listed in Table I. In each of these conditions, the pathophysiology of POF may involve both premature follicular depletion associated with the inflammatory process and follicular dysfunction; hence, their classification here is arbitrary.

In 119 karyotypically normal POF patients prospectively screened for various autoimmune conditions such as thyroid disease, adrenal dysfunction, hyperparathyroidism, diabetes mellitus, and pernicious anemia, hypothyroidism was the most common comorbid diagnosis with POF (found in 27% of screened POF patients), with 2.5% of patients having diabetes mellitus and 2.5% having Addison's disease. Three percent of POF patients are diagnosed with autoimmune polyglandular failure syndrome types

Table I Autoimmune Diseases Commonly Associated with Premature Ovarian Failure

| |
|---|
| Hypothyroidism |
| Type I diabetes mellitus |
| Hyperparathyroidism |
| Addison's disease |
| Myasthenia gravis |
| Thymic hypoplasia/aplasia |
| Crohn's disease |
| Vitiligo |
| Pernicious anemia |
| Systemic lupus erythematosus |
| Rheumatoid arthritis |
| Type I autoimmune polyglandular failure syndrome (hypoparathyroidism, adrenal failure, and chronic mucocutaneous candidiasis) |
| Type II autoimmune polyglandular failure syndrome (adrenal failure and hypothyroidism) |

I and II. In fact, over 60% of type I patients will have either primary amenorrhea or POF, although the association of POF with type II is more variable. It has also been suggested that bacterial, protozoal, or viral infections may induce a cross-reacting anti-ovarian autoimmune response that could result in POF. For example, oophoritis has been reported in 3–7% of women infected with the paramyxovirus causing mumps. POF has also been noted to occur after varicella, shigellosis, and malaria infection. It also has been associated with cytomegalovirus infections in immunocompromised patients with human immunodeficiency virus and lymphoma. However, the true incidence of ovarian failure related to systemic infections and the exact pathophysiology of POF remain unknown. The infectious relationship with POF discussed here is distinct from that associated with tubo-ovarian abscess formation that actually destroys sufficient ovarian tissue to cause failure of ovarian function.

Lymphocytic oophoritis has been described in some cases of POF. Hoek reviewed 215 cases of POF with ovarian biopsies. Eleven percent of these patients had histologic evidence of oophoritis. Of the patients evaluated for anti-steroid cell antibodies, all of those with oophoritis were positive for these antibodies, suggesting that the inflammatory process was directed, at least in part, at the steroidogenic apparatus of the follicle. Lymphocytic oophoritis has been described clinically as POF associated with tender, palpably enlarged ovaries. Histologically, there is a neutrophilic infiltrate concentrated around developing follicles, with notable sparing of primordial follicles. It has been proposed that the local production of lymphokines and cytokines results in follicular dysfunction, impairing steroid production.

FOLLICULAR DYSFUNCTION SYNDROMES

Antibodies interfering with normal FSH–receptor interactions have been found in some women with POF, analogous to the blocking antibodies described in myasthenia gravis, primary hypothyroidism, and insulin-resistant diabetes mellitus. For example, an IgG antibody blocking FSH binding to its receptor has been demonstrated in patients with myasthenia gravis who have POF. It is conceivable that the FSH and luteinizing hormone (LH) receptors may act as inciting antigens leading to a localized autoimmune response, since they are unique to the ovary. It has

also been postulated that antibodies against the gonadotropins themselves may be involved in the pathogenesis of POF.

The zona pellucida (ZP) is also unique to the ovary and antibodies against it have been proposed as a mechanism for infertility in women with premature ovarian dysfunction, although not POF. These antibodies are thought to interfere with sperm binding. In several animal models, inoculation with ZP has led to follicular dysfunction and eventual depletion.

Enzyme deficiencies that result in insufficient production of androgens and specifically estrogens can result in follicular dysfunction and clinical POF. Cholesterol desmolase deficiency results in insufficient androgens, estrogens, and corticosteroids and hence is usually incompatible with life, but a partial enzymatic defect may result in ovarian follicle dysfunction secondary to the lack of steroid production in the follicle required for proper oocyte development. Similarly, deficiencies of 17- α -hydroxylase or 17,20-desmolase can result in inadequate estrogen production and follicular dysfunction. Steroidogenic acute regulatory protein is a mitochondrial phosphoprotein that catalyzes the rate-limiting step in steroid synthesis, i.e., translocation of cholesterol from the outer to the inner mitochondrial membrane. The absence or dysfunction of the steroidogenic regulatory protein results in a rate-limiting defect in adrenal and gonadal steroid synthesis. Women with this condition, congenital lipoid adrenal hyperplasia, develop ovarian failure as a result of accumulation of cholesterol in the parenchyma of the ovary.

Although they do not result in elevated gonadotropins, defects in gonadotropin production that can result in secondary amenorrhea and POF have been described. An example is a case of X-linked adrenal hypoplasia in which the DAX-1 mutation results in defective pituitary gonadotropin production.

Any abnormality in gonadotropin structure, gonadotropin receptor, or second-messenger proteins can result in follicular dysfunction, although acquired isolated FSH deficiency causing POF is rare. Examples include FSH receptor abnormalities that have been described in a Finnish cohort with POF; these POF women have follicles present on ultrasound and a normal complement of primordial follicles on ovarian biopsy. Abnormal LH receptors have also been found in POF kindreds. Finally, a patient presenting with secondary amenorrhea and hypergonadotropic hypoenestrogenism was discovered to have a defective cyclic AMP second-messenger system with POF and concurrent pseudo-hypoparathyroidism.

DIAGNOSIS OF PREMATURE OVARIAN FAILURE

Clinical features of premature ovarian failure, though variable from patient to patient, are usually fairly obvious and hence establishing the diagnosis is not usually difficult. However, because of the impact of this diagnosis on the prognosis for future fertility, general health, and the possibility of coexisting conditions, the diagnosis should always include confirmatory gonadotropin testing. In a woman less than 40 years of age, the findings of amenorrhea for greater than 4 months with significantly elevated gonadotropins (> 40 mIU/ml) on two occasions more than 1 month apart allows diagnosis of POF.

History

POF is not associated with a characteristic preceding menstrual history. The development of amenorrhea may be acute or it may be insidious. A failure to resume menses after a pregnancy or discontinuing oral contraceptives may be the presenting history. The majority of patients with POF develop secondary amenorrhea after having years of established regular menses and normal fertility. Rarely, secondary amenorrhea may follow menarche without ever establishing regular menses. Most cases of POF are sporadic, but 4% of POF patients do have a family history of the condition. Ten to 15% of POF patients had primary amenorrhea and delayed menarche and, if associated with pubertal delay, 40% of these will have chromosomal abnormalities. Prodromal premature ovarian failure should also be considered in any young woman with menstrual irregularities and elevated gonadotropins, but not yet 4 months of amenorrhea. In the case of prodromal premature ovarian failure, polymenorrhea or oligomenorrhea may occur and can be associated with hot flushing and vaginal dryness. These are the most important patients to diagnose, because a delay in diagnosis may result in irretrievable loss of fertility. A woman with such a diagnosis should be counseled that delaying childbearing, if genetic children are desired, may not be feasible. Young women with amenorrhea, oligomenorrhea, or polymenorrhea who are considering delaying childbearing should have an FSH level measured for diagnostic and prognostic purposes.

Depending on the level of estrogen production, associated symptoms may or may not include vasomotor instability with hot flashes or flushing, vaginal

dryness, genitourinary atrophic symptoms, skin thinning, mild alopecia or hirsutism, insomnia, and emotional or behavioral changes including irritability, anxiety, depression, etc. If the patient has been anovulatory for a time, dysfunctional uterine bleeding may be present.

Patients with suspected premature ovarian failure should be questioned regarding previous ovarian surgery, chemotherapy, or radiation therapy, or a personal or family history of autoimmune disorders such as hypothyroidism, Addison's disease, diabetes mellitus, Graves' disease, vitiligo, systemic lupus erythematosus, rheumatoid arthritis, or inflammatory bowel disease. Sensorineural deafness in association with POF is Perrault's syndrome, a rare familial autosomal disorder

Physical Examination

A complete physical examination with a specific search for findings linked with the above-noted conditions should be performed. Evidence of genital tract atrophy should be documented. Bimanual examination may contribute to the diagnosis of oophoritis or an enzyme defect if the ovaries are enlarged. A search for physical stigmata of Turner's syndrome should also be noted.

Laboratory Studies

A karyotype is not useful in establishing the diagnosis of POF. However, because neither parity nor age eliminates the possibility of a chromosomal abnormality, karyotypic analysis should be completed in all

patients diagnosed with POF. Because of the well-documented association between POF and other autoimmune processes, patients should also be screened for other endocrinopathies. Suggestions for the evaluation of patients diagnosed with POF are indicated in [Table II](#).

Although up to 67% of patients with POF have been reported to have anti-ovarian antibodies (depending on the assay system used), they can also be demonstrated in approximately 30% of normal ovulatory women. Specific steroid cell antibodies have been identified in several disease processes including Addison's disease patients who then go on to develop POF within 15 years. However, the incidence remains very low, with only approximately 3% of POF patients having demonstrable steroid cell antibodies. For both anti-ovarian antibodies and anti-steroid cell antibodies, there is no proven therapy that restores ovarian function if they are discovered. As a result, an assay for ovarian or steroid cell antibodies is not thought to be helpful in the evaluation of POF patients.

THERAPEUTIC CONSIDERATIONS

Health Maintenance

As described above, the significant association of premature ovarian failure with autoimmune disorders argues for the routine screening of these conditions. After initial screening, periodic reassessment should be considered, especially for Addison's disease and bone demineralization.

Hormone replacement should be strongly considered once the diagnosis of POF is made, since

Table II Tests Useful in the Evaluation of a Patient Diagnosed with Premature Ovarian Failure

| |
|---|
| Peripheral blood karyotype |
| Free thyroxine and thyroid-stimulating hormone (TSH), anti-thyroid antibodies if thyroid abnormalities are discovered |
| Fasting glucose and electrolytes, including calcium and phosphorous (to evaluate the parathyroids) |
| Corticotropin stimulation test to exclude adrenal insufficiency [administer 250 µg synthetic corticotropin (Cosyntropin) im or iv, check initial plasma cortisol levels and check levels 30 and 60 min after the administration of the corticotropin; peak cortisol ≥ 20 µg/dl indicates a normal adrenal reserve] |
| CBC and erythrocyte sedimentation rate |
| Urinalysis |
| Antinuclear antibody titer, rheumatoid factor, quantitative serum IgA (IgA deficiency is the most common immunodeficiency associated with autoimmune disorders) |
| Magnetic resonance imaging of the sella turcica [used to exclude a mass lesion when a rare gonadotropin-secreting pituitary adenoma is considered; a thyrotropin (TRH) stimulation test can be used to confirm this tumor, since such tumors are known to disproportionately secrete free α- and β-LH subunits in response to an infused 500 µg bolus of TRH] |
| Pelvic ultrasound |
| Bone densitometry |

these women are at higher risk for osteopenia, osteoporosis, and accelerated atherogenesis. Cyclic or continuous estrogen and progestogen are useful to relieve symptoms of hypoestrogenism and to maintain bone density. Additional benefits of estrogen therapy include potential cardioprotective effects, delayed onset of Alzheimer's disease, decreased incidence of colorectal cancers, and improved vulvovaginal and urethral tissue structure and function. However, some of these possible benefits of estrogen replacement therapy have been brought into question in postmenopausal women by the recent Women's Health Initiative (WHI) study findings. The implications of these findings for women with premature ovarian failure are unclear; an NIH trial to answer these questions is underway. Calcium supplementation and weight-bearing exercise are also important for skeletal health.

Importantly, psychological support should be provided to patients afflicted with this difficult diagnosis. Frequently, these women feel that fertility potential is taken away from them before they have even had the option to consider their reproductive desires. This can be devastating and threatening to their self-esteem. Thorough education regarding their general health and fertility options is important. A premature ovarian failure support group exists at www.POFsupport.org. In certain circumstances, individual counseling may also be appropriate.

Family Building

The natural history of premature ovarian failure includes spontaneous pregnancies in 10% of women after diagnosis. Hormone replacement therapy does not provide birth control and those not desiring pregnancy should be placed on oral contraceptives. Episodic ovarian function has been documented in up to 50% of women with the diagnosis of POF, as demonstrated by intermittently elevated estradiol levels. Approximately 20% of these patients will be found to have elevated progesterones, indicating sporadic ovulation.

Patients with established POF do not respond to ovulation induction using either clomiphene citrate or exogenous urinary or recombinant gonadotropins. Sporadic case reports of successful induction of ovulation with pregnancy are most likely the result of fortuitous spontaneous reversal of POF at the time ovulation induction agents are employed. In fact, some believe that exogenous gonadotropin

administration is harmful, since this might increase the antigen load and stimulate anti-ovarian antibody production.

Ovulation induction after endogenous gonadotropin or ovarian suppression using gonadotropin-releasing hormone agonists, oral contraceptives, danazol, or continuous progestins has been attempted with very limited success. The strategy behind this suppression is to induce a rebound endogenous gonadotropin secretion and/or enhanced ovarian responsiveness to gonadotropins, after the period of suppression. However, despite anecdotal successes with this approach no prospective randomized trials have shown this treatment to be beneficial. There are anecdotal reports of pregnancies occurring after immunosuppressive therapy in patients with autoimmune POF and a trial of every-other-day corticosteroids for autoimmune lymphocytic oophoritis is under way at the National Institutes of Health Clinical Center. However, long-term steroid use has significant risks associated with it, such as osteoporosis, which is already a problem in these patients. Plasmapheresis, thymectomy, and intravenous immune globulin have also been successful anecdotally, although the use of these immunotherapies cannot be recommended since there are no randomized, controlled trials proving their efficacy.

Contemporary assisted reproductive technologies allow new options for these patients. Provided that the woman is otherwise in good health, oocyte donation with *in vitro* fertilization using her partner's sperm is an option in most programs at least to 45–50 years of age; implantation rates using young oocyte donors are very favorable and pregnancy outcome in these women who have donated oocyte-derived embryos is excellent. Other possible strategies that may develop in the future include harvesting of immature oocytes from POF patients with their *in vitro* maturation and co-culture prior to *in vitro* fertilization and prospective identification of women at risk for developing POF with oocyte harvest and cryopreservation for subsequent use before the onset of clinical ovarian failure.

Expectant management with the small possibility of resolution or even temporary remittance may result in pregnancy for some of these women. After the initial diagnosis and education process, these patients should be encouraged to take some time to allow for spontaneous remission or opt for adoption or oocyte donation if they have already suffered from infertility for a number of years or if family building is a pressing issue for them.

CONCLUSION

As mentioned above, prospective cryopreservation of primordial follicles may become a more practical option in the future for women at risk of developing POF. This availability stresses the importance of early diagnosis and specific testing of women with POF and their younger female relatives. With increasing capabilities in molecular medicine and diagnosis, it may soon become possible to diagnose specific genetic anomalies that will result in follicular dysfunction or premature follicular depletion in the future. With this same advancing technology, genetic therapies to correct the dysfunction or prevent the follicular loss can be envisioned. Improved measures of protecting primordial follicles during cytotoxic therapies and the ability to preserve primordial follicles *in vitro* and mature them successfully are also therapeutic strategies under intense investigation. Specific therapy for autoimmune POF—which could include highly specific blocking antibodies that would potentially prevent the follicular dysfunction and loss and avoid the adverse systemic effects associated with corticosteroids and other immunomodulatory therapies—will be possible in the future.

menstrual cycle draws near but remit at or soon after menstruation. There are 7–10 days free of symptoms.

Although this history is characteristic of PMS, it is not sufficient for its diagnosis. Because some women may have selective recall of their symptoms, prospective charting of the symptoms is necessary to establish the relationship of these symptoms to the onset of the menstrual period and to establish a diagnosis. The diagnosis of PMDD also requires prospective daily self-ratings of symptoms for at least two cycles. Though prospective charting is ideal for establishing the diagnosis of PMS/PMDD, some women presenting for evaluation and treatment will be unwilling or unable to prospectively record their daily symptoms and it may be necessary to initiate therapy without adequate prospective charting. In an attempt to establish more objective criteria for the diagnosis of PMDD, some investigators and clinicians have administered psychometric tests to women during both the follicular and the luteal phases of the menstrual cycle. Though the results of psychometric testing in women with PMDD may be normal during the follicular phase, they may be abnormal during the luteal phase. However, the use of psychometric tests is not necessary to make the diagnosis of PMDD. Finally, the fact that the symptoms never last for more than 2 weeks distinguishes PMS and PMDD from other mood or physical disorders.

It is important during the course of the evaluation to rule out other conditions such as anxiety disorders, depressive disorders, anemia, hypothyroidism, chronic fatigue syndrome, chronic fatigue syndrome, central nervous system tumors, or autoimmune disorders. It is also important during the course of evaluation of the patient with PMS/PMDD to evaluate the impact of the symptoms on her self-esteem as well as her relationships with family, friends, and co-workers. Finally, it is also helpful to discuss stresses in the lives of these women for they may exacerbate the symptoms of PMS/PMDD. Medical, physiological, and social stressors that are common in the lives of women with PMS/PMDD include emotional or physical abuse, financial distress, alcohol or substance abuse, or stress from school or work.

TREATMENT

Overview

Because no single treatment is universally effective for PMS/PMDD, many have doubted the existence of this disorder and criticized attempts to help women with their premenstrual symptoms. However, in the past

decade there have been over 100 prospective randomized clinical trials of various therapies, which have led to an evidence-based approach to the treatment of PMS/PMDD.

Initial Nonspecific Therapy

The initial treatment of PMS/PMDD can begin during the phase of evaluation using nonspecific therapies. These nonspecific therapies include nonpharmacologic approaches such as patient education, validation of symptoms through daily prospective charting, relaxation training, and self-help measures such as exercise and nutrition. Because social support is often essential for relief of symptoms, it may be helpful to the women with PMS/PMDD if the clinician involves family members or friends in the process of evaluation so that they may support her and help validate her symptoms. Although data supporting the effectiveness of these nonpharmacologic therapies are limited, these therapies are often used because they lack significant side effects, are very practical, and may benefit the woman's physical and emotional health.

First-Line Pharmacologic Therapies

Once the diagnosis of premenstrual syndrome has been made, more specific therapy can be initiated for those women who desire pharmacologic intervention. Because of their demonstrated effectiveness in prospective randomized clinical trials, selective serotonin reuptake inhibitors (SSRIs) or agents that inhibit the reuptake of both serotonin and norepinephrine are commonly used. The four commonly prescribed SSRIs (fluoxetine, paroxetine, sertraline, and citalopram) are often effective in their usual starting dose when used daily throughout the menstrual cycle. However, sertraline has been demonstrated to be effective when administered only in the luteal phase (last 14 days) of each menstrual cycle. In contrast to the gradual and delayed response of individuals with chronic depressive disorders to SSRIs, women with premenstrual syndrome may note improvement of their symptoms within days of starting their medication. In addition to the SSRIs, first-line therapies may include venlafaxine or calcium carbonate. Several prospective randomized studies have shown calcium carbonate to be effective in reducing premenstrual syndrome such as depression, water retention, food cravings, fatigue, abdominal bloating, headache, breast fullness, and pain. Finally, mefenamic acid and naproxen sodium have also been shown to be effective

therapies. When administered in the luteal phase of the menstrual cycle, these agents may reduce physical as well as emotional symptoms.

Second-Line Therapies

When these first-line therapies are either ineffective or unacceptable to the patient, there are other therapies that may be helpful even though scientific support for their use is not as strong as for the first-line therapies. Second-line, nonpharmacologic therapies include biofeedback, bright light therapy, cognitive behavioral therapy, and massage therapy. Second-line pharmacologic agents include the antidepressants fluvoxamine maleate, clomipramine, nefazodone, and phenylpiprazine and the anti-anxiety medication alprazolam. These agents have not been studied to the same extent as the first-line SSRIs, but there are some data to support their use. In addition, the side effects of these medications are infrequent and usually mild. Although obliteration of the menstrual cycle and ovulation by danazol or gonadotropin-releasing hormone (GnRH) agonists has been shown to be effective, their side effects limit their widespread use. Danazol is often associated with fluid retention, acne, facial hair growth, and muscle cramps. GnRH agonists are associated with menopausal symptoms including hot flashes, night sweats, and insomnia.

This wide array of potentially effective therapies offers new hope to women with PMS or PMDD. However, the therapy of PMS/PMDD should be more than just pharmacologic and should include

self-help measures so that the patient becomes an active partner in her therapy. In addition, attempts should be made to recognize and help the patient deal with stresses in her life and to help her establish an effective social support system. The importance of validation, social support, and the elimination of stress cannot be emphasized enough. It is hoped that further research will uncover new and even more effective and safe therapies for premenstrual syndrome.

stimulation of aldosterone production throughout several days of synthetic adrenocorticotrophic hormone (ACTH) administration (tetracosactrin 1 mg every 12 h by intramuscular injection). These features permitted the clear distinction of this subtype from the non-glucocorticoid-remediable forms of PAL even when they occurred in a familial setting. The familial occurrence of APA and other non-glucocorticoid-remediable forms of PAL was first described by the Greenslopes Hospital Hypertension Unit (GHHU) in Brisbane, Australia in 1991, and was termed familial hyperaldosteronism type II (FH-II) in order to differentiate this new familial form of PAL from the glucocorticoid-remediable variety [familial hyperaldosteronism type I (FH-I)]. Diagnosis of FH-I was simplified even further following the elucidation of the “hybrid” 11 β -hydroxylase/aldosterone synthase gene mutation that causes this condition and the development of sensitive and specific genetic tests that followed.

Seeking the Optimal Approach for the Differentiation of APA from BAH

The differentiation of APA from BAH has proven far less straightforward than the differentiation of FH-I from other subtypes of PAL and has been the subject of intense investigation. Early attempts at imaging APAs involved relatively insensitive and invasive procedures such as adrenal venography, which carried with it a significant risk of contrast extravasation and adrenal hemorrhage. In general, patients with APA have demonstrated somewhat more severe biochemical abnormalities than those with BAH and some investigators have attempted to develop multiparameter biochemical models, incorporating such variables as plasma sodium, potassium, total carbon dioxide, aldosterone, and renin, in order to distinguish the two subtypes. However, the degree of overlap was great and an assessment of the severity of PAL proved to be of little value in determining the subtype in the individual patient.

It was a finding of considerable significance, therefore, that plasma aldosterone levels in patients with APA failed to rise in response to a change in posture from recumbency to an upright position, or to infusions of angiotensin II (Ang II), as was also the case in patients with FH-I, whereas in patients with BAH, responsiveness of plasma aldosterone to these maneuvers was retained, and perhaps even enhanced. In the 1980s, patients with APA or FH-I were further found to differ from those with BAH by demonstrating elevated levels of hybrid steroids, 18-hydroxy-cortisol

and 18-oxo-cortisol. In 1987, however, the GHHU reported unilaterality of aldosterone production on adrenal venous sampling in patients in whom aldosterone was responsive to both posture and Ang II infusion and whose hypertension was subsequently cured by unilateral adrenalectomy. Furthermore, urinary levels of 18-hydroxy-cortisol and 18-oxo-cortisol were usually normal. These patients thus masqueraded biochemically as BAH, yet, like those with classic Ang II-unresponsive APA, could be cured of hypertension following removal of their tumors by unilateral adrenalectomy. The discovery of this new subtype of Ang II-responsive APA meant that APA could not be excluded on the basis of retained aldosterone responsiveness to posture or Ang II infusion or normal hybrid steroid levels.

Newer methods of adrenal imaging, such as scintigraphic scanning following injection of radiolabeled methylcholesterol, computerized tomography (CT) scanning, and magnetic resonance imaging, though relatively noninvasive, have frequently been found to be associated with false-negative studies owing to the small size of many APAs. Furthermore, apparently nonfunctioning adrenal tumors (“incidentalomas”) can masquerade as APA and thereby produce false-positive results on imaging studies.

The procedure that has stood the test of time in terms of reliability in differentiating unilateral, surgically correctable forms of PAL (including APA) from bilateral forms (BAH) is adrenal venous sampling (AVS), in which right and left adrenal venous aldosterone/cortisol ratios are compared to those in simultaneously collected peripheral venous blood. Since imaging studies lack reliability, the argument that AVS should be performed in every case of PAL following exclusion of FH-I by genetic testing, in order to differentiate APA from BAH and lateralize APAs preoperatively, has gathered increasing support.

Prevalence—The PAL Renaissance

For most of its history, PAL was regarded as being a rare condition, accounting for 1% of hypertension at best. Hypokalemia was thought to be present in almost all cases, so that the search for PAL was considered to be unnecessary in normokalemic individuals.

In the 1990s, and into the 2000s, evidence gathered by the GHHU and subsequently by an increasing number of other investigators suggested that PAL is much more common than previously thought, accounting for at least 5–10% of hypertensives, and that most patients are normokalemic. These findings arose from the availability of improved methods of

screening [and in particular the plasma aldosterone/plasma renin activity (PRA) ratio (ARR)] and the application of the ARR to a widened population of hypertensives to include normokalemic (and not just hypokalemic) patients and those with less resistant forms of hypertension. These measures led to a 10-fold increase in the detection of PAL (including a 4-fold increase in the identification of patients with APA), providing the opportunity for specific and potentially curative treatment to a great many more hypertensive patients than was previously possible.

PATHOGENESIS

In PAL, excessive production of the salt-retaining hormone aldosterone results in excessive sodium reabsorption via amiloride-sensitive epithelial sodium channels within the distal nephron (leading to hypertension) and continues in the face of renin–Ang II suppression. All grades of hypertension have been observed, although malignant hypertension has only rarely been reported. Family screening, by genetic testing in families with FH-I and ARR testing in those with FH-II, has permitted the identification of normotensive individuals with PAL, suggesting that this condition may evolve through a normotensive “phase,” the duration of which may depend on the presence and efficiency of counter-regulatory (including genetic) mechanisms protecting those individuals against the development of hypertension. Urinary loss of potassium and hydrogen ions, exchanged for sodium at the distal nephron, may eventually result in hypokalemia and metabolic alkalosis if severe and prolonged enough. At the GHHU and Princess Alexandra Hospital Hypertension Unit (PAHHU), where PAL is sought by measuring the ARR in all referred hypertensives, hypokalemia is present in less than one-quarter of patients detected and in less than one-half of those with APA. If hypokalemia does develop, it may be associated with nocturia, polyuria, muscle weakness, cramps, paresthesias, and/or palpitations.

Morbidity in PAL primarily results from hypertension. However, experimental and clinical evidence suggests that aldosterone excess can bring about cardiovascular injury (including inflammation, fibrosis, and remodeling) independently of blood pressure elevation. These effects appear to be preventable by the administration of mineralocorticoid receptor antagonists. Doses of aldosterone used in experimental studies have been very large and the clinical relevance of the resulting cardiovascular changes remains uncertain. Nevertheless, several groups have demonstrated

abnormalities in cardiac morphology or function in patients with PAL that appear to be out of proportion to the elevation in blood pressure and which improved following specific treatment of PAL.

With the exception of the glucocorticoid-remediable variety (FH-I), the etiology of PAL remains unknown. The “hybrid gene” mutation that causes FH-I is composed of 5′ (including regulatory and some coding) sequences derived from the 11 β -hydroxylase gene (*CYP11B1*) and 3′ (including all remaining coding) sequences derived from the aldosterone synthase gene (*CYP11B2*) (see Fig. 1). This gene has sufficient *CYP11B2* coding sequences to encode an enzyme that efficiently synthesizes aldosterone from its precursors, deoxycortisone and 18-hydroxycorticosterone. Unlike *CYP11B2*, however, which is predominantly regulated by Ang II, the hybrid gene is regulated by ACTH by virtue of its *CYP11B1* regulatory sequences. Aldosterone production in FH-I is therefore regulated by ACTH rather than by Ang II, which renders it glucocorticoid-suppressible. Unlike *CYP11B2*, the hybrid gene is expressed not only in the zona glomerulosa, but also in the zona fasciculata. Here cortisol is available as a substrate for its 18-hydroxylase and 18-oxidase gene product activities, which probably explains the excessive production of 18-hydroxy-cortisol and 18-oxo-cortisol (“hybrid steroids”) in FH-I.

Other forms of PAL may also have a genetic basis and the familial occurrence of non-glucocorticoid-remediable PAL (FH-II, which includes APAs and BAH) is in keeping with this. Within the GHHU and PAHHU, new families with FH-II have been detected five times more frequently than those with FH-I and affected patients have demonstrated clinical, biochemical, and adrenal morphological features that are indistinguishable from those with apparently sporadic PAL. Mutations responsible for FH-II may therefore be more common, at least collectively, than the hybrid gene and may be operative in patients with apparently sporadic PAL. The genetic bases of FH-II remain uncertain, but in two affected families thus far studied, linkage studies have implicated a locus in chromosome 7p22.

SUBTYPES

Pathological

Pathological expression of PAL is highly variable and different histological subtypes frequently coexist in the one patient. The most common is adrenal cortical hyperplasia (which may be diffuse or nodular), followed by adenoma, and adrenocortical carcinoma is

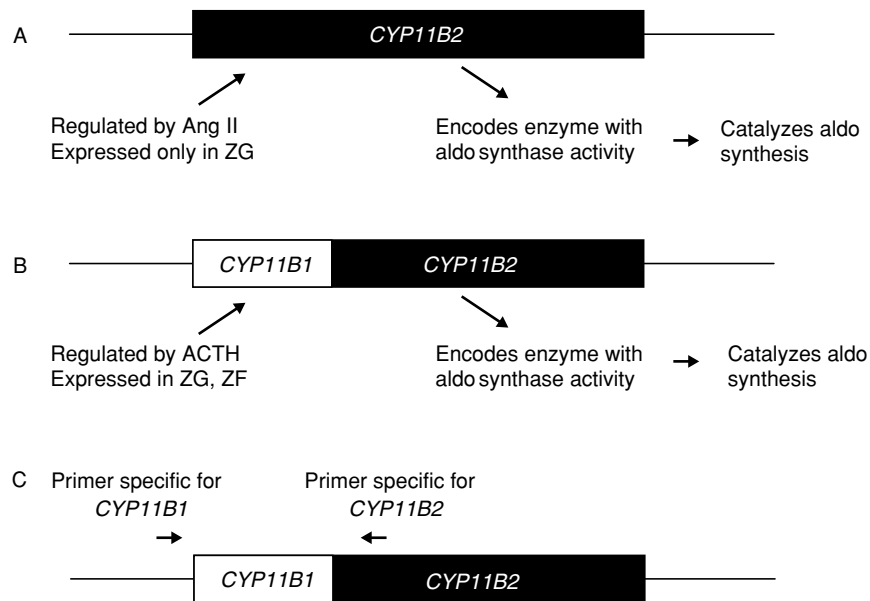

Figure 1 Regulation and outcome of expression of (A) the wild-type aldosterone synthase gene (*CYP11B2*) and (B) the “hybrid” 11 β -hydroxylase (*CYP11B1*)/*CYP11B2* gene. (C) The strategy used for amplification of the hybrid gene by long-polymerase chain reaction. *CYP11B2* sequences are represented as black boxes and *CYP11B1* sequences as open boxes. Ang II, angiotensin II; ACTH, adrenocorticotropic hormone; ZG, zona glomerulosa; ZF, zona fasciculata. See text for detailed description.

fortunately very rare. Cells contained in APAs may resemble those of the zona fasciculata (ZF), zona glomerulosa (ZG), or zona reticularis or may have cytological features of both ZF and ZG (“hybrid cells”). The predominant cell type may help to determine the biochemical behavior of the tumors, with the presence of at least 80% non-ZF (ZG, reticularis or hybrid)-type cells seeming to confer Ang II-responsiveness, whereas unresponsiveness has usually been observed in APAs in which 50–100% of the cells were ZF-like.

Functional

From a management point of view, it is more useful to subclassify PAL according to functional (rather than morphological) characteristics and in particular whether the PAL is:

1. glucocorticoid-remediable (FH-I, which makes up less than 1% of patients with PAL), in which case treatment with small doses of glucocorticoids would be expected to result in excellent hypertension control;
2. non-glucocorticoid-remediable and lateralizes to one adrenal (consistent with APA, which constitutes approximately one-third of patients with PAL; or with aldosterone-producing carcinoma, which is rare), in which case unilateral adrenalectomy would be expected to bring about cure or marked improvement in hypertension; or

3. non-glucocorticoid-remediable and bilateral (consistent with BAH, which constitutes approximately two-thirds of patients); it usually is managed medically with aldosterone antagonist medications.

DIAGNOSIS

Screening for PAL

Because hypokalemia is present in only a minority of patients, measurement of plasma potassium lacks sensitivity for detecting PAL. On the other hand, the occurrence of hypokalemia in a hypertensive patient, in the absence of an alternative explanation (for example, treatment with diuretics or gastrointestinal loss of potassium accompanying vomiting or diarrhea), is highly suggestive of PAL.

Plasma aldosterone levels frequently lie within the wide normal range in patients with PAL, including those with APA, and a normal level therefore does not exclude the diagnosis. Although the demonstration of suppressed PRA levels is highly sensitive for PAL, it lacks specificity, occurring in several other inherited and acquired salt-loaded hypertensive states (including high dietary salt intake, Liddle’s syndrome, inherited deficiency of 11 β -hydroxysteroid dehydrogenase type 2 or inhibition of this enzyme by licorice abuse or carbenoxolone treatment, deoxycortisone-secreting tumors, hypertensive forms of congenital

adrenal hyperplasia, and inherited activating mutations of the mineralocorticoid receptor).

Measurement of the ARR has become widely regarded as the most reliable available means of screening for PAL. Many factors, however, including the presence of hypokalemia, medications, dietary salt intake, posture, and time of day, can affect the ARR level and reduce its reliability. Before measuring the ARR, therefore, it is important to: (1) correct hypokalemia (which can lower plasma aldosterone and cause false-negative results); (2) where possible, replace potentially interfering medications (such as beta-blockers, α -methyl dopa, clonidine, and nonsteroidal anti-inflammatory drugs, which can cause false-positive results; and diuretics, dihydropyridine calcium antagonists, Ang II-converting enzyme inhibitors, and Ang II receptor blockers, which can cause false-negative results) for several weeks (at least 4 weeks for diuretics and at least 2 weeks for the rest) with others that have minimal effects on the ARR (such as verapamil slow-release, hydralazine, or alpha-blockers), or at least be prepared to take the effects of interfering medications into account, and (3) encourage a liberal dietary salt intake (rather than a salt-restricted diet, which can cause false-negative results).

Sensitivity of the ARR is optimized by collecting blood at midmorning (at 9:00 to 10:00 A.M.) rather than later in the day and from seated (rather than recumbent) patients who have been upright (sitting, standing, or walking) for at least 2 h.

Under the above conditions, a ratio of greater than 30 (plasma aldosterone in nanograms per 100 ml; PRA in nanograms per milliliter per hour) is considered suggestive of PAL.

Confirmation of PAL

As the ARR is a screening test only, further testing is necessary to definitively confirm or exclude the diagnosis of PAL. The most reliable of these, used by the GHHU and PAHHU, is the fludrocortisone suppression test, in which failure of upright (collected at 10:00 A.M.) plasma aldosterone to suppress to less than 6 ng/100 ml at the conclusion of 4 days of fludrocortisone (0.1 mg every 6 h) and slow-release sodium chloride (Slow Na⁺, 1800 mg thrice daily with meals) administration is considered diagnostic. To avoid the potentially confounding effects of abnormal potassium levels on plasma aldosterone, plasma potassium is measured frequently (three to four times daily) over the 4-day test and slow-release potassium chloride (Slow K⁺) is given every 6 h in doses sufficient to maintain levels within the normal range.

An alternative approach, used at the Mayo Clinic, involves the measurement of 24 h urinary aldosterone levels during the third day of oral salt loading (sufficient to achieve a urine sodium excretion of > 200 mmol/day, with enough potassium supplementation to maintain normokalemia). Failure to suppress to 12 μ g/day or less is regarded as diagnostic.

The saline infusion test involves measurement of plasma aldosterone at the conclusion of an intravenous infusion of 0.9% saline (usually 2 liters over 4 h). Cut-off values for the diagnosis of PAL have varied from > 5 to > 10 ng/100 ml. Although this approach is more convenient than fludrocortisone suppression testing, as it requires only a brief visit, it was found by the GHHU to lack sensitivity for the detection of PAL (including APA).

Determining the Subtype

Confirmation or Exclusion of FH-I

The glucocorticoid-remediable form of PAL can be rapidly confirmed or excluded by genetic testing of peripheral blood DNA for the presence of the hybrid gene either by Southern blot or by a faster, polymerase chain reaction-based method. This has rendered as obsolete other, biochemical methods of identifying FH-I (in particular, dexamethasone suppression testing), being far more convenient yet highly reliable.

Differentiating Lateralizing Forms of PAL from Bilateral Forms of PAL

The great majority of patients with PAL test negative for the hybrid gene. In these patients, AVS is the most reliable means of distinguishing lateralizing forms of PAL, including APA and aldosterone-producing carcinoma, from BAH. This procedure is highly specialized and requires an experienced, highly skilled, and dedicated radiologist to achieve optimal rates of successful cannulation (at GHHU, > 90% for the right adrenal vein and > 95% for the left). Several samples are collected from each side during the procedure to maximize the chances of success, which can be gauged by comparing adrenal and peripheral venous cortisol levels, with gradients of at least 3 indicating an "adequate" sample. AVS should be performed in the morning hours following overnight recumbency in order to avoid the confounding effects of changes in posture on aldosterone levels and to take advantage of the effect of high early morning endogenous ACTH levels on aldosterone production. Provided that adrenal venography is avoided, the risk of adrenal hemorrhage associated with AVS is low.

Calculation of the aldosterone/cortisol ratio for each adrenal and peripheral venous sample corrects for differences in “dilution” of adrenal with nonadrenal venous blood. If the average ratio on one side is significantly (usually two times or more) higher than the simultaneous peripheral venous ratio, and the ratio on the other side is no higher than the peripheral venous ratio, the study is considered to show lateralization, indicating that unilateral adrenalectomy should cure or improve the hypertension.

Fine-cut adrenal CT fails to detect at least one-half of APAs (which average only 1 cm in diameter) and may be misleading by demonstrating nonfunctioning nodules. The use of magnetic resonance imaging does not overcome these limitations. Adrenal CT is nevertheless useful for detecting larger lesions (> 2.5 cm), which may warrant removal based on their malignant potential. Adrenal selenocholesterol scanning has been reported to be useful by some centers, but not by most others (including the GHHU), which have found it to lack sensitivity and specificity for APA.

The demonstration of aldosterone responsiveness (defined as a rise of at least 50% over basal levels) during 2 h of upright posture following overnight recumbency or during a 1 h infusion of Ang II (2 ng/kg/min) was once thought to be specific for BAH, but was later recognized to lack discriminatory value in differentiating BAH from APA. At least one-half of APAs removed at the GHHU and PAHHU have been of the Ang II-responsive variety and at least one-fifth with BAH have demonstrated a lack of responsiveness. Hence, regardless of the presence or absence of Ang II-responsiveness, AVS is required to definitively differentiate APA from BAH and to lateralize APAs preoperatively. Hybrid steroid levels, though elevated in FH-I and Ang II-unresponsive APA, again provide only limited value in differentiating subtypes, since levels are usually normal in both BAH and Ang II-responsive APA.

TREATMENT

Patients with FH-I

In FH-I, hypertension is readily controlled by giving glucocorticoids in low doses (e.g., 0.125–0.5 mg of dexamethasone per day). Complete suppression of ACTH-regulated aldosterone production is rarely required and raises the risks of Cushingoid side effects. Alternative approaches include the use of spironolactone and amiloride. Amiloride may be a preferred option for affected children, since it avoids potential problems of growth retardation associated with the

use of glucocorticoids and androgen blockade due to spironolactone. Family screening by genetic testing should be undertaken to identify affected relatives.

Patients who Lateralize on AVS

In patients who lateralize on AVS, unilateral adrenalectomy (performed laparoscopically, enabling a faster recovery than the open approach) results in cure of hypertension in 50–60% and significant improvement in the remainder and correction of hypokalemia in virtually all who were hypokalemic preoperatively (see Fig. 2). Operated patients usually report a marked improvement in quality of life. Sometimes no further antihypertensives are required after surgery, but usually more gradual withdrawal of antihypertensive medications is possible over the ensuing 3 to 12 months.

Surgical treatment may be inappropriate in a small number of patients who lateralize, including those in whom surgery is considered unsafe because of coexisting medical conditions or those who would prefer not to undergo surgery for a variety of reasons. These patients can be treated medically with aldosterone antagonists using principles similar to those described below for the medical treatment of patients with nonlateralizing PAL.

Patients with Bilateral, Non-Glucocorticoid-Remediable Adrenal Aldosterone Overproduction

For patients demonstrating bilateral aldosterone production on AVS, treatment with aldosterone antagonists usually brings about significant and often marked improvement in hypertension control. The results, however, are generally not as gratifying as those in patients with FH-I treated with dexamethasone or in lateralizing patients who undergo unilateral adrenalectomy. Only small doses of spironolactone (12.5mg daily–25mg twice daily) or amiloride (2.5mg daily–7.5mg twice daily) are usually required, provided weeks or months are allowed for the drug to demonstrate its full effect. Even at these low doses, side effects (gynecomastia, menstrual irregularities, and reduced libido) occur in approximately 10% of patients taking spironolactone. A more selective aldosterone antagonist (eplerenone) with less affinity for sex steroid receptors appears to be relatively free of these side effects and has been shown to be effective as an antihypertensive agent in “essential hypertensives.” However, clinical experience with eplerenone in PAL remains limited.

Figure 2 Aldosterone-producing adenomas (APAs) removed laparoscopically from four patients in whom preoperative adrenal venous sampling lateralized aldosterone production to the side of the subsequently removed adrenal and in whom surgery resulted in cure of hypertension. Preoperative patient characteristics are as follows: (A) male, 57 years, hypokalemic, posture-unresponsive, left APA (0.8 cm) not visible on CT; (B) male, 48 years, hypokalemic, posture-responsive, right APA (0.8 cm) not visible on CT; (C) female, 42 years, normokalemic, posture-unresponsive, left APA (0.9 cm) detected by CT; (D) female, 25 years, normokalemic, posture-responsive, right APA (0.9 cm) not visible on CT.

Aldosterone antagonists must be used with caution in patients with impaired renal function because of their increased tendency to develop hyperkalemia. Concurrent administration of a potassium-wasting diuretic in low doses may help to avoid hyperkalemia, but potassium and creatinine levels still require close monitoring.

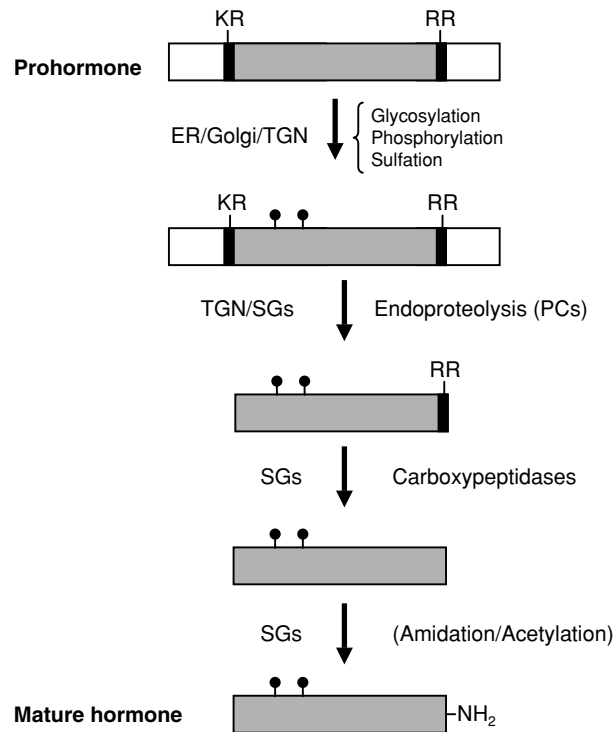

Figure 1 Prohormone processing by prohormone convertases. The mature peptide hormone sequence (gray) is flanked by pairs of basic amino acids (black) within the prohormone. Prohormones may be glycosylated (black lollipop) in the Golgi en route to secretory granules. The PCs cleave on the carboxyl end of the dibasic cleavage site, and carboxypeptidases remove the C-terminally extended basic amino acids. Finally, peptide hormones may be amidated or acetylated to attain biological activity. K, lysine; R, arginine; ER, endoplasmic reticulum; TGN, *trans*-Golgi network; SGs, secretory granules.

ENDOPROTEASES IN PROHORMONE PROCESSING

PC1 and PC2: Biological Activity, Structure, and Cellular Trafficking

Biological Activity

Both PC1 and PC2 have been localized within the secretory granules of the anterior and neurointermediate lobes of the pituitary, pancreatic islets, endocrine cells of the heart, and neuropeptide-rich regions of the intestine and brain. Within these tissues, PC1 and PC2 exhibit distinct distributions, and this in turn is responsible for the tissue-specific processing observed for several prohormones. For example, proopiomelanocortin (POMC) is expressed in both the anterior and neurointermediate lobes (NILs) of the pituitary but is processed to a different complement of

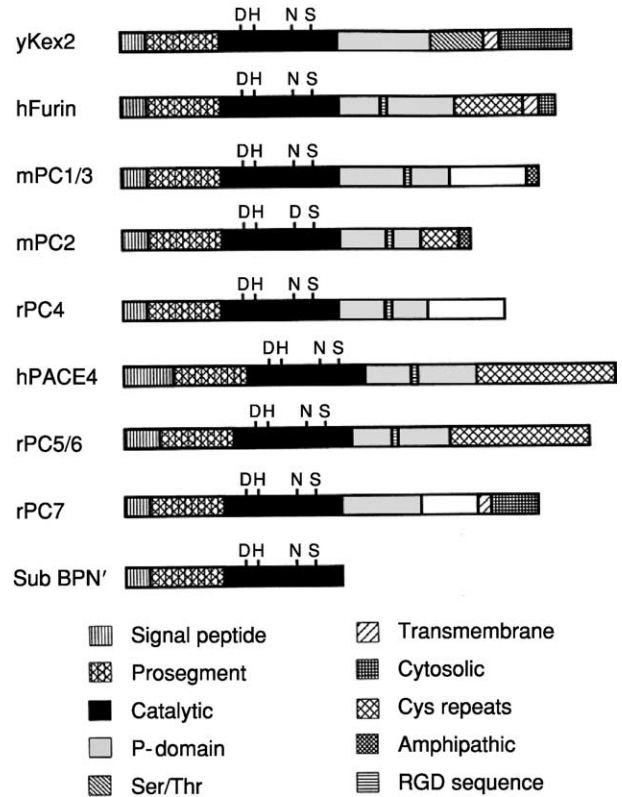

Figure 2 Schematic representations of the structures of the known endoproteolytic prohormone convertases. These enzymes were identified based on sequence homology with the catalytic domain of bacterial subtilisin (Sub BPN'). All enzymes contain the catalytic triad D (aspartic acid), H (histidine), and S (serine) characteristic of all serine proteases. The asparagine (N) residue in the catalytic domain is also conserved throughout the family except in PC2, where it is replaced by an aspartate (D). All prohormone convertases are also glycosylated at multiple sites (not shown). y, yeast; h, human; m, mouse; r, rat.

peptides in each lobe due to the differential distribution of PC1 and PC2. In the anterior lobe, PC1 is highly expressed and cleaves POMC to adrenocorticotrophic hormone (ACTH) and β -lipotropic hormone (β -LPH). In the NILs, both PC1 and PC2 are expressed and cleave POMC in a sequential fashion to yield smaller peptides, melanocyte-stimulating hormone (α -MSH) and β -endorphin, which are unique to the NILs. Similarly, the tissue-specific processing of proglucagon in the alpha cells of the pancreatic islets and the L cells of the distal small intestine is the result of differential expression of PC1 and PC2. Proglucagon is processed to glucagon largely through the actions of PC2 in the pancreatic islets, whereas PC1 cleaves proglucagon in the intestine to yield the gastrointestinal hormones glucagon-like peptide-1 (GLP-1) and GLP-2. Finally, both PC1 and PC2

cleave proinsulin in a concerted manner to yield insulin and C peptide in the pancreatic beta cell. The B-chain/C-peptide junction is cleaved by PC1, followed by cleavage at the C-peptide/A-chain junction by PC2.

Both PC1 and PC2 require high intracellular calcium concentrations (10–20 mM) and an acidic pH (5.0–5.5) for optimal activity. These conditions exist within the secretory granules, the subcellular compartment to which the PCs are transported and in which prohormone processing takes place.

Structure

The structure of PC1 and PC2 can be organized into discrete domains (Fig. 2). Each enzyme contains an N-terminal signal peptide, which is removed on translocation of the nascent peptide into the endoplasmic reticulum (ER). Both enzymes contain an N-terminal prodomain, which inhibits the catalytic activity of the PCs. Sequence alignment of PC1 and PC2 shows a 55% amino acid identity within the catalytic domains, which contain the highly conserved active site Asp, His, and Ser. Other sites of sequence identity include Asn-282, which is replaced by Asp-285 in PC2 and is associated with development of the oxyanion hole in bacterial subtilisins. The catalytic domain is followed by the P domain, which contains the conserved tripeptide sequence Arg–Gly–Asp, a recognition sequence by cell surface antigens implicated in cell–cell adhesion. The C-terminal end of the P domain plays a role in regulating the stability, calcium dependence, and pH dependence of the convertases. The C-terminal sequences of PC1 and PC2 contain an amphipathic α -helical structure that functions in membrane anchoring.

Subcellular Trafficking and Activation

PC1

The subcellular trafficking of PC1 and PC2 has been thoroughly investigated and follows slightly different routes for processing and activation. Both are initially synthesized as proenzymes in the ER. Within this compartment, the route for processing and activation of PC1 diverges from that of PC2.

The 86- to 89-kDa pro-PC1 is quickly converted to an 83- to 86-kDa PC1 by removal of its prodomain at an RSKR cleavage site in an autocatalytic intramolecular manner in the ER. Full-length PC1 is transported through the Golgi in association with a molecular chaperone, pro-SAAS, which inhibits the catalytic activity of PC1. The PC1 inhibitory sequence of pro-SAAS is comprised of a 10- to 12-amino

acid segment near its C terminus and contains a critical Lys–Arg-244 dibasic motif. Targeting of PC1 to the regulated secretory pathway is dependent on sorting information contained within its C-terminal domain, which anchors it to lipid raft microdomains within the membranes of the *trans*-Golgi network (TGN). In the immature granule, PC1 is processed at an Arg–Arg-618 site at its C terminal end in an autocatalytic manner to yield a soluble 64- to 66-kDa form. The catalytic activity of 64- to 66-kDa PC1 is optimal between pH values 5.0 and 5.5, the pH values of the mature and immature secretory granules, respectively. Although PC1 activity has been measured as soluble activity, a significant proportion of PC1 remains membrane associated within the immature and mature secretory granule.

PC2

The mechanism of activation of pro-PC2 is more complex than that of PC1. PC2 is unique among the PC family in that it requires an acidic, post-Golgi compartment for processing and activation. Initially synthesized as a 75-kDa proenzyme, pro-PC2 is folded and subsequently associates with 7B2, a 27-kDa neurosecretory protein of the granin family. The 21-kDa N-terminal portion of 7B2 binds to the catalytic domain of pro-PC2 via a polyproline helical structure. The 6-kDa C-terminal peptide of 7B2 inhibits PC2 activity. The pro-PC2–7B2 complex then exits the ER. On reaching the TGN, 7B2 is cleaved by furin to liberate the N-terminal portion of 7B2, allowing for the removal of the prodomain of PC2 in an autocatalytic intramolecular manner. The C-terminal peptide remains associated with pro-PC2; once the prodomain is removed, the inhibitory C-terminal peptide can access the active site of PC2 previously occupied by the propeptide. The C-terminal peptide of 7B2 contains a Lys–Lys pair that is a site of slow cleavage by PC2. Final inactivation of the C-terminal peptide occurs in the secretory granules through the removal of the Lys–Lys pair by CPE.

Both the C-terminal amphipathic α -helical region and the N-terminal propeptide may serve as sorting signals to direct pro-PC2 to the regulated secretory pathway. Association of the propeptide with lipid rafts in the TGN also directs pro-PC2 into secretory granules. The catalytic activity of active PC2 is optimal between pH values 5.0 and 5.5, the pH values of the mature and immature secretory granules, respectively. Like PC1, a significant amount of PC2 remains bound to membranes of secretory granules.

Yapsins

In yeast *Saccharomyces cerevisiae* mutants, that lack the subtilisin-like serine protease kexin, a number of aspartyl proteases were able to compensate for its activity, demonstrating that these new enzymes could also be classified as prohormone convertases. These aspartyl proteases are known as yapsins. There are now five members in the yapsin family: three from *S. cerevisiae* (yapsins 1, 2, and 3), one from *Candida albicans* (SAP9), and one from bovine pituitary intermediate and neural lobe secretory granules previously characterized as pro-opiomelanocortin-converting enzyme (PCE, now named yapsin A). Their unique specificity for the basic residue cleavage sites of prohormones such as POMC, proinsulin, cholecystokinin (CCK), and prosomatostatin added a new understanding to the field of aspartyl proteases because it was well known that all previously characterized enzymes of the aspartyl protease family preferred substrates with hydrophobic residues.

Prohormone Thiol Protease

Another enzyme that has the properties consistent with being a prohormone convertase is the 33-kDa prohormone thiol protease purified and characterized from the chromaffin granules of the adrenal medulla. Within the chromaffin granule, this enzyme is capable of cleaving proenkephalin at either paired or monobasic cleavage sites. It has also been shown to process recombinant proneuropeptide Y but cleaves protachykinin and POMC poorly. It has an optimal pH activity at pH 5.5 and is potently inhibited by thiol-specific protease inhibitors. It has also been found in some lung cancer cells, where it can process parathyroid hormone-related protein (PTHrP) at basic residue cleavage sites to generate bioactive peptides. This enzyme has been identified as cathepsin L.

Dynorphin-Converting Enzyme

Distinct from the prohormone thiol protease, two other enzymes have been purified from the neurointermediate lobe of the pituitary and from brain and are also thiol sensitive. These enzymes are known as dynorphin-converting enzyme (DCE) and dynorphin A-17-processing enzyme. These enzymes are metalloproteases with molecular masses of 54 and 65 kDa and exhibit isoelectric points of 5.1 and 5.8, respectively. They both have a neutral pH optimum and appear to cleave on the N-terminal side of single basic residue cleavage sites.

CARBOXYPEPTIDASE AND AMINOPEPTIDASE PROTEASES IN PROHORMONE PROCESSING

Following endoproteolytic cleavage of prohormones by the PCs, exopeptidases such as carboxypeptidases and aminopeptidases remove the basic residue extensions from peptide hormones to yield the active hormone. CPE, found exclusively in endocrine and neuroendocrine tissues, is the primary enzyme that cleaves basic residues from the C-terminally extended peptide hormones. A second carboxypeptidase, carboxypeptidase D (CPD), has the same specificity as CPE and may also play a role, but it is present in endocrine tissues in much lower amounts than CPE. Aminopeptidase activities that specifically remove basic residues from the N terminus of peptides have been found in pituitary and chromaffin granules.

CPE

Activity

CPE has been purified and cloned from bovine, human, rat, and mouse endocrine tissue. It is also present in brain. CPE is primarily localized to the secretory granules of neuroendocrine cells where prohormone processing occurs. CPE specifically cleaves C-terminally extended Lys and Arg residues from peptide hormones. It functions optimally between pH values 5.5 and 6.0, the intragranular pH. Its activity is stimulated by Co^{2+} and inhibited by metal ion chelators (EDTA, 1,10-phenanthroline) and the active site inhibitor guanidine-ethylmercaptosuccinic acid (GEMSA), which distinguishes it from carboxypeptidase B-like activities in lysosomes.

Structure

There are two forms of CPE: a 50-kDa soluble form and a 55-kDa membrane-bound form. Both forms are derived from the same mRNA encoding prepro-CPE. Prepro-CPE contains a signal peptide and a prodomain at the N terminus that is separated from the mature enzyme by an RRRRR (where R = Arg) sequence. Mature soluble CPE contains a substrate-binding site, a Zn^{2+} binding site, and a catalytic pocket (Fig. 3). In addition, the membrane form contains a 22-amino acid C-terminal domain that forms an amphipathic α -helix. This domain is transmembrane, with the last 4 to 6 residues forming the cytoplasmic tail (Fig. 3), and functions to anchor CPE to lipid rafts at the TGN. This anchoring is essential for targeting CPE to the regulated secretory pathway.

Figure 3 Molecular model of carboxypeptidase E (CPE). The three-dimensional structure of CPE shows the orientation of the luminal domain and transmembrane region. The zinc atom is drawn as a sphere to mark the enzymatic pocket. The POMC sorting signal-binding region, R255-K260, is exposed on the surface of the molecule and is spatially distinct from the enzymatic pocket. The transmembrane region forms a partial amphipathic α -helix at acidic pH that is stabilized through interaction with the lipid bilayer. The C-terminal 4 to 6 amino acids are exposed on the cytoplasmic side of the secretory granule and so comprise a cytoplasmic “tail.”

When anchored to secretory granule membranes, CPE has less enzymatic activity relative to the soluble form that is five to six times more active. Soluble CPE is derived from the membrane form by removal of the C-terminal transmembrane domain. The amount of soluble CPE in the secretory granule ranges from 10 to 70%, depending on the tissue.

Membrane CPE: A Prohormone Sorting Receptor

In endocrine tissue, the amount of CPE present is in excess of the other prohormone convertases, a significant amount of which is the membrane form. Membrane CPE functions as a sorting receptor for POMC by facilitating the entry of POMC into the regulated secretory pathway. By antisense-mediated depletion of CPE in neuroendocrine cells, Loh was able to show that the sorting of POMC to the regulated secretory pathway was impaired, resulting in constitutive secretion of the prohormone. In addition, her experiments using pituitaries from mutant CPE^{fat/fat} mice depleted of CPE also showed constitutive rather than regulated secretion of POMC.

CPD

CPD has a substrate specificity and pH optimum (5.5–6.5) that is consistent with a role in peptide hormone processing. However, it is more widespread in distribution and has a subcellular localization in the TGN, but not in secretory granules where much of the processing occurs, especially the later steps requiring an exopeptidase action.

Aminopeptidases

An aminopeptidase activity that cleaves N-terminal basic residues from peptide hormones has been isolated from bovine pituitary secretory granules. It has been characterized as a thiol-metallo-aminopeptidase with a pH optimum of 6.0, is stimulated by Co^{2+} and Zn^{2+} , and is inhibited by EDTA. Two similar thiol-metallo-aminopeptidase activities have also been found in chromaffin granules. One, termed the Arg-MCA activity, is stimulated by Co^{2+} , but the other, termed the Lys-MCA activity, is not. However, it is unclear whether the two activities are derived from one enzyme. Unlike aminopeptidase B-like activities from other tissues, these thiol-metallo-aminopeptidase activities are not inhibited by Cl^- .

THE PROHORMONE CONVERTASES AND DISEASE

Mutations in the genes encoding specific prohormones that lead to a defect in, reduction in, or elimination of biologically active peptide hormones may cause certain types of endocrine disorders. For example, some mutations in the POMC gene result in obesity and red hair pigmentation, whereas some mutations in the proinsulin gene result in familial hyperproinsulinemia. In addition, mutations in the genes encoding the prohormone convertases PC1, PC2, and CPE may also result in endocrine disorders. The conversion of proinsulin to insulin and of POMC to ACTH, α -MSH, and β -endorphin are two obvious endocrine systems that would be greatly disturbed by defects in the PCs. To address the *in vivo* physiological importance of convertases in general, a number of “knockout mice,” in which the gene of a particular PC has been deleted, have been engineered. This approach has been used to study the function of a number of the PCs, including furin, PC4, PC1, and PC2. For CPE, an alternative mouse model is discussed in what follows.

Genetic deletion of furin, a ubiquitously expressed convertase active in the constitutive secretory pathway

of every cell, resulted in lethality and the mice died *in utero*. For PC4, a convertase expressed exclusively in germ cells, the knockout mice survived. The male mice were infertile and the female mice exhibited decreased folliculogenesis in the ovaries, demonstrating a specific function of PC4 in reproduction.

PC1

Like the furin knockout mouse, the PC1 knockout mouse did not survive, demonstrating an essential role for this neuroendocrine-specific enzyme in embryonic development. However, there are reports of PC1 deficiencies in some human patients. One such patient was characterized as a compound heterozygote, where each allele of the PC1 gene contains a distinct mutation, one that causes expression of a mutant protein that is misfolded and not secreted and one that causes a frame-shift mutation, resulting in a premature stop codon that produces a truncated form of the enzyme. In this individual, PC1 activity was absent and the patient was extremely obese and hypoglycemic. The patient also exhibited endocrine imbalances such as hyperproinsulinemia with very low levels of mature insulin, hypogonadotropic hypogonadism, and increased plasma levels of both POMC and cortisol. Another case report described a patient with isolated congenital ACTH deficiency due to impaired processing of POMC. However, the gene for POMC was normal, and the activities of PC1 and PC2 also appeared to be normal, suggesting the possibility that a defect in another POMC processing enzyme may have been responsible for the observed lack of ACTH. The identity of this enzyme was unknown, but a good candidate is the previously described PCE or yapsin A.

PC2 and 7B2

The PC2 knockout mice are normal in their appearance besides having a slight decrease in growth rate. However, the mice are chronically hypoglycemic, and at the endocrine level there is impaired processing of proglucagon, proinsulin, and prosomatostatin in pancreatic islets. Histologically, the islets display marked alpha cell hyperplasia and hypertrophy, with a corresponding reduction in the beta cell population. These mice secrete large amounts of unprocessed proglucagon, and the resulting lack of active circulating glucagon explains the observed hypoglycemia. The absence of PC2 also results in the elevation of the des-31,32-proinsulin intermediate, reflecting the preference of PC2 for this substrate.

Endocrine disruptions were also observed in the 7B2 knockout mice. The absence of 7B2, a chaperone necessary for normal PC2 activation, obliterated PC2 enzymatic activity. As a result, the mice developed hypoglycemia, hyperproinsulinemia, and hypoglycagonemia. Interestingly, 7B2 knockout mice also had symptoms of Cushing's disease due to very high circulating levels of ACTH. The overproduction of ACTH originated from the intermediate lobe of the pituitary, in which POMC is normally processed to α -MSH by PC2. In the absence of active PC2, POMC was instead processed to ACTH, which acted on the adrenal cortex and caused hypercortisosteronemia. Because the intermediate lobe is under tonic inhibitory control by dopamine, production and secretion of the ACTH are not controlled by the normal inhibitory feedback mechanism of corticosterone. Therefore, production of both ACTH and corticosterone is unregulated, resulting in severe Cushing's disease, and the mice died at 9 weeks of age.

CPE

In the absence of an engineered CPE knockout mouse, much has been learned from an obese mouse model known as the CPE^{fat/fat} mouse. This mouse carries an autosomal recessive mutation that arose spontaneously in the HRS/J inbred strain of mice that maps to the Cpe locus. The CPE gene in these mice showed a T-to-C point mutation within the coding region that resulted in a conversion of Ser-202 to Pro. This mutant CPE lacks enzymatic activity, and the protein is totally degraded in the pituitary and partially degraded in the pancreatic islets and brain. Deficiency in CPE in these mice leads to a phenotype of infertility and obesity. A number of endocrine disruptions are evident, including diabetes due to hyperproinsulinemia, a lack of stimulated secretion of CCK in response to refeeding after fasting, and a severe reduction in intestinal GLP-1 production. These defects are the result of the incomplete processing, or sorting, of gonadotropin-releasing hormone, proinsulin, pro-CCK, and proglucagon.

Several mutations in the human CPE gene have been described in Japanese and Caucasian patients with type 2 diabetes. However, there appears to be no causative relationship between mutations in the CPE gene and type 2 diabetes.

The studies described in this article demonstrate the utility of knockout mice in determining the functions of the PCs in the whole organism. Importantly, these studies highlight the requirement of proper

prohormone processing in the maintenance of endocrine function and shed light on the role of PC defects in endocrine disorders. Further studies of other peptide hormones and neuropeptides affected by processing enzyme deficiencies should clarify the extent of the involvement of various endoproteases in prohormone processing in the nervous and endocrine systems.

PROCESSING OF PROHORMONES

Prohormone Convertase Discovery

With the discovery of proinsulin and other prohormone precursors and the realization that cleavage occurred at paired basic residues to generate the biologically active peptide, the search for the enzyme capable of making the physiological cleavage began. Kemmler and colleagues proposed that a trypsin-like enzyme would be responsible for cleavage at paired basic residues followed by a carboxypeptidase B-like enzyme that would remove the C-terminal basic amino acids. It has become apparent that trypsin-like limited proteolysis (as opposed to complete protein digestion) of a wide variety of precursors at paired or occasional single basic residues occurs in the *trans*-Golgi network (TGN) and/or secretory granules. The search for these physiological processing enzymes was an arduous task that took more than 20 years and was fraught with false positives due to contaminating enzymes from organelles other than the TGN and secretory granules. The major advance was the finding that the yeast gene kexin (Kex2) encoded an endopeptidase that cleaved pro- α -factor and pro-killer toxin of *Saccharomyces cerevisiae* at paired basic residues similar

to trypsin. Yeast Kex2 was found to cleave mammalian prohormones. Most serendipitously, computer alignment revealed consider homology in the catalytic region of Kex2 with the protein product, called furin, from the gene (*fur*) that was immediately upstream of the tyrosine kinase *fps/fes* oncogene. Shortly thereafter, the proprotein-processing activity of furin at paired basic amino acids was demonstrated. However, the ubiquitous distribution of furin (highest levels in kidney and brain) led investigators to postulate that other prohormone processing enzymes with catalytic sites homologous to Kex2 and furin would have a distribution limited to neuroendocrine cells.

Using polymerase chain reaction (PCR) techniques, two groups (Steiner and colleagues in Chicago and Seidah and colleagues in Montreal) simultaneously isolated two mammalian prohormone processing enzymes with a tissue distribution limited to endocrine and neuroendocrine cells. Steiner and colleagues used the consensus sites from Kex2 for PCR amplification from human insulinoma RNA to yield a probe that was used to screen a human insulinoma library and isolate a full-length cDNA coding for the novel PC, called PC2. Independently, Seidah and colleagues, using primers based on the furin sequence and cDNA from

mouse pituitary RNA, generated a PCR product that was used as a probe to screen mouse pituitary and insulinoma libraries to isolate full-length cDNA clones coding for mouse PC2 and another for a PC named PC1. Both PC1 and PC2 have an endocrine and neuroendocrine distribution and cleave prohormones on the C-terminal side of paired basic residues. It is noteworthy that the same two laboratories that identified prohormones (i.e., those of Steiner and Chretien) identified the PCs more than 20 years later.

Prohormone Convertase Family Members

Seven members of the PC family have been cloned: furin, PC1 (also referred to as PC3), PC2, PACE4, PC4, PC5/6, and PC7/PC8. Furin, PACE4, PC6B (an isoform of PC5/6), and PC7 are localized in the distal Golgi/TGN, are ubiquitously distributed among cell types, and act predominantly on precursors of growth factors, growth factor receptors, and viral or other secreted glycoproteins. PC1, PC2, PC4, and PC5/6A are localized in the dense core vesicles of the regulated secretory pathway and process neuropeptide and hormonal precursors. Both PC1 and PC2 are widely distributed in the brain. PC1 appears to be present in both the anterior and intermediate lobes of rodent pituitary, whereas PC2 is found predominantly in the intermediate lobe. PC4 is found in the testis, whereas PC5/6A is expressed in the gastrointestinal tract and the brain. Both PC1 and PC2 process a variety of prohormones, including POMC, prosomatostatin, provasopressin, proneurotensin, pro-TRH, proenkephalin, and pro-corticotropin-releasing hormone (pro-CRH). The general consensus is that PC1 is involved in the earlier steps in prohormone processing where a more neutral pH exists, consistent with an earlier activation in the secretory pathway, whereas PC2 is involved in later cleavage steps and requires a more acidic pH, consistent with activation in the maturing secretory granules.

Prohormone Convertase Knockout Mice

Insights into the role of the PCs in hormonal biosynthesis have been elucidated from studies of mice lacking PC2, PC4, and (more recently) PC1 and in a patient with defective PC1 (discussed later). Mice with a knockout of PC2 developed normally and were fertile but had absent proglucagon processing and impaired proinsulin processing and were hypoglycemic. In the brain, there was impaired biosynthesis of several

neuropeptide precursors, including enkephalin, dynorphin, β -endorphin, melanin-concentrating hormone, neuropeptide E, and neurotensin. Male mice with a knockout of PC4 had impaired fertility, possibly due to altered biosynthesis of PACAP. Interestingly, mice lacking PC1 appear normal at birth but, starting at 3 days, have decreased growth and are about 60% of normal size at 10 weeks. They have multiple defects in processing many hormone precursors, including hypothalamic growth hormone-releasing hormone (GHRH), POMC to ACTH, proinsulin to insulin, and intestinal proglucagon to glucagon-like peptide-1 (GLP-1) and GLP-2. The impaired GHRH processing is thought to contribute to their dwarfism. Most interestingly PC1 heterozygotes are mildly obese and appear to be insulin resistant.

Other enzymes, such as the prohormone thiol protease (PTP), the N-arginine dibasic convertase (NRD convertase), the dynorphin-processing endoprotease and pro-opiomelanocortin-converting enzyme (PCE), have been proposed to be involved in the prohormone process. However, the lack of unexpected cleavage of prohormones so far characterized in PC2 and PC1 knockout mice suggests that enzymes other than PC1 and PC2 do not have an important physiological role in hormonal biosynthesis.

Prohormone Processing

Thus, hormonal biosynthesis can be viewed as a multistep process (Fig. 2, which uses provasopressin as an example of posttranslational modifications). The initial step in the secretory cells is removal of the hydrophobic N-terminal signal peptide by signal peptidases. The prohormone may then undergo N-glycosylation, protein folding, and disulfide formation in the endoplasmic reticulum as well as phosphorylation, O-glycosylation, and sulfation in the *cis*-Golgi. The initial PC1 or PC2 endopeptidase cleavage at the carboxy side of paired basic residues in the prohormone can occur as early as the TGN. However, for most prohormones, the initial cleavage is thought to take place in the immature secretory granule. Processing can also occur at single basic residues or between or on the N-terminal side of the paired basic residues. The resulting C-terminal basic residue(s) is removed by a member of the metallo-carboxypeptidase family of carboxypeptidases, of which carboxypeptidase E (H) is mostly likely the relevant physiological enzyme. In many but not all hormones, the C-terminal amino acid is α -amidated by peptidyl α -amidating mono-oxygenase (PAM), an enzyme that

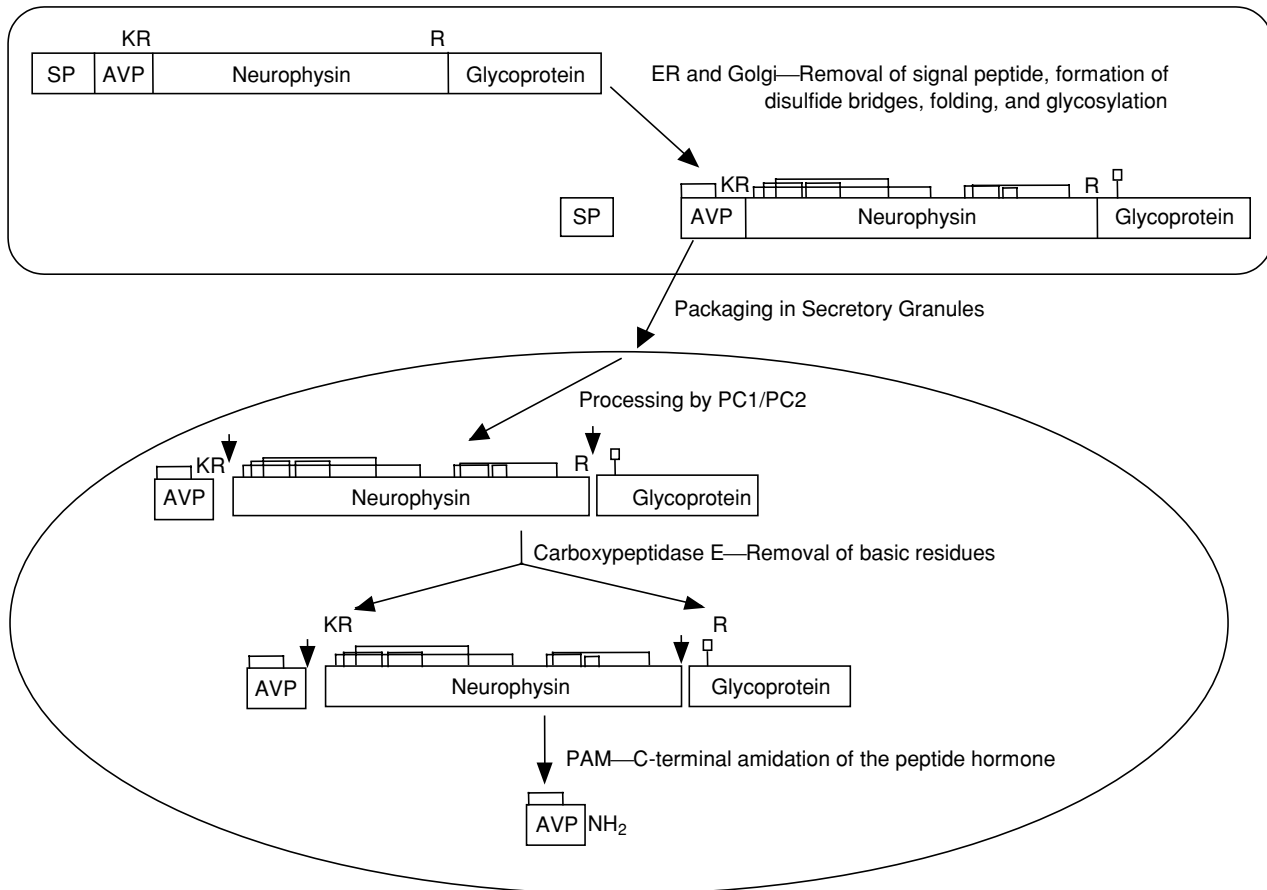

Figure 2 Posttranslational modification scheme of provasopressin. SP, signal peptide.

uses an exposed carboxy-terminal glycine amino acid as the amide donor. Additional posttranslational modifications include removal of free amino acids by aminopeptidases, acetylation of N-terminal amino acids, and conversion of N-terminal glutamate residues to pyroglutamate residues prior to secretion. This pathway is highly regulated to enable the precise amount of active hormone to be synthesized and released.

PROHORMONE SORTING

Prohormones and peptide hormones follow a unique pathway in their movement through endocrine and neuroendocrine cells. For prohormones to be processed and secreted correctly, they must first be packaged in the same compartment or secretory granule with the processing enzymes. Two popular models have been proposed to explain the sorting process. In the first, the sorting by entry model, prohormones

contain a tertiary structure or “sorting signal” that is responsible for directing the prohormone and some enzymes to the budding secretory granules. The sorting signal has negatively charged amino acids at its core that bind to positively charged regions of membrane-bound proteins or receptors in the TGN and are incorporated into granules budding from the TGN. One such receptor has been identified as the regulated secretory granule processing enzyme, carboxypeptidase E. In contrast, a second model exists in which the prohormones are sorted by retention; that is, aggregates of the prohormone and other proteins are packaged together into immature secretory granules. Once packaged together, nonregulated secretory proteins are removed from the granules by a housekeeping, constitutive-like, secretory pathway, leaving only the prohormones, processing enzymes, and other regulated secretory granule proteins. Both models have gained support and are probably not mutually exclusive. That is, the prohormones first must be sorted and enter the immature secretory granules

and then must be retained in the same granules to be processed. Recent investigations have focused on identifying membrane components to which the sorting signal binds such as cholesterol, a major membrane component of the TGN and the immature secretory granules. Depleting the cells of cholesterol causes mis-sorting of prohormones such as POMC and insulin. Thus, the correct packaging of prohormones in the maturing granules of the regulated secretory pathway is a highly regulated process and a key step in the formation of biologically active peptide hormones from prohormones.

EXAMPLE OF PROHORMONE

In this section, proglucagon is described as an example of a prohormone and its tissue-specific processing.

Proglucagon is synthesized in the alpha cells of the pancreas and is processed to bioactive glucagon, glycyntin-related polypeptide (GRPP), intervening peptide-1 (IP-1), and the major proglucagon fragment (MPGF), with the formation of only minimal amounts of GLP-1 (Fig. 3). Glucagon acts to raise plasma glucose levels by stimulating hepatic glycogenesis and gluconeogenesis, whereas the bioactive form of GLP-1, GLP-1₇₋₃₆ amide, lowers plasma glucose levels by stimulating insulin release. The processing of proglucagon in the alpha cell of the pancreas differs from that in the L cell of the intestine due to different levels of PC1 and PC2. In the alpha cell of the pancreas, the major hormonal product is glucagons, with only trace amounts of GLP-1 formed, due to the exclusive presence of PC2 in that cell. In contrast, higher levels of PC1 (but not PC2) in the L cells of the intestine lead to GLP-1 biosynthesis. The role of PC2 in generating glucagon in the alpha cell in physiological conditions

and the role of PC1 in generating GLP-1 and GLP-2 in the L cells of the intestine were confirmed by the absence of glucagon in PC2 knockout mice and the absence of intestinal GLP-1 and GLP-2 in PC1 knockout mice, as discussed previously.

In contrast to the normal condition, rats treated with the beta cell-damaging agent streptozotocin (STZ) had a profound increase in both PC1 and PC2 expression in the alpha cell of the pancreas. PC1 and PC2 expression was unchanged in beta cells. Thus, PC1, which is only minimally expressed in normal alpha cells, is induced in the diabetic state (Fig. 3). This was accompanied by an increase in bioactive GLP-1₇₋₃₆ amide in the pancreata and serum of the STZ-treated rat, and the ratio of pancreatic amidated GLP-1 immunoreactivity to total glucagon immunoreactivity was also increased. This is the first example of how regulation of processing enzymes can alter the ratio of bioactive hormones. The insulin staining in the remaining beta cells appeared to be increased after STZ treatment. We conclude that in the presence of hyperglycemia, the rat regulates its prohormone-converting enzymes in islet alpha cells, leading to an increase in amidated GLP-1, which can then exert an insulinotropic effect on remaining beta cells.

HUMAN DISEASE DUE TO PROHORMONE OR PROHORMONE PROCESSING DEFECTS

Patients having frank defects in genes for prohormones or prohormone processing enzymes are probably rare. Recently, a patient with early-onset obesity and postprandial hypoglycemia with elevated glucose,

Figure 3 Diagrammatic representation of proglucagon and proglucagon-related peptides: general and tissue specific (pancreatic alpha cells vs small intestine L cells). Arrows indicate the sites of cleavage. GRPP, glycyntin-related polypeptide; MPGF, major proglucagon fragment; IP, intervening peptide.

proinsulin, and des-64,65-proinsulin levels, but no detectable insulin, following an oral glucose tolerance test was described. This patient had low levels of ACTH and cortisol, with elevated levels of POMC. The patient was found to have mutations in both alleles of PC1, resulting in complete absence of active enzyme. A second patient with a defect in PC1 and severe diarrhea and obesity has also been reported.

Familial hyperproinsulinemia is a genetic syndrome characterized by markedly increased levels of proinsulin or its conversion intermediates. It is a rare disorder inherited in an autosomal dominant fashion. Earlier studies suggested a defect in the conversion of proinsulin to insulin in these patients. More recent studies using molecular biology techniques have identified six different point mutations in the insulin gene; however, only three of these mutations are associated with hyperproinsulinemia. These defects either lead to proinsulin not being correctly targeted to the regulated secretory pathway or lead to proinsulin not being recognized by the PCs.

Recently, three different mutations in the POMC gene were identified in two unrelated children that led to early-onset extreme obesity, adrenal insufficiency, and red hair pigmentation. The obese phenotype is likely due to the deficiency of melanocortins (most likely α -melanocyte-stimulating hormone [α -MSH]), which act in the brain to reduce food intake and are potential mediators of leptin action. Because α -MSH also influences hair pigmentation, patients deficient in POMC have red hair.

Alterations in the intracellular processing and blood levels of arginine vasopressin (AVP) have been associated with diseases such as familial neurohypophyseal diabetes insipidus (FNDI) and Prader–Willi syndrome. In the autosomal dominant disease FNDI, mutations occur in two general areas of the provasopressin gene. In the first case, mutations are found in genes coding for the signal peptide region that is responsible for entry of the protein into the endoplasmic reticulum (ER), the signal peptide is not cleaved from provasopressin, and the protein is retained in the ER. In the latter case, more than 20 mutations have been identified in the neurophysin region that is responsible for transporting the biologically active peptide hormone, AVP, into the regulated secretory granules. Single amino acid mutations in the neurophysin region cause mis-folding of the prohormone and either mis-sorting of the prohormone to the constitutive secretory pathway or retention of the prohormone in the Golgi. Initially, this causes a lack of biologically active AVP in the blood, resulting in diabetes insipidus. Over a longer time, the magnocellular

neurons responsible for vasopressin synthesis are found to undergo neurodegeneration, most probably due to accumulation of mis-folded provasopressin.

Prader–Willi syndrome is a congenital disease, with more than 70% of the cases associated with a defect in chromosome 15q11-q13. This region is close to the region coding for the neuroendocrine molecular chaperone protein, 7B2, that binds to and prevents premature activation of pro-PC2 in the ER and Golgi. In a subset of these patients, levels of 7B2 are attenuated, resulting in a lack of active PC2 in the regulated secretory granules. Analysis of patients with this defect shows a lack of processing of provasopressin to AVP. How this defect relates to the obese phenotype of Prader–Willi patients is unclear.

REGULATION OF PROHORMONE PROCESSING: IMPLICATIONS FOR DISEASES

It is unlikely that patients with common multigenetic diseases, such as diabetes and obesity, will have a defect in prohormones or processing enzymes. A more likely scenario is that levels of PCs are altered in various diseases, leading to abnormal levels of at least one hormone. A likely example is type 2 diabetes, in which there is an increased proportion of proinsulin and proinsulin conversion intermediates in the circulation. The elevated ratio of proinsulin to insulin is correlated with the degree of hyperglycemia and also occurs in patients with impaired glucose tolerance, indicating that the defect in conversion of proinsulin to insulin may predate the development of diabetes. In analogy to other endocrine systems, one would expect increased—not decreased—conversion of proinsulin to insulin in the face of high glucose to maintain glucose homeostasis. The fact that there is impaired insulin biosynthesis in the setting of hyperglycemia suggests that this may be a likely underlying defect in some patients with type 2 diabetes. As discussed previously, one of the most intriguing findings from the PC1 knockout mouse is that the heterozygote mouse (decreased but not absent expression of PC1) is mildly obese and has high levels of proinsulin and insulin (indicating insulin resistance), with an increased proinsulin to insulin ratio—all similar to the patient with type 2 diabetes. Proving that a component of human diabetes is dependent on impaired levels of PCs remains difficult and will probably be elucidated by examining proinsulin processing and levels of PCs in the pancreas of deceased diabetic organ donors.

In animal studies, the PCs are regulated by agents that alter cyclic AMP (cAMP) levels. Both the PC1 and PC2 promoters contain consensus cAMP response elements (CREs). Binding to the dopamine D2 receptor decreases intracellular cAMP. Thus, treatment with the dopamine antagonist haloperidol, which would be expected to raise intracellular cAMP levels, increased rat pituitary message levels for PC1, PC2, and POMC but not for furin, whereas the dopamine agonist bromocriptine decreased rat pituitary PC1, PC2, and POMC mRNA levels. Similarly, CRH, which stimulates intracellular cAMP levels, increased PC1 mRNA and promoter activity. Glucose, another agent that stimulates intracellular cAMP levels in islet cells, stimulated PC1, PC2, and proinsulin mRNA levels in insulin-producing β TC3 cells.

Agents that do not alter intracellular cAMP levels have also been found to regulate PC1 or PC2 levels. For example, dexamethasone treatment of AtT-20 cells decreased both PC1 and PC2 mRNA levels, suggesting that excess glucocorticoids can suppress the levels of PCs in corticotroph cells. More recently, Jansen and colleagues demonstrated that the transcription factor, early growth response-1 (EGR-1), stimulates PC2 promoter activity.

Most interestingly, thyroid hormone status regulates PC1 and PC2 levels in rodents, offering an explanation for the protean effects of thyroid hormone. In the pituitary, thyroid hormone directly or indirectly regulates gene expression in all cell types. We demonstrated that 6-*n*-propyl-2-thiouracil (PTU)-induced hypothyroidism stimulated, whereas triiodothyronine (T_3)-induced hyperthyroidism suppressed, PC1 and PC2 expression in the rat anterior pituitary. Both the PC1 and PC2 promoters were found to have multiple negative thyroid hormone response elements. Many hormones are increased in the anterior pituitary of hypothyroid rodents. The simultaneous alterations of both PC1 and PC2 by thyroid hormone (as compared with the alterations in either PC1 or PC2 alone, in the patient deficient in PC1, and in the mouse with a knockout of PC1 or PC2) may mediate profound alterations in levels of many hormones.

CONCLUSION

Processing of prohormones by proteolytic enzymes is an important aspect of hormonal biosynthesis. The control of posttranslation processing represents an additional mechanism (in addition to transcriptional and translational regulation) for the organism to alter levels of bioactive hormones. Although patients with

a genetic defect in either their prohormones or their prohormone processing enzymes are likely to be rare, we postulate that many common polygenic diseases, such as diabetes and obesity, may be due in part to impaired prohormone processing. The fact that two closely related processing enzymes, PC1 and PC2, likely process most prohormones leads to the concept that many hormone levels will change in parallel with exposure of the cell to agents that regulate activity of the PCs. For example, an agent that increases intracellular cAMP response element-binding protein (CREB) levels will increase PC1 and PC2 activity (there are CREs on the promoters of both PC1 and PC2). This will lead to increased prohormone processing in that cell and could result in concurrently altered levels of many hormones. We call this the “milieu hypothesis.”

Figure 1 Diagram of the human PRL gene (A), mRNA transcript (B), and mature PRL (C). The left and right arrows designate extrapituitary and pituitary transcription start sites, respectively. The numbers designate the exons. Note that extrapituitary PRL is longer in the 5' untranslated region.

than the pituitary counterpart in the 5' untranslated region. Both pituitary and extrapituitary sites produce an identical PRL protein.

The PRL protein is made of a single chain of 199 residues that is stabilized by three intramolecular disulfide bridges. A model of PRL predicts its arrangement in four antiparallel α -helices organized in an “up–up–down–down” fashion (Fig. 1), a motif that is shared with some hematopoietic factors and interleukins. Posttranslational modifications generate PRL variants that differ in size or functional groups and account for the functional diversity of PRL. Larger forms result from dimerization or aggregation, whereas smaller forms are produced by proteolysis. Some variants retain PRL-like activities, whereas others have unique properties or no known functions. A 22-kDa form is important in female reproduction, whereas a 16-kDa product possesses antiangiogenic activity. Glycosylated PRL is detected in serum, amniotic fluid, and milk at variable ratios, but it is unknown whether it possesses unique physiological functions. PRL can also be phosphorylated on

serine and/or threonine residues, resulting in charge variability and altered function.

REGULATION

PRL is the primary secretory product of the pituitary lactotroph. The lactotrophs comprise 20 to 30% of total anterior pituitary cells and show significant heterogeneity in morphology, basal hormone release, and responsiveness to secretagogues. Lactotrophs retain proliferative capacity during adulthood, and their numbers increase during pregnancy and lactation. Their proliferative potential accounts for a higher incidence of lactotroph tumors (prolactinomas) than of other types of pituitary tumors. Pituitary PRL is subjected to multiple regulators that are classified into four broad categories: endocrine, paracrine, juxtacrine, and autocrine. Endocrine agents originate from the hypothalamus and gonads, and they reach the lactotrophs via the blood. Paracrine factors reach the lactotrophs by diffusion from neighboring

pituitary cells. Juxtacrine interactions emanate from the extracellular matrix of adjacent cells. Autocrine agents are synthesized by the lactotrophs themselves. Consequently, the overall secretory activity of the lactotrophs reflects a balance between local and distant releasing and inhibiting factors.

Pituitary PRL gene expression is affected by multiple hormones, neurotransmitters, and growth factors. Compounds that bind to G protein-linked receptors (e.g., thyrotropin-releasing hormone [TRH], vasoactive intestinal peptide [VIP], dopamine) activate protein kinase A, protein kinase C, and/or calcium/calmodulin-dependent pathways. These are mediated via a variety of transcription factors that bind to consensus sequences within the PRL promoter. Estrogens, on the other hand, diffuse into the nucleus, where they bind to their receptors. The activated receptors act as transcription factors by binding to an estrogen response element (ERE) located within the distal region of the proximal PRL promoter. Among growth factors, insulin and epidermal growth factor (EGF) stimulate, whereas transforming growth factor- β (TGF- β) suppresses, the PRL gene. Many of the growth factors bind to transmembrane receptors with intrinsic tyrosine kinase activity and exert pleiotropic actions such as stimulation of PRL gene transcription, increases in hormone storage, and alterations of lactotroph morphology.

The pituitary lactotroph is unique in its capacity for high constitutive PRL secretion, but its activity is tonically suppressed by hypothalamic dopamine. Dopamine binds to a type II dopamine receptor and exerts multiple actions on the lactotrophs, including lowering of intracellular calcium and cyclic AMP (cAMP) levels, inhibition of PRL gene expression and release, and suppression of cell proliferation. PRL itself, acting via a short-loop negative feedback mechanism, is the primary regulator of the dopaminergic system. Although a singular releasing factor for PRL has not been identified, several neuropeptides, including TRH and VIP, are capable of acute stimulation of PRL release under some conditions.

RECEPTORS AND SIGNAL TRANSDUCTION

PRL exerts its actions by binding to high-affinity plasma membrane receptors. The gene encoding the human PRL receptor is located on chromosome 5 and contains at least 10 exons encompassing more than 100 kb. The PRL receptor belongs to the

cytokine/GH/PRL receptor superfamily, characterized by a single-pass transmembrane stretch that divides the receptor into an extracellular ligand-binding domain and an intracellular domain. The extracellular domain contains two disulfide bonds and a WS motif (Trp-Ser-x-Trp-Ser) that is required for receptor folding and may participate in the formation of a ligand-binding pocket. The cytoplasmic domain has a proline-rich motif ("box 1") near the plasma membrane that couples to intracellular signaling molecules. Humans express primarily one "long" form of the receptor, whereas rats have three isoforms. However, several receptor isoforms with deleted or truncated sequences have been detected recently in normal and malignant human tissues, although their function remains unknown. The PRL receptor is expressed by most tissues, with the highest expression in the liver and the mammary gland. PRL receptor expression is altered in response to changes in circulating PRL and steroid hormones.

Binding of PRL to its receptor induces sequential receptor dimerization. Two binding sites on the PRL molecule, site 1 (made of helices 1 and 4) and site 2 (made of helices 1 and 3), are required for induction of receptor homodimerization and formation of an active complex. The receptor is devoid of intrinsic tyrosine kinase activity and uses the JAK2-STAT pathway as its main signaling cascade. JAK2 (Janus kinase 2) is rapidly phosphorylated on PRL binding and induces the phosphorylation of the receptor itself, other associated kinases, and STAT (signal transducers and activators of transcription) proteins. Of the seven known STAT proteins, STAT1, -3, and -5 are activated by PRL, with STAT5a and -5b being especially important for mammary gland development and function. The activated STAT proteins dimerize, translocate to the nucleus, and bind to specific sequences on target genes. The ras/raf/MAP kinase cascade and fyn, a member of the Src kinase family that phosphorylates phosphatidylinositol 3-kinase (PI3K), are also activated by PRL in a cell-specific manner. All of the preceding pathways have been characterized under acute conditions, whereas the mechanism mediating long-term effects of PRL are not well understood. In addition, human GH and PL also bind to the PRL receptor and mimic some of the actions of PRL.

PROLACTIN AS A CYTOKINE

Although PRL was initially considered an exclusive pituitary hormone, many nonpituitary tissues were

Table I Extrapituitary Tissues and Cell Types That Synthesize PRL and Fluid Compartments That Contain Detectable Amounts of PRL in Humans

| Tissue | Cell type | Fluid compartment |
|-----------------|---------------------|---------------------|
| Brain | Neurons | Cerebrospinal fluid |
| Thymus | T lymphocyte | |
| Lacrimal glands | Epithelium | Tears |
| Lymph nodes | Lymphocytes | |
| Sweat glands | Epithelium | Sweat |
| Breast | Epithelium, adipose | Milk |
| Spleen | B lymphocytes | |
| Skin | Fibroblasts | |
| Uterus | Myocytes, stroma | Amniotic fluid |
| Prostate | Epithelium | |

later found to contain immunoreactive PRL. The widespread distribution of tissues capable of PRL synthesis as well as those that contain PRL is illustrated in [Table I](#). The most established extrapituitary sites that produce PRL in humans are the decidua, immune system, brain, and myometrium, with emerging evidence for PRL synthesis by the skin and exocrine glands, including mammary, sweat, and lacrimal. PRL is produced by a wide variety of cells of different embryonic origin, morphology, and physiological functions. Some (e.g., lymphocytes, epithelia) are less differentiated and have a high proliferative capacity, whereas others (e.g., neurons) are postmitotic and terminally differentiated. Immunoreactive PRL is also present in tissues that do not produce PRL but are capable of concentrating PRL from the blood.

Another remarkable feature of PRL is its presence in many body fluid compartments. Although all hormones are present in serum and most are excreted into urine, PRL is also found in cerebrospinal fluid (CSF) and the amniotic fluid and is also secreted into milk, tears, and follicular fluid. Whereas PRL in the amniotic fluid originates from a local source (decidua), PRL in milk and in CSF is derived from both locally produced and circulating PRL. Significant cellular resources must be spent in transporting PRL into these compartments, yet little is known about the functions subserved by PRL in these sites. In contrast to the pituitary, little is known about the regulation of PRL production/release in extrapituitary sites except that they do not respond to dopamine, neuropeptides, or estrogens but are regulated by local autocrine/paracrine factors. A superdistal promoter upstream of exon 1a regulates PRL gene expression in extrapituitary sites and is silenced in the pituitary gland ([Fig. 1](#)).

BIOLOGICAL FUNCTIONS

PRL is one of the most versatile hormones, fulfilling more than 100 functions and thereby surpassing the number of known actions of all other pituitary hormones combined. PRL functions are associated with reproduction, growth/development, osmoregulation, metabolism, immune regulation, and brain function/behavior. The effects of PRL on reproduction involve multiple systems and tissues that differ in their importance in a species-specific manner. The principal target for PRL is the mammary gland, where it promotes growth and differentiation of the lobuloalveolar structures and is essential for the initiation and maintenance of lactation and for the production of milk proteins. However, in some species, continuous lactogenesis is supported by GH rather than by PRL. In rodents, PRL has both luteotropic and luteolytic actions on the ovary and supports progesterone production. Therefore, in these species, PRL plays a major role in modulating the reproductive cycle and is crucial for pregnancy and lactation. PRL also has well-established mitogenic, secretory, and morphogenic effects on the prostate.

PRL plays a major role in regulating water and electrolyte balance in fish and amphibians, with lesser osmoregulatory actions in birds and mammals. Whereas the control of development and body growth is normally ascribed to GH, there are some functional overlaps between GH and PRL, especially in lower vertebrates. PRL stimulates proliferation of the pancreatic islets and increases insulin secretion primarily during pregnancy. In the immune system, PRL induces proliferation and differentiation of functional activity of various lymphoid cells, but transgenic animals lacking PRL or its receptor have little if any immune disturbances. Within the brain, PRL affects the production and release of several hypothalamic releasing/inhibiting hormones and has significant effects on maternal behavior.

PHYSIOLOGY AND PATHOPHYSIOLOGY IN HUMANS

Consistent with PRL's function as an adaptive hormone rather than an indispensable one, the profile of PRL release varies under many physiological conditions and is dissimilar among species. There are no sex differences in serum PRL concentrations in children, but PRL levels are twice as high in women than in men after puberty. Adult women do not exhibit marked changes in the PRL secretory profile throughout the menstrual cycle. This is in contrast to rodents, where a clear preovulatory surge of PRL is evident. Stress

conditions, including anesthesia, surgery, electric shock, exercise, and insulin-induced hypoglycemia, also stimulate PRL release in both men and women. PRL release progressively rises throughout gestation, and its elevated levels are essential for the preparation of the breast for the initiation of lactation, which is prevented during pregnancy by progesterone. Pregnancy is also associated with lactotroph hypertrophy and hyperplasia, accounting for enlargement of the pituitary. During pregnancy, large amounts of PRL are independently produced by the decidua, and the amniotic fluid contains large concentrations of PRL whose function remains unknown. Suckling is the most potent physiological stimulus for PRL release. The magnitude of the suckling-induced PRL rise is robust during early lactation but wanes thereafter. Tactile stimuli of the breast can increase serum PRL in nonlactating women but not in men.

Under normal conditions, PRL has permissive effects on human reproduction. However, PRL overproduction (hyperprolactinemia) is a pituitary-related disorder that interferes with reproductive processes. Hyperprolactinemia results from several causes, including PRL-secreting tumors and therapy with certain dopaminergic-blocking drugs. Common manifestations of hyperprolactinemia include amenorrhea (lack of menstrual cycles) and galactorrhea (inappropriate milk production) in women and hypogonadism, decreased sex drive, and impotence in men. The inhibitory effects of excess PRL occur at both central (hypothalamic-pituitary) and peripheral (gonadal) sites. Estrogens are responsible for a higher incidence of prolactinomas in women but have little acute effects on PRL release in humans, in contrast to their effects in rats. Oral contraceptives do not increase serum PRL levels appreciably and do not contribute to prolactinoma initiation or progression. Lactational amenorrhea, used by some postpartum women as a method of contraception, appears to be linked to the frequency and duration of suckling episodes rather

than to a persistent hyperprolactinemia. Recent evidence indicates that PRL may play a role as a mitogen/antiapoptotic factor in breast and prostatic cancer.

teleost PRL are in equivalent positions (amino acid 46, 160, 177, and 187) to those in the mature tetrapod protein. The difference in structure, caused by the absence of one disulfide bridge, has been proposed to be one of the factors limiting biological activities of PRL in fish compared with those in mammals.

There is a variable degree of sequence homology between PRL molecules in various vertebrate species that tends to reflect their phylogenetic relationship. For example, sequence similarity between fish and higher vertebrate PRL is low at about 25 to 30%, compared with 60 to 95% sequence similarity shared between PRLs of mammals. Comparison of the primary sequence of PRL from representative species of various vertebrates reveals that conserved residues are

found along the entire length of the molecule (Fig. 1). In the mammals and birds, the conserved residues appear to cluster into four relatively distinct regions that are separated by regions of lower homology. Inclusion of PRL from fishes in such analysis results in the identification of only two relatively well-conserved segments of nearly identical or chemically similar sequence.

PROLACTIN GENES

The GH/PRL/PL/SL gene family has arisen as a consequence of a fairly complex evolutionary process. All of these molecules are proposed to have evolved from a common ancestral gene that underwent at least

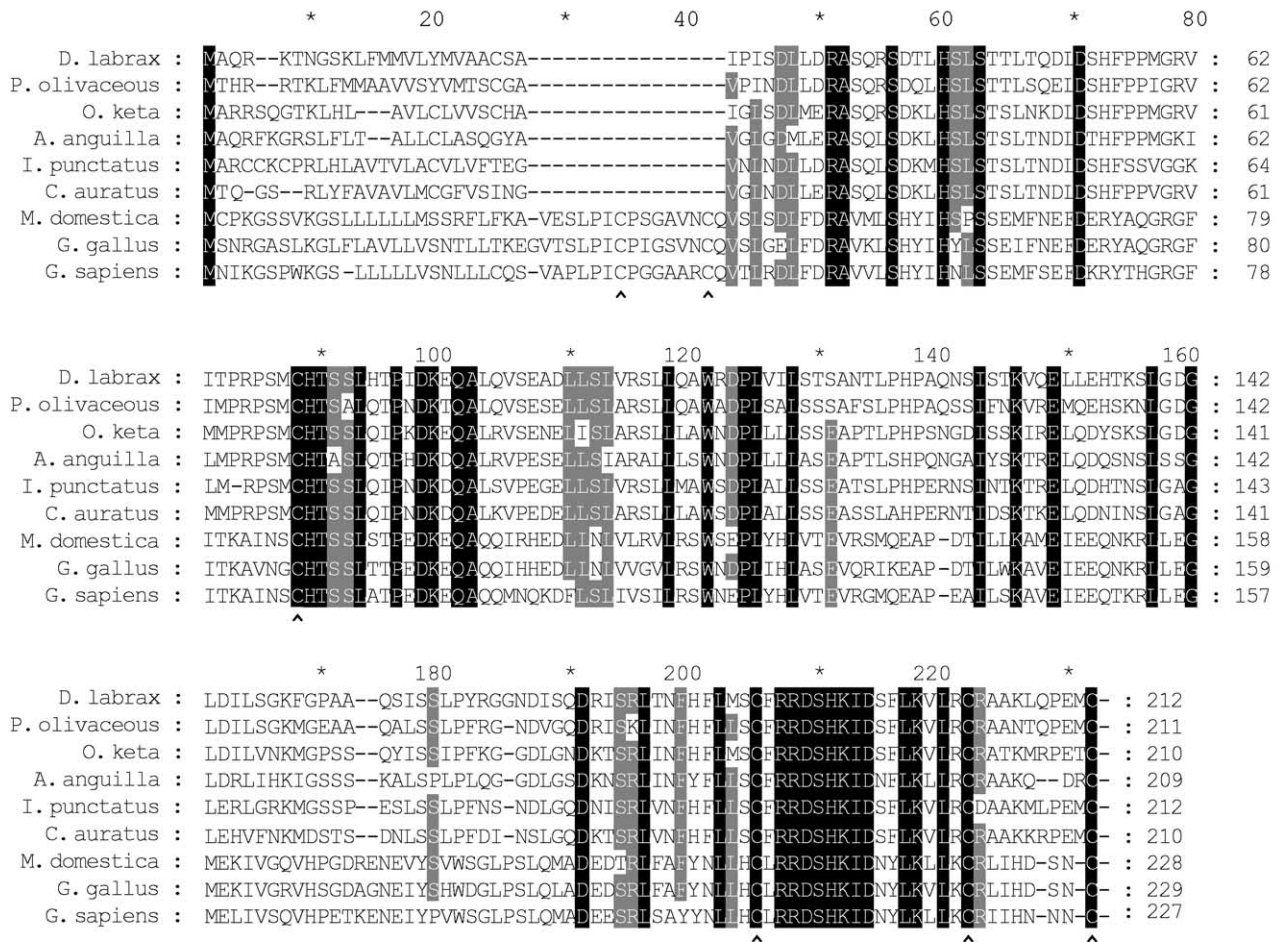

Figure 1 Multiple sequence alignment of the amino acid sequence of PRL, including the signal sequence, from a mammal (*Homo sapiens*), a bird (*Gallus gallus*), a marsupial (*Monodelphis domestica*), and six teleost fishes (*Paralichthys olivaceus*, *Dicentrarchus labrax*, *Oncorhynchus keta*, *Anguilla anguilla*, *Ictalurus punctatus*, and *Carassius auratus*). The conserved cysteine residues are indicated by an arrowhead; totally conserved amino acids in all of the sequences are highlighted by a black background; and conservative substitutions are indicated by a gray background. Note that there are two principal regions of sequence conservation between the fish and the tetrapods.

two successive rounds of gene duplication between 500 and 400 million years ago. Primate PLs belong to the GH lineage, whereas rodent and ungulate PLs are members of the PRL lineage. Additional family members have been identified in several mammals and include mouse proliferin, bovine PRL-related cDNA I, and rat PRL-like protein A.

Gene Organization

A single gene for PRL has been identified in most mammals, although the bovine genome has been shown to contain several genes that encode PRL-like proteins. In addition, in teleosts such as the salmonids and cyprinids, as a consequence of their tetraploid/polyloid nature, at least two PRL genes are known to exist. The PRL gene is present as a single copy on chromosome 6 in humans, chromosome 17 in rats, and chromosome 13 in mice. The chromosome localization of PRL has not been reported for any other species. The PRL gene has been characterized in several mammals and teleosts and is composed of 5 exons and 4 introns, with the human gene being the exception by having an additional exon at the 5' end of the gene that is designated exon Ia. PRL gene organization in the vertebrates has been well conserved, as have the position and type of each exon/intron splice site. In all vertebrate genes characterized, exon I encodes the 5' untranslated region and part of the signal sequence, exon II encodes the remainder of the signal peptide and the N terminus of the mature protein, exons III and IV encode the mature peptide, and

exon V encodes the C-terminal region of the hormone and the 3' untranslated region. In the human gene, the additional noncoding exon, Ia, contains an alternative transcriptional start site whose use is placenta specific and so likely to be a more recent evolutionary development.

The molecular mechanisms underlying the pituitary-specific transcription of the PRL gene in tetrapods has been studied extensively. Two distinct, highly conserved regions are involved in this process: (1) an activating region immediately upstream of the TATAA box and (2) an enhancer region between -1.8 and -1.5 kb distal to the transcription start site. The transcription factor PIT1/GHF1 binds at several sites in both of these regions of the PRL gene and regulates its expression, although binding of other factors is proposed to be required for full promoter activity. Far fewer studies exist characterizing transcriptional activation of teleost PRL genes, and although considerable sequence divergence is found in the promoter region of the fish and mammalian gene transcription is regulated by the same transcription factor. In fact, the sequence conservation between the mammalian and fish PIT1/GHF1 transcription factor is far higher than that found for PRL, and it is also highly conserved both structurally and functionally.

of the exons to the mature pituitary PRL mRNA transcript are indicated.

EVOLUTION OF PROLACTIN FUNCTIONS

Precursor molecules for GH and PRL probably existed in ancestors of the chordates, and a distinct PRL molecule has not been isolated from agnathans; instead, cells in the proximal pars distalis react with antisera to both fish GH and PRL. The specialization of pituitary cells secreting PRL occurred first in teleost fishes, but in higher vertebrates there is a mosaic of cells producing both GH and PRL as well as each individual hormone.

The functions of PRL fall into the broad categories of hydromineral balance, growth and energy metabolism, development, reproduction, immunomodulation, and behavior, but it is clear that PRL, through its multiple interactions, is an important coordinating factor for seasonal and reproductive cycles as well as for survival.

Hydromineral Balance

Probably one of the earliest functions of PRL in vertebrates concerned ion and water homeostasis in aquatic species. In freshwater and euryhaline species of fishes, PRL ensures survival in water of low ionic and osmotic content by reducing sodium efflux and water influx. These effects result from impermeabilization and increases in mucus secretion of skin, gill, and buccal epithelia and a reduction in gill $\text{Na}^+ \text{K}^+$ ATPase activity. In the fish kidney, PRL stimulates $\text{Na}^+ \text{K}^+$ ATPase activity, urine flow, glomerular size, and sodium absorption. In the gut, water, ion absorption, and $\text{Na}^+ \text{K}^+$ ATPase activity are reduced by PRL, whereas mucus production is stimulated. In the urinary bladder, water absorption is reduced, sodium absorption and $\text{Na}^+ \text{K}^+$ ATPase activity are increased, and calcium retention may be promoted.

In the aquatic larval stages of Anuran amphibians and in newts (Urodeles), PRL has functions similar to those in euryhaline fishes in controlling sodium and water fluxes across permeable epithelia such as the skin and bladder. There is a lack of information about a possible role for PRL in hydromineral balance in reptiles, and a postulated effect stimulating salt secretion from nasal salt glands of birds and reptiles has not been substantiated unequivocally.

There is only fragmentary evidence of a role for PRL in hydromineral physiology of mammals in that

it affects movement of sodium, calcium, and chloride ions as well as water across intestinal membranes; however, it may be especially important for uptake of minerals and amino acids across mammary epithelial cells for incorporation into milk. In addition, milk contains PRL that may be important for stimulation of calcium uptake across small intestine epithelia in the suckling young. PRL affects water movement across amniotic membranes, being stimulatory in pig and sheep but inhibitory in humans.

Thus, the physiological actions of PRL that are important for survival in low osmotic aquatic environments have been adapted particularly for use in epithelia concerned with reproduction and nurture of offspring.

Growth, Development, and Nurture

The similarities between GH and PRL of fishes suggested that PRL is also a growth-promoting hormone, and both Tilapia PRLs (tPRL177 and tPRL188) have shown growth-promoting effects (although they are measured by different criteria). In fish (Tilapia) and mammals (rat), PRL promotes insulin-like growth factor-1 (IGF-1) production by the liver, stimulating sulfate uptake into cartilage. Several epidermal tissues respond to PRL by cell proliferation, including melanocytes in fish and mammals, epidermal tissues in molting reptiles and amphibians, and keratinocytes and hair in mammals.

PRL is regarded as a postembryonic developmental hormone, particularly during metamorphosis of amphibian vertebrates, where it prevents thyroid hormone stimulation of both apoptosis of tail cells and morphogenesis of limbs; thus, the PRL that allows survival of aquatic stages of amphibian development opposes metamorphic progression. In mammalian development, deciduum-derived PRL in the amniotic fluid reduces fluid volume by transfer of water but may also enter the fetal circulation and affect lung and immune system maturation. In the mammalian hypothalamus, PRL influences maturation of the neonatal neuroendocrine system. PRL has been shown to affect development of bone in mice, specifically to inhibit endochondral ossification *in vivo* and to depress alkaline phosphatase activity of osteoblasts *in vitro*.

Secretion of PRL is coordinated with cycles that may be diurnal or seasonal. In fish, these are related to metabolic responses. In general, fish acclimated to long photoperiods respond to PRL injections early during the light period by reducing lipid stores and increasing nonlipid tissue accumulation; however,

similar treatments midway through the light period cause fat deposition. In rats, there is a diurnal cycle of PRL release; however, in mature females, the surge of PRL release during proestrus is linked to the development of the corpus luteum that follows the fall in PRL release.

A role for PRL in fat metabolism has also been established in birds. For example, in penguins, which fast while incubating eggs, circulating PRL levels remain high until fat stores are critically reduced when increased corticosterone production causes a fall in plasma PRL; at this point, penguins return to the sea to replenish the lipid energy store. In mice, leptin from adipose tissue may control release of neural PRL-releasing peptide (PrRP), resulting in reduced food intake and increased body weight; short-term treatments of adipocytes *in vitro* with PRL reduce insulin-stimulated leptin production. In fetal sheep, PRL is required for the up-regulation of the specific uncoupling protein-1 (UCP1) that enables rapid production of heat from brown adipose tissue after birth. So, PRL can affect metabolism of both white and brown adipose tissues, demonstrating conservation of roles in lipid metabolism among fish, birds, and mammals.

PRL effects on epithelia can also be directly important for nutrition of offspring. For example, in cichlid fish, PRL stimulates mucus production by the epidermis and the young fry feed on this; interestingly, the mucus also contains PRL and GH. The crop sac mucosa of pigeons responds to tetrapod PRL by extreme hyperplasia, forming a cheesy mass on which the offspring feed. Regurgitation of food for the offspring is also dependent on PRL. In most mammals, PRL is necessary for mammary gland development, growth, and lactogenesis, although this is not the case in goats and cows.

Thus, in fish, birds, and mammals, PRL is important for providing essential nutrients on which the offspring depend for survival during early development.

Reproduction

The functions of PRL in controlling and modulating reproduction are numerous but are only clearly defined in mammals. They include growth and differentiation of the mammary gland, luteotropic and luteolytic actions in the ovary, stimulation of gonadotropin receptors in the testis, and stimulation of prostate epithelium activities. From reported studies, it appears that roles for PRL in lower vertebrate reproduction are more closely related to behavioral responses than to

specific interactions with reproductive tissues. From an evolutionary viewpoint, PRL may have been important for reproduction of marine fishes; when the crossopterygian ancestors migrated to fresh water, PRL, already functioning as a reproductive hormone, would have been important for their survival in the low sodium/low osmotic environment.

Behavior

The effects of PRL on behavior are frequently correlated with successful reproduction; in fish, eggs and fry are protected by fin fanning and PRL stimulates building a nest of foam from secreted mucus by paradise fish. In birds, PRL encourages nesting and nest building, nest attendance, and egg incubation. PRL is needed for the migration of salamanders (red eft) to return to water for breeding and for the movement of sticklebacks to fresh water to breed. Maternal behavior in mammals, including feeding offspring and grooming, may also be dependent on PRL.

Immunomodulation

PRL has multiple roles in the mammalian immune system through interactions in the spleen and thymus and various differentiated lymphocytes and macrophages. Anemia, leukopenia, and thrombocytopenia caused by hypophysectomy all are reversed by PRL replacement therapy. Macrophages, which are immune cells of ancient lineage, are activated by PRL in both fish and mammals. Augmentation of immune responses by PRL may be due to its antiapoptotic action in lymphocytes. The source of the PRL, acting as a paracrine or autocrine factor, may be leucocytes themselves given that granulocytes contain a high molecular weight PRL of 43 kDa.

Evolution of Prolactin Function

The brief overview of PRL functions suggests a broad outline of the evolution of the wide range of PRL functions throughout the vertebrates. The initial role, which may well predate the chordates, was probably as a responsive factor to osmotic changes due to variations in environmental ion concentrations of PRL-secreting cells located at interfaces. The specialization of cells of the pituitary to secrete PRL developed during fish evolution as direct contact with the environment decreased, although some fish retain direct environmental contact via the orohypophyseal duct. Nevertheless, fish pituitary PRL cells remain sensitive

to plasma and medium osmotic pressures, resulting in control of hydromineral balance, particularly sodium ion concentrations. This function persists into mammals, where ion uptake into mammary epithelium and extrusion into milk are controlled by PRL. The functions of PRL in the immune system and in bone cells are likely to have evolved from the head kidney cells of teleost fishes; these cells are lymphopoietic and hemopoietic and are considered to be the evolutionary precursors of bone marrow in higher vertebrates.

CONTROL OF PROLACTIN SECRETION

Because PRL is a very important coordinating factor between an organism and its environment, control of its secretion by the pituitary is multifactorial, including environmental cues such as light, scent, sound, external osmotic pressure, and ion content that interact with factors from the brain (both neurotransmitter and neuroendocrine) and from reproductive organs (especially the ovary).

The most ancient controlling factor for release and synthesis of PRL is probably the external osmotic pressure that would operate in isolated cells of simple metazoa. Against this background of a basic physicochemical control mechanism, numerous external and internal agents have been identified as influencing PRL secretion by pituitary cells. In euryhaline teleosts, low external osmotic pressure, generally due to low sodium ion content, is the most potent stimulating agent for PRL secretion.

However, throughout the vertebrates, pituitary PRL cells are principally under tonic inhibitory control by dopamine from the tuberoinfundibular dopaminergic (TIDA) neurons of the hypothalamus, and when removed from hypothalamic connection, pituitaries continue to secrete PRL—although, somewhat perversely, very low dopamine concentrations (e.g., 10^{-12} M) are stimulatory. Changes in the pattern of dopamine release from the TIDA neurons in rats correlate with the cyclical peaks and troughs of plasma PRL concentrations. A principal stimulatory factor of both PRL secretion and PRL cell hyperplasia is estrogen, which again affects PRL cells throughout the vertebrates. Other stimulatory agents are mainly hypothalamic hypophysiotropic factors, including thyrotropin-releasing hormone (TRH), vasoactive intestinal polypeptide (VIP), somatostatin, and gonadotropin-releasing hormone (GnRH) in some fish, as well as neurotransmitters, including γ -amino butyric acid (GABA), endorphins, and enkephalins. Two

specific PrRPs, PrRP20 and PrRP 31, have been identified in brains of rats, cattle, and humans, and a homologue of PrRP20 has been identified in carp (Ca-RF) and tilapia (tPrRP), suggesting a conserved function throughout the vertebrates.

Circadian rhythms of PRL secretion in mammals are controlled by neurotransmitter/neuroendocrine inputs from the hypothalamus and correlate with dopamine release, but light patterns control cycles (e.g., in the rat). Extrapituitary PRL secretion appears to be influenced most strongly by steroids such as progesterone (e.g., in the deciduum and estrogens in the brain), but more data are required for comprehensive understanding of these tissue systems. Steroids are ancient “bioregulators” originally found in surrounding water of early life forms, and their interaction with PRL-secreting cells in extant vertebrates was probably established a very long time ago—before the first vertebrates evolved.

CONCLUSION

PRL genes and proteins have been modified to only a limited degree during evolution from fishes to mammals, but their functions have been adapted for physiological systems as vertebrates progressed from aquatic to terrestrial and aerial forms. However, the earliest precursor genes and peptides for PRL will have to be sought in genomes and tissues of primitive chordates and invertebrates to understand their origins and evolution to the versatile and important endocrine and paracrine factor of vertebrates.

The presence of even minute amounts of milk expressible from one or both breasts justifies the diagnosis of galactorrhea. Its persistence for more than 1 year after normal delivery and cessation of breast-feeding, or its occurrence in the absence of pregnancy, generally is taken as a definition of inappropriate lactation.

The incidence of galactorrhea has been variously reported in normal women as ranging from 1 to 45% of women tested. This variability probably is the result of differences in the techniques used to express milk from the breast and the way in which nonmilky secretions are classified. Lowering the blood prolactin (PRL) level in patients with normal or elevated PRL levels almost always will lead to a marked decrease in, or an abolition of, lactation.

Galactorrhea may be present in approximately 5 to 10% of normally menstruating women, and recent experience has shown that basal PRL levels are normal in more than 90% of these women. When amenorrhea or oligoamenorrhea is associated with galactorrhea, approximately 75% of these women will be found to have hyperprolactinemia.

Galactorrhea in men has been reported in 10 to 20% of cases and is virtually pathognomonic of a prolactinoma.

FEMALE REPRODUCTIVE FUNCTION

Hyperprolactinemia has been found in most studies to suppress luteinizing hormone (LH) pulsatile secretion by decreasing pulse amplitude and frequency. With menopause, hyperprolactinemia can prevent the expected rise in gonadotropins; normalization of PRL levels with bromocriptine results in elevation of gonadotropin levels and hot flashes. The pituitary gonadotroph response to gonadotropin-releasing hormone (GnRH) in hyperprolactinemia has generally been found to be normal, increased, and decreased in humans. Hyperprolactinemia in women has been associated with loss of positive estrogen feedback on gonadotropin secretion. High concentrations of PRL are inhibitory to progesterone and estrogen production by the ovary. PRL can inhibit estrogen formation by antagonizing the stimulatory effects of follicle-stimulating hormone (FSH) on aromatase activity, and direct inhibition of aromatase synthesis has been shown.

Although the amenorrhea caused by hyperprolactinemia usually is secondary, it also can be primary if the disorder begins before the usual age of puberty. In patients with primary amenorrhea due to hyperprolactinemia, estrogen deficiency and failure to develop

normal secondary sexual characteristics may be the presenting problem. Galactorrhea is variable in this setting because the breast might not have been exposed to appropriate priming with estrogen and progesterone. Patients with primary amenorrhea tend to have macroadenomas more commonly than do those with secondary amenorrhea, although the reasons for this are unknown.

A short luteal phase is the first evidence of interference in the normal cycle by hyperprolactinemia. Subsequently, ovulation is inhibited and oligomenorrhea occurs. Finally, amenorrhea may take place. In a summary of 18 series of 1409 women with prolactinomas undergoing transsphenoidal surgery, the frequency of oligomenorrhea was 94.0% and that of galactorrhea was 85.9%.

Infertility may be a presenting symptom of patients with hyperprolactinemia and is invariable when gonadotropin levels are suppressed with anovulation. In three series of women (a combined 367 cases) studied for infertility, one-third were found to have hyperprolactinemia. Most of the women had amenorrhea and galactorrhea as well, but in one series of 113 cases of infertility, 5 of the 22 hyperprolactinemic women had neither amenorrhea nor galactorrhea. That PRL excess may be important in these types of patient is suggested by the finding that treatment of similar patients with bromocriptine restored fertility. In some of these women, transient hyperprolactinemia lasting for 1 to 2 days during the cycle can be documented; this subset usually responds to bromocriptine with increased progesterone during the luteal phase as well as improved fertility.

Reduced libido and orgasmic dysfunction are found in most hyperprolactinemic amenorrheic women when such complaints are specifically elicited. Reduction in PRL levels to normal restores normal libido and sexual function in most of these women.

PRL levels have been found to be elevated in 19 to 50% of women with polycystic ovaries (PCOs). Bromocriptine treatment of hyperprolactinemic patients with PCOs usually results in a reduction of testosterone and LH levels and resumption of ovulatory cycles. Why many patients with PCOs have hyperprolactinemia is not clear. It has been hypothesized that the increased estrogen levels found in PCOs stimulate increased PRL secretion; however, no correlation has been found between estrone levels and PRL levels in these patients. The increased androgen secretion associated with PCOs may cause hirsutism and other excessive androgen action, such as acne and seborrhea, although these features may also be caused by excessive androgen secretion by the adrenal.

MALE REPRODUCTIVE FUNCTION

In hyperprolactinemic men, there is a decrease in the pulsatile secretion of LH and FSH, and testosterone levels are low or in the lower part of the normal range. The testosterone response to stimulation with human chorionic gonadotropin (hCG) has been reported to be both decreased and normal; in those with decreased responses, there is improvement in the response when PRL levels are lowered with bromocriptine. If there is sufficient normal pituitary tissue, reduction in elevated PRL levels to normal usually results in a return of normal testosterone levels. Although some studies have suggested that drug-induced elevated PRL levels cause a partial block in the enzyme 5 α -reductase, resulting in a decrease in dihydrotestosterone (DHT) levels, this has not been found in studies of men with prolactinomas. Testosterone therapy of hyperprolactinemic men does not always correct the impotence until PRL levels are brought down to normal. Whether this is due to a decrease in DHT levels has not been verified directly.

Chronic hyperprolactinemia in males results in impotence and decreased libido in more than 90% of cases. Other findings of hypogonadism, such as decreased beard growth and decreased strength, are less common.

Sperm counts and motility are decreased with an increase in abnormal forms, and histological studies reveal abnormal seminiferous tubule walls and altered Sertoli cell ultrastructure. The semen analysis does not always return to normal despite a return to normal of testosterone levels with restoration of normoprolactinemia.

A number of surveys have attempted to assess the frequency of hyperprolactinemia among men with complaints of impotence or infertility. Between 2 and 25% of males with impotence have been found to be hyperprolactinemic in various series. However, only 1 to 5% of men with infertility have been found to be hyperprolactinemic.

EFFECT OF PROLACTIN ON BONES

Hyperprolactinemic women have a decreased bone mineral density, but whether this effect is mediated by estrogen deficiency or is a direct effect of the hyperprolactinemia is controversial. Correction of the hyperprolactinemia results in an increase in bone mass. Studies of hyperprolactinemic women who were not amenorrheic and hypoestrogenic have shown that their bone mineral density is normal, confirming the initial hypothesis that it is the estrogen deficiency that mediates the bone mineral loss. A similar, androgen-dependent loss of bone mineral that is reversible with reversal of the hypoandrogenic state is found in hyperprolactinemic men. However, as determined by recent studies in men with an aromatase gene defect, it is likely that the osteopenia in the hyperprolactinemic, androgen-deficient men is due to reduced estrogen levels as well.

Table 1 Etiologies of Hyperprolactinemia**Pituitary disease**

Prolactinomas
 Acromegaly
 Empty sella syndrome
 Lymphocytic hypophysitis
 Cushing's disease

Hypothalamic disease

Craniopharyngiomas
 Meningiomas
 Dysgerminomas
 Nonsecreting pituitary adenomas
 Other tumors
 Sarcoidosis
 Langerhans cell histiocytosis
 Neuraxis irradiation
 Vascular
 Pituitary stalk section

Medications

Phenothiazines
 Haloperidol
 Atypical antipsychotics
 Monoamine-oxidase inhibitors
 Tricyclic antidepressants
 Reserpine
 Methyl dopa
 Metoclopramide
 Amoxepin
 Cocaine
 Verapamil
 Serotonin reuptake inhibitors
 Protease inhibitors

Neurogenic

Chest wall lesions
 Spinal cord lesions
 Breast stimulation

Other

Pregnancy
 Hypothyroidism
 Chronic renal failure
 Cirrhosis
 Pseudocyesis
 Adrenal insufficiency

Tricyclic antidepressants cause modest hyperprolactinemia in approximately 25% of patients. Monoamine oxidase inhibitors may also cause a minimal elevation of PRL levels. These drugs likely facilitate several possible stimulatory pathways, and their effects on dopamine are uncertain. Serotonin reuptake

inhibitors, by increasing synaptic serotonin levels, rarely cause hyperprolactinemia.

Chronic opiate abuse is associated with mild hyperprolactinemia and menstrual dysfunction. Cocaine abuse can also cause chronic mild hyperprolactinemia.

Antihypertensive Drugs

Alpha-methyl dopa causes moderate hyperprolactinemia by reducing the level of dopamine that reaches the pituitary by inhibiting the enzyme L-aromatic amino acid decarboxylase, which is responsible for converting L-dopa to dopamine, and by acting as a false neurotransmitter to decrease dopamine synthesis. Reserpine, now a little-used antihypertensive drug, causes hyperprolactinemia by interfering with the storage of hypothalamic catecholamines in secretory granules.

Verapamil increases basal PRL secretion acutely and chronically, and patients have been described with galactorrhea associated with sustained hyperprolactinemia. In a survey of patients taking verapamil, PRL levels were found to be elevated in 8.5% of these patients. Verapamil raises PRL by blocking the hypothalamic generation of dopamine by blocking N-type calcium channels. Other classes of calcium channel blockers (e.g., dihydropyridines, benzothiazepines) do not increase PRL levels.

Protease Inhibitors

Several patients have been reported with galactorrhea and hyperprolactinemia due to protease inhibitors. The frequency of this phenomenon and the mechanism by which this occurs are unknown.

PATHOLOGICAL CONDITIONS CAUSING HYPERPROLACTINEMIA**Stress**

Physical stress (e.g., physical discomfort, exercise, hypoglycemia) and psychological stress can cause an acute transient rise in PRL levels. Chronic hyperprolactinemia due to prolonged physical or psychological stress has not been reported except for pseudocyesis, in which PRL levels fall with psychotherapy.

Renal Disease

Hyperprolactinemia occurs in approximately 75% of women and 50% of men with end-stage renal disease. Although metabolic breakdown of PRL is delayed in renal failure, there is also increased production. Therefore, there is disordered regulation of PRL

secretion, although the exact nature of the defect has not been defined. About one-quarter of individuals with renal insufficiency not requiring dialysis (serum creatinine 2–12 ng/ml) have PRL levels in the 25- to 100-ng/ml range. When such patients take a medication known to alter hypothalamic regulation of PRL, such as methyl dopa or metoclopramide, PRL levels may rise to more than 2000 ng/ml. Correction of the renal failure with transplantation causes a return of PRL levels to normal.

Cirrhosis

Basal PRL levels are increased in patients with alcoholic cirrhosis in frequencies varying from 16 to 100% and in patients with nonalcoholic cirrhosis in frequencies varying from 5 to 13%. In one study, 50% of patients with hepatic encephalopathy were found to be hyperprolactinemic. It is thought that the hyperprolactinemia is due to disordered hypothalamic neurotransmitter regulation, although there are no specifics in this regard.

Hypothyroidism

Primary hypothyroidism is associated with a modest increase in the level of PRL in 40% of patients, but levels greater than 25 ng/ml are reached in only 10% of patients. The mechanisms involved include increased thyroid-releasing hormone (TRH) production, increased sensitivity of lactotrophs to TRH, and (possibly) increased pituitary vasoactive intestinal peptide (VIP) generation. Because many patients with long-standing hypothyroidism may have evidence of pituitary enlargement on X rays, the finding of hyperprolactinemia, galactorrhea, and/or amenorrhea associated with an enlarged pituitary seen in hypothyroidism may be easily confused with a prolactinoma. Therapy with L-thyroxine will cause the PRL levels to return to normal and can even result in a regression of pituitary size.

Adrenal Insufficiency

Glucocorticoids have a suppressive effect on PRL gene transcription and PRL release. Rare cases of hyperprolactinemia occurring in patients with adrenal insufficiency in whom the PRL levels returned to normal with glucocorticoid replacement have been reported.

Neurogenic

Sexual breast stimulation, suckling, and nipple rings cause a reflex release of PRL that is mediated, in part,

by afferent neural pathways going through the spinal cord. Chest wall lesions (e.g., herpes zoster, cancer, burns, surgery) and cervical cord lesions have been reported to result in elevated PRL levels and galactorrhea through stimulation of these afferent neural pathways.

Ectopic Prolactin Secretion

Ectopic production of PRL is exceedingly rare. Symptomatic hyperprolactinemia due to well-documented PRL production from a renal cell carcinoma, a gonadoblastoma, and ectopic pituitary tissue in ovarian teratomas has been reported. Given the great frequency of prolactinomas, "idiopathic hyperprolactinemia," and other causes of hyperprolactinemia, a search for an ectopic source of PRL secretion is not warranted unless some other tumor shows up coincidentally.

HYPOTHALAMIC/PITUITARY STALK DISEASE CAUSING HYPERPROLACTINEMIA

Hyperprolactinemia caused by mass and infiltrative lesions of the hypothalamus and the pituitary stalk, such as clinically nonfunctioning adenomas and craniopharyngiomas (Table I), is due to disturbance of the neuroendocrine mechanisms that control PRL secretion. It is generally assumed that this PRL elevation is due to disinhibition of the tonic dopamine inhibitory action at the level of the pituitary lactotrophs. Because other pituitary function may remain normal in many of these patients, it is apparent that there still is significant transmission of hypothalamic-releasing factors to the pituitary in most of these cases despite increased PRL levels. Patients with fairly high levels (e.g., 100–300 ng/ml) associated with hypothalamic/stalk disease likely have continued PRL-releasing activity along with dopamine deficiency, resulting in higher PRL levels.

IDIOPATHIC HYPERPROLACTINEMIA

When no specific cause is found with the evaluation outlined later, the hyperprolactinemia is of uncertain etiology and has been designated to be idiopathic. It is recognized that, in many such cases, small prolactinomas that are too small to be detected by current radiological techniques may be present. In other cases, the hyperprolactinemia is due to presumed hypothalamic regulatory dysfunction, but no dysfunction specific to idiopathic hyperprolactinemia has

been definitively elucidated. Long-term follow-up has found that PRL levels return to normal in about one-third of such patients, there is a rise in PRL levels to more than 50% over baseline in 10 to 15% of them, and prolactin levels remain stable in the remaining patients. Over a 2- to 6-year follow-up of 199 patients, only 23 developed evidence of microadenomas and none developed macroadenomas.

PROLACTINOMAS

When there is no obvious cause of the hyperprolactinemia from the routine screening outlined later, a radiological evaluation of the hypothalamic-pituitary area is mandatory to define a possible prolactinoma or other mass lesion. This includes patients with even mild PRL elevations. MRI with gadolinium enhancement generally provides the best anatomic detail. It should be emphasized that it is very important to distinguish between a large nonsecreting tumor causing modest PRL elevations (usually <150 ng/ml) and a PRL-secreting macroadenoma (PRL levels usually >250 ng/ml) because the therapy will be quite different. One potential additional problem in investigating patients with mild hyperprolactinemia is the finding of a false-positive computed tomography (CT) or MRI scan. Because these techniques are now able to pick incidental nonsecreting tumors, cysts, infarcts, and the like, the finding of a “microprolactinoma” on scan in a patient with elevated PRL levels might not always be a true-positive finding, and cases have been reported with the hyperprolactinemia being due to a medication and an apparent adenoma on MRI being a false-positive finding. When there is no obvious cause for the hyperprolactinemia and the MRI or CT scan is normal, the patient is deemed to have idiopathic hyperprolactinemia.

Uncommonly, prolactinomas will secrete growth hormone in addition to PRL. Some of these patients have little in the way of acromegalic features, and their clinical presentation is that of a prolactinoma. Even more rare are tumors secreting PRL and adrenocorticotrophic hormone (ACTH).

CLINICAL TESTING

PRL is secreted episodically, and some PRL levels during the day may be above the upper limit of the normal established level for a given laboratory. Thus, the finding of minimally elevated levels in blood requires confirmation in several samples. As indicated in the previous section, there are a number of conditions that may cause moderate PRL elevations, although

generally less than 250 ng/ml. A careful history and physical examination, screening blood chemistries, thyroid function tests, and a pregnancy test will exclude virtually all causes except for hypothalamic-pituitary disease.

However, a specific caution is needed when two-site immunoradiometric assays or chemiluminometric assays are used because patients with large prolactinomas with very high PRL levels may appear to have PRL levels that are only moderately elevated or even normal (i.e., on the order of 10–200 µg/L) due to the “hook effect.” This can cause confusion with clinically non-functioning adenomas, which may cause a similar elevation of PRL due to “disinhibition” of PRL secretion, as noted earlier. This confusion can be avoided by always remeasuring the PRL in such patients at 1:100 dilution given that PRL levels in samples with the hook effect will then increase dramatically.

Stimulation and suppression tests have given nonspecific results, and consensus has developed that such tests reveal no more information than just measurement of basal PRL levels and so are worthless.

receptor-deficient mice develop lactotroph hyperplasia and prolactinomas. During recent years, attention has been focused on the role of various molecular events involved in prolactinoma pathogenesis.

Genes

Several genes involved in carcinogenesis in other tissues are also overexpressed or underexpressed in prolactinomas. However, the distinct role of the large majority of these genes involved in prolactinoma pathogenesis is unclear. Oncogenes and proto-oncogenes (which have to be converted to active oncogenes to become active) are dominant mutated proteins that can induce cancer. Until now, activating mutations of the *gsp* oncogene have not been detected in prolactinomas, but these mutations seem to be specific for the somatotroph tumor lineage. Activating mutations of the *H-ras* proto-oncogene have been found only in the relatively rare pituitary carcinomas, for example, in only one case of an aggressive prolactinoma.

In contrast to the dominant proto-oncogenes and oncogenes, tumor suppressor genes can initiate tumor cell growth only when both recessive alleles are lost or altered. The most studied and well-known tumor suppressor gene, *p53*, probably plays little or no role in pituitary tumorigenesis given that neither gene mutations nor gene deletions could be detected in pituitary adenomas or carcinomas. Pituitary tumors can also develop as one of the clinical manifestations of the multiple endocrine neoplasia type 1 (MEN1) syndrome. The MEN1 tumor suppressor gene (MIM 131100) is located on chromosome 11q13 and encodes a 610-amino acid protein named MENIN. However, LOH analysis failed to show that inactivation of this gene plays an important role in the pathogenesis of sporadic prolactinomas.

Growth Factors

Fibroblast growth factor-2 (FGF-2: basic FGF) is expressed within folliculostellate cells in the anterior pituitary and stimulates prolactin secretion by both normal lactotrophs and prolactinomas. FGF-4 is encoded by the heparin-binding secretory transforming gene (*hst*). Like FGF-2, *hst*/FGF-4 stimulates pituitary prolactin secretion, but it also stimulates lactotroph proliferation and development of prolactinomas. Pituitary tumor-derived transforming gene-1 (*pttg*) is another paracrine growth factor gene that is probably involved in prolactinoma pathogenesis. It is highly expressed in pituitary tumors and is a

vertebrate analogue of the yeast securin inhibitors of sister chromatid separation. FGF-2 and estrogens both induce *pttg*, and *pttg* regulates FGF-2 secretion. The *pttg* protein may be involved in pituitary angiogenesis and prolactinoma tumorigenesis. Also, transforming growth factor- α may play a role in the pathogenesis of prolactinomas.

CONCLUSION

The unraveling of defects and/or processes leading to prolactinoma formation is still in its infancy, and the mechanism of prolactinoma formation grossly remains elusive.

normal. Some patients have excellent reduction in PRL levels into the normal range but only modest changes in tumor size, whereas others have persistent mild hyperprolactinemia (but >88% suppression from basal values) with nearly complete disappearance of their tumors. A reduction in PRL levels always precedes any detectable change in tumor size, and PRL nonresponders are also tumor size nonresponders. Once maximum size reduction is achieved, the dose of bromocriptine can often be gradually reduced or even tapered off without tumor regrowth.

The most common side effects of bromocriptine are nausea and vomiting; these are usually transient but may recur with each dose increase. Orthostatic hypotension usually is a problem only when initiating therapy and rarely recurs with dose increases. Limiting nausea and vomiting occurs in 3 to 5% of patients, and digital vasospasm, nasal congestion, psychosis, and depression occur rarely. Side effects can be minimized by starting with 1.25 mg daily with a snack at bedtime. The dose is gradually increased to 2.5 mg twice daily with meals over 7 to 10 days, and PRL levels are checked after 1 to 2 months. Intravaginal administration usually abolishes problems of persistent nausea and vomiting. Most patients respond within 1 to 2 months if they are going to respond at all. Between 5 and 10% of patients either do not respond to bromocriptine or have only minimal responses. Doses higher than 7.5 mg daily are usually not necessary except in some patients with very large tumors.

Pergolide

Pergolide (Permax) has been approved by the U.S. Food and Drug Administration for the treatment of Parkinson's disease. Although such approval for the treatment of hyperprolactinemia is lacking, there is considerable experience with its use in prolactinoma patients. Hyperprolactinemia can be controlled with single daily doses of 50 to 250 μ g with tolerance and efficacy comparable to those with bromocriptine. Tumor size change is similar to or slightly better than that seen with bromocriptine. Questions regarding possible cardiac valve abnormalities with the high doses used to treat Parkinson's disease have recently been raised.

Quinagolide

Quinagolide (CV 205-502) is a nonergot dopamine agonist, with tolerance and efficacy similar to bromocriptine and pergolide in terms of control of hyperprolactinemia and tumor size, and it can also be given once daily. Approximately 50% of patients who

are resistant to bromocriptine respond to quinagolide. Although side effects are similar, some patients appear to tolerate quinagolide better than they do bromocriptine. Quinagolide is not available in the United States.

Cabergoline

Cabergoline (Dostinex) is different from the other drugs in that it has a very long half-life and can be given orally once or twice weekly. The long duration of action stems from its slow elimination from pituitary tissue, high-affinity binding to pituitary dopamine receptors, and extensive enterohepatic recycling. A number of studies have shown that cabergoline is generally more effective than bromocriptine at lowering PRL levels and reducing tumor size with a substantial reduction in side effects. Rare patients who experience limiting nausea and vomiting can also be treated with intravaginal cabergoline. Comparison of patient groups shows that 96% of those who had never received prior dopamine agonists had tumor shrinkage of more than 50%, whereas similar reductions were seen in 68% of those who had been intolerant of prior bromocriptine, 64% of those who had been resistant to bromocriptine, and 70% of those who had been responsive to bromocriptine.

With any dopamine agonist, in some patients PRL levels decrease but plateau before they reach normal. Often, the dose continues to be increased in such patients in the hope of achieving normal levels; however, once this is recognized, the dose should gradually be decreased until the lowest dose that achieves the maximum effect is reached. Although most patients respond to dopamine agonists with a rapid fall in PRL levels, some experience stepwise reductions with each stepwise increment in dose. As long as there is a continued fall with each increase, the dose can be increased further to quite high amounts, recognizing that much larger doses are used to treat Parkinson's disease without substantial adverse effects.

Estrogens

In women with idiopathic hyperprolactinemia or microadenomas in whom fertility is not an issue, galactorrhea is not bothersome, and lack of estrogen is the major concern, consideration can be given to using estrogen replacement rather than dopamine agonists. No tumor enlargement has been found with estrogen treatment in such patients. However, individual cases with enlargement of tumors during estrogen therapy have been reported, so that such

patients should be followed carefully with periodic monitoring of PRL levels. Because of concerns regarding tumor size, dopamine agonists are preferred for women with macroadenomas.

SURGERY

The success rates for transsphenoidal surgery are highly dependent on the experience and skill of the surgeon as well as on the size of the tumor. Approximately 70 to 80% of patients with microadenomas and 25 to 35% of those with macroadenomas can be expected to have PRL levels normalized by 1 to 12 weeks following surgery. Postoperative recurrence of hyperprolactinemia is found in approximately 20% of patients within the first year following surgery. Therefore, the ultimate, long-term, surgical cure rate for microadenomas is approximately 50 to 60% and for macroadenomas is approximately 25%, using a normal PRL level as the criterion. For patients with giant prolactinomas and those with considerable cavernous sinus invasion, the chance of surgical cure is essentially zero.

Complications from transsphenoidal surgery for microadenomas are quite infrequent, with the mortality and morbidity rates being 0.3% to 0.4%. The mortality and morbidity rates for transsphenoidal surgery for all types of secreting and nonsecreting macroadenomas are 0.9% and 6 to 20%, respectively, depending on the experience of the surgeon. Surgery involving craniotomy is much more hazardous.

RADIOTHERAPY

Because of the excellent therapeutic responses to transsphenoidal surgery and medical therapy, radiotherapy is generally not considered to be a primary mode of treatment for prolactinomas. Normalization of PRL occurs in less than one-third of patients. Gamma knife-focused radiotherapy is used when there is a residual tumor in the cavernous sinus left after surgery is carried on patients who did not respond to medical therapy with somewhat better and faster efficacy compared to conventional radiotherapy. The major adverse effect of all types of radiotherapy is hypopituitarism.

THERAPY IN THE PREGNANT WOMAN

When a woman harbors a prolactinoma as the cause of the hyperprolactinemia, two major issues arise when

ovulation and fertility are restored: (1) the effects of the dopamine agonist on early fetal development occurring before a pregnancy is diagnosed and (2) the effect of the pregnancy itself on the prolactinoma.

Effects of Dopamine Agonists on the Developing Fetus

As a general principle, it is advised that fetal exposure to the dopamine agonist be limited to as short a period as possible. Mechanical contraception should be used until the first two to three cycles have occurred, so that an intermenstrual interval can be established and a woman will know when she has missed a menstrual period. Thus, the dopamine agonist can be stopped after being given for only approximately 3 to 4 weeks of the gestation. When used in this fashion in more than 6000 pregnancies, bromocriptine was not found to cause any increase in spontaneous abortions, ectopic pregnancies, trophoblastic disease, multiple pregnancies, or congenital malformations. Experience was limited to just over 100 women with the use of bromocriptine throughout the gestation; however, no abnormalities were noted in the infants except for one with an undescended testicle and one with a talipes deformity. Few data are available on the safety during pregnancy of pergolide or quinagolide. Outcome data available on 265 pregnancies in which cabergoline was administered to facilitate ovulation do not show increased risks of preterm, ectopic, or multiple birth deliveries or malformations. However, these data are relatively sparse compared with the data in more than 6000 pregnancies with bromocriptine, so that bromocriptine is favored when fertility is the major reason for treatment. On the other hand, these data are encouraging, so that mothers may be reassured if they get pregnant while taking cabergoline.

Effect of Pregnancy on Prolactinoma Size

Estrogens have a marked stimulatory effect on PRL synthesis and secretion, and the hormonal milieu of pregnancy can stimulate lactotroph cell hyperplasia. In women with prolactinomas, this can result in tumor growth. The risk of clinically significant tumor enlargement (e.g., headaches, visual disturbances) is 1.4% for women with microadenomas and 26.2% for those with macroadenomas unless they have had prior surgery or irradiation, which lowers the risk to 3.0%. Reinstitution of bromocriptine is usually successful in reducing symptomatic tumor enlargement rapidly, and no ill effects on the infants have been observed

in these cases. Surgical decompression may be needed (rarely) if bromocriptine is not successful in reducing tumor size.

Recommendations for Management

For the hyperprolactinemic woman with a microadenoma or macroadenoma that is intrasellar or extends infrasellarly, bromocriptine is preferred as the primary treatment because of its efficacy in restoring ovulation and very low (1.4%) risk of clinically serious tumor enlargement. Such a patient should be followed carefully throughout gestation. PRL levels do not always rise during pregnancy in women with prolactinomas as they do in normal women. However, they may rise substantially without tumor enlargement; conversely, PRL levels might not rise with tumor enlargement. Therefore, periodic checking of PRL levels is of no benefit. Because of the low incidence of tumor enlargement, routine, periodic, visual field testing is not cost-effective. Visual field testing and scanning are performed only in patients who become symptomatic.

In a woman with a larger macroadenoma that may have suprasellar extension, there is a 26% risk of clinically significant tumor enlargement during pregnancy when only bromocriptine is used. There is no clear-cut best therapeutic approach, and this has to be a highly individualized decision that the patient must make after a clear documented discussion of the following therapeutic alternatives. One approach is just to use bromocriptine to allow ovulation, discontinue it when pregnancy is documented, and then observe the patient carefully for evidence of tumor growth. Second, prepregnancy transsphenoidal surgical debulking of the tumor greatly reduces, but does not eliminate, the risk of serious tumor enlargement. After surgical debulking, bromocriptine is still required to restore normal PRL levels and allow ovulation. A third approach, that of giving bromocriptine continuously throughout gestation, has been advocated, but data regarding the effects of continuous bromocriptine therapy on the developing fetus are still quite meager, and such therapy cannot be recommended without reservation.

For pregnant patients with macroadenomas treated with bromocriptine alone or after surgery, careful follow-up with monthly visual field testing is warranted. Repeat scanning is reserved for patients with symptoms of tumor enlargement, evidence of a developing visual field defect, or both. If symptomatic tumor enlargement occurs with any of these approaches, reinstatement of bromocriptine is probably less

harmful to the mother and child than is surgery. However, such medical therapy must be monitored very closely, and transsphenoidal surgery or delivery (if the pregnancy is far enough advanced) should be performed if there is no response to bromocriptine and vision is progressively worsening.

The presence of genetic factors affecting the risk of prostate cancer is also supported by data on the incidence of prostate cancer in different racial groups. The prostate cancer incidence rate is highest for men of African American descent (149/100,000 person-years), with intermediate rates for U.S. Caucasian men (107/100,000) and lower rates for men of Asian descent (39/100,000 for Japanese men and 28/100,000 for Chinese men). For Asian men who migrate to the United States, the rate of prostate cancer increases dramatically, although it remains lower than that observed for U.S. white males. Even when corrected for stage of detection and access to medical care, black men with prostate cancer tend to have lower survival rates than white men with the same disease status.

The increase in prostate cancer incidence for men who migrate from Japan to the United States suggests the presence of environmental factors, especially dietary risk factors, in the development of prostate cancer. However, there is controversy regarding the role of dietary factors in the development of prostate cancer. Several studies have suggested that dietary fat, especially fat from red meat, appears to be an important risk factor for the development of this disease. Other dietary elements may have an acute effect on PSA, a marker for prostate cancer growth. Lycopenes (a substance derived from tomato with antioxidant activity) or soy protein (a phytoestrogen) have apparent anti-tumoral effects in men with prostate cancer. It is not clear whether soy protein acts directly or only through its estrogenic activity against prostate cancer.

Hormonal factors are critical for the development of prostate cancer. Testosterone is necessary for prostate epithelium to grow, and early prostate cancer has been shown to be androgen dependent.

Prevention of Prostate Cancer Deaths

It has not been definitively established that early detection of prostate cancer will lead to improved survival. However, the clinical approach of the widespread use of PSA blood tests, coupled with regular digital rectal examination (DRE), is an attempt to decrease the potential significant morbidity and mortality of prostate cancer. Prostate cancer, the second leading cause of cancer deaths in men after lung cancer, shortens life expectancy dramatically. In addition, ineffective treatment of this disease and disease progression can cause significant morbidity.

Prostate cancer screening may decrease the risk of subsequent death from this disease. The decreased death rate from prostate cancer in the United States

during the past few years is associated with the introduction of PSA and the widespread application of local treatment. This suggests that prostate cancer surgery coupled with earlier detection using the PSA blood test may have had a positive effect on the rate of prostate cancer death. Labrie *et al.* studied men who were aggressively screened with DRE and yearly serial PSA blood tests compared to men who received routine medical care. They observed a statistically significant decrease in prostate cancer deaths after 7 years for the screened group. Preliminary studies from the Tyrol region of Austria, where PSA screening was introduced in 1987 and has been extensively applied since 1994, also demonstrate a marked decrease in prostate cancer deaths compared to historical control data and prostate cancer death rates in other regions of Austria.

DIAGNOSIS

Detection of Prostate Cancer

Suspicion of the Presence of Cancer

An abnormal DRE of the prostate or an elevated PSA blood test level suggest the presence of prostate cancer. An abnormal exam includes the presence of nodular areas of the prostate or an asymmetric prostate gland. The presence of either of these factors is an indication for prostate biopsy in men who would benefit from the diagnosis of prostate cancer (men with a >10-year life expectancy and the possibility of localized disease or those with symptoms of metastatic disease).

Prostate-Specific Antigen

PSA is an enzyme normally produced by the glandular tissue of the prostate. It is produced at detectable levels only by prostate tissue. PSA is normally secreted outside of the body in urine or semen. If PSA backs up into the body and is present at elevated levels in the blood, then an abnormal condition is present within the prostate. This abnormality may be caused by trauma to the prostate (such as occurs after biopsy or cystoscopy), infection, benign enlargement, or prostate cancer. Therefore, an elevated PSA level does not diagnose the presence of prostate cancer, and prostate biopsy is required to confirm a clinical suspicion of cancer.

Since PSA levels tend to increase with prostatic enlargement, PSA can be normalized to total prostate volume using the index of PSA (ng/ml)/prostate volume (cc). Prostatic enlargement tends to occur with age; therefore, it is possible to assume increased

prostatic size as men age. This approach allows assessment of age-specific PSA levels. For men younger than 50 years of age, PSA levels should be 0–2.5 ng/ml. For men 50–59 years of age, normal PSA levels are 0–3.5 ng/ml. For men 60–69 years of age, PSA should be 0–4.5 ng/ml. For men 70–79 years old, PSA levels of 0–6.5 ng/ml are considered normal.

The specificity of the PSA blood test has been improved by the use of a derivation of the PSA. PSA may exist free in serum or bound to large proteins such as α_1 -antichymotrypsin inhibitor. The percentage of free PSA is a measurement of the proportion of PSA protein that is free in the bloodstream versus that which is bound to other proteins. Men with low PSA levels (<1.0 ng/ml) rarely have cancer, and the vast majority of men with markedly elevated PSA levels (>30 ng/ml) have cancer. The percentage of free PSA is useful for determining whether biopsies are needed for men with a PSA between 3 and 10 ng/ml. Prostate cancers tend to release PSA into the bloodstream that is bound to proteins, whereas benign prostatic tissue tends to release more free PSA. Therefore, men with a low percentage of free PSA (<25% free) are more likely to have prostate cancer than men with elevated percentage free levels in the presence of an abnormal serum PSA level (between 3 and 10 ng/ml).

Prostate Biopsy

Prostate cancer is detected using biopsies of the prostate. Biopsies should be performed by a transrectal approach using ultrasound guidance. Transrectal ultrasound (TRUS) is used to evaluate prostate size and to ensure that biopsies have an adequate distribution of samples throughout the prostate gland. Typically, at least a sextant pattern of biopsies is performed to effectively detect any tumor in the peripheral zone of the prostate that is at least 1 cm in size. Additional samples of the anterior (transitional zone) are obtained. Although TRUS is used to guide the biopsies and many tumors are hypoechoic, there is no diagnostic appearance of cancers on ultrasound.

Latent vs Clinical Prostate Cancer

More than 90% of prostate cancers are adenocarcinomas. They are present as microscopic lesions in the majority of men older than age 50. These microscopic (latent) tumors cannot generally be detected by standard biopsies and are detectable only at autopsy. Latent tumors progress into clinically detectable prostate cancer in approximately 10% of all men. The mechanisms by which latent prostate cancer progresses to

clinically significant and detectable tumors are poorly understood. All racial groups have similar rates of latent cancer, but the rate of progression to clinically significant cancer and death differs greatly. Therefore, some genetic factors appear to act by accelerating the rate of transformation of latent prostatic tumors into clinically significant tumors.

PSA-based screening for prostate cancer does not significantly increase the frequency of detection of small, presumably latent and clinically insignificant cancers. Therefore, it is inaccurate to state that a cancer found on biopsy is unimportant. Longitudinal series of men from Sweden (where prostate cancer management is usually expectant) who have prostate cancer and who live 10 years or more have shown that the majority who are not provided initial treatment die of the disease.

Precursors of Prostate Cancer

There is no *in situ* carcinoma of the prostate that progresses to an invasive tumor. However, high-grade (grade II or III) prostatic intraepithelial neoplasia (PIN) is associated with invasive carcinomas. For men with high-grade PIN in the absence of an invasive carcinoma on prostate biopsies, a subsequent diagnosis of invasive cancer is made in at least 30–50%. Low-grade PIN (PIN I) is of no clinical significance. It is not associated with subsequent detection or development of prostate cancer.

Cancer Location and Volume

Based on the site of detection of early palpable and nonpalpable tumors, most (85%) prostate cancers develop out of the peripheral part of the prostate, primarily in the posterior part of the gland. At the time of detection, prostate cancers are usually multifocal, with an average of seven sites observed on serial sectioning of the entire gland. Cancers less than 0.2 cc in volume and of low grade (Gleason sum <7) are rarely aggressive and are most commonly found in autopsy series or in prostates removed for benign prostatic hypertrophy (BPH). Cancers less than 4 cc in volume rarely invade the seminal vesicles or metastasize to pelvic lymph nodes.

Grade

Prostate cancers are graded using the Gleason system. This approach evaluates the glandular pattern of the tumor as examined at relatively low-power magnification. Cytologic features of the tumor are not considered in the Gleason grading system. The predominant and secondary patterns of glands within the tumor are identified and each is assigned a grade of 1–5,

with 1 being the least aggressive (most differentiated) and 5 being the most aggressive (least differentiated) pattern. The two grades are added together to provide a Gleason sum score of 2–10. The Gleason score is often the most important prognostic factor of the progression of prostate cancer. For Gleason scores of 2–4, cancers rarely progress early or cause death within 10 years. Localized tumors are most commonly detected with the intermediate grades of 5 or 6. Gleason 7 cancers have a significantly worse prognosis than Gleason 5 or 6 tumors. Most Gleason 8–10 tumors have at least microscopically metastasized prior to detection, although a subset of men with disease are cured with local treatment only. There is good intraobserver concordance within one Gleason sum score; however, low-grade tumors may dedifferentiate over time into more aggressive tumors. The detection of limited amounts of prostate cancer is clinically important because the volume of cancer on prostatic needle biopsy is unrelated to the amount of cancer actually present within the prostate gland.

Staging

Prostate cancers are staged using the T, N, and M classification system. Localized tumors include clinical T1 or T2 tumors (N0M0), whereas clinical T3 (N0M0) tumors are considered locally advanced, and any nodal or metastatic involvement constitutes systemic prostate cancer. Clinical staging is primarily performed by DRE. The most common stage at which prostate cancers are detected is T1c (a nonpalpable lesion detected on biopsy evaluation of an elevated PSA). Nodal involvement may be detected with computed tomography (CT) of the pelvis, whereas metastases to bone (the next most common site) is primarily performed by radionuclide bone scan. For most men with localized disease (T1c, Gleason sum score 5–6, or PSA <10), there is a <2% risk of finding metastatic disease on bone scan or CT scan.

TREATMENT

Treatment of prostate cancer is generally limited to those men with a life expectancy >10 years or men with symptomatic metastatic disease. Therefore, it is possible to discuss treatment options for prostate cancer based on the stage of disease diagnosed.

Localized Disease

The goal of treatment of clinically localized disease is the eradication of all local tumor. Despite apparently

effective treatment, some men with clinically localized disease may have micrometastatic disease that limits local treatment to a less than 100% success rate. Nevertheless, the majority of men with clinically localized disease are potentially curable with effective treatment.

Watchful Waiting

Many men with prostate cancer have long-term survival without aggressive treatment. For men with Gleason grade 2–4 tumors, the survival rate for more than 5–10 years is nearly identical to that of untreated patients, and aggressive treatment may not be needed. Only if survival >10 years is expected should treatment be considered. Alternatively, for men with Gleason grade 8–10 tumors, the 5-year death rate from prostate cancer is approximately 50%. These observations suggest that watchful waiting may be very appropriate for patients with a life expectancy of <10 years and well-differentiated tumors. For most men with more aggressive tumors or longer life expectancy, effective local treatment is necessary to avoid death from prostate cancer. For younger men with prostate cancer, treatment may be critical to avoid death from this disease.

Radiation Therapy

Radiation may be delivered to the prostate using external beam therapy, which is commonly applied using a three-dimensional conformal technique, interstitial radiation delivered by seeds placed directly into the prostate gland, or a combination of both treatments. The effectiveness of radiation therapy is limited by the relative insensitivity of prostate cancer to radiation. With increasing radiation doses, there is a lower risk of subsequent positive biopsies. When radiation doses of 60–70 cGy are delivered to the prostate, positive biopsies occur in 30–40% of treated patients. These results are not acceptable for long-term cure, although short-term control of cancer may be provided. Only when doses higher than 81 cGy are applied do positive biopsy rates decline below 10%. This dose of radiation is difficult to apply because the small intestine, bladder, and rectum are all highly sensitive to radiation damage. The observation of locally persistent prostate cancer (on biopsy) after attempted definitive radiation provides a possible explanation for the slightly lower 10-year disease-free rates observed after radiation therapy compared to results obtained with surgical therapy. However, the difference in survival after treatment of clinically localized disease is primarily due to patient selection biases rather than the effectiveness of the treatment. Selection biases in treatment arms can be controlled to some degree by

categorization of disease status based on PSA, clinical stage, and Gleason grade. Unfortunately, disease status has to be categorized to allow comparison of different treatment regimens because randomized trials of treatment modalities for localized prostate cancer have not been performed.

Surgical Treatment

Surgical prostatectomy has been used as a treatment for prostate cancer since 1904. However, successful early results were dependent on the detection of small-volume cancers, which was rare. In addition, a poor understanding of pelvic anatomy resulted in high complication rates (impotence and infection) after surgical prostatectomy. Furthermore, the surgical margins of resection around the prostate are limited by the apposition of the prostate to the bladder and sphincteric muscles as well as the rectum.

Significant advances in the surgical treatment of prostate cancer depended on an improved understanding of the anatomic relationship of the prostate to the nerves that provide erectile function as well as the relationship of the prostate to the sphincteric muscles. These observations were made possible because of the anatomic observation of the relationship of blood vessels to the prostate. With better control of blood loss, identification and preservation of urethral sphincteric muscles and the neurovascular bundles containing the nerves responsible for erectile function became possible. It is now possible to allow preservation of erectile function for 50–80% of men after radical prostatectomy at selected centers, with incontinence rates of 2–10%. The rate of complications is related in large part to the age of the patient.

Despite the potential risks of surgical therapy, prostate cancer appears to be better controlled with surgery than radiation therapy in most series of patients with 10–15 years of follow-up. Thus, radical prostatectomy is the primary choice for treatment of localized prostate cancer for most men who have a life expectancy >10 years and who are candidates for a major surgical operation.

Systemic Disease

Systemic prostate cancer may involve a wide spectrum of disease, from biochemically detected cancer detectable only on PSA blood test with no evidence of lesions on bone scan or CT scan to symptomatic, extensive metastatic lesions easily seen on bone scan with extensive replacement of bone marrow by disease.

The initial treatment of systemic prostate cancer has changed little since the 1940s, when it was demonstrated that hormonal therapy with androgen deprivation can result in dramatic antitumor responses for men with disabling metastatic prostate cancer.

Hormonal Therapy

Androgen withdrawal, by either castration or medical therapy, can result in dramatic responses of PSA levels and clinical disease in the vast majority of men with advanced prostate cancer. Medical therapy usually involves administration of gonadotropin-releasing hormone (GnRH) agonists, which with tonic administration results in ablation of luteinizing hormone (LH) secretion by the pituitary and castrate levels of testosterone production by the testes. GnRH is normally released in a pulsatile fashion from the hypothalamus, in which it directly acts on the pulsatile release of LH (and follicle-stimulating hormone) from the pituitary. Tonic high-level GnRH stimulation of the pituitary (in distinction to pulsatile stimulation) results in a bimodal effect on LH secretion. Tonic pituitary stimulation (as provided by long-acting, potent GnRH agonists) causes an initial surge in LH secretion with increased testosterone, maximally noted approximately 1 week after GnRH agonist treatment. This tonic stimulation results in down-regulation of GnRH receptors on the gonadotrope cells of the pituitary so that the pituitary becomes unresponsive to GnRH and LH secretion stops. The net effect of GnRH agonist treatment is an initial increase in testosterone levels (a flare effect), followed by suppression of LH with a decrease in testosterone to castrate levels within 1 month of continued treatment. No flare effect should be seen with repeated doses of an effective GnRH agonist, usually given as a depot injection or implant.

Obstruction of androgen action by competitive androgen receptor blockers can prevent the action of testosterone and other androgens on prostate cancer cells. Prostate cancer is remarkably androgen dependent and will usually respond to androgen deprivation for a median duration of 18 months in men with extensive prostate cancer. For many men who are treated with androgen deprivation for a prolonged period of time and subsequently have progression of disease, as measured by increased PSA levels, a partial agonist effect of the competitive androgen receptor blocking agents (flutamide and bicalutamide) referred to as antiandrogens may be observed. Cessation of the

antiandrogens will result in a decrease in PSA levels for many patients.

Chemotherapy

Multiple single-agent chemotherapy regimens have been applied in the treatment of prostate cancer with limited success. Objective responses occur in 10–20% of men with extensive prostate cancer treated with single agents. Combinations such as estramustine-based regimens with docetaxol or other microtubule-inhibiting agents may provide objective responses in 40–60% of patients.

Immunotherapy

A series of new agents that are based on immune-based treatments for prostate cancer have been applied on an investigational basis for advanced prostate cancer. Using antibody-based treatments, vaccines, or other immune-stimulating treatments, objective responses in 50% or more of men have been demonstrated. The role of these treatments in the management of men with advanced prostate cancer is yet to be demonstrated.

Radiation

Metastatic lesions typically respond to either spot radiation therapy or systemic radiation directed to bony lesions, such as with intravenous injection of strontium-89. Relief of pain occurs in 60–80% of patients with local bone pain from metastatic prostate cancer. For men with solitary symptomatic deposits, local radiation is most appropriate, whereas patients with multiple sites of symptomatic involvement are best treated with systemic administration of strontium-89.

CONCLUSION

Prostate cancer is a significant health concern for nearly one in nine men in the United States. Although effective local therapies are available, early detection is necessary to allow local treatments such as surgery or radiation. Hormonal therapy is the mainstay of systemic therapy, but it is not a curative therapy since most tumors develop cell lines whose growth is androgen independent. Effective systemic therapies for prostate cancer are still needed. Further understanding of the pathophysiology of prostate cancer is progressing rapidly, in conjunction with improved methods of early detection and improved local treatments.

Figure 1 A diagram illustrating the roles of testosterone and dihydrotestosterone (DHT) in male sexual differentiation *in utero*. Dark shading indicates regions where male sexual differentiation and development are dependent on testosterone; light shading indicates regions where male sexual differentiation and development are dependent on DHT.

functions as a prehormone, where its conversion to DHT results in differentiation of the external genitalia and prostate. These findings are supported by studies demonstrating that in the human fetus DHT formation occurs in the urogenital sinus, urogenital tubercle, and urogenital swellings at the time of sexual differentiation, but does not occur in the Wolffian anlage until sexual differentiation is completed. Animal studies by using a 5 α -reductase-2 inhibitor provide further evidence to support the differential roles of testosterone and DHT in male sexual differentiation.

With puberty, the affected males have an increase in muscle mass and deepening of the voice. There is growth of the phallus with rugation and hyperpigmentation of the scrotum. Inguinal testes descend into the scrotum at puberty in some patients. Libido is intact and patients are capable of erections. Although patients are generally oligo- or azoospermic, normal sperm concentrations have been reported in some patients who have descended testes. Affected patients have been reported to father children, suggesting that DHT does not play a major role in spermatogenesis and sperm function. These clinical findings suggest that pubertal events, including male sexual function and spermatogenesis, are primarily testosterone mediated, although the role of DHT produced by 5 α -reductase-1 remains to be defined.

The prostate in the affected males is nonpalpable on rectal examination. It is rudimentary on transrectal ultrasound and magnetic resonance imaging visualization and is approximately 1/10 the size of age-matched normal controls. Prostate diseases, such as prostate cancer and benign prostatic hyperplasia, have

not been reported in male pseudohermaphrodites with 5 α -reductase-2 deficiency. The treatment for benign prostate hyperplasia with 5 α -reductase inhibitors evolved in part from the clinical observation that adult male pseudohermaphrodites with 5 α -reductase-2 deficiency have rudimentary prostates.

Affected adult males have less facial and body hair than their nonaffected male relatives; male pattern baldness has never been observed in affected males.

Sebum production is dependent on androgen action. No demonstrable sebum is produced in 46,XY subjects with complete androgen insensitivity due to mutations in the androgen receptor. Although affected males with 5 α -reductase-2 deficiency rarely have acne, they produce normal amounts of sebum, suggesting that sebum production is regulated by the 5 α -reductase-1 isozyme.

BIOCHEMICAL FEATURES OF 5 α -REDUCTASE-2 DEFICIENCY

The biochemical characteristics of 5 α -reductase-2 deficiency have been well defined over the years. The condition is characterized by the following: (1) normal to elevated levels of plasma testosterone; (2) decreased levels of plasma DHT, with an increased testosterone/DHT ratio at baseline and/or following human chorionic gonadotropin stimulation; (3) a decreased conversion of testosterone to dihydrotestosterone *in vivo*, with conversion ratios of testosterone to DHT of <1%; (4) normal metabolic clearance rates of testosterone and DHT; (5) decreased production of

urinary 5 α -reduced androgen metabolites with increased 5 β /5 α urinary metabolite ratios; (6) decreased plasma and urinary 3 α -androstane-17 β -diol glucuronide, a major metabolite of DHT; and (7) a global defect in steroid 5 α -reduction as demonstrated by decreased urinary 5 α -reduced metabolites of C-21 steroids, such as cortisol and corticosterone, in addition to C-19 steroids. Although the defect of 5 α -reduction of steroids is generalized, only the defective reduction of testosterone appears to be of clinical significance.

Increased plasma levels of luteinizing hormone (LH) and an increased LH pulse amplitude with a normal LH frequency have been reported in three subjects. The elevated mean plasma LH level occurs despite normal to elevated mean plasma testosterone, suggesting a role for DHT in the negative feedback control of LH. Plasma follicle-stimulating hormone (FSH) levels may be elevated. Although some of the elevation in FSH is undoubtedly attributable to cryptorchidism and seminiferous tubular damage, a role for DHT in the feedback control of FSH cannot be ruled out.

BIOCHEMISTRY AND MOLECULAR BIOLOGY OF 5 α -REDUCTASE ISOZYMES

Steroid 5 α -reductase isozymes located in the microsomes of the cell are NADPH-dependent proteins that reduce the double bond at the 4–5 position of a variety of C-19 and C-21 steroids. These isozymes convert testosterone to the more potent androgen, DHT. Testosterone and DHT bind to the intracellular androgen receptor (a member of the nuclear steroid/thyroid hormone receptor superfamily) and interact with a cognate androgen DNA-response element to regulate target gene expression. Although testosterone and DHT interact with the same androgen receptor, they produce distinct biological responses under certain conditions. The molecular mechanism for this is unclear even though DHT has been reported to bind to the androgen receptor more avidly than testosterone and the DHT–receptor complex is more efficiently transformed to the DNA-binding state than is the testosterone–receptor complex.

In the early 1960s, it was theorized that multiple 5 α -reductase isozymes existed. In 1975 and 1976, Moore and Wilson detected different pH optima for 5 α -reductase activity in genital and nongenital skin. In the genital skin, the major enzymatic activity had a narrow, acidic pH optimum of 5.5, which was found to be expressed at a low level in the genital skin of male

pseudohermaphrodites with 5 α -reductase deficiency; another enzymatic activity observed had a neutral to alkaline pH (pH 7–9), was present in both normal genital and nongenital skin, and was shown to be expressed at a normal level in the genital skin of male pseudohermaphrodites with 5 α -reductase deficiency. Kinetic analysis of 5 α -reductase activity in the epithelium and stroma of the prostate also suggested that there were different 5 α -reductase activities.

In the early 1990s, two genes encoding two isozymes were cloned using expression cloning technology: steroid 5 α -reductase type 1 (gene symbol: *SRD5A1*) and steroid 5 α -reductase type 2 (gene symbol: *SRD5A2*). Mutations in the 5 α -reductase-2 gene are responsible for male pseudohermaphroditism due to 5 α -reductase deficiency.

The human 5 α -reductase-2 gene has five exons and four introns, encodes a highly hydrophobic 254-amino-acid protein with a molecular weight of approximately 28.4 kDa, and maps to the short arm of chromosome 2 band 23. The type 2 isozyme has a much higher affinity for testosterone (apparent $K_m = 4\text{--}50\text{ nM}$) than the type 1 isozyme ($K_m = 1\text{--}5\text{ }\mu\text{M}$). However, the apparent K_m (3–10 μM) for the NADPH cofactor is similar in both isozymes. The type 2 isozyme is sensitive to finasteride, a 5 α -reductase inhibitor, and has an acidic pH optimum in enzymatic assays. However, it may work at a neutral pH optimum in its native state.

The type 2 isozyme is expressed in the external genital tissues early in gestation. In adulthood, its expression in prostate, genital skin, epididymis, seminal vesicle, and liver is relatively high but is quite low in other tissues. It has been reported that this isozyme may also be expressed in the ovary and hair follicles.

The 5 α -reductase-1 gene is normal in male pseudohermaphrodites with 5 α -reductase deficiency. It also has five exons and four introns and is located on the short arm of chromosome 5 band 15. This isozyme has 259 highly hydrophobic amino acids with a molecular weight of approximately 29.5 kDa. There is approximately 50% homology between human type 1 and type 2 isozymes in amino acid compositions. 5 α -Reductase-1 has a broad alkaline pH optimum, a low substrate affinity, and a low sensitivity to finasteride inhibition. This isozyme is expressed in nongenital skin, liver, and certain brain regions. However, its expression in the prostate, genital skin, epididymis, seminal vesicle, testis, adrenal, and kidney is low. Its expression in the liver and nongenital skin is detected at birth and is present throughout life, whereas its expression in embryonic tissues is low.

The physiological function of 5 α -reductase-1 is still obscure. It may play a significant role in parturition.

MOLECULAR GENETICS OF 5 α -REDUCTASE-2 DEFICIENCY

More than 33 mutations in the 5 α -reductase-2 gene have been identified, including mutations in the three largest kindreds of male pseudohermaphrodites with 5 α -reductase-2 deficiency in the world—the Dominican, New Guinean, and Turkish kindreds. Subjects from the New Guinean kindred have a large deletion of more than 20 kb in the 5 α -reductase-2 gene. Subjects in the Dominican kindred have a missense mutation in exon 5 of the 5 α -reductase-2 gene, which substitutes thymidine for cytosine and results in a substitution of the nonpolar amino acid tryptophan for the basic, polar amino acid arginine at position 246 of the isozyme. This missense mutation causes a decrease in binding of the cofactor NADPH, an altered pH optimum, and a dramatic loss of enzymatic activity. In the Turkish kindred, a single base deletion in exon 5 of the 5 α -reductase-2 gene has been detected. This single-base deletion (adenine) results in a frameshift at amino acid position 251 and an addition of 23 amino acids at the carboxyl terminus of this 254-amino-acid isozyme. This mutation in the isozyme results in a complete loss of enzymatic activity without an alteration in gene expression.

Mutations in the 5 α -reductase-2 gene are found throughout all five exons of the gene and range from a single point defect to a deletion of the entire gene. These mutations result in various types of enzymatic dysfunction including impaired binding of substrate and cofactor to the isozyme, blocked formation of a functional isozyme (deletions, nonsense mutations, splice-junction alterations), and an unstable isozyme. Although various individual mutations have been characterized, no correlation between the severity of the syndrome and a particular gene defect has been observed.

5 α -Reductase-2 deficiency is an inherited autosomal recessive disease as evidenced by pedigree analysis, biochemical analysis, and molecular genetic analysis. Heterozygotes have a normal male phenotype. It should be noted that approximately 35% of patients with 5 α -reductase-2 deficiency from different families worldwide have been found to be either compound or inferred compound heterozygotes, with mutations in two independent loci resulting in the disease phenotype. This suggests that the carrier frequency of a single mutant allele is higher than previously suggested due to the rarity of the disease phenotype.

GENDER IDENTITY AND GENDER ROLE IN MALE PSEUDOHERMAPHRODITES WITH 5 α -REDUCTASE-2 DEFICIENCY

Male pseudohermaphrodites with 5 α -reductase-2 deficiency provide a unique genetic model for studying hormonal influence in the development of male gender identity. The psychosexual studies in these subjects demonstrate that, in humans, environmental or sociocultural factors are not solely responsible for the formation of a male gender identity; androgens make a strong and definite contribution. These data support the “hormonal influence theory” in the development of gender identity.

SUMMARY

Studies of male pseudohermaphrodites with 5 α -reductase-2 deficiency over the past 2–3 decades have provided valuable information about male sexual development and have elucidated the roles of testosterone and DHT in human physiology and pathophysiology. Studies of subjects with this inherited condition have led to the development of specific 5 α -reductase-2 inhibitors for the treatment of benign prostate hyperplasia and male pattern baldness.

Figure 1 Brachydactyly in Albright's hereditary osteodystrophy. This female patient with pseudohypoparathyroidism shows the typical foreshortened fourth and fifth metacarpals that result in brachydactyly.

in the renal tubules; it mobilizes calcium from the mineral store in the skeleton; and it increases serum calcium indirectly by promoting the renal conversion of 25-hydroxyvitamin D to calcitriol, which in turn increases intestinal calcium absorption. PTH is also an important regulator of phosphate metabolism, and it acts within the renal tubule to promote phosphate clearance. Calcitriol counterbalances this by promoting phosphate absorption from the gut.

The principal stimulus to PTH secretion is a decline in serum calcium that is detected by calcium-sensing receptors on the parathyroid cell surface. The same calcium-sensing receptor is also present within the renal tubule, where it acts to increase calcium

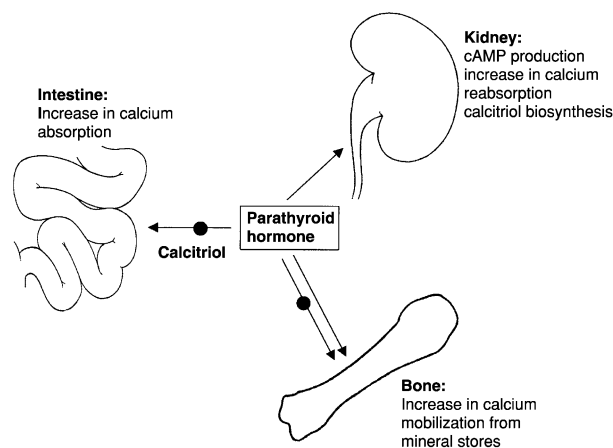

Figure 2 Parathyroid hormone action. The receptor for parathyroid hormone can be found in a wide variety of tissues, although the calciotropic actions of PTH are dependent on its actions within the kidney and bone and indirectly via increased serum calcitriol concentrations that promote increased intestinal absorption of calcium.

Figure 3 The PTH/PTHrP receptor couples to G proteins. PTH signal transduction via its receptor causes $G_{s\alpha}$ protein to release GDP and bind GTP. Thereafter, GTP-bound $G_{s\alpha}$ dissociates from its $\beta\gamma$ subunits and continues to activate adenylate cyclase until hydrolysis of GTP occurs. Inactive $G_{s\alpha}$ then reassociates with the $\beta\gamma$ subunits. Not shown is the association of the PTH/PTHrP receptor with other G proteins known to account for some of its actions.

reabsorption when serum calcium decreases. Calcium homeostasis is therefore coordinately regulated by PTH, calcitriol, and calcium to ensure the strict maintenance of serum calcium within a narrow physiologic range.

PTH Deficiency

A deficiency of PTH as seen in surgical or autoimmune hypoparathyroidism or in patients with congenital absence of parathyroid glands leads to hypocalcemia and hyperphosphatemia. Mild hypocalcemia may be asymptomatic, particularly if it develops slowly. Alternatively, acute development of hypocalcemia may precipitate carpopedal spasm, laryngeal spasm, and/or seizures and may be accompanied by two cardinal physical signs: facial nerve irritability elicited by

tapping over the facial nerve (Chvostek's sign) and carpal spasm that can precipitated by increasing the pressure of a tourniquet to above systolic pressure (Trousseau's sign). Chronic hypocalcemia may paradoxically be accompanied by calcification of soft tissues and/or the basal ganglia and frontal lobes.

PTH Resistance

Resistance to PTH is defined biochemically as the association of hypocalcemia, hyperphosphatemia, and elevated serum PTH concentrations. Uncommonly, these biochemical features may be due to clinically silent malabsorption. Acquired PTH resistance also occurs in renal disorders (because of calcitriol deficiency, tubular dysfunction, and metabolic acidosis) and may occur in hypomagnesemia. Occasionally, hypocalcemia is seen in severe/catastrophic illnesses such as pancreatitis when the other clinical features overwhelm the biochemical problems. When secondary causes have been excluded, PTH resistance is usually due to congenital "pseudohypoparathyroidism," although some cases lack an identified family history of the condition. An etiological classification of pseudohypoparathyroid states is listed in Table I.

Table I Etiological Classification of Disorders Associated with PTH Resistance

| Etiology | Disorder [Mendelian Inheritance in Man (MIM) No.] |
|------------------------------------|--|
| Congenital | |
| Mutation in PTH receptor | Bloomstrand's chondrodysplasia (MIM 215045) |
| Mutation in <i>GNAS1</i> | |
| Maternal allele | Pseudohypoparathyroidism type Ia (MIM 103580) |
| Paternal allele | Pseudopseudohypoparathyroidism (MIM 300800) |
| Paternal allele | Progressive osseous heteroplasia (MIM 166350) |
| Methylation defect in <i>GNAS1</i> | |
| Maternal allele | Pseudohypoparathyroidism type Ib (MIM 603233) |
| Unknown | Pseudohypoparathyroidism type II |
| Acquired | |
| Deficient renal PTH action | Renal failure Magnesium deficiency Malabsorption |
| Unknown | Pseudohypoparathyroidism type III |

PSEUDOHYPOPARATHYROID STATES

Concept of Hormone-Resistant States

The major historical advances in understanding pseudohypoparathyroid states are listed in Table II. Albright recognized that the hypoparathyroid state in some patients was not due to PTH deficiency but rather to target organ resistance to PTH. Pseudohypoparathyroidism thus became the first hormone-resistance syndrome recognized in humans. Resistance syndromes have since been described for many hormones. In steroid hormone-resistance syndromes (e.g., androgen-insensitivity syndrome), the causative defect often resides in the hormonal receptor, whereas resistance to peptide hormones (e.g., insulin) is more commonly associated with alterations in postreceptor signaling.

Subsequent efforts to understand PTH action were led by Aurbach, who observed that many of the actions of PTH are mediated by generation of cAMP. In normal subjects and in patients with PTH deficiency, acute bolus infusions of PTH extract or synthetic PTH (1–34) result in 50- to 100-fold increases in urinary cAMP but less dramatic effects on

Table II Historical Milestones in the Study of Pseudohypoparathyroidism

| Year | Milestone |
|------|---|
| 1942 | Albright <i>et al.</i> describe the first cases of pseudohypoparathyroidism. |
| 1952 | Albright recognizes that the skeletal features of pseudohypoparathyroidism can occur without accompanying hypocalcemia and terms this condition pseudopseudohypoparathyroidism. |
| 1957 | Rall and Sutherland identify cAMP as a second messenger for several hormonal systems. |
| 1967 | Chase and Aurbach show that urinary cAMP increases rapidly in response to purified parathyroid hormone. |
| 1980 | Bourne and Aurbach separately show that G_{sec} activity is reduced by approximately 50% in erythrocyte membranes from patients with pseudohypoparathyroidism type Ia or pseudopseudohypoparathyroidism. |
| 1983 | Davis and Hughes propose an imprinting model for inheritance of pseudohypoparathyroidism type Ia and pseudopseudohypoparathyroidism. |
| 1988 | The gene encoding G_{sec} , <i>GNAS1</i> , is cloned. |
| 1989 | Patten and colleagues identify <i>GNAS1</i> mutation in a kindred with pseudohypoparathyroidism type Ia. |
| 2000 | Liu and colleagues identify methylation defects in the promoter region of <i>GNAS1</i> that are associated with pseudohypoparathyroidism type Ib. |

phosphate clearance. In patients with pseudohypoparathyroidism, these responses are blunted or absent. This fundamental test of PTH action in combination with the presence of hypocalcemia and/or Albright's hereditary osteodystrophy became the basis for the phenomenological classification of pseudohypoparathyroid states discussed next.

Pseudohypoparathyroidism Type Ia

Pseudohypoparathyroidism type Ia [Mendelian Inheritance in Man (MIM) No. 103580] is classically defined as the combination of hypocalcemia and Albright's hereditary osteodystrophy, or "generalized" PTH resistance. This syndrome is known to result from heterozygous mutations in *GNAS1* that cause a reduction in or a malfunction of the $G_{s\alpha}$ protein. The fact that G proteins are responsible for signaling by a number of other hormones explains the occurrence of hypothyroidism (TSH resistance), hypogonadism (gonadotropin resistance), and other signaling defects in some patients with pseudohypoparathyroidism type Ia. A 50% reduction in $G_{s\alpha}$ activity may be demonstrated in erythrocyte membranes from these subjects, although this $G_{s\alpha}$ deficiency appears to have no deleterious effect on red cell function.

Variable serum calcium concentrations in some affected individuals, ranging at times into the normal range, occasionally cause some difficulty in distinguishing this disorder from pseudopseudohypoparathyroidism. However, the response of nephrogenous cAMP to infused PTH is reliably blunted in pseudohypoparathyroidism type Ia, whereas pseudopseudohypoparathyroidism is associated with normal cAMP production.

Pseudopseudohypoparathyroidism

Pseudopseudohypoparathyroidism (MIM 300800) is defined as the occurrence of Albright's hereditary osteodystrophy without hypocalcemia. The absence of biochemical PTH resistance is consistent with normal renal responsiveness to infused PTH in this condition. Although renal $G_{s\alpha}$ activity is preserved in pseudopseudohypoparathyroidism, erythrocyte $G_{s\alpha}$ bioactivity is reduced in a manner comparable to that in pseudohypoparathyroidism type Ia. Moreover, $G_{s\alpha}$ deficiency in this disorder is associated with similar *GNAS1* mutations that cause pseudohypoparathyroidism type Ia. How does the same *GNAS1* mutation cause pseudohypoparathyroidism type Ia in one patient but pseudopseudohypoparathyroidism in another?

Remarkably, inheritance of $G_{s\alpha}$ deficiency from an affected mother leads to pseudohypoparathyroidism type Ia, whereas paternal transmission of the defect leads to pseudopseudohypoparathyroidism (Fig. 4). The explanation for this phenomenon was provided by the discovery that some autosomal genes are expressed from only a single allele, determined by its parent-of-origin status, in a process called imprinting. We each inherit two copies of the genes on autosomal chromosomes, one from either parent. For imprinted genes, expression of only the maternal or paternal allele occurs in some tissues, and the other allele is silenced. In the renal tubule, only the maternal *GNAS1* gene is expressed; the paternal gene is imprinted and therefore silenced and not expressed. Thus, in pseudohypoparathyroid syndromes, a paternally inherited mutation is not expressed in the kidney and renal PTH resistance is not present. Conversely, in bone, both paternal and maternal alleles are equally expressed so that an inactivating mutation of *GNAS1* in either allele causes a 50% reduction in $G_{s\alpha}$ protein. For reasons incompletely understood but probably related to the actions of PTH or PTH-related peptide (PTHrP) during the development of the cartilaginous growth plate, skeletal $G_{s\alpha}$ deficiency may lead to a shortening of metacarpals and metatarsals as well as other features of Albright's hereditary osteodystrophy listed in Table III. Imprinting of the *GNAS1* locus adequately accounts for the complex inheritance pattern of pseudohypoparathyroidism type Ia and pseudopseudohypoparathyroidism (Fig. 5).

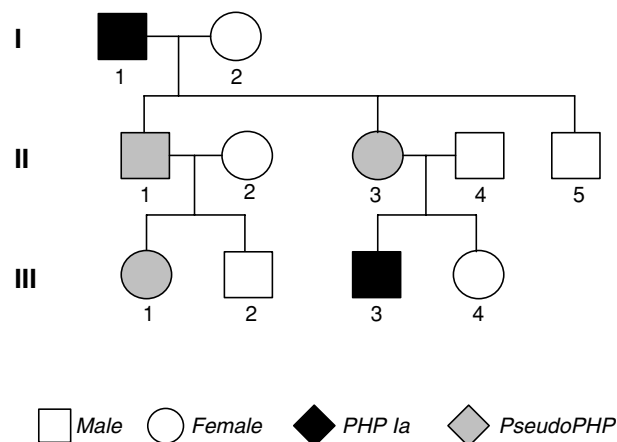

Figure 4 Complex inheritance of pseudohypoparathyroidism. Hypothetical pedigree illustrating the occurrence of pseudohypoparathyroidism type Ia (PHP Ia) or pseudopseudohypoparathyroidism (pseudoPHP) depending on parent-of-origin inheritance of the *GNAS1* defect. For example, pseudoPHP is inherited from a father affected by either PHP Ia (I.1) or pseudoPHP (II.1), whereas PHP Ia is inherited from a mother with either condition (II.3).

Table III Features of Albright's Hereditary Osteodystrophy

| | |
|--|--|
| Skeletal | |
| Short metacarpals (usually fourth and/or fifth) | |
| Short distal phalanx of thumb | |
| Frontal bossing (hyperostosis frontalis externa) | |
| Round face | |
| Short stature (short limb length) | |
| Advanced bone age | |
| Heterotopic ossification in skin | |
| Extraskeletal | |
| Obesity | |
| Dental abnormalities (dentin and/or enamel hypoplasia, delayed or absent tooth eruption) | |
| Developmental delay | |

Pseudohypoparathyroidism Type Ib

Pseudohypoparathyroidism type Ib (MIM 603233) is defined by selective resistance to PTH in the kidney without the features of Albright's hereditary osteodystrophy. PTH infusion in patients with this syndrome results in deficient stimulation of nephrogenous cAMP or urinary phosphate clearance, whereas $G_{s\alpha}$ bioactivity in erythrocyte membranes is normal. Furthermore, *GNAS1* gene mutations are not found in pseudohypoparathyroidism type Ib. An early clue to understanding the etiology of this syndrome was the recognition that *GNAS1* is paternally imprinted as described previously, such that only the maternal *GNAS1* allele is

expressed in the kidney. Moreover, when inherited, pseudohypoparathyroidism type Ib is maternally transmitted in a manner similar to that of type Ia. Therefore, this syndrome is thought to result from defective $G_{s\alpha}$ expression in the renal tubule.

The molecular basis has been clarified with some surprising results. Affected patients show a loss of methylation in an upstream region of the maternal *GNAS1* allele (Fig. 6). In effect, both alleles have the unmethylated pattern usually associated only with the paternal allele. This is perhaps counterintuitive since DNA methylation within gene regulatory elements is typically associated with transcriptional silencing, whereas methylation of the *GNAS1* locus appears to promote renal $G_{s\alpha}$ expression. The *GNAS1* gene locus is complex and encodes at least three different transcripts from alternative exons upstream of those that otherwise encode $G_{s\alpha}$. One possibility is that unmethylated DNA in this region allows expression of alternative mRNA transcripts at the expense of normal $G_{s\alpha}$ expression in the proximal renal tubule. Attempts to map the causative gene in affected kindreds have identified a candidate locus close to the *GNAS1* gene on chromosome 20. Presumably, this gene, as yet unidentified, regulates the methylation status of *GNAS1* in a tissue-specific manner.

Pseudohypoparathyroidism Type II

Pseudohypoparathyroidism type II is characterized by hypocalcemia and hyperphosphatemia in the presence

Figure 5 Tissue-specific expression of $G_{s\alpha}$ in relation to parent-of-origin and pseudohypoparathyroid phenotype. Only the maternal *GNAS1* allele is expressed in the proximal renal tubules. In bone, both maternal and paternal alleles are expressed.

Figure 6 Methylation of exons upstream of *GNAS1* determines renal expression of $G_{s\alpha}$. Liu *et al.* and Bastepe *et al.* clarified the role of methylation of these alternate exons. In particular, when exon A/B is not methylated (and presumably therefore transcribed), expression of $G_{s\alpha}$ in the kidney is inhibited. On the other hand, methylation of this exon permits renal $G_{s\alpha}$ expression. In normal circumstances, only the maternal allele is methylated. In pseudohypoparathyroidism type Ib, neither allele is methylated at this locus (not shown).

of a normal increase in urinary cAMP but blunted phosphaturic response to infused PTH. This disorder has no clear genetic basis, and its cause remains obscure. Defective activation of targets downstream of cAMP production may be responsible, but this has not been established. The features of pseudohypoparathyroidism type II are present in some patients with vitamin D deficiency. Indeed, the ability of PTH to stimulate urinary phosphate clearance is at least partially vitamin D and/or calcium dependent. Vitamin D replacement in some patients with pseudohypoparathyroidism type II has been noted to restore their phosphaturic response to PTH.

Pseudohypoparathyroidism Type III

The existence of a third subtype of pseudohypoparathyroidism remains controversial. Two independent case reports described hypocalcemia that was postulated to be the result of selective skeletal resistance to PTH. The merit behind this hypothesis is the knowledge that the calcemic actions of PTH are partly due to its actions on the skeleton, and therefore skeletal resistance to PTH might cause hypocalcemia. Nevertheless, $G_{s\alpha}$ deficiency limited to the skeleton (pseudopseudohypoparathyroidism) is not accompanied by hypocalcemia. Although it is possible that defects in other second messenger pathways may contribute to a separate phenotype, no conclusive evidence for this has been presented.

Mutations in the PTH Receptor

Although suspected, defects in the PTH receptor have not been implicated in the classical forms of pseudohypoparathyroidism. This receptor also responds to

PTHrP, a hormone that was first identified as the principal cause of humoral hypercalcemia of malignancy but that has important paracrine actions in the control of bone growth. Surprisingly, the first naturally occurring mutations identified in the PTH/PTHrP receptor caused activation of receptor signaling and were associated with a rare skeletal disorder, Jansen's metaphyseal chondrodysplasia (MIM 156400). Subsequently, inactivating mutations in the PTH/PTHrP receptor were identified that were associated with striking effects on skeletal development in Blomstrand chondrodysplasia (MIM 215045), a perinatally lethal condition characterized by advanced bone maturation and chondrocyte differentiation. This lethality probably explains the absence of PTH/PTHrP receptor gene mutations in any form of pseudohypoparathyroidism.

Progressive Osseous Heteroplasia

Progressive osseous heteroplasia (MIM 166350) is a rare congenital disorder characterized by heterotopic ossification occurring primarily within the dermis, skeletal muscles, and deep connective tissue. Autosomal dominant inheritance has been described in some cases. A connection with pseudohypoparathyroidism was initially suggested by the presence of brachydactyly in some affected individuals and further strengthened by the description of one kindred in which paternal inheritance resulted in progressive osseous heteroplasia, whereas maternal inheritance resulted in Albright's hereditary osteodystrophy. Shore and colleagues identified *GNAS1* mutations in this and other kindreds affected by progressive osseous heteroplasia, and in each case the condition was associated with paternal transmission of the defect. Surprisingly, some of the mutations associated with progressive osseous heteroplasia are the same as those previously identified in patients with either pseudohypoparathyroidism type Ia or pseudopseudohypoparathyroidism. The presence of other genes or epigenetic mechanisms modifying the phenotype caused by *GNAS1* mutations has been invoked to explain this remarkable phenomenon, although the specific details are unclear.

FUTURE CHALLENGES

Although substantial progress has been made toward determining the pathogenesis of PTH resistance, many uncertainties remain, including the following:

1. The pathophysiology of skeletal defects in Albright's hereditary osteodystrophy: PTH resistance

within bone cells may not necessarily explain the occurrence of skeletal defects in this condition since PTH-stimulated cAMP production from cultured bone cells has been reported to be normal. Perhaps the G_{sex} deficiency in bone cells interrupts other signaling pathways or variably affects skeletal response to PTH or PTHrP during development.

2. The role of other second messenger systems known to be activated by PTH-receptor signaling in pseudohypoparathyroidism: In particular, it will be interesting to learn whether a specific phenotype is associated with impaired signal transduction via the phospholipase C/inositol triphosphate pathway.

3. The role of other genes modifying the phenotype of pseudohypoparathyroid syndromes, particularly the divergent outcomes of paternal *GNAS1* allele mutation in either pseudopseudohypoparathyroidism or progressive osseous heteroplasia.

4. The mechanism of *GNAS1* genetic imprinting: Further studies of pseudohypoparathyroid type Ib kindreds will likely identify the molecular defect responsible for defective methylation of the *GNAS1* locus. This information will help clarify the mechanism of tissue-specific expression of maternal or paternal *GNAS1* alleles.

Perhaps the most compelling mystery is why imprinting of the G_{sex} gene occurs at all. It is unclear what teleological advantage could be gained by suppressing the expression of one copy of a gene that is clearly critical for calcium homeostasis. Further study of this syndrome will undoubtedly continue to be rewarding for admirers of the rich tapestry of endocrinology in the future.

Acknowledgments

We are indebted to Sol Posen for critical review and helpful guidance in the preparation of the manuscript. Moreover, he has shaped our approach to metabolic bone disease both at the bedside and in the laboratory as the founding father of the academic study of calcium metabolism in Australia. He has been a mentor to A.M. for more than 30 years.

elevated in estrogen-secreting tumors. Plasma testosterone levels are high in the case of virilizing tumors. 17α -hydroxyprogesterone, adrenal androgens, and metabolites are increased in virilizing congenital adrenal hyperplasia and adrenal cortex tumors. Some tumors may secrete Müllerian-inhibiting hormone and/or inhibin. Some may be caused by a loss of a tumor suppressor gene, whereas others may result from activating mutations of stimulatory G proteins.

Etiology

The etiology of pseudoprecocious puberty is presented in [Table I](#). The diagnosis of ovarian tumors is made by radiological imaging of the pelvis. The majority of them are benign (e.g., granulosa cell tumor, teratoma, dermoid cyst) and unilateral. Benign follicular cyst is the most frequent tumor with isosexual pseudoprecocious puberty. Exploratory examination or laparoscopy may be necessary to recognize granulosa cell tumors. Tumors of the granulosa and theca are usually palpable; they secrete large amounts of

estrogens, in particular estradiol, and often progesterone (as in luteomas). The following up of plasma estradiol levels is useful for detecting metastases.

Rarely, ovarian tumors are gonadoblastomas that develop in the fibrous streaks of Turner syndrome or are lipid tumors. Teratomas, teratocarcinomas, and arrhenoblastomas can secrete estrogens, androgens, or both as well as hCG.

Recurrent follicular cysts may be one symptom of McCune–Albright syndrome.

Management and Therapy

Management of pseudoprecocious puberty is summarized in [Table II](#).

Cancer markers, such as α -feto-protein and carcinoembryonic antigen, are of great help in the case of malignancy, as they are increased, in particular hCG. Metastases of the lungs can be found in the case of malignancy.

In the case of ovarian or adrenal tumor, management consists of the ablation of the tumor. Ablation of a large cyst is generally indicated. If malignancy is present, radiotherapy and/or chemotherapy should be considered. In the case of late-onset congenital virilizing adrenal hyperplasia, hydrocortisone therapy is indicated.

PARTIAL OR INCOMPLETE PRECOCIOUS PUBERTY

Premature Pubarche or Premature Adrenarche

This condition represents premature and isolated development of pubic and/or axillary hair. This precocious development is due to premature maturation of the androgenic secretions of the adrenal cortex and/or premature changes in the sensitivity to androgens of the target tissue receptors. This condition is observed from 6 years of age. A higher frequency of this condition has been reported in girls born with intrauterine growth retardation. A moderate increase in height and weight is often observed, as is a moderately advanced bone age. The clitoris is usually normal or slightly increased in size. Plasma concentrations of adrenal androgens (e.g., dehydroepiandrosterone [DHEA], dehydroepiandrosterone sulfate [DHEA-S]) are moderately elevated in relation to the age of the girl and usually correspond to the bone age. In some cases, testosterone, androstenedione, and estrone are slightly elevated. Ovarian or adrenal tumors must be

excluded. A normal plasma level of 17 α -hydroxyprogesterone rules out a late-onset congenital adrenal hyperplasia. Evolution is usually benign, puberty occurs normally, and menarche happens at a normal age. However, in some cases, premature adrenarche leads to the development of polycystic ovary syndrome during adolescence or adulthood. No therapy is needed in the case of premature adrenarche.

Premature Thelarche

This condition represents a premature isolated development of the breast that is usually observed between 1 and 3 years of age. Signs of estrogenization are always absent; there are no modifications of the areolae, labia minora, or labia majora. The vaginal mucosa has a nonsecreting aspect. There is no sexual hair. Growth is not accelerated, and bone age is not advanced. No sign of estrogenization can be seen on the vaginal smear. Ultrasonographic examination of the uterus and ovaries reveals a prepubertal status. In half of the cases, gynecomastia has been noticed during the neonatal period. Plasma estradiol levels are usually in the prepubertal range. Infrequently, a slightly elevated plasma concentration of estradiol is encountered, suggesting the possibility of some transitional forms of true precocious puberty. In these cases, the follow-up will permit the correct diagnosis. Basal concentrations

of LH and FSH are usually normal, although FSH can be slightly elevated in some cases. An exaggerated response of FSH is observed after GnRH stimulation. LH response remains prepubertal. These abnormalities could explain the premature thelarche. However, an increased sensitivity of the breast tissue to the circulating levels of estradiol at this particular age is not excluded. No therapy should be instituted; the spontaneous evolution is generally excellent, with disappearance of the breasts in most cases. In the vast majority of cases, puberty occurs at the normal age. Follow-up of these cases is necessary because precocious puberty may be observed a few years later in rare cases.

Premature Menarche

This condition is defined by the occurrence of vaginal bleeding without any sign of pubertal development. In the absence of any pubertal sign, it suggests foreign body, vaginal infection, and/or sexual abuse, but it also suggests possible tumors of the genital tract (Table III). Malodorous vaginal discharge suggests the presence of a foreign body, which is the most frequent cause of vaginal bleeding before puberty. A hymenal opening larger than 5 mm, posterior notches, or lesions of the vulvae is compatible with sexual abuse. In rare cases, the origin of the vaginal bleeding remains unknown.

choriocarcinoma, chorioepithelioma, dysgerminoma, hepatoblastoma, hepatoma, and teratoma. The secreted gonadotropin is hCG, which acts via the LH receptor and is easy to detect as a tumor marker because healthy boys do not produce hCG. LH and follicle-stimulating hormone (FSH) levels remain low in these boys. Both testes increase in size as in normal puberty. However, if the tumor is testicular, that causes asymmetric growth of the gonad and often irregularity on the surface. Treatment aims at the elimination of the tumor and depends on the location, size, and metastatic status of the tumor.

Leydig Cell Tumors

Solitary Leydig cell tumors are also rare and account for only 1 to 3% of all testicular tumors. In children, the tumors are most often found between 5 and 10 years of age when the signs of precocious puberty become apparent. Testosterone production is gonadotropin independent; therefore, FSH and LH remain on the prepubertal level. The tumors are usually unilateral, causing asymmetric growth of the testes. Gynecomastia can be found in approximately 10% of these patients because either the tumor itself also produces estrogens or androgens are converted to estrogens by peripheral aromatase activity. Gynecomastia is more common in adults than in children.

Leydig cell tumors are always benign in children, whereas adults may have malignant tumors. The standard treatment is orchidectomy, but if the tumor is encapsulated, surgical enucleation is sufficient.

Adrenal Rest Tumors

The interstitial compartment of the testis can also harbor adrenal rest tumors that are stimulated by a

chronically elevated adrenocorticotropic hormone (ACTH) level. This can happen in undertreated 21-hydroxylase deficiency or after adrenalectomy (Nelson's syndrome). Adrenal rest tumors closely resemble Leydig cell adenomas, but adrenal rest tumors are bilateral, whereas Leydig cell tumors are usually unilateral. Adequate glucocorticoid substitution causes regression of the adrenal rests in 75% of cases. The tumors are always benign, and glucocorticoid treatment inactivates them even when the tumors are still visible by ultrasound. If the hormonal activity cannot be controlled by glucocorticoids, antiandrogens and aromatase inhibitors can be used to prevent the effects of androgens. Sometimes even testis-sparing surgery can be considered.

Mixed Sex Cord Stromal Tumors

Mixed sex cord stromal tumors can contain combinations of Leydig, Sertoli, granulosa, and theca cells. These rare tumors can be found at any age, and the most common endocrine manifestation is gynecomastia. These tumors are always benign in children and can be treated by orchidectomy.

ADRENAL TUMORS

Virilizing Adrenocortical Tumors

Functioning adrenocortical tumors in children are rare. The peak incidence occurs during the first decade of life, and tumors are found more often in girls than in boys. The neoplasms are usually unilateral. The majority of tumors secrete predominantly androgens, causing virilization and thereby pseudoprecocious puberty. Very rarely, the tumor secretes only glucocorticoids, whereas some tumors secrete both androgens and glucocorticoids, causing both virilization and cushinoid features.

Adrenocortical tumors can be either benign or malignant. Adrenocortical carcinomas in children have a favorable prognosis if they can be removed completely by surgery. However, these tumors are often aggressive, and the outcome is poor when the tumors cannot be eradicated. The adjuvant chemotherapy and radiotherapy have been of little value. Benign tumors are also treated surgically, and their prognosis is good.

Prognosis of the tumor is related to its staging. In stages I and II, the tumor shows neither invasion nor metastasis; therefore, it is easy to excise completely. Size of the tumor distinguishes stages I and II, in which the tumor is less than 5 cm and more than 5 cm, respectively. In stage III disease, there is local invasion without involvement of adjacent organs or

regional lymph nodes. Metastasis or spread to adjacent organs and lymph nodes is a sign of stage IV disease. Children's tumors are usually in stage I or II, thereby explaining the favorable prognosis compared with that of adult patients.

Diseases Associated with Adrenocortical Tumors

Cancer genetics and studies on molecular mechanisms of tumorigenesis have advanced our knowledge regarding biology of adrenal tumors. [Table II](#) indicates some of the diseases that are associated with adrenocortical tumors. In Li–Fraumeni syndrome, the P53 tumor suppressor gene is mutated, and patients are susceptible to multiple cancers. Deregulation of imprinted genes located at chromosome 11p15.5 causes Beckwith–Wiedemann syndrome, which is characterized by omphalocele, macroglossia, hemihypertrophy, and gigantism. These patients are also susceptible to carcinogenesis in adrenal glands. Patients with Carney complex usually have multiple myxoid skin tumors and may have cardiac myxomas, Sertoli cell tumors, and adrenal tumors. Two genetic loci for Carney complex have been identified: one at chromosome 2p16 and the other at chromosome 17q23–q24. The Carney complex susceptibility gene in chromosome 17 was found to be the type I α regulatory subunit of protein kinase A. In multiple endocrine neoplasia type 1 (MEN1), the molecular defect is in the MEN1 locus in chromosome 11q13, and the syndrome often involves hyperparathyroidism, pituitary tumors, and pancreaticoduodenal tumors. McCune–Albright syndrome, with constitutively activating mutation of the Gs protein, can also manifest in the adrenal gland.

DIAGNOSIS

Hormonal and Physical Examination

Diagnostic workup of testicular and adrenal tumors includes analysis of both testicular and adrenal steroids, gonadotropins, and ACTH. Careful measurement

Table II Complex Tumor Diseases Associated with Adrenocortical Tumor

| |
|-------------------------------------|

| McCune–Albright syndrome |
| Multiple endocrine neoplasia type 1 |

of the size of the gonads is important. Increased penile size and virilization in boys who have small testes (longitudinal axis less than 2 cm) indicates an adrenal source of androgens. Symmetric growth of the testes points to gonadotropin stimulation that may be tumor-derived hCG in the case of pseudopuberty or pituitary LH in the case of central precocious puberty. Testicular tumors may cause asymmetric growth of the testes. Testosterone, androstenedione, and dehydroepiandrosterone all are elevated in children with virilizing adrenocortical tumors, whereas the dehydroepiandrosterone sulfate level may overlap with the normal range. 17-hydroxyprogesterone may also be elevated, whereas glucocorticoid levels and estradiol are in the normal range unless the patient has a mixed type of tumor secreting both androgens and cortisol. Testicular Leydig cell tumors may secrete both testosterone and estradiol.

Imaging Studies

Ultrasonography is a good technique for finding both testicular and adrenal tumors. Visualization of the adrenal glands may be difficult for technical reasons (e.g., obesity, intestinal gas). The use of different positions and oblique scanning planes allows accurate imaging.

Computed tomography (CT) is an excellent method for evaluating adrenal tumors. Thin-section CT scanning finds even the small nodules (3 mm). Homogeneity of contrast enhancement, size of the lesion, and regularity of the borders help in distinguishing between malignant and benign tumors. CT is a sensitive method, but its specificity is limited. Magnetic resonance imaging (MRI) may help in tissue-specific diagnosis of adrenal masses. Chemical-shift MRI has been shown to have good accuracy in distinguishing between benign and malignant adrenal tumors. CT and MRI can be complemented with functional localization techniques such as adrenocortical scintigraphy, which is based on accumulation of radiocholesterol into the adrenal cortex. The radiocholesterol that can be used is ^{131}I -6- β -iodomethyl-19-norcholesterol (NP-59). This technique makes it possible to analyze the functional status of the tumor. There is little use for native X-ray imaging, although malignant tumors in the adrenal gland may sometimes have calcifications.

Puberty, Delayed

see Delayed Puberty

which is characterized by an absence of GnRH production, failure to enter puberty, and anosmia.

In the normal male fetus, GnRH, follicle-stimulating hormone (FSH), and LH production begin in the brain by week 10, and the anterior pituitary releases gonadotropins by weeks 11 to 12. During the second trimester of gestation, the GnRH–gonadotrope–testicular axis is very active, leading to enlargement and growth of the already differentiated penis and testes, hence the normal sizes of these structures in the healthy full-term newborn male. Failure of the GnRH–gonadotrope component of the axis during this critical midgestational period results in isolated unambiguous microgenitalia in male infants (i.e., micropenis and hypoplastic testes). The differential diagnoses include absence of the GnRH neuron, birth defects or genetic mutations involving the hypothalamic–pituitary area, and failure of gonadotrope development or function (e.g., Prop-1 mutations). In contrast, primary testicular abnormalities, androgen resistance, or lack of 5 α -reductase will result in ambiguous genitalia or sex reversal in 46,XY infants (i.e., more female-appearing genitalia). Placental human chorionic gonadotropins (hCG) during the first trimester stimulate Leydig cells to produce androgens that require functional androgen receptors and conversion to 5 α -dihydrotestosterone. These mechanisms control the differentiation of the penis. The GnRH neuron returns to a state of quiescence during the third trimester of gestation.

Postnatal Period

Within a few minutes following delivery, the circulating levels of LH in the human male neonate increase rapidly and are followed by an increase in serum testosterone concentrations during the first 3 to 21 h of postnatal life. FSH levels are slightly elevated in males during the first 3 months of life and then decline. Serum testosterone levels remain high for the first 2 to 4 months of life. By 6 months of postnatal life, the high LH and testosterone levels decline and remain low throughout childhood, indicating that the hypothalamic–pituitary–testicular axis is quiescent during this period because of decreased GnRH production.

The female fetus has lower estrogen concentrations during midgestation, in contrast to the high testosterone levels present in males at the same gestational age. The female fetus has higher pituitary gonadotropin content and higher circulating levels of FSH and LH than do males at a similar age. Castration of male fetal monkeys results in higher serum gonadotropin levels,

similar to those present in the intact fetal female at a similar age. This evidence suggests that gonadal sex steroids do have a negative feedback effect on the active GnRH neuron in fetal life.

Gonadal steroids are not the cause of the inactivity observed in the GnRH neuron during the childhood years. Prepubertal children with gonadal absence or dysgenesis lack gonadal steroids and have low levels of gonadotropins, similar to those present in eugonadal individuals. However, strikingly high levels of LH and FSH are seen in children with primary gonadal failure during the first months of life when the GnRH neuron is in its active phase.

Childhood

The decreased activity of the GnRH neuron during childhood is a relative phenomenon based on information provided by new highly sensitive assays that have detected low-amplitude pulses of LH and FSH during this period. As the child ages, prior to the appearance of any physical signs of puberty, slightly higher nocturnal gonadotropin pulses have been detected.

Puberty

The hormonal patterns observed throughout puberty are the result of gradual changes in the development of the GnRH neurosecretory system. Increases in GnRH pulse amplitude initially becomes evident during the interval period between the end of childhood and the onset of puberty. Following the onset of puberty, first there is augmentation of GnRH pulse amplitude, increased FSH and LH pulse amplitude, and enhanced nocturnal gonadotropin release. Soon thereafter, an increase in GnRH pulse frequency develops. Initially, the mean FSH levels increase, and this is followed by an increase in mean LH levels. As puberty progresses, mean basal LH levels increase, the amplitude and frequency of LH pulses increase, and nocturnal LH secretion increases. The nocturnal increase in GnRH release is particularly prominent during midpuberty. Subsequently, GnRH secretion and gonadotropin pulses during daytime hours are similar to the nocturnal pattern.

Attainment of the adult stage of GnRH pulsatile release is a prerequisite for the positive feedback effect of estrogen during puberty. In primates, estrogen stimulates an increase in GnRH release and also directly enhances LH secretion from the gonadotrope.

Gonadarche involves maturation of the testes during puberty, whereas adrenarche refers to maturation of the reticularis zone of the adrenal gland and

production of weaker adrenal androgens such as dehydroepiandrosterone and its sulfated form (DHEA-S). Adrenarche occurs at an earlier age (i.e., beginning at 6–7 years), is not linked to the GnRH–gonadotrope–testicular axis, and is not a prerequisite for pubertal development.

MECHANISMS CONTROLLING THE ONSET OF PUBERTY: TWO HYPOTHESES

Gonadostat Hypothesis

The gonadostat hypothesis was initially proposed during the 1930s and was based on the belief that onset of puberty resulted from a differential sensitivity of the pituitary to the feedback effects of ovarian sex steroids. According to this hypothesis, puberty begins when gonadotropin secretion becomes insensitive to the negative feedback effect of gonadal steroids. This hypothesis lacked applicability to primates because it was evident that decreased sensitivity to the negative feedback of estrogens on gonadotropin secretion coincided with the midpubertal stage rather than with the actual onset of puberty. The hypothesis had been based on studies in castrated immature and adult rats; suppression of gonadotropins was achieved with a smaller dose of estrogen in immature castrated rats than was the case in adult castrated rats. The role of the GnRH neuron was not appreciated at that time.

Central Inhibition of GnRH Release Hypothesis

The central inhibition of GnRH release hypothesis states that childhood is due to central inhibition independent of gonadal sex steroids. Removal of CNS inhibition of the GnRH neuron leads to an increase in pulsatile GnRH that triggers the onset of puberty. The evidence for this hypothesis includes the following. First, gonadectomized monkeys and humans (e.g., gonadal dysgenesis) have low levels of gonadotropins during childhood and very elevated levels that coincide with periods of increased GnRH activity (e.g., during the postnatal and pubertal periods). Second, direct measurement of stalk–median eminence levels of GnRH in rhesus monkeys show low levels of GnRH if gonadectomy is done during the prepubertal stage and high levels if gonadectomy is done during puberty. Third, estrogen injections into gonadectomized prepubertal primates has no effect on GnRH release.

In summary, the onset of puberty is triggered by maturational changes in the hypothalamic mechanisms that control GnRH release independent of gonadal sex steroids. Evidence indicates that the GnRH neurosecretory system is actually more sensitive to ovarian feedback, in contrast to the assumptions proposed in the gonadostat hypothesis. Grumbach and colleagues suggested that gonadal steroids may increase GnRH secretion at the onset of puberty in children, but further investigation is needed to clarify whether subtle species differences exist in humans versus rhesus monkeys.

NEUROBIOLOGY OF PUBERTY

The GnRH neuron intrinsically is able to secrete GnRH pulses but is incapable of triggering the onset of puberty by itself. GnRH neuronal activity is controlled by inputs from neuronal and astroglial-neuronal networks that are functionally connected. The regulatory processes controlling the input to the GnRH neuron appear to constitute the “central drive” of puberty. Fundamentally, these processes inhibit GnRH production during childhood. Over time, the inhibition is lifted and the dominant input involves stimulatory signals to the GnRH neuron. The central drive is regulated by three major events: two that are transsynaptic and one that involves a glial-to-neuron pathway. The following discussion summarizes these mechanisms.

Inhibitory Neurotransmitters

Decaval and van der Pol reported that γ -aminobutyric acid (GABA) is the dominant inhibitory neurotransmitter in the hypothalamus that suppresses GnRH release during childhood. Disinhibition involves removal of GABA's negative influence on the GnRH neuron and appears to be a prerequisite for the onset of puberty in primates. GABA is synthesized in GABAergic neurons from glutamate by decarboxylation in the presence of glutamic acid decarboxylase (GAD 65 and GAD 67). It is stored in vesicles and released by exocytosis following depolarization by extracellular Ca^{2+} . GAD 65 and GAD 67 are also located in pancreatic beta cells, and elevated GAD 65 antibody titers occur in patients with type 1 diabetes mellitus. GABA synthesis also occurs in perikarya and dendrites but not in glial cells. The latter neurons influence GABA metabolism by providing precursors

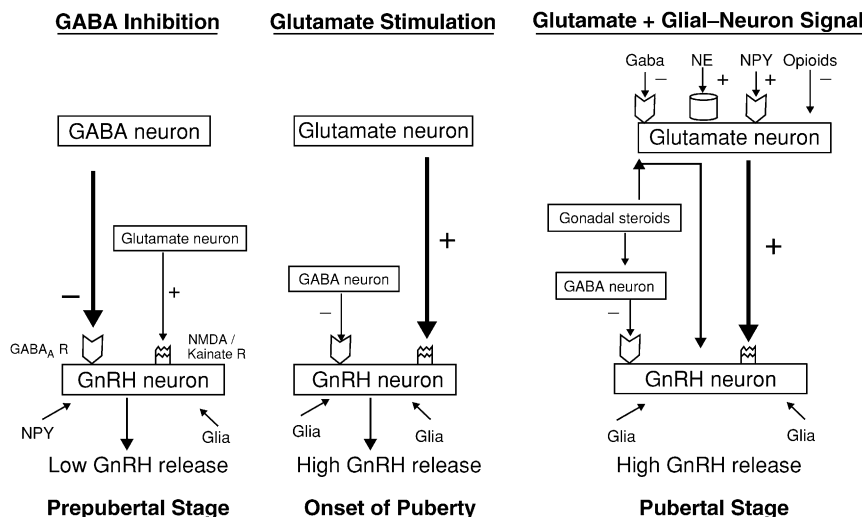

Figure 1 Diagram showing the prepubertal stage, the onset of puberty, and the pubertal stage. During the prepubertal stage, GABAergic mechanisms in primates predominate and the GnRH neurons are inhibited by GABA working directly through the GABA_A receptors and indirectly by suppressing glutamate neurons. At the onset of puberty, GABA release is inhibited and glutamate neurons are activated, resulting in a dominant glutamatergic stimulation of GnRH neurons. Reduced production of GABA and increased production of glutamate induce the pubertal augmentation in pulsatile GnRH secretion that enhances the pulsatile release of gonadotropins. The ensuing gonadarche results in increased sex steroid production. Glial-to-neuron signaling complements the glutamatergic process. During late puberty, glutamatergic neurons and other signaling pathways (e.g., glial-to-neuron, growth factors, NE, NPY, sex steroids) lead to the attainment of adult GnRH neuronal function.

and degrading overflows of GABA from the synapse. GABA signals through the GABA_A receptor (Fig. 1).

Other inhibitory neurotransmitters (e.g., opioids, neuropeptide Y [NPY], and melatonin) do not appear to significantly suppress the GnRH neuron during childhood.

Stimulatory Neurotransmitters

The amino acid glutamate (l-glutamic acid) is the main excitatory neurotransmitter in the hypothalamus, and the GnRH neuron directly receives glutamatergic innervations (glutamatergic system). Enhanced glutamatergic neurotransmission is the main excitatory transsynaptic signal that increases pulsatile GnRH secretion and triggers the onset of puberty. Glutamatergic neurons control GnRH secretion via ionotropic the glutamate receptors NMDA and kainite. The latter is mainly on the GnRH neuron, whereas the former is located on interneurons that are synaptically connected to the GnRH neuron.

In addition, other possible stimulatory neurotransmitters include NPY and norepinephrine (NE), but the evidence is mixed and needs clarification.

Role of Glial-to-Neuron Signaling and the Influence of Growth Factors

Astroglial cells and the growth factors released by glial cells appear to play an important role in stimulating GnRH release at the onset of puberty. Glia increases the GnRH pulsatility by synthesizing growth factors (transforming growth factors- α and - β [TGF- α and TGF- β]), epidermal growth factor (EGF), insulin-like growth factor-1 (IGF-1), basic fibroblast growth factor (BFGF), neuron cell adhesion molecules (NCAM), cytokines (interleukins-1 and -6 [IL-1 and IL-6]), and (NO). Also, astroglia induces plastic rearrangements within the median eminence where there is an abundance of neuroterminals. Lastly, astroglial cells activate specific glial-to-neuron and glial-to-glia signaling pathways that involve a number of the growth factors that increase GnRH release. These signaling pathways are set in motion by ligand-dependent activation of astroglial ErbB tyrosine kinase receptors. Although glutamatergic neurotransmission and astroglial-mediated signaling increase GnRH secretion, the functional relationship of these two regulatory pathways has not been defined.

In conclusion, great progress has been made in our understanding of the complex controls on GnRH release, but the precise mechanisms that initiate the inhibition and stimulation of the GnRH neuron have not been defined.

PUBERTAL DEVELOPMENT IN BOYS: CLINICAL FEATURES

Tanner and colleagues established standards for the stages of puberty, with Tanner 1 representing the prepubertal phase and Tanner 5 representing adulthood. The relationships between the Tanner stages and serum levels of testosterone, FSH, and LH are illustrated in Fig. 2.

The first physical sign of puberty in boys is growth of the testes, which is defined as a length greater than 2.5 cm or a volume greater than 4 ml. The range of age at onset of puberty is 9 to 14 years (mean age = 11.3 years), and pubertal development is completed in a mean of 3.5 years (range = 2.0 to 4.5 years). Increased testicular volume is brought about mainly by FSH stimulation of the seminiferous tubules that manifest increasing lumen diameter. The interstitial and Leydig cells do not contribute significantly to testicular volume. Prior to onset of puberty, Sertoli cells predominate, whereas later the main cells in the seminiferous tubules are germ cells. African American boys have been reported to begin puberty earlier than white and Hispanic boys. The pace of pubertal progression is variable among healthy boys. Genetics, nutrition,

Figure 2 Mean circulating levels of FSH, LH, testosterone, and bone age in healthy boys for each stage of puberty. Stage 1 is prepubertal and stage 5 is adult. Baseline levels of FSH and LH increase as puberty progresses, with the FSH level becoming higher than the LH level. However, when GnRH is administered, the peak level of LH is higher than that of FSH, and this finding is evidence of central GnRH control of the gonadotrope.

and freedom from chronic disease are the dominant influences on the age at onset of puberty.

Spermatogenesis appears between 11 and 15 years of age, and sperm is detected in first morning urine at a mean age of 13.3 years. Spermaturia is evidence of spermatogenesis, but the adult stage of sperm maturation is not reached until bone age equals 17 years. Mean age of ejaculation is 13.5 years. The onset of spermatogenesis occurs early in puberty prior to the attainment of peak growth velocity.

Growth of pubic hair begins at a mean age of 11.2 years and reaches adult density at the mean age of 15 years. Axillary hair appears at a mean age of 14 years, although African American boys show this feature at a mean age of 12 years.

Prior to onset of puberty, the growth rates of boys and girls are similar. The growth rate during puberty is greater than that during childhood but is less than the rapid velocities observed during infancy and fetal life. Boys reach peak velocity 2 years later than do girls, and boys are taller at onset of the pubertal growth spurt phase. Peak growth rate occurs at Tanner stage 3 to 4 in boys or at the bone age of 14 years (13.5–14.0). Boys gain approximately 28 cm, and girls gain approximately 25 cm, during puberty. The height difference in adult men and women is due to the taller baseline height, the later age at onset of puberty, and the greater pubertal height gain in boys.

The hormones that control the growth spurt of puberty involve increased production of growth hormone (GH), elevated levels of IGF-1 (GH-IGF-1 axis), sex steroids (mainly estrogens), and nutrition. Estrogens stimulate bone maturation and closure of the epiphyseal growth plate. Bone mineral density increases during puberty if the calcium intake is adequate and if nutrition and pubertal hormones are normal. Peak bone mass is reached at 17 years of age in boys and is reduced in individuals with delayed puberty.

Body composition and energy requirements change greatly during puberty due to the hormonal influences. Men have 1.5 times the lean body mass and 1.5 times the skeletal mass compared with women. The greater strength of men, as compared with women, is due to the increased muscle mass present. Excess weight gain due to overnutrition and lack of exercise are increasing the national prevalence of obesity, type 2 diabetes mellitus, hypertension, and heart disease in young men and women.

Striking changes occur in behavior, mood, and sexuality during puberty. The hormonal changes that are indicative of puberty involve increasing serum levels of testosterone, FSH, and LH. The

GnRH stimulation test is essential for distinguishing gonadotropin-dependent or central puberty from gonadotropin-independent puberty. The pubertal response to GnRH is characterized by a dominance of LH over FSH after administration of GnRH versus the prepubertal pattern that shows a higher FSH peak than LH after GnRH administration. Gonadotropin-independent puberty is characterized by low or negligible rises in FSH and LH. GnRH analogues completely desensitize the gonadotrope and suppress gonadotropin responses because they continuously occupy the GnRH receptor, in contrast to the physiological episodic stimulation of the receptor that occurs in nature.

CONCLUSIONS

The essential components of puberty in boys involve the following. First, the GnRH neurons migrate from the olfactory placode to the hypothalamus, where they are dispersed even though their activity is functionally synchronized. Second, the GnRH neuron *in vitro* exhibits intrinsic pulsatility of GnRH release. Third, the GnRH neuron is integrated into a functional network that controls its activity throughout life (i.e., the GABAergic, glutamatergic, and glial-to-neuron signaling systems that either suppress or enhance pulsatile GnRH release). Fourth, GnRH and gonadotropin pulsatility are essential for gonadarche. Fifth, the morphologically diffuse yet highly synchronized neuronal network that regulates GnRH release has been termed the GnRH pulse generator. Sixth, the GnRH–gonadotrope–testicular axis is active during midgestation and postnatal life, followed by period of quiescence due to inhibition of the GnRH neuron. Seventh, the onset of puberty is marked by removal of the CNS inhibitory influences on the GnRH neuron and by the dominance of stimulatory signals that have a diurnal pattern during early to mid-puberty, followed by GnRH pulsatility that is similar in the daytime and nighttime periods. Eighth, during puberty, the GnRH pulses develop greater amplitude and frequency.

Ninth, gonadarche is independent of adrenarche and is characterized by increased sex hormone biosynthesis and spermatogenesis.

GROWTH AND MATURATION OF ATHLETES IN WEIGHT-CONTROL SPORTS

Physical activity is an important component of a healthy lifestyle. It produces many physiologic benefits, including increased strength, bone mineralization, favorable blood lipid concentrations, and improved motor control. It also produces psychological benefits, such as a sense of competence and well-being, increased confidence and self-esteem, and social development. For almost all youth, physical activity and sport training have no effect on growth or maturation. Youth who participate in sports are normal or slightly advanced in their rates of growth and maturation, but these traits are probably self-selected because strength and power advantages due to earlier maturation are major factors that attract children to sports and also influence their success in sports.

Only a small number of athletic youth experience a combination of great energy expenditure and restricted energy intake that slows growth and maturation. The remainder of this article focuses on the growth and maturation of two of these athletic groups, male wrestlers and female gymnasts.

Wrestling

Wrestlers compete in weight classes and weigh in before each competition to certify that their body weight is within the limits of the weight class. In the hope of gaining a competitive advantage by competing in a lower weight class against a younger and less experienced opponent, some wrestlers reduce their body weight through a combination of exercise and dietary restriction. The typical wrestler practices 2–2.5 h per day, 5 or 6 days per week and, after correction for the basal metabolic rate, expends approximately 800 kcals per practice. During a 3- or 4-month season, wrestlers may have nutrient intakes 50% below recommended amounts (Fig. 1). The amount of nutrient intake is not adequate to meet the combined requirements of resting metabolism, sport training, and growth and results in reduced protein nutritional status (Fig. 2).

This undernutrition produces low testosterone and free testosterone concentrations while maintaining serum luteinizing hormone (LH) concentrations (Fig. 3). In a well-nourished individual, testosterone produces negative feedback on LH secretion. Low testosterone concentrations in wrestlers should result in elevated serum LH concentrations. The lack of

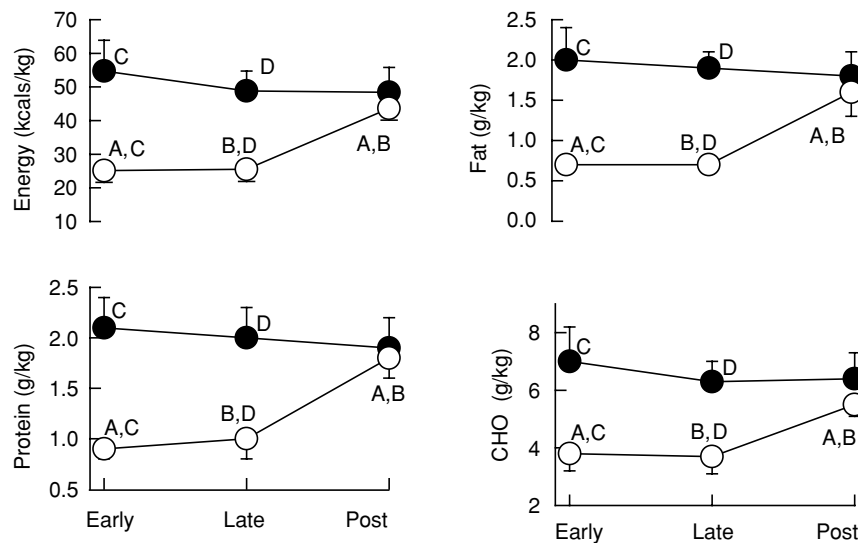

Figure 1 Relative intake of energy (kcal/kg/day), protein (g/kg/day), fat (g/kg/day), and carbohydrate (CHO; g/kg/day) for wrestler (○; $n=9$; age, 15.4 ± 0.3 years) and control (●; $n=7$; age, 15.0 ± 0.4 years) groups. All subjects were tested in mid-November, 1 or 2 weeks prior to the first wrestling match (Early), 3.5–4 months later (Late) depending on when the wrestlers no longer qualified for tournament competition, and 3.5–4 months after the wrestling season ended (Post). increased LH secretion suggests a central disruption of the HPG axis, most likely a reduction in gonadotropin-releasing hormone secretion from the hypothalamus. GH-IGF-1 axis function is also disrupted (Fig. 4). Partial GH resistance occurs, as indicated by late-season elevations in serum GH concentrations while IGF-1 concentrations are reduced. Decreases

in serum growth hormone-binding protein (GHBP) concentration may also modulate serum GH concentrations. GHBP enhances the growth-promoting effects of GH. When GHBP concentrations are reduced, more GH is released to continue growth at its genetically determined rate. Reductions in GHBP concentrations may also signify a down-regulation of GH receptors since GHBP is an index of GH tissue receptor number. Down-regulation results in GH resistance and reduced growth, so even with increased GH concentrations, growth is slowed to conserve energy for critical body functions.

Although these nutritional and hormonal alterations have the potential to change the rates of growth and maturation of wrestlers during a season, the incremental growth in stature and rate of skeletal maturation of wrestlers are similar to those of controls both during and after the season (Fig. 5). However, growth of fat-free mass and other soft tissues is slowed during the season, followed by catch-up growth in the postseason (Fig. 6). Generally, wrestlers are shorter than average for their age, but this is probably due to self-selection. A cross-sectional study found that a reference group of boys was taller (1.9%) than a large group of wrestlers after the age of 16.4 years, but that the slope values for gain in height did not differ.

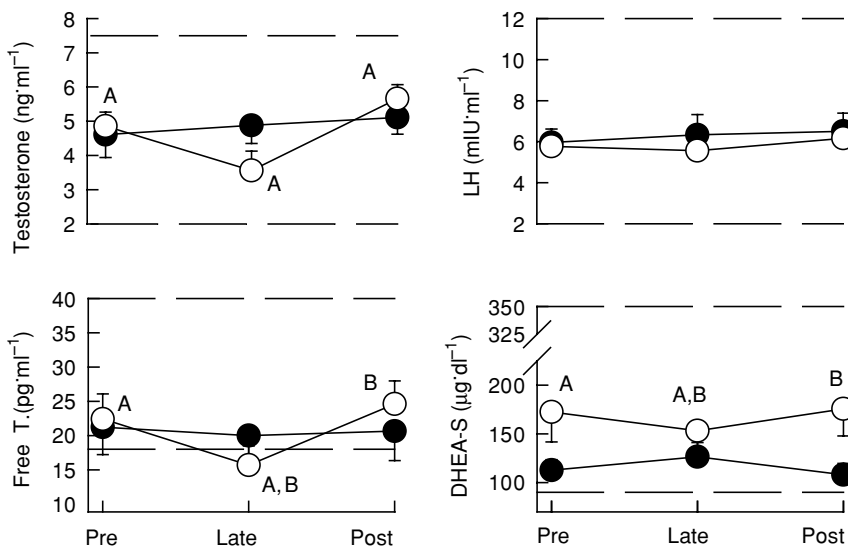

Figure 3 Mean (\pm SE) concentrations of testosterone, free testosterone (Free T), luteinizing hormone (LH), and sex hormone-binding globulin (DHEAS) in the wrestler (○; $n = 9$) and control (●; $n = 7$) groups. Like letters are significantly different ($p \leq 0.05$). Serum hormone concentrations are the mean of eight samples drawn every 20 min. Dashed lines indicate the upper and lower normal range for each hormone concentration. For definitions, see the legend to Fig. 1. Redrawn from Roemmich, J. N., and Sinning, W. E. (1997). Gymnastics

Gymnasts gain a competitive advantage when they develop muscular strength within a shorter and lighter frame. The performance of female gymnasts often decreases after the onset of puberty due to increases in height and fat mass and the development of secondary sexual characteristics. There has long been concern that gymnasts use sport training and exercise to maintain a lean physique and to delay puberty and growth,

Figure 5 Height for the wrestler (\circ ; $n=9$) and control (\bullet ; $n=7$) groups. Like letters are significantly different. Data are expressed as mean (\pm SE). and a controversial study reported the lack of a normal adolescent growth spurt. Female gymnasts training 18 h/week had a delayed age at menarche, slowed linear growth, and reduced growth potential. Leg length velocity slowed at puberty, with almost no growth after a bone age of 12 years (Fig. 7). Although additional longitudinal studies have not replicated these results, others have observed reduced serum IGF-1 concentrations in gymnasts and relatively short lower limbs of female and male gymnasts. Similar to wrestlers, the growth and maturation of gymnasts may be explained by self-selection because gymnasts tend to be the children of short parents who also had later than average puberty, and shorter limb lengths are present at baseline and do not diminish with training.

CONCLUSION

Sport training for most youth does not alter their genetically programmed growth or pubertal development. Normal linear growth encompasses the 3rd to 97th percentile for height and height velocity. When growth continues to track along the same percentile as before initiating training, there is little cause for concern. Individual differences in pubertal timing may cause some athletes to temporarily track along a new percentile. Early maturing athletes will realize an increased height percentile, whereas late-maturing athletes will have a decrease in height percentile.

Although the average height for participants in some sports may be less than the 50th percentile, this is probably due to self-selection rather than sport training. For example, boys and girls who participated in gymnastics as children and became relatively tall

may become involved in basketball or volleyball during adolescence because greater height can be a disadvantage in gymnastics but beneficial in other sports. Boys and girls with genetically determined delayed puberty and/or short stature may migrate

Figure 7 Growth in sitting height (○) and leg length (●) from bone age 10 to 16 years. Gymnasts are shown in A and swimmers in B. Note the lack of increase in leg length after bone age 12 years in the gymnasts. Reproduced from Theintz, G. E., Howald, H., Weiss, U., and Sizonenko, P. C. (1993). toward gymnastics and wrestling because their smaller size is an advantage in these sports.

When wrestlers lose weight to fill empty weight classes or to gain a competitive advantage, or when gymnasts try to delay puberty and growth through dietary restriction, undernutrition can occur. Undernutrition caused by wrestling training and dietary restriction appears to produce a disruption of the pituitary–testicular axis and partial GH resistance. Wrestling training has little effect on linear bone growth or pubertal maturation. The 3- or 4-month period of undernutrition is followed by a long period of adequate nutrition, so the period of undernourishment is not long enough to slow growth or maturation or to reduce the adult height of wrestlers. Female gymnasts who are chronically training and limiting their dietary intake may be at greater risk for limiting their growth. Gymnastics training may slow growth of the lower limbs, but more data are needed to confirm this result, and the effect of sport training and dietary restriction on the neuroendocrine axes of gymnasts has not been adequately studied. The shorter limb lengths of gymnasts may be self-selected because gymnasts have shorter limb lengths when they begin training and the limb length discrepancy does not increase with training.

IDENTIFICATION AND STRUCTURE OF RECEPTOR SERINE/THREONINE KINASES

Prior to the cDNA cloning of TGF- β family receptors, these receptors had been identified and characterized by cross-linking studies using radiolabeled ligands. By affinity labeling with radiolabeled TGF- β , three classes of receptors with distinct sizes were identified on responsive cells: type I (53 kDa), type II (75 kDa), and type III receptor (also termed betaglycan) or endoglin. Whereas type I and type II receptors were both found to be required for signaling, T β R-III and endoglin are structurally related proteins with very short intracellular domains lacking signaling motifs that are indirectly involved in signaling; T β R-III has been shown to present TGF- β to signaling TGF- β receptors.

Activins and BMPs were also found to have type I (50–60 kDa) and type II (70–80 kDa) receptors. Expression cloning of receptors for TGF- β and activin revealed that TGF- β type II and activin type II receptors encode similar transmembrane proteins that contain cytoplasmic domains with predicted serine/threonine kinase activity. Each member of the TGF- β superfamily binds to a characteristic combination of type I and type II receptors. Based on sequence similarity, cDNAs for other type I and type II receptors were identified. In mammals, five type II receptors have been identified [TGF- β type II receptor (T β R-II), activin type II and type IIB receptors (ActR-II and ActR-IIB), BMP type II receptor (BMPR-II), and MIS type II receptor (MISR-II/AMHR-II)] as well as seven type I receptors, also termed activin receptor-like kinases (ALKs) (ALK-1, ALK-2, BMPR-IA/ALK-3, ActR-IB/ALK-4, T β R-I/ALK-5, BMPR-IB/ALK-6, and ALK-7). In addition, several splice variants of type I and type II receptors have been reported, but their functions are unknown. Type I and type II serine/threonine kinase receptors are structurally similar; they have small extracellular cysteine-rich domains, single transmembrane domains, and intracellular parts that consist mainly of the serine/threonine kinase domain. The crystal structure of the ActR-II extracellular domain revealed a three-finger fold structure with a scaffold of four disulfide bridges similar to that found in several toxins and one additional disulfide bridge. Type I and type II receptors have similar folds, but sufficient differences exist to suggest that they have different binding modes to the ligand. Interestingly, the crystal structure of T β R-I kinase domain indicates that its catalytic center is more reminiscent of tyrosine kinases rather than serine/threonine kinases. Type I

Figure 1 Structures of TGF- β family type I and type II serine/threonine kinase receptors.

receptors, but not type II receptors, have a juxtamembrane region rich in glycine and serine residues (GS domain); this region plays a pivotal role in the activation of type I receptor kinases. Type II receptors, particularly BMPR-II, have longer C-terminal extensions rich in serine residues (Fig. 1), for which the function is unclear.

MECHANISM OF ACTIVATION OF TGF- β SUPERFAMILY RECEPTORS

Genetic and biochemical studies have revealed that both type I and type II receptors are essential for signaling. TGF- β_1 , TGF- β_3 , and activins bind to type II receptors and subsequently recruit type I receptors. T β R-III is required to enable binding of TGF- β_2 to T β R-II, for which it has only weak affinity. Recent elucidation of the crystal structure of T β R-II ectodomain with TGF- β_3 suggests an assembly mechanism in which the ectodomains of one T β R-I and one T β R-II bind to adjacent positions on a TGF- β monomer and make contact with each other. BMPs have high affinity for type I receptors and low affinity for type II receptors and (like TGF- β_2) display high affinity for preexisting heteromeric type I and type II receptor complexes. The crystal structure of BMP-2 in complex with two BMPR-IA ectodomains revealed that the two receptor ectodomains each contact both BMP-2 monomers on opposite sites of the symmetrical BMP-2 dimer at “wrist” epitopes, without direct contact between the

Figure 2 Mechanism of TGF- β receptor activation. (A, B) TGF- β initially binds to T β R-II. (C) Subsequently, T β R-I is recruited into the complex. (D) Thereafter, T β R-I is phosphorylated (asterisks) by the constitutively active T β R-II kinase (1). Activated T β R-I propagates the signal downstream through phosphorylation of downstream targets (2).

two type I receptor ectodomains. Differences in the mode of ligand binding between type I and type II receptors are, in part, determined by the presence of helix α_1 , unique for type I receptors, which contains a large hydrophobic amino acid residue that sticks out of the helix and that fits into the hydrophobic pocket present in the wrist epitopes of the ligands.

The type II receptor has a constitutively active kinase that, upon ligand-induced heteromeric complex formation between type I and type II receptors, phosphorylates the type I receptor predominantly on serine and threonine residues in its glycine-serine residue-rich (GS) domain. Recent structural studies on the activated T β R-I suggest that phosphorylation activates T β R-I by converting the GS domain into an efficient substrate recruitment motif and not by increasing the overall kinase activity of the type I receptor. The immunophilin FKBP-12 was identified as a type I receptor-interacting protein that binds to the unphosphorylated GS region and inhibits TGF- β signaling by blocking access of phosphorylation sites to the type II receptor kinase. Through this mechanism, FKBP-12 appears to stabilize the inactive conformation of T β R-I in the absence of ligand.

The type I receptor acts downstream of the type II receptor and, consistent with this notion, it has been shown to confer signaling specificity within the receptor complex (Fig. 2). The activated type I receptor initiates intracellular signaling by phosphorylating downstream components, including the nuclear effector proteins known as Smads. The L45 loop regions

in the kinase domain of type I receptors were found to be important determinants for signaling specificity.

ACTIVATION OF DOWNSTREAM EFFECTORS BY TGF- β FAMILY RECEPTORS

Genetic studies of *Drosophila* and *Caenorhabditis elegans* have led to the identification of a conserved family of proteins, Smads, that play a pivotal role in intracellular signaling downstream of serine/threonine kinase receptors. Smads have two regions of homology at the amino and carboxy terminals—Mad homology domains MH1 and MH2, respectively—that are connected by a proline-rich linker sequence. Based on their functional properties, Smads can be divided into three distinct subclasses:

Receptor-regulated Smads (R-Smads), which transiently interact with activated type I receptors and become phosphorylated on two serine residues in their carboxy-terminal SSXS motif. Whereas Smad2 and Smad3 are phosphorylated by T β R-I, ActR-IB, and ALK-7, Smad1, Smad5, and Smad8 are phosphorylated by ALK-1, ALK-2, BMPR-IA/ALK-3, and BMPR-IB/ALK-6.

Common-partner Smads (Co-Smads; e.g., Smad4), which assemble into heteromeric complexes with R-Smads that efficiently accumulate in the nucleus to regulate the transcription of target genes.

Inhibitory Smads (I-Smads; e.g., Smad6 and Smad7), which potentially interfere with signaling by competing with R-Smads for interaction with type I receptors, by competing with Smad4 for binding to R-Smads, or by inducing receptor degradation.

The first step in the TGF- β /Smad pathway is the recruitment of R-Smads to the receptor complex. Several proteins with scaffolding, anchoring, and/or chaperone activity have been identified that regulate or facilitate this process. Smad anchor for receptor activation (SARA) presents Smad2 or Smad3 to activated TGF- β receptor complexes, whereby SARA interacts directly with the nonactivated R-Smads and the TGF- β receptor complexes (Fig. 3). SARA is associated with membranes via its FYVE domain, which interacts with phosphatidylinositol 3-phosphate. The localization of SARA on endosomal membranes

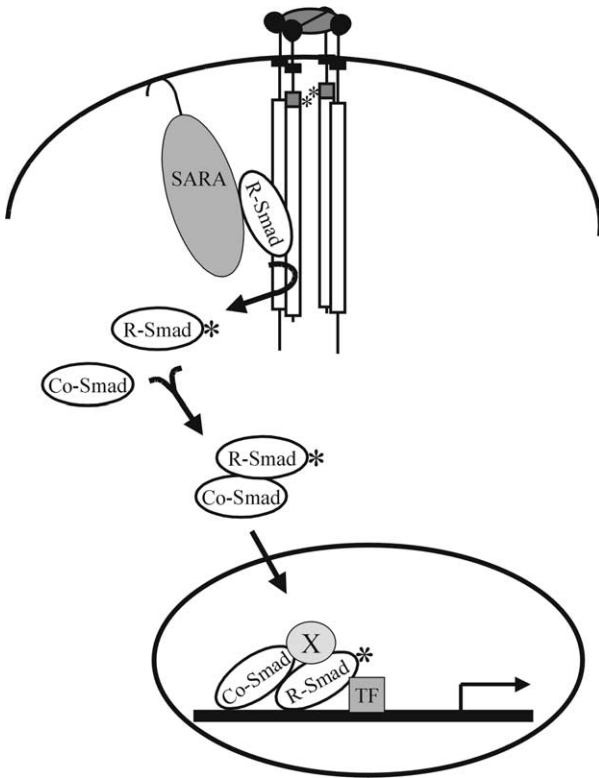

Figure 3 TGF- β /Smad signal transduction. Upon TGF- β -mediated heteromeric complex formation of T β R-I and T β R-II and activation of T β R-I by T β R-II kinase, the activated T β R-I phosphorylates Smad2 and Smad3 (R-Smad) at two C-terminal serine residues. Smad2 and Smad3 are presented to activated receptor complex by SARA. Upon their phosphorylation (asterisks), Smad2 and Smad3 assemble into heteromeric complexes with Smad4 (Co-Smad) that translocate into the nucleus. The nuclear Smad complex, in combination with other transcription factors (TF), coactivators, and corepressors (X), regulates the transcription of target genes.

suggests that TGF- β receptors may have to internalize for SARA to present the R-Smads for phosphorylation to the TGF- β receptors. Transforming growth factor- β receptor-associated protein-1 (TRAP1) binds to inactivated receptor complexes and is thought to act as a Smad4 chaperone. Following receptor activation, TRAP1 leaves the receptor complex, interacts with Smad4, and may facilitate binding of Smad4 to activated R-Smads, after which it dissociates from Smad4.

In the interaction between the activated type I receptor and R-Smad, at least two distinct regions in each protein contribute. First, the L45 loop in the type I receptor interacts with the L3 loop in the MH2 domain of the R-Smad and determines specificity between receptor and R-Smad. Second, the phosphorylated GS domain interacts with a basic surface patch in the L3 loop of the R-Smad, which ensures that only active type I receptors bind R-Smads. Thus, phosphorylation of T β R-I introduces a conformational change in the GS region, which switches this domain from a binding site for the inhibitor FKBP-12 into a binding surface for substrate. Phosphorylation of R-Smads on the last two serine residues by the type I receptor kinase triggers their assembly into trimers, mediated via conformational changes in the R-Smad MH2 domains and stabilization of the trimeric complexes through interaction of the phosphoserine binding pockets in the L3 loops with the phosphorylated C-terminal tails of neighboring R-Smad MH2 domains. The activated type I receptors and the phosphorylated C-terminal tails of R-Smads compete for the same L3 loop region of R-Smads, thus providing a mechanism by which activated R-Smads can dissociate from type I receptors. The R-Smad homotrimer is energetically less stable than the R-Smad/Co-Smad heteromeric complex, thus favoring the formation of this heteromeric complex. The stoichiometry between R-Smad and Co-Smad in the heteromeric complex is controversial.

In their basal state, R-Smads and Co-Smads are predominantly localized in the cytoplasm, and ligand stimulation induces their nuclear accumulation. R-Smads and Co-Smads were found to have a nuclear localization sequence (NLS) in their N-terminal regions. Smad4 was also found to have a nuclear export signal (NES) in its linker region. Smad4 is proposed to shuttle constitutively between the nucleus and the cytoplasm. The nuclear accumulation of the heteromeric complex may be stimulated by the shielding of the NES and/or unmasking of the NLS on R- and/or Co-Smad.

Within the nucleus, R- and Co-Smads are transcription factors; transcriptional activation is mediated

via their MH2 domains, which can recruit transcriptional coactivators CBP/p300, whereas their MH1 domains (except for Smad2) can bind to specific DNA sequences. The affinity of Smads for DNA is weak; thus, Smads need to cooperate with other DNA-binding factors to bind efficiently to promoters of target genes (Fig. 3). The first identified Smad transcriptional partner was forkhead activin signal transducer-1 (FAST-1). Smad2 also interacts with the paired-like homeodomain proteins Mixer and Milk. Interestingly, a common Smad interaction motif, containing the PPNK amino acid sequence, was identified in FAST-1 and Mixer/Milk. A large number of transcription factors, of which the activity and expression are also regulated, have been found to interact with Smads to positively or negatively regulate transcriptional responses. This explains, in part, the tissue-specific regulation of target genes by TGF- β family members.

PHENOTYPES OF TGF- β FAMILY RECEPTOR KNOCKOUTS AND TRANSGENIC MICE OVEREXPRESSING DOMINANT NEGATIVE RECEPTORS

As found for mice deficient in TGF- β_1 that are embryonic lethal, mice deficient in T β R-I, T β R-II, ALK1, or endoglin died at approximately midgestation due to defects in angiogenesis. TGF- β_1 knockout mice that survived embryogenesis through maternal supply of TGF- β died 3 or 4 weeks after birth from excessive inflammatory response. Studies using transgenic mice with conditional loss of T β R-II expression in B cells support a critical role for TGF- β in homeostasis of particular B-cell populations as well as in IgA class switching. Transgenic mice with targeted expression of dominant negative (dn) T β R-II in T cells showed impaired T-cell homeostasis, manifested by spontaneous differentiation of T cells into effector T cells, and developed autoimmune disease with inflammation of multiple organs. The effect of overexpression of dnT β R-II in transgenic mice has also been investigated in several tissue contexts. Expression of dnT β R-II in the epidermis induced a hyperplastic and hyperkerotic epidermis and led to a thickened and wrinkled skin. Overexpression of dnT β R-II in mammary glands combined with carcinogen treatment resulted in enhanced tumorigenesis in the mammary gland, whereas dominant negative interference of T β R-II signaling in the gastrointestinal tract enhanced tumor incidence after challenge with *Helicobacter pylori* or carcinogen. Overexpression of

dnT β R-II in osteoblasts resulted in an increase in trabecular bone mass due to reduced bone resorption by osteoclasts. Expression of dnT β R-II under control of a metallothioneine promoter revealed a role for TGF- β in maintaining epithelial homeostasis and the differentiated phenotype in the exocrine pancreas.

Transgenic mice lacking expression of ActR-II were viable but displayed reduced follicle-stimulating hormone levels and reproductive defects. Mice deficient in ActR-IIB died after birth with severe cardiac defects due to abnormalities in axial patterning and lateral asymmetry. Intercrossing of ActR-II^{-/-} and ActR-IIB^{-/-} mice caused embryonic lethality as a result of impaired egg cylinder formation, failure to undergo gastrulation, and impaired primitive streak formation, a phenotype that is very similar to that of mice deficient in ActR-IB. Lack of ALK2 expression leads to embryonic lethality soon after onset of gastrulation and is further characterized by defective primitive streak elongation. BMPR-II and BMPR-IA appear to play similar roles during embryonic development since mice lacking expression of either of these receptors are arrested at the egg cylinder stage, do not form mesoderm, and lack development of organized structures. Lack of proper epiblast differentiation might contribute to these developmental defects. In contrast, mice deficient in expression of BMPR-IB are viable but show defects in chondrogenesis and, as a result, in appendicular skeleton formation. Conditional loss of BMPR-IA in limb ectoderm indicates that signaling through this receptor is important for formation of the apical-ectodermal ridge and for dorsal-ventral patterning during limb development. Targeted deletion of BMPR-IA in cardiac myocytes reveals an important role for this receptor in heart morphogenesis and endocardial cushion formation at midgestation of mouse embryonic development.

HUMAN ABNORMALITIES CAUSED BY MUTATIONS IN TGF- β FAMILY RECEPTORS

Tumor cells have been shown to escape the potent growth inhibitory effects of TGF- β by decreasing receptor expression levels or by inactivating mutations in the TGF- β receptor genes. T β R-II is frequently mutated in an inherited form of colorectal cancer with a microsatellite instability phenotype. In addition, microsatellite instability in the T β R-II gene has been reported in atherosclerotic and restenotic vascular cells, providing a mechanistic explanation for the inability to inhibit their cell growth. Loss-of-functional

expression of the T β R-II receptor was found to correlate with resistance to TGF- β -mediated growth inhibition in chronic lymphocytic leukemia.

Hereditary hemorrhagic telangiectasia, a disease that manifests with vascular dilatation leading to severe hemorrhage, is caused by mutations in endoglin or ALK-1, suggesting that both receptors are involved in the same signaling pathway. Mutations in BMPR-II have been identified in patients with primary pulmonary hypertension, characterized by occlusion of small pulmonary arteries. Mutations in BMPR-IA frequently occur in patients with juvenile polyposis syndrome, indicating a role for BMPR-IA in growth control of colon epithelial cells. The majority of patients with persistent Müllerian duct syndrome, characterized by lack of regression of Müllerian derivatives leading to the development of the female reproductive tract in males, harbor mutations in either AMH or AMHR-II.

CONCLUSION

Since the identification of serine/threonine kinase receptors in animals in the early 1990s, our knowledge of them has increased dramatically; their ligands have been identified, the molecular mechanisms for activation of these receptors have been revealed, and their intracellular substrates have been identified. TGF- β family members regulate the transcriptional program of cells by specific binding and heteromeric complex formation of transmembrane serine/threonine kinase receptors, followed by phosphorylation of intracellular effector proteins called Smads. We have gained our first insights into the three-dimensional structures of the extracellular and kinase domains of TGF- β family receptors. However, further studies in which different interacting proteins are cocrystallized with the receptors will provide important information on the structural basis for the activation of serine/threonine kinase receptor complexes and the structural determinants of binding and specificity between ligand-type I/type II receptor, type I-type II receptor, and type I receptor-R-Smad interactions in various TGF- β superfamily signaling pathways. This information will perhaps make it possible to rationally design antagonists that block specific responses of TGF- β family members.

Perturbed TGF- β family signaling has been implicated in or associated with many diseases. In the near future, the translation of our findings of TGF- β signaling pathways to clinical applications will be intensely investigated. Animal models with perturbed

TGF- β signaling that mimic certain human diseases will increasingly be used to obtain new insights and methods for diagnosis, prognosis, and therapeutic intervention. The generation of floxed TGF- β receptors that allow for conditional loss of TGF- β receptors in particular tissues and at specified times will be extremely useful in this respect. Moreover, a specific TGF- β receptor kinase inhibitor was recently identified. The availability of this inhibitor not only for *in vitro* studies but also for *in vivo* studies in mouse and man and the development of specific inhibitors for type II and other type I receptors are eagerly awaited.

kinases. Phosphorylation of tyrosine residues in the activation loop induces vigorous conformational change, leading to making the space in the kinase domain where adenosine triphosphate (ATP) and the peptide

Figure 2 Model for stimulation of RTK activity by receptor dimerization. Conformation of RTK in the basal state interferes with protein substrate binding and perhaps ATP binding. The A-loop of RTK is relatively mobile. In the absence of ligand, the probability of a trans-autophosphorylation event occurring between randomly colliding receptor is low (step 1). Binding of ligand to the extracellular domain substantially increases local receptor (substrate/enzyme) concentration, providing sufficient opportunity for trans-autophosphorylation of the A-loop to occur (arrow). Autophosphorylation of A-loop tyrosine(s) shifts the A-loop equilibrium toward the active conformation, accommodating substrate binding and facilitating the proper position of residues involved in Mg-ATP binding (step 2). Autophosphorylation occurs on additional tyrosines (arrowhead) that serve as binding sites for downstream signaling proteins (step 3). From Hubbard *et al.*, 2002.

as substrate can enter. This status is the activated condition of the tyrosine kinase.

Following RTK activation, the initial intracellular signaling events occur. Dimerized RTKs phosphorylate the mutual tyrosine residues in the cytoplasmic region of the coupled receptors (Fig. 3A, step 1). In the next step, the phosphorylated tyrosine, with a few amino acids in the activated RTK, is capable of binding to the proteins that are able to bind to phosphorylated tyrosine residue with a specific module. This module is the SH2 (Src homology 2) domain and the PTB (phosphorylated tyrosine binding) domain (Fig. 3A, step 2). In response to extracellular stimuli, RTK transmits the signals to the small G protein Ras, which works as the molecular “on/off switch” for cell proliferation/differentiation signals. Also, Ras is activated by the guanosine diphosphate (GDP)/guanosine triphosphate (GTP) exchange protein Sos. However, RTKs do not bind directly to Sos. The adapter protein Grb2 mediates the interaction between RTK and Sos. Grb2 contains the SH2 domain, which binds to phosphorylated tyrosine of the activated RTK (Fig. 3A, step 3).

The SH2 domain consists of approximately 100 amino acids. The distinct SH2 domain recognizes different amino acid motifs. For example, the SH2 domain of p85 (phosphatidylinositol 3-kinase [PI3K]) binds to the pY-X-X-M motif (where pY = phosphorylated tyrosine and X = arbitrary amino acids). The SH2 domain of Grb2 binds to the pY-X-N-X motif. Also, the SH2 domain of phospholipase C γ (PLC γ) binds to the pY-(V/I/L)-X-(V/I/L) motif, and the SH2 domain of SHP2 binds to the pY-(I/VB)-X-(V/I/L)

Figure 3 Sequence of events following RTK activation. (A) Adapter molecules mediated signaling events. Receptor dimerization leads to autophosphorylation of the noncatalytic region of the cytoplasmic domain, creating docking sites for downstream cytoplasmic targets (step 1). Phosphorylated tyrosine of RTK is recognized by the SH2 or PTB domain of adapter proteins such as Grb2 (step 2). Adapter protein constitutively associates with GDP/GTP exchange proteins such as Sos. Sos, which is recruited to RTK with Grb2, activates Ras (step 3). (B) Docking molecules mediated signaling events. Phosphorylated tyrosine of RTK is recognized by the SH2 domain of docking molecules such as IRS1, FRS2, or Gab1 (step 1). Subsequently, docking molecules are also phosphorylated (step 2) and phosphorylated tyrosine is further recognized by the SH2 domain of various effectors such as PI3K, SHP2, and Grb2 (step 3).

motif (Fig. 4A). Also, the F-L-V-R-E-S sequence in the SH2 domain is required for binding to the phosphorylated tyrosine residue. In particular, the positive charge of the basic amino acid arginin (R) in the F-L-V-R-E-S sequence is critical to electrically bind to the negative charge of phosphorylated tyrosine (Fig. 4B). In addition, other major signaling pathways of activated RTK for cell growth or differentiation are the PI3K–Akt pathways and the PLC γ –calcium pathways. PI3K and PLC γ also contain the SH2 domain and bind directly to activated RTK, leading to their activation. The PTB domain is the other module to recognize phosphotyrosine. The PTB domain consists of approximately 150 amino acids. The consensus-binding motif of the PTB domain is N-P-X-pY. However, some of the PTB domain binds to N-P-X-Y (nonphosphorylated tyrosine). On the other hand, the group of “docking molecules” works as the signal amplifier. Docking molecules bind

to activated RTK with its SH2 domain, and this is followed by phosphorylation at its multiple tyrosine residues. Subsequently, multiple phosphorylated tyrosine residues of docking molecules recruit multiple effector proteins with their SH2 domain, enabling amplification of the RTK signaling (Fig. 4B).

Furthermore, physical association between Grb2 and Sos is mediated by the interaction between the SH3 (Src homology 3) domain of Grb2 and the prolin-rich motif of Sos (Fig. 3A). The prolin-rich motif is B-X- ϕ -P-X- ϕ -P or ϕ -P-X- ϕ -P-X-B (where B = basic amino acid and ϕ = aliphatic amino acid). An additional important domain for RTK signal transduction is the PH (pleckstrin homology) domain. The PH domain binds to PI. PIs are the products of PI3K such as PI-(3,4,5)-P $_3$ and PI-(3,4)-P $_2$. Because PIs are produced on the plasma membrane, the function of the PH domain is to recruit proteins to the plasma membrane. Such translocation to the plasma membrane is critical for the activation of many signaling proteins.

DOWNSTREAM SIGNALING MOLECULES OF RTK

One of the final signaling targets of the RTK pathway is activation of the transcription factors. The main pathway leading to the activation of transcription factor is divided into two parts: one to induce Ras activation and the other to induce activation of the transcription factor. Activation of Ras requires the exchange of Ras-bound GDP to GTP that is catalyzed by the GDP/GTP exchange factor (GEF), Sos. Activated RTK recruits a Grb2–Sos complex. Translocation of Sos at the RTK on the plasma membrane enables interaction with and activates Ras. Meanwhile, many RTKs phosphorylate the docking proteins, which recruit multiple Grb2–Sos complexes. For example, on stimulation with fibroblast growth factor (FGF), the FGF receptor binds to and phosphorylates the docking protein FRS2 (Fig. 3B). Subsequently, phosphorylated FRS2 recruits multiple Grb2–Sos molecular complexes, leading to enhanced Ras activation. Also, FRS2 recruits SHP2 (Src homology 2 containing phosphatase 2). SHP2 also works as adapter molecules for the Grb2–Sos complex, leading to Ras activation. Thus, docking molecules amplify the signals to activate Ras. Activated Ras leads to activation of the serine/threonine kinase cascade following activation of the transcription factor.

The other final target of the RTK signaling pathway is the cytoskeleton, whose regulation changes the

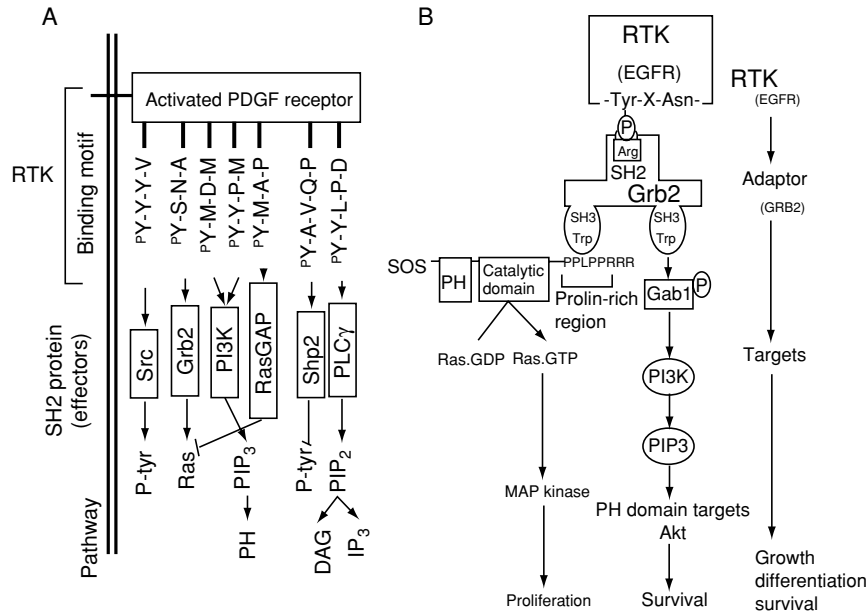

Figure 4 Illustration of phosphotyrosine sites of RTK being recognized by SH2 domains of different effector proteins. (A) Stimulation of PDGF receptor leads to autophosphorylate multiple tyrosines. A distinct phosphotyrosine motif recruits the SH2 domain of different effectors. (B) Arginin in the F-R-V-R-E-S motif in the SH2 domain plays a critical role in interaction with phosphorylated tyrosine of RTK. Grb2 binds to Sos, leading to Ras-MAP kinase activation and then to cell proliferation. Also, the SH3 domain of Grb2 binds to docking protein Gab1, which binds to PI3K, followed by activation of Akt, eventually leading to cell survival. Thus, activated RTK binds to adapter/docking molecules that associate with and activate multiple effectors. From Pawson, T. (2002). Regulation and targets of receptor tyrosine kinases. *Eur. J. Cancer* 38, S3-S10.

cell shape. Rho family small G protein plays a critical role in regulation of cytoskeleton structure. RTK also activates the GEF for Rho family GTPase. For example, the guanine nucleotide exchange factor (GEF) for Rho family small G protein, ephexin, binds to RTK (EphA). Subsequently, EphA activates Rho, leading to a change of cytoskeleton such as the regression of the growth cone of neurite.

POSITIVE EFFECTORS IN THE RTK SIGNALING PATHWAY

Ras

Ras works as the on/off switch in the signaling of molecules leading to cell proliferation. Ras is farnesylated at the C-terminal cysteine residue, which anchors Ras to the cytoplasmic membrane. This anchoring is critical for activation of Ras. Activated Ras recruits the serine/threonine kinase, Raf, to the plasma membrane following autophosphorylation of Raf at serine 388 and its activation. Activated Raf elevates the activity of the MEK-KAPKK-MAPK cascade, leading to activation of the transcription factor Elk1. Other

effectors of Ras are PI3K and RalGDS, which regulate cytoskeleton structure.

Rho Family Small GTP-Binding Protein

On stimulation with growth factor, the change of the cytoskeleton structure, including plasma membrane ruffling, lamellipodia protrusion, and eventually cell migration, occurs. Rho promotes the formation of F-actin stress fiber and focal contact. Rac promotes lamellipodial formation, and Cdc42 promotes filopodia formation. Stimulation of RTK induces activation of Rho family small G protein, leading to change of the cytoskeleton structure. For example, activated platelet-derived growth factor (PDGF) receptor associates with the molecular complex Ras-GTPase-activating proteins (GAP) with RhoGAP. Also, the GEF for Rac/Rho, Vav, is activated by tyrosine phosphorylation. Furthermore, the RTK Eph receptor is involved in cell migration and formation of neuronal and vascular network. Eph binds to ephexin, the GEF for Rho family GTP-binding protein. Ephexin activates RhoA and, in contrast, inactivates Rac as well as Cdc42. Hence, tyrosine kinases regulate Rac, Rho,

and Cdc42 through their GAP or GEF, leading to cytoskeleton regulation.

The effector of Rho for the change of cytoskeleton structure is the serine threonine kinase ROCK. Another effector of Rho is mDia, which leads to promotion of actin polymerization. The effector of Cdc42 is the neural Wiskott–Aldrich syndrome protein (N-WASP). Also, the effector of Rac is the WASP family verprolin-homologous protein (WAVE). The WASP family protein contains a VCA (verprolin, cofilin, and actin) domain that binds to the actin monomer and actin-related proteins 2 and 3 (Arp2 and Arp3), leading to promotion of F-actin polymerization with the role of Arp2 and Arp3 as the core.

PI3Kinase

PI3K is the heterodimer of the p85 subunit with the p110 subunit. The p85 subunit contains the SH2 domain, which recognizes the p-Y–M–X–M motif (where p-Y = phosphorylated tyrosine, M = methionine, and X = arbitrary amino acid) of an activated receptor. The interaction of the p85 domain with the phosphorylated receptor activates the kinase activity of the p110 subunit. The p110 subunit phosphorylates the 3-position of PI, PI-(4)-P, and PI-(4,5)-P2 to produce PI-(3)-P, PI-(3,4)-P, PI-(3,4,5)-P3, and PI-(3,4)-P3 that recruit the PH domain-containing proteins such as serine/threonine kinases PDK and Akt as well as tyrosine kinase Btk. Akt phosphorylates the pro-apoptotic protein Bad, which traps it to 14-3-3 protein on the plasma membrane.

On the contrary, the phosphorylated 3-position of PI-(3,4,5)-P3 is dephosphorylated by phosphatase and tensin homologue (PTEN). Actually, Akt or PI3K works as an oncogene, whereas PTEN works as a tumor suppressor gene.

PLC γ

PLC γ also contains the SH2 domain, which makes its translocation to the activated RTK. Then, PLC γ is phosphorylated and activated. PLC γ hydrolyzes PI, leading to the production of diacylglycerol (DAG) and inositol-(1,4,5)-triphosphates (IP3). The former activates protein kinase C, whereas the latter elevates cytoplasmic calcium concentration by its mobilization from the endoplasmic reticulum (ER). Both molecules activate versatile signaling pathways. The vascular endothelial growth factor (VEGF) receptor activates Raf–MEK–MAPK pathways by activation of PLC γ without Ras activation.

STAT

Signal transducers and activators of transcription (STAT) family proteins are activated by the non-receptor-type tyrosine kinase JAK in the cytokine receptor signaling pathway, and subsequently it translocates to the nucleus as transcription factors. Also, STAT activation is required for the epidermal growth factor (EGF) receptor signaling pathway to lead MAP kinase activation and gene expression.

NEGATIVE EFFECTORS IN THE RTK SIGNALING PATHWAY

Although plasma membrane receptors transmit “positive signaling” involved in cell stimulation and induction of various cellular responses, specific mechanisms have evolved to ensure that appropriate thresholds of signals are achieved and maintained for the right length of time. These mechanisms are referred to as “negative signaling.” In most cases, the same receptor simultaneously induces positive and negative pathways that appear to be functionally connected by numerous feedback mechanisms. A delicate balance between positive and negative signals is critical for normal cell homeostasis, and its deregulation is often implicated in the development of human diseases. Transient inhibition interferes with the strength and duration of the signal in a defined window of time, thereby fine-tuning signal transduction. Several regulatory mechanisms for RTK signaling pathways have been clarified. One example is degradation of the receptor and its ligand by endocytosis followed by degradation in lysosome (Fig. 5). Also, there are negative regulatory molecules specific for each signaling molecule (Fig. 5). Many protein tyrosine phosphatases (PTPs) dephosphorylate and inactivate the protein tyrosine kinases. RasGAP inactivates Ras. MAP kinase phosphatase (MKP) dephosphorylates and inactivates MAP kinase. This section discusses the main negative regulatory molecules.

Protein Tyrosine Phosphatase

Dephosphorylation of RTK by PTPs is the most elucidated mechanism for inactivation of RTK signaling pathways. Dephosphorylation of activation loop sites in RTK leads to inactivation of the kinase domain, whereas phosphate removal from docking tyrosine blocks activation of specific signaling pathways. The function of PTP is tightly regulated by the change of its localization within the cell. For example,

Figure 5 Illustration of Grb2 playing role as negative regulator in RTK signaling pathway. The adapter protein Grb2 serves as a regulated scaffold for the binding of other signaling proteins that include both positive (Sos) and negative (Cbl, Sprouty, SHIPs, and SOCS suppressors of cytokine signaling) regulators. In that way, Grb2 can link RTKs with activation of the Ras–MAP kinase pathway via its association with Sos while it promotes receptor ubiquitination and endocytosis by binding to the Cbl–CIN85–endophilin complex. Furthermore, Grb2 recruits Sprouty, SHIPs, and SOCS to further attenuate receptor signaling pathways. Ub, ubiquitin. From Dikic, I., and Giordano, S. (2003). Negative receptor signalling. *Curr. Opin. Cell Biol.* 15, 128–135.

the PTP SHP1 is recruited to the activated RTK Kit (the receptor for the stem cell factor), with interaction of SH2 domains of SHP1 with phosphorylated tyrosine of Kit, and subsequently inactivates it by dephosphorylation. Also, the PTP 1B (PTP1B) colocalizes with the activated PDGF receptor, which is internalized at the ER, followed by its inactivation. Inactivation of RTK reduces its biological function. For example, PTP1B dephosphorylates the insulin receptor, leading to reduced insulin action or so-called insulin resistance. On the other hand, SHP2 associates with the phosphorylated receptor with its SH2 domain and works as an adapter for transmitting the positive signals into the Grb2–Sos–Ras pathway. For example, insulin-induced binding of SH-PTP2 to IRS-1 generates the signal to activate the Ras protein.

SHIP and PTEN

Both the SHIP (Src homology inositol phosphatase) and PTEN molecules block the PI3K-signaling pathway by degradation of the PI3K products,

PI-(3,4,5)-triphosphate. SHIP dephosphorylates the 5'-position of PI-(3,4,5)-P₃, leading to the production of PI-(3,4)-P₂. SHIP is recruited to the phosphorylated immune tyrosine-based inhibitory motif (ITIM) of the immunological receptors with its SH2 domain and inhibits RTK–PI3K signals. PTEN negatively dephosphorylates the 3'-position of PI-(3,4,5)-P₃, leading to the production of PI-(4,5)-P₂.

Cbl

Cbl is the cytoplasmic protein that consists of the SH2 domain and RING finger domain at the N-terminal region as well as the proline-rich motif. Cbl works as negative regulatory molecules for RTK. Cbl binds to activated RTKs through its SH2 domain and subsequently works as an E₃ ubiquitin ligase and interacts with enzymes of the E₂ type such as UbcH7 by the RING finger domain, leading to ubiquitination of tyrosine kinase and eventually its degradation. In addition, Cbl regulates endocytosis of RTK by binding to the CIN85–endophilin complex. Interaction between CIN85 and Cbl is mediated by binding of the SH3 domains of CIN85 to the C-terminal region of Cbl (Fig. 6). The proline-rich motif in CIN85 mediates its constitutive association with the SH3 domain of endophilins, a family of proteins able to regulate negative curvature of the plasma membrane during the early steps of endocytosis. Inhibition of Cbl–CIN85–endophilin interaction was sufficient to block endocytosis of RTK following its degradation (Fig. 5).

SOCS

Suppressor of cytokine signaling (SOCS) is the inhibitory molecules for the cytokine receptor–JAK–STAT signaling pathway. SOCS1/JAB1 (JAK-binding protein) directly binds to JAK. SOCS2 binds to the cytokine receptor, or SOCS3/CIS3 binds to both the receptor and JAK. Subsequently, SOCS family proteins inhibit the cytokine receptor signaling pathway. Besides cytokine receptor signaling molecules, SOCS2 inhibits the insulin-like growth factor (IGF) receptor signaling pathway.

Negative Regulation for RAS

Ras is one of the most important molecules for cell proliferation. This is assumed from the evidence that the constitutive active mutant of Ras was detected in 30% of cancer. Therefore, to protect excessive activation of Ras, its activation should be tightly regulated. Although Ras itself has intrinsic GTPase activity that converts GTP-bound Ras (activated form) to

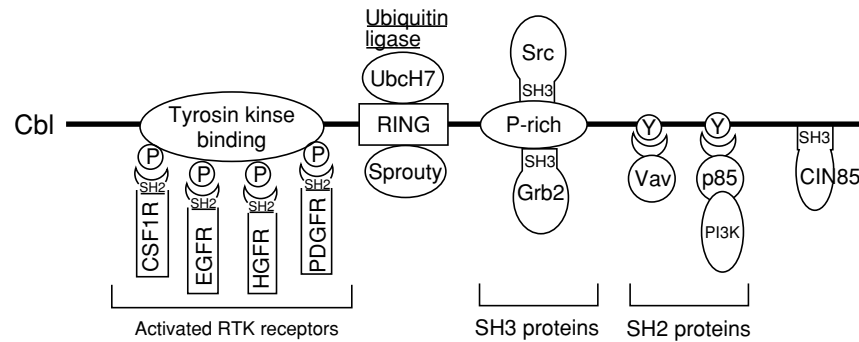

Figure 6 Cbl, a ubiquitin ligase and a multiadapter protein. Cbl consists of several distinct domains. The amino-terminal portion contains the tyrosine kinase-binding domain that interacts with activated RTKs. Cbl is an E₃ ubiquitin ligase and interacts with enzymes of the E₂ type such as UbcH7. The RING finger domain is responsible for Cbl enzymatic activity. A prolin-rich (P-rich) motif is critical for interaction with SH3-containing proteins such as Grb2 and Src. The Cbl carboxyl terminus contains several tyrosine residues (Y) that, on phosphorylation (P), interact with SH2-domain-containing proteins such as Vav and the regulatory subunit of PI3K (p85). The binding site for the SH3 domains of CIN85 is found in the distal carboxyl terminus of Cbl. From Dikic, I., and Giordano, S. (2003). Negative receptor signalling. *Curr. Opin. Cell Biol.* **15**, 128–135.

GDP-bound Ras (inactivated form), its intrinsic activity is not enough for full inactivation of Ras. Therefore, RasGAP is responsible for full extinction of Ras activity. Meanwhile, the adapter molecule Dok, which binds to RasGAP, also works as a negative inhibitor for the Ras–MAP kinase pathway. In *Drosophila*, RasGAP associates with pY918 of torso RTK and works as a negative effector for signaling molecules of torso. Also, PTP corkscrew (CSW), which associates with pY630, specifically dephosphorylates the negative pY918 torso signaling site, and CSW serves as an adapter protein for DRK (Grb2 homologue) binding, physically linking torso to Ras activation. Thus, opposing actions of CSW and RasGAP modulate the strength of the torso RTK signals. Also, PI3K-dependent membrane recruitment of Dok is essential for its negative effect on mitogen-activated protein. Thus, RasGAP negatively regulates the RTK signaling pathway *in vivo* (Fig. 7).

Rap-1 also works as an inhibitor for Ras. Although Rap-1 is the small GTP-binding protein and has a structure similar to that of Ras, it inhibits activation of Ras. The balance between Rap-1 and Ras is important for cell condition. In the immune-ergic or immune-tolerant condition of the T cell, Rap-1 is dominant. Also, insulin regulates the dynamic balance between Ras and Rap1 signaling by coordinating the assembly states of the Grb2–SOS and CrkII–C3G complexes.

Grap has a structure similar to that of Grb2 and the SH2–SH3–SH2 domain. Grap couples with tyrosine kinases and suppresses the RAS/MAP kinase pathway.

Negative Regulator for the Ras–MAP Kinase Pathway and Sprouty

Sprouty was recently found to be an inhibitory factor for Raf kinase in the FGF receptor signaling pathway that is involved in formation of bronchial branching in *Drosophila*. Four homologous proteins in the Sprouty family were found. The transcription of Sprouty was induced by MAP kinase on stimulation with EGF as well as FGF. Also, Sprouty inhibited VEGF-induced endothelial cell proliferation and angiogenesis. Although the inhibitory mechanism of Sprouty in the growth factor receptor signaling pathway has not been elucidated in detail, in *Drosophila* it has been shown to inhibit the Grb2 homologue Drk and may also inhibit Raf.

Also, Spred (Sprouty-related EVH1-domain containing) proteins are identified. Spred proteins are able to inhibit Ras–MAP kinase signaling by interfering with Raf kinase activation without reducing Ras activity.

CONCLUSION

Stimulation of RTK leads to multiple cellular functions that depend on protein–protein, protein–phospholipid, and protein–nucleic acid interactions. Protein interaction domains and motifs provide a basic mechanism to organize signaling pathways and other forms of information of transfer in cells (e.g., cell cycle, protein trafficking, gene expression, DNA repair). The combination use of interaction domains

Figure 7 Negative regulators for the RTK–Ras–MAP kinase pathway. Signaling molecules of the RTK–Ras–MAP kinase pathway are negatively regulated by several inhibitors. Phosphorylated tyrosine is dephosphorylated by protein tyrosine phosphatase. Activated (GTP-bound) Ras is converted to inactivated (GDP-bound) Ras by RasGAP. Also, RasGAP is recruited to RTK by the adapter molecule Dok. Sprouty and its related molecule, Spred, recently have been shown to possibly inhibit Grb2, Ras, or Raf. MAP kinase is dephosphorylated by MKP. Expression of Sprouty, Spred, or MKP is increased under the MAP kinase pathway.

has allowed the creation of novel signaling pathways and networks. Although much progress has been made in understanding the outline of the RTK signaling pathway, it is still difficult to explain diversity of the cell biological phenomenon. More effort is required to link findings in signal transduction to the cell biological phenomenon.

Recklinghausen's Disease

see Neurofibromatosis

during the early 1980s and served thereafter as a paradigmatic signal transduction pathway for “Ca²⁺-mobilizing” receptors. The subsequent years have seen the emergence of many additional phospholipases that were found to be activated in a signal-dependent manner. The phospholipid substrates of SAPLs include not only quantitatively minor membrane constituents, such as PIP₂ and phosphatidic acid (PA), but also major structural building blocks of the bilayer, such as phosphatidylcholine (PC), phosphatidylethanolamine (PE), and sphingomyelin (SM). Thus, PI-PLC turned out to be a model for a large number of SAPLs, including phospholipases of the types A₂, C, and D, which use various phosphoinositides, PC, PE, PA, and SM as substrates. SAPLs are coordinately activated by given receptor agonists in a defined cell type-specific sequence and play important roles in cell regulation. This article reviews the major classes of SAPLs, emphasizing established facts pertaining to their structure, activity, localization, receptor activation, targets, and functions.

PHOSPHOINOSITIDE-SPECIFIC PHOSPHOLIPASE C

Overview

The first and best characterized among the SAPLs, PI-PLC catalyzes the hydrolysis of PIP₂ to form two messengers, inositol-1,4,5-trisphosphate (IP₃) and 1,2-*sn*-diacylglycerol (DAG), that target Ca²⁺ storage organelles and protein kinase C (PKC), respectively. The PI-PLC family is now known to include 11 mammalian isozymes in four classes: PLCβ(1–4), PLCγ(1,2), PLCδ(1–4), and PLCε. PI-PLC isozymes exhibit only subtle differences in their catalytic properties but have distinct tissue-specific expression and mode of activation. The emerging picture is one where enzymes that belong in different PI-PLC classes are regulated by different mechanisms. The mechanisms of activation of two isozymes, PLCβ₁ and PLCγ₁, are particularly well understood and involve interactions with stimulatory guanine nucleotide-binding (G) proteins and tyrosine kinases, respectively. PLCβ₁ is activated by members of the G_q class of pertussis toxin-insensitive G proteins. PLCγ₁ is activated by phosphorylation on specific tyrosine residues by receptor tyrosine kinases as well as by the cytoplasmic, receptor-activated Src family tyrosine kinases.

Structure and Catalytic Properties

All mammalian PI-PLC genes share a catalytic core consisting of two conserved, noncontiguous domains

designated X and Y. In addition, all PI-PLCs have an N-terminal pleckstrin homology (PH) domain and an EF-hand domain as well as a C-terminal C2 domain. PLCδ, considered to be an archetypal PI-PLC isozyme, contains only these five structural elements. PLCβ has an additional C-terminal “tail” domain with a PDZ-binding motif. PLCγ has a large insert between domains X and Y that includes a second split PH domain, two SH2 domains, and an SH3 domain. PLCε has an N-terminal RasGEF domain and two C-terminal RA domains. The function of these domains in regulation of PLC activity of the different isozymes is discussed later. All PI-PLC isozymes hydrolyze PIP₂ exclusively in a catalytic mechanism that requires Ca²⁺ ions. The membrane association of PLCδ by a “tether and fix” mechanism may be generalized for the binding of the catalytic core of all PI-PLCs. According to this theory, PLCδ is initially tethered to PIP₂ by the PH domain, and this is facilitated by binding of Ca²⁺ to the EF domain. The enzyme is then fixed to the bilayer by formation of a ternary complex among Ca²⁺, phosphatidylserine (PS), and the C2 domain, allowing interaction of the catalytic domains with the PIP₂ substrate. The hydrolysis of PIP₂ then occurs by a sequential reaction mechanism that involves a general acid–base catalysis with formation of a cyclic inositol phosphate intermediate. A Ca²⁺ ion within the catalytic pocket plays an important role in catalysis, and the hydrophobic rim of the active site is necessary for penetration of the active site into the bilayer. In PLCβ and PLCγ, the tethering of the enzyme to the membrane involves interaction of the PH domain with phosphatidylinositol 3-P and phosphatidylinositol 3,4,5-trisphosphate (PIP₃), respectively. This interaction may be part of these isozymes’ activation mechanism.

Receptor-Mediated Activation

PI-PLC isozymes are normally cytosolic proteins that are translocated to the plasma membrane on receptor activation. PLCβ₁ and PLCβ₃ are relatively widely expressed, whereas the expression of PLCβ₂ and PLCβ₄ is limited to hematopoietic cells and the brain, respectively. All PLCβ forms are stimulated by G protein-coupled receptors (GPCRs) through direct interaction with the subunits of activated G_q subfamily proteins. Ligand binding to relevant GPCRs results in exchange of guanosine diphosphate (GDP) for guanosine triphosphate (GTP) on the Gα-subunit and subsequently dissociation of the Gβγ dimer. The active, GTP-bound α-subunit interacts with the C-terminal tail region of PLCβ, where it binds the C2 domain and

two clusters of basic residues. The G $\beta\gamma$ dimer is also involved in activation of PLC β isozymes, especially of PLC β 2, with which it interacts with high affinity via the latter's PH domain. PLC γ 1 is expressed ubiquitously, and PLC γ 2 is expressed mainly in the hematopoietic system. PLC γ 1 is recruited via its N-terminal SH2 domain to specific phosphotyrosine residues on activated receptor tyrosine kinases. PLC γ 1 is then phosphorylated on three tyrosine residues. Both association and tyrosine phosphorylation are essential for activation of PLC γ 1 by growth factors receptors. Full activation also requires the production of PIP $_3$, which participates in membrane association of PLC γ 1 by interaction with its PH domain and/or the C-SH2 domains. The activation of PLC γ 1 and PLC γ 2 by immune cell receptors is similar in principle, except that PLC γ is recruited to phosphotyrosine residues on adapter/scaffold proteins that are phosphorylated by nonreceptor Src-like kinases. PLC δ , the smallest and likely the archetypal PI-PLC, is most sensitive to Ca $^{2+}$ ions and is believed to be regulated primarily by changes in intracellular Ca $^{2+}$ concentrations, secondary to activation of other Ca $^{2+}$ -mobilizing pathways. The most recently discovered isozyme, PLC ϵ , has both Ras activation and Ras effector domains, strongly suggesting that Ras is involved in its regulation, but the details of the bidirectional relationship between these two enzymes are not clear. It should be noted that in addition to PI-PLC-mediated signaling in the plasma membrane, PIP $_2$ hydrolysis may occur intracellularly, for example, in the nucleus and the Golgi apparatus. The mechanisms of PI-PLC activation in endomembrane compartments and its function(s) remain to be fully elucidated.

Targets of IP $_3$ and DAG

IP $_3$ mobilizes Ca $^{2+}$ ions from intracellular stores in the endoplasmic reticulum (ER) by interacting with a family of IP $_3$ receptors, ion channels that allow efflux of sequestered Ca $^{2+}$ to the cytosol. IP $_3$ may be converted to other inositol phosphates by one or more inositol ring phosphorylation/dephosphorylation reactions, but the specific functions of the resulting inositides are not fully established. DAG is involved in membrane translocation and activation of PKC isozymes. DAG interacts with an N-terminal C1 domain found in conventional (PKC α , β , and γ) and novel (PKC δ , ϵ , η , and θ) isoforms as well as in protein kinase D. The C1 domain is also found in nonkinase proteins such as RasGRPs, chimaerins, and Munc13 isoforms that act as phorbol ester receptors and potentially also serve as downstream targets of DAG.

PHOSPHOLIPASE D

Overview

Phospholipase D (PLD) hydrolyzes phospholipids to PA and a free polar headgroup. PLD activity is rapidly and dramatically activated in response to extracellular stimuli. The signal-dependent activation of PLD was demonstrated in numerous cell types stimulated with various hormones, growth factors, cytokines, neurotransmitters, adhesion molecules, drugs, and physical stimuli. Studies into the mechanisms of receptor-PLD coupling have implicated multiple pathways, including small GTPases, Ser/Thr kinases, and tyrosine kinases. A number of eukaryotic PLD genes have been identified, including numerous plant genes, a yeast PLD gene, and two mammalian genes: PLD1 and PLD2. Significant advances were made in understanding the structure, regulation, and localization of PLD1 and PLD2, but less is known about their isoform-specific functions. Mammalian PLD1 and PLD2 hydrolyze PC preferentially. It is generally assumed that PA is the major messenger molecule generated by PLD. However, the molecular targets of PA *in situ* have not been identified.

Structure and Catalytic Properties

Most mammalian PLD genes cloned so far belong to an extended gene superfamily, designated the "HKD" superfamily, that includes the eukaryotic PLDs, certain bacterial PLDs, phosphatidyltransferases/phospholipid synthases, endonucleases, and certain viral envelope proteins and their mammalian homologues. All members of this superfamily share a conserved motif (HxKx $_4$ Dx $_6$ GG/S) that confers a similar mechanism of catalysis. Mammalian PLD1 and PLD2 have a catalytic core region with significant internal homology between its N- and C-terminal halves. Noncatalytic N-terminal sequences include a Phox (PX) domain and a PH domain, both implicated in phospholipid binding and protein-protein interactions. An essential C-terminal region is also present.

Subcellular Localization and Receptor-Mediated Activation

The precise localization of PLD1 and PLD2 is cell type and cell state specific. However, some common themes have emerged. Subcellular fractionations have demonstrated the presence of mammalian PLD1-like activities in multiple cellular membranes, including the nuclear envelope, ER, Golgi apparatus, transport/

secretory vesicles, and plasma membrane. In further studies, PLD1 localization was found predominantly in a perinuclear endomembrane system, including the Golgi apparatus and vesicles identified by organelle-specific markers as comprising the endosomal/lysosomal compartment. PLD1 is transiently translocated to the plasma membrane on stimulation of exocytosis in secretory cells. In contrast to PLD1, in resting cells, PLD2 is localized mainly in the plasma membrane, where it is associated in part with lipid rafts and caveolae. On stimulation, PLD2 is internalized to an endocytic compartment. Additional evidence suggests a role for PLD2 in receptor-mediated endocytosis. Finally, like PLD1, PLD2 also was localized to the Golgi apparatus. Receptor-mediated activation of PLD is complex and still incompletely understood. The activity of PLD1 is strictly receptor dependent and involves its interaction with proteins of the ARF, Rho, and PKC families. GPCRs activate PLD1 via a mechanism that requires PKC α and RhoA as upstream regulators, whereas its activation by immunoglobulin receptors requires Rac1 and ARF6. The activation of the Rho and ARF GTPases depends on stimulation of upstream exchange factors that, in turn, are recruited and stimulated by products of phosphoinositide 3-kinase and PI-PLC. However, much further work is required to fully elucidate these pathways in different cells stimulated by different receptor types. The regulation of PLD2 activity is less well understood and is certainly less signal dependent as compared with PLD1.

Targets of PA and PA Metabolites

Numerous studies have described *in vitro* effects of PA on various enzyme activities. PA stimulates Ser/Thr kinase activity in cell extracts, although the specific kinases were not yet identified. PKC isoforms that are activated by PA *in vitro* include PKC η and PKC ζ . More recently, PA was reported to interact with Raf1, a MEK kinase in the Erk1/2 cascade. A PA-activated tyrosine kinase activity present in neutrophil cytosol was identified recently as the proto-oncogene c-Fgr. Conversely, a protein tyrosine phosphatase (PTP1C/SHP1) was also shown to bind to, and be activated by, PA. Similarly, both a lipid kinase involved in biosynthesis of PIP₂ (PI 4-phosphate 5-kinase- α) and a PIP₂-specific phospholipase C (PLC γ) are regulated by PA *in vitro*. In addition, PA regulates the activity of several GTPases (e.g., ARF, dynamin) and GTPase-activating proteins (GAPs) as well as at least one cyclic AMP (cAMP) phosphodiesterases (PDE4D3 and PDE4A1).

Recently, PA was implicated as an activator of mTOR, a PI kinase-like protein involved in mitogenic signaling and reorganization of the actin cytoskeleton. Although PA-sensitive enzymes are candidate PA targets, direct evidence showing interaction with and regulation by PA *in situ* is still lacking and signaling pathways wherein PA produced by PLD plays an essential role have not been elucidated. Finally, it should be noted that PA may be converted into other signaling molecules (e.g., lyso-PA, DAG) that may act as additional downstream mediators of PLD activation. DAG may activate PKC isozymes and other targets, whereas lyso-PA is a ligand of the Edg GPCR family.

SPHINGOMYELINASE

Overview

Certain cytokines, neurotropic factors, apoptosis-inducing stimuli (e.g., cytotoxic drugs, loss of survival factors), and other environmental stresses trigger the cellular accumulation of ceramide. Receptor agonist-dependent production of ceramide occurs predominantly via activation of sphingomyelinase (SMase), a specific phospholipase C-type enzyme that catalyzes SM hydrolysis to ceramide and phosphocholine. However, *de novo* synthesis of ceramide has also been implicated in some cases. Ceramide regulates the action of target protein kinases and phosphatases, leading to cell growth arrest, senescence, differentiation, and apoptosis, depending on cell type and physiological context. Several distinct SMase activities have been identified in mammalian cells. An acid sphingomyelinase (A-SMase) and a Mg²⁺-dependent neutral sphingomyelinase (N-SMase) both are strongly implicated in signal transduction. A-SMases were purified and cloned and are implicated in the Niemann–Pick disease types A and B. Using A-SMase null mice, A-SMase activation was clearly implicated in radiation-induced apoptosis in lung and brain endothelial cells, in Fas-induced apoptosis in hepatocytes, and in apoptosis of mammalian oocytes. Similarly, A-SMase-deficient human lymphoblasts derived from Niemann–Pick patients were protected from radiation-induced apoptosis. An N-SMase activity has also been implicated in apoptosis triggered by death receptors, but the N-SMase gene(s) involved have not been identified conclusively.

Structure and Catalytic Properties

The A-SMases comprise a group of 70- to 75-kDa proteins that have an N-terminal saposin B domain

and a C-terminal metallo-phosphoesterase domain. The former domain is likely to be involved in substrate-binding/membrane translocation, whereas the latter is the catalytic domain. As expected from its endosomal/lysosomal localization, A-SMase is optimally active at approximately pH 5. A secreted form of A-SMase, derived from the same gene, requires physiological concentrations of Zn^{2+} for activity. Several putative N-SMase genes were cloned, but it is still uncertain which one represents the signaling, plasma membrane-associated form. Two of these genes, N-SMase1 and N-SMase2, are related to bacterial neutral SMase and contain a catalytic endo/exonuclease/phosphatase domain. However, N-SMase1 is localized to the ER and it exhibits lyso-PAF activity *in vivo*. In contrast, recent work has shown that N-SMase2, which is localized mainly to the Golgi apparatus, exhibits a receptor-stimulated SMase activity *in vivo*.

Receptor-Mediated Activation

A-SMase is a lysosomal/endosomal enzyme that is translocated to the plasma membrane outer leaflet on activation of the death receptor Fas. Although A-SMase is required for death receptor-induced apoptosis in some systems, it is not known how A-SMase translocation and activation occur except that recruitment of death receptor-associated adapter proteins (e.g., FADD, TRAF) are required. The activation of N-SMase presents a similar enigma. However, the picture that emerges is one where N-SMase activation is downstream to stimulation of cPLA₂ activity, formation of reactive oxygen species, and activation of upstream caspases.

Targets of Ceramide and Ceramide Metabolites

Bona fide targets of ceramide should bind ceramide specifically and with high affinity *in vitro*, be recruited or activated in response to ceramide generation *in vivo*, and be implicated directly in ceramide signaling pathways. A relatively large number of putative ceramide targets have been suggested, among which are PKC ζ , cathepsin D, and protein phosphatases PP1 and PP2A. A canonical ceramide-binding domain has not yet been identified, although C1 domain variants have been proposed to act as ceramide-binding modules. However, ceramide may also act as a regulator of membrane dynamics by directly affecting membrane physical properties and thereby modulating intermembrane vesicle trafficking and intramembrane microdomain aggregation.

PHOSPHOLIPASE A₂

Overview

Phospholipase A₂ (PLA₂) hydrolyzes the *sn*-2 ester bond in PC and PE, releasing a free fatty acid and generating a lyso-phospholipid. The *sn*-2 position is often occupied by arachidonic acid (eicosatetraenoic acid [C_{20:4}]), a precursor to a diverse group of important lipid mediators, termed eicosanoids, that include prostaglandins, thromboxanes, leukotrienes, and lipoxins. The release of arachidonic acid by PLA₂ is rate limiting for eicosanoid production and is a major receptor-regulated event catalyzed by a cytosolic, Ca²⁺-dependent enzyme designated cPLA₂ α that, together with cPLA₂ β and cPLA₂ γ , comprise the group IV PLA₂ gene family. The regulation of cPLA₂ β and cPLA₂ γ by receptors and their role in arachidonic acid mobilization have not been clarified. Another form, a Ca²⁺-independent PLA₂ (iPLA₂), appears to be a constitutive housekeeping enzyme. Several secretory PLA₂ (sPLA₂) forms comprise low-molecular weight proteins (13–15 kDA) that are released from the cells into the extracellular space. Although these enzymes play important roles in digestion and inflammation, they are not involved in receptor-regulated intracellular signal transduction pathways.

Structure and Catalytic Properties

cPLA₂ α is a 749-amino acid protein that is composed of four distinct domains: an N-terminal C2 domain implicated in membrane binding; a catalytic domain A, containing a lipase consensus sequence; a non-conserved, isoform-unique linker sequence; and a C-terminal catalytic domain B. cPLA₂ α exhibits a preference for phospholipids with a polyunsaturated fatty acid at the *sn*-2 position but shows little selectivity among linolenic acid, arachidonic acid, or eicosapentaenoic acid. However, because of the low abundance of other polyunsaturated fatty acids, arachidonic acid is the major product *in vivo*. Although it was initially designated as a Ca²⁺-dependent PLA₂, cPLA₂ α does not require Ca²⁺ for catalysis. Instead, Ca²⁺ is involved in membrane interaction through the C2 domain. The catalytic center of cPLA₂ α includes at least three essential amino acid residues (Arg²²⁰, Ser²²⁸, and Asp⁵⁴⁹) identified by homology to other lipases and by site-directed mutagenesis.

Membrane Translocation and Activation

cPLA₂ α is normally localized in the cytosol. Activation of appropriate cell surface receptors results

in translocation of the enzyme to a nuclear and/or perinuclear compartment, enabling the enzyme to gain access to its membrane substrates. Translocation is dependent on persistent elevation of intracellular Ca^{2+} concentrations, and it can be mimicked by a Ca^{2+} ionophore. The C2 domain of cPLA₂α is both necessary and sufficient for mediating its Ca^{2+} -dependent binding to membrane phospholipids. However, the selective perinuclear localization of cPLA₂α indicates that an additional determinant(s) may participate in mediating its translocation. Indeed, the C2 domain is able to interact with vimentin in the presence of Ca^{2+} , whereas vimentin expression was shown to modulate arachidonic acid release. In addition, a plasma membrane-resident complex of p11/annexin II may prevent cPLA₂α from translocating to the plasma membrane on activation, limiting cPLA₂α translocation to the perinuclear region. Thus, the translocation of cPLA₂α may readily provide arachidonic acid to the eicosanoid-producing enzymes, most of which are either constitutive or stimulus-dependent residents of the nuclear envelope and/or the ER.

Receptor-Mediated Activation of cPLA₂α

The current model for cPLA₂α activation requires two independent events, namely a Ca^{2+} -dependent membrane translocation and phosphorylation by the MAP kinases Erk1 and p38. Persistent elevation of cytosolic free Ca^{2+} concentrations resulting from receptor-dependent activation of Ca^{2+} channels or mobilization of Ca^{2+} from intracellular stores is absolutely required for translocation to perinuclear membranes. The activation of cPLA₂α also involves its phosphorylation on a critical Ser⁵⁰⁵ residue found within a PXSP MAP kinase consensus motif. It is phosphorylated by several MAP kinases, including Erk1 and p38, and this is essential for maximal activation of cPLA₂α. Phosphorylation of Ser⁷²⁷ also appears to be required for maximal activation. However, the kinase responsible for Ser⁷²⁷ phosphorylation has not been identified with certainty. The MAP kinases may be stimulated by Ca^{2+} -mobilizing receptors via activation of PKC or activation of Src-like kinases.

Targets of Free Arachidonic Acid and Eicosanoids

Activation of cPLA₂α generates free arachidonic acid, which may itself regulate downstream targets or be

further converted to bioactive eicosanoids. Among the possible direct targets of arachidonic acid are PKC isozymes, a N-SMase, PLC-γ, and phospholipase D. However, conversion of arachidonic acid to eicosanoids is probably the major physiological outcome of cPLA₂α activation, as indicated by compartmentalization of the enzymes that produce prostaglandins, thromboxanes, leukotrienes, and lipoxins in the perinuclear region. Many eicosanoids are released from the cells and then act as extracellular agonists of specific cell surface receptors in an autocrine and/or paracrine mode of action. However, eicosanoids are now also recognized as ligands of nuclear receptors (e.g., peroxisome proliferator-activated receptors [PPAR]-α, -γ, and δ) that act intracellularly to transcriptionally regulate gene expression.

OTHER PHOSPHOLIPASES

PC-PLC

Soon after the second messenger function of DAG was established, it became apparent that a second phase of DAG production is generated by hydrolysis of PC. Whereas the source of “early” DAG is PIP₂, “late” DAG is probably derived by hydrolysis of PC, either directly via PC-phospholipase C or indirectly via PLD and phosphatidic acid phosphohydrolase. Direct PC-phospholipase C-mediated generation of DAG has been suggested to occur in the absence of PI-PLC and PLD activation in a number of cells, especially in response to cytokines and growth factors. A related enzyme may be activated by certain GPCRs in fibroblasts. Unfortunately, the enzyme(s) involved in these responses have not been purified or cloned; consequently, their mechanism(s) of activation by receptors and function(s) are completely obscure.

Lysophospholipase D

A plasma lysophospholipase (LPLD/autotaxin) catalyzes the hydrolysis of lyso-PC to lyso-PA, an important ligand of the Edg subfamily of GPCRs involved in regulation of cell growth and differentiation. Unlike the other phospholipases discussed herein, LPLD/autotaxin has not been shown to be acutely regulated by receptors, but its expression varies under different physiological and developmental conditions. Future studies may shed more light on its receptor-mediated regulation.

CONCLUSION

This article has provided an overview of well-established SAPLs. Although much has been learned in the 20-plus years since the discovery of the first lipid-signaling pathway, a complete understanding of the role of phospholipases and their lipid messengers remains an elusive goal. It should be borne in mind that these signaling effector enzymes would always operate within a signaling network that involves a host of other pathways, all engaged in massive parallel processing of the receptor-initiated signal. Complete understanding of such networks, and in particular the role of SAPLs within them, is a future goal that requires much further research to attain. Another important issue is that receptor-regulated phospholipases, unlike other effector enzymes involved in signal transduction, generate messengers that are lipids. Such molecules reside in the lipid bilayer; thus, they may act not only to recruit and modulate activity of downstream target proteins but also to modify the membrane's biophysical properties and thereby membrane dynamics. Finally, unlike most other messengers, lipid messengers are interconvertible; that is, they can be metabolically converted from one biologically active form into another. This would add additional spatial and temporal complexities to any attempt to define, in molecular terms, the logic of phospholipase-dependent signaling pathways.

interactions are possible sources of the observed alteration in ligand binding and signaling (e.g., the site of modification may be a significant distance from the ligand binding site). Despite these concerns, results from site-directed mutagenesis identify the amino acids of the receptor that play a role (although not necessarily a direct role) in the functioning of the receptor.

In specific cases, evidence of a direct interaction between ligand and receptor can be obtained by a combination of receptor modification via site-directed mutagenesis and alteration of the ligand. With mutation of either the ligand or the receptor alone, function is lost, but when there is mutation of both, a fully functional receptor results; this is often called rescue of function. Often, this is achieved by switching the amino acids of the ligand and receptor. For example, replacing a negatively charged residue with a positively charged residue of the ligand leads to loss of activity in the natural receptor, but when a positively charged residue is replaced by a negatively charged amino acid the receptor is fully functional. This is a clear indication of a direct interaction between the ligand and the receptor.

PHOTOAFFINITY LABELING

An alternative method for determining direct interactions is photoaffinity labeling. Here, the ligand is modified to incorporate a photoreactive amino acid (or moiety). Upon reaction with a light source of the appropriate frequency, this amino acid forms a covalent bond with a residue of the receptor. Upon purification of the ligand–receptor photo adduct (covalent

ligand–receptor complex) and enzymatic cleavage to break the receptor into small fragments, the site of the receptor labeled by the ligand can be identified.

This approach provides an exact point of contact between the receptor and its ligand, but caution must be used in the design of the experiment and in the interpretation of the result. The biological properties of the modified ligand should be very similar to those of the wild-type ligand and should always be taken into account in the interpretation of the results. Unfortunately, only a limited number of photo-labile amino acids are available; therefore, they often deviate in physical properties (e.g., hydrophobicity and size) from those of the amino acids that they replace. Electrostatic and hydrophobic contributions and steric complementarity play a major role in defining the receptor–ligand interaction, and alteration in any of these properties may lead to an altered mode of binding. An indication may be the modification of binding affinity or signaling properties. [Figure 1](#) illustrates how a change in bulkiness may affect the specific point of interaction.

Early studies by Rosenblatt on the interaction of PTH with PTH-1 used a photoreactive PTH agonist in which residue 13 (a positively charged lysine) was modified with a photoreactive benzoylphenone moiety. The agonist cross-links specifically to the PTH-1 receptor, but the modification introduced alters both the electrostaticity (positive charge substituted by hydrophobic moiety) and the size (a bulky benzoylphenone added to the lysine side chain) of the targeted site of interaction (position 13). The agonist displays reduced binding affinity to the receptor, and the effect of the chemical modifications must be taken into account in the interpretation of results. [Figure 2](#) illustrates the

Figure 1 Map of ligand–receptor interactions by photoaffinity labeling. The binding pockets in the PTH1 receptor are denoted by circles [pocket of amino acid in wild-type (WT) PTH] and squares (binding pocket of the photolabile residue). The physical properties of the photolabile residue differ from those of the natural residue of the ligand; therefore, the photolabile residue may not bind to the exact location of the natural amino acid.

Figure 2 Resolution obtained from photoaffinity-labeling experiments resulting from the inherent flexibility of the ligand containing the photolabile amino acid. Superposition of the possible orientations of the photolabile residue (left) leaves uncertainty in defining the position of the ligand within the receptor (right) as determined by the photoaffinity contact points.

uncertainty at the structural level introduced by the use of an extended side chain at the cross-linking site: The conformational flexibility of the side chain (which links the ligand to the receptor) exemplified on the left results in uncertainty in the position of the ligand (right). The practical consequence is that the characterization of the interaction is an approximation, as could be derived by a picture with a resolution of approximately 10 Å.

STRUCTURAL INSIGHT

The results from the site-directed mutagenesis and photoaffinity-labeling studies provide loosely defined distance restraints between the ligand and receptor. As noted previously, care must be used when applying these restraints in the generation of a model of the ligand–receptor complex. Nonetheless, these loose restraints are important guides for the description of ligand–receptor interactions in the context of existing models or experimental structures of the ligand and receptor.

Confidence in the results of combining the ligand and receptor is greatly enhanced by knowledge of the structures of the two players; experimental data defining the conformational preferences of the ligand and the receptor is vital for the development of a meaningful ligand–receptor complex. The more detailed the structural features of the ligand and receptor, the more detailed the resulting model of the ligand–receptor complex.

Unfortunately, in the case of the PTH-1 receptor, no experimental structure of the intact receptor is available. Based on sequence homology (a measure of similarity of the amino acid sequences of two protein receptors), it is assumed that PTH-1 is similar in structure to the transmembrane receptors bacteriorhodopsin and rhodopsin, for which limited

structural data are available. Indeed, the PTH-1 receptor has been shown to contain seven transmembrane helices, an extracellular N terminus, and an intracellular C terminus (Fig. 3). One of the major limitations of the structural features of the bacteriorhodopsin and rhodopsin receptors is that the extracellular region, most important for ligand binding as indicated by both site-directed mutagenesis and photoaffinity labeling, is poorly defined. The temperature factors (measures of the definition of the structure, with the lower factor being the more defined) of the extracellular portion in the X-ray structures of these receptors are very high. Therefore, in the development of the model for the PTH-1

Figure 3 Incorporation of experimentally determined structural features into the ligand–receptor model. The nuclear magnetic resonance structure of the first extracellular loop of the PTH1 receptor is seamlessly inserted into the model of the seven-transmembrane helices of the receptor. Such structural insight greatly enhances the reliability of the computational models of the ligand–receptor complexes.

receptor, only the topological display and orientation of the seven transmembrane helices could be used. No knowledge of the extracellular domains, the N terminus, and three extracellular loops could be ascertained.

To build a model structure in our laboratory, we used the known characteristics of the receptor (e.g., the presence of seven transmembrane helices), experimental structures derived by NMR studies on receptor fragments, and extensive computer refinement. [Figure 3](#) illustrates how the NMR structure of the first extracellular loop of PTH-1 contributes to the overall model.

Using a similar approach for the other extracellular domains of the PTH-1 receptor, a high-resolution picture, containing the structural preferences of these domains important for the interaction of PTH, can be developed. The insight obtained from this model should afford the development of novel therapeutic agents for the control of this important receptor.

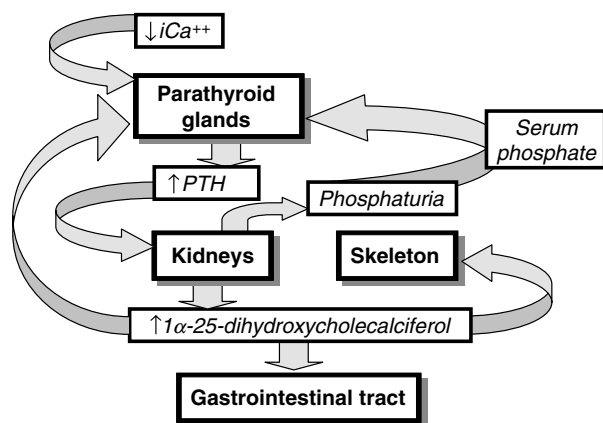

Figure 1 Pathogenic factors in the development of secondary hyperparathyroidism in patients with chronic renal disease.

integrin α -V- β -3. Local chemotactic factors, such as osteopontin and bone sialoprotein, may act as the natural ligands for this integrin and thus direct chemotaxis and organize the osteoclast for its resorptive role in bone turnover.

Osteoclastic activity is inhibited by products of bone resorption, namely calcium and transforming growth factor- β (TGF- β). This is achieved by separation of osteoclasts from the bone surface. Osteoblastic growth factors, including TGF- β , basic and acidic fibroblast growth factor, and bone morphogenic protein, are released during bone resorption as well.

Bone formation is initiated by the release of osteoblastic precursors from the marrow stromal cells. The precursor pool mobilizes to the active resorptive site, forming cuboidal osteoblasts, resulting in matrix synthesis and mineralization. Under direct stimulation by PTH, insulin-like growth factor-1 (IGF-1), along with calcitriol, promotes osteoblast proliferation.

In adults, the remodeling cycle results in a discrepancy between bone formation and bone resorption, with the latter predominating. This difference increases with age, predisposing the elderly to osteopenia.

PATHOPHYSIOLOGY

High-Turnover Bone Disease (Secondary Hyperparathyroidism)

Osteitis fibrosa is the most common form of ROD. In this form, both bone resorption and remodeling are increased. However, the remodeled bone is mostly nonlamellar, or non-nutrient supplied, rendering it weak with a predisposition to osteopenia and fractures.

The underlying pathophysiologic mechanism is a combined effect of a reduction in 1-hydroxylation of

25-hydroxyvitamin D₃ in the kidney and hyperphosphatemia due to the presence of renal disease. Diminished circulating levels of calcitriol and its associated hypocalcemia, along with (and perhaps even more important) an elevated serum phosphate concentration, lead to the development of secondary hyperparathyroidism (Fig. 1). This phenomenon is usually seen once the GFR reaches 50–70% of the normal GFR of 100–125 ml/min.

In normal circumstances, calcitriol inhibits PTH synthesis at the pre-pro-PTH mRNA level by binding to calcitriol receptors located in the parathyroid gland. In the presence of renal disease, however, the density of these calcitriol receptors is diminished. Some authors suggest that this leads to a loss of feedback inhibition and a lower threshold for PTH secretion. Furthermore, it has been postulated that the parathyroid gland may lack efficient control of PTH synthesis and secretion in response to the plasma ionized calcium concentration in the presence of uremia. Using *in situ* hybridization and immunohistochemistry techniques, the expression of the calcium-sensing receptor (CaSR) in parathyroid tissue from nonuremic and uremic patients with hyperparathyroidism has been compared. In patients with uremia, the expression of both receptor mRNA and protein is substantially depressed in nodular areas of parathyroid tissue. Furthermore, the presence of hyperphosphatemia stimulates release of PTH by the parathyroid glands in the absence of changes in serum ionized calcium or calcitriol concentrations. The combined effect of hypocalcemia, hyperphosphatemia, and calcitriol deficiency leads to parathyroid glandular hypertrophy and hyperplasia (Fig. 1).

As observed in animal studies, there appears to be end-organ resistance to the effects of PTH in the presence of uremia. It has been suggested that downregulation of PTH receptors plays a potential role in the expression of secondary hyperparathyroidism in uremia. A blunted calcemic response to PTH stimulation in both uremic dogs and rats has been observed. Using *in situ* hybridization techniques, the expression of cellular PTH/PTH-related protein (PTH/PTHrP) receptor (PTH1R) mRNA in human osteoblasts in the presence and absence of renal disease has been examined. Studies show a lower density of PTH1R mRNA in uremic patients when compared to normal bone and high-turnover bone in those without renal disease. Another potential mechanism for skeletal resistance to PTH in uremia is the overproduction of osteoclastogenesis inhibitory factor (OCIF) or osteoprotegerin. OCIF acts as a “decoy” receptor for osteoclast differentiation factor, produced by osteoblasts in

response to PTH stimulation, and inhibits osteoclastic differentiation and maturation. In patients with advanced renal disease, serum OCIF levels increased as renal function decreased. An approximately four-fold elevation in OCIF levels was observed in ESRD patients. Furthermore, OCIF levels have been shown to return to normal as early as 2 weeks following renal transplantation. It is therefore possible that OCIF may act at the skeletal level to produce resistance to the action of PTH.

Additional studies have focused on the potential role of both circulating and locally produced cytokines and growth factors in the development of ROD. TGF- β , in particular, is synthesized by both osteoblasts and osteoclasts and stored in bone matrix. Through *in situ* hybridization techniques, TGF- β mRNA was primarily localized to osteoblasts and appeared to promote osteoblastic activity and thus bone formation. The degree of TGF- β mRNA expression correlated with markers of bone formation, such as bone formation rate (BFR), trabecular apposition rate, and mineralizing surfaces. Furthermore, PTH has been shown to stimulate TGF- β expression in cultures of normal human osteoblastic-like cells.

In addition to TGF- β , IGF-1 and IGF-2 have been studied as potential mediators of ROD. IGF-1 and IGF-2 play important roles in bone formation by inhibiting the degradation of collagen and promoting osteoblastic recruitment and matrix deposition. It has been suggested that patients with uremia have resistance to the effects of IGF-1, which may be due to a defect at the receptor site. Using *in situ* hybridization techniques, a reduction in IGF-1 mRNA in bone of

subjects with renal disease compared to that in normal and high-turnover bone in the absence of renal disease has been observed.

Low-Turnover Bone Disease (Adynamic Bone Disease and Osteomalacia)

Many patients with renal disease have normal or near-normal circulating PTH levels, often as a result of the treatment of abnormalities of calcium and phosphate metabolism. As many as 40% of patients with ROD have low-turnover bone disease. In both adynamic bone disease (ABD) and osteomalacia, bone formation and turnover are decreased (Table I). The distinction, however, is in the quality of the bone formed. In osteomalacia, newly formed bone collagen, or osteoid, is largely unmineralized. This defect has historically been attributed to vitamin D deficiency and, recently, to the use of aluminum and other heavy metal compounds in patients with renal disease.

Aluminum affects the skeleton and its mineralization in several ways. Chronic intoxication leads to sustained inhibition of osteoblastic differentiation and osteoclastic activity. Furthermore, *in vitro* studies have shown impaired secretion of PTH from parathyroid cells in the presence of aluminum. The role of calcitriol deficiency in the pathogenesis of osteomalacia is uncertain. Other factors may play a role in osteomalacia associated with uremia because this disease remains problematic despite the dramatic reduction in the use of aluminum-based phosphate binders during the past decade.

Table I Clinical Characteristics of Renal Osteodystrophy^a

| | Ca | Phos | Alk phos | PTH | Histology |
|------------------------------|-------------|-------------|-------------|---|---|
| <i>Osteitis fibrosa</i> | Variable | ↑ | ↑ | ↑↑ | Peritrabecular and marrow fibrosis ↑ osteoclasts and osteoblasts ↑ BFR |
| <i>Osteomalacia</i> | Variable | Normal or ↑ | Normal or ↑ | Slightly ↑ | ↓ osteoclasts and osteoblasts ↑ osteoid ↑ osteoid seam width ↓ BFR ↑ aluminum |
| <i>Adynamic bone disease</i> | Normal or ↑ | Normal or ↑ | Normal or ↑ | Less than twice upper limit of normal | ↓ osteoclasts and osteoblasts ↓ osteoid seam width ↓ BFR |

^aAbbreviations used: Alk phos, serum alkaline phosphatase; Phos, serum phosphorus; Ca, serum calcium; PTH, serum parathyroid hormone; BFR, bone formation rate.

ABD represents an emerging problem in patients with renal disease. The disease is characterized by a low bone turnover rate with a decrease in both the number and activity of osteoclasts and osteoblasts (Table I). The pathogenesis of ABD is unclear; however, various potential mechanisms have been proposed. Several bone-suppression factors have been implicated, including IL-4, IL-11, nitric oxide, and fragments of PTH-related protein. A deficiency of bone morphogenic protein-7, a member of the family of TGF- β cytokines normally produced by renal tubular cells, may play a role in the development of ABD. Patients who have undergone parathyroidectomy are particularly prone to the development of ABD.

The presence of near-normal or normal levels of circulating PTH is thought to be the predominant predisposing factor for the development of ABD. Use of calcium supplementation, either in ingested form as a phosphate binder or in aqueous form in dialysate solution, when combined with decreased skeletal uptake of calcium increases the propensity to develop hypercalcemia and thus decrease secretion of PTH (Fig. 1). Perhaps even more important, the widespread use of vitamin-D analogues in patients with renal disease leads to a secondary reduction in circulating PTH levels. The combination of hypercalcemia and near-normal or normal levels of circulating PTH is classically associated with the presence of ABD on bone histology.

HISTOLOGIC CHARACTERISTICS OF ROD

Bone biopsy is the definitive method of establishing the type of osteodystrophy present in a patient with renal disease. Although not universally performed in patients with renal disease, primarily due to patient discomfort and the relatively few pathology centers in the United States that interpret bone biopsies, the histologic characteristics provide valuable insight into the potential pathophysiologic mechanisms involved in the development of bone disease in patients with uremia.

In general, bone histology provides the clinician with important structural determinants of both trabecular bone and marrow. Particular static bone histomorphometric parameters include the number of osteoclasts and osteoblasts, the degree of marrow fibrosis, the amount of unmineralized bone matrix (osteoid), the length and thickness of osteoid seams, the amount of aluminum staining, and the extent of iron stores in the marrow. In addition, dynamic properties such as BFR, estimated by tetracycline

labeling, can be determined and provide valuable insight into the rate of bone turnover.

High-Turnover Bone Disease

In osteitis fibrosa, significant fibrosis is observed within the peritrabecular areas and marrow, in part due to the secretion of fibrous tissue by fibroblast-like cells. There is an increase in both the number and the size of osteoclasts, with an associated increase in the number of resorptive areas within cancellous bone. In addition, the number of osteoblasts and amount of newly formed osteoid are increased. There is derangement of collagen fibrils, forming a woven straw basket appearance within osteoid seams. As calculated from tetracycline labeling, the BFR is increased. There is only mild staining for aluminum, covering less than 30% of the trabecular surface.

Low-Turnover Bone Disease

There is an overall reduction in the number of osteoblasts and osteoclasts. The number of bone resorptive sites is decreased. There is either a normal or reduced quantity of unmineralized bone, with relatively few sites of active bone formation. In osteomalacia, defective bone mineralization leads to excessive osteoid formation, with a widened osteoid seam width. In ABD, however, bone mineralization may exceed collagen formation, leading to a normal or narrower osteoid seam width. The characteristic changes seen in secondary hyperparathyroidism, such as peritrabecular and marrow fibrosis, are absent. The rate of bone turnover, as assessed by tetracycline labeling, is dramatically decreased and may approach zero. In aluminum-associated osteomalacia, aluminum staining covers more than 30% of the trabecular surface, with the degree of staining correlating with the degree of histologic changes.

CLINICAL CHARACTERISTICS OF ROD

Although the definitive diagnosis of ROD is made by bone biopsy, there are several important clinical features that may help the clinician distinguish high-turnover from low-turnover bone disease. In general, the following laboratory markers are useful when assessing bone disease in patients with renal disease: serum alkaline phosphatase, serum calcium, serum phosphate, and serum PTH levels (Table I). It is important to follow such laboratory markers once the reduction in GFR has reached approximately 50% of normal. Furthermore, roentgenographic

features may provide insight into the type of ROD present in a particular patient.

High-Turnover Bone Disease

The most common symptoms associated with osteitis fibrosa are bone pain and pruritis. Joint discomfort and stiffness, often localized to the lower back, hips, and legs, may be present and can be attributed to arteriolar and periarticular calcification. These symptoms may mimic acute arthritis and must be distinguished from other arthropathies that might be present in patients with chronic renal disease. Symptoms are usually insidious in onset and frequently nonspecific and generalized. The discomfort may be aggravated by either movement or change in posture. On physical examination, bony tenderness, palpable parathyroid glands, and skin excoriations with palpable subcutaneous calcium deposits may be seen. In extreme cases of secondary hyperparathyroidism with an elevated calcium phosphate product (usually more than 65–70), ischemic necrosis of the skin, muscles, and subcutaneous tissues, called calciphylaxis, may ensue. Furthermore, fractures and pseudofractures of the rib cage may lead to pulmonary insufficiency (restrictive lung disease).

In osteitis fibrosa, serum alkaline phosphatase levels are elevated due to the presence of high bone turnover (Table I). Serum calcium levels (either total or ionized) are usually normal or slightly low, attributable to the reduction in 1-hydroxylation of 25-hydroxyvitamin D₃ by the kidneys. Serum phosphate levels are usually elevated, often 6 or 7 mg/dl or higher. Levels of circulating intact PTH (iPTH) are elevated, often >300 pg/ml. Serum PTH levels >1000 pg/ml suggest marked parathyroid glandular hyperplasia (Table I).

Radiologic findings in osteitis fibrosa are highly variable. In mild or early disease, radiologic findings may be absent. However, in advanced disease, subperiosteal bone loss can be seen, which can be best detected on the radial side of the second and third phalanges, the distal ends of the clavicles, and at the sacroiliac joints. Occasionally, blunting of the fingertips is present. In addition, the presence of disorganized high bone turnover may present as osteosclerosis on radiographic examination, producing a “rugger jersey” appearance of the thoracic spine. Bony derangement of the skull may produce a characteristic “salt and pepper” appearance. Calcifications in blood vessels and subcutaneous tissues are occasionally seen. Technetium bone scintigraphy shows increased uptake in various areas of the skeleton.

Low-Turnover Bone Disease

Adynamic ROD was originally described in the 1970s and 1980s as a consequence of aluminum toxicity related to the use of dialysate water and aluminum-based phosphate binders. Patients presented with bone and muscle discomfort and had significant aluminum staining on bone biopsies. The recognition of aluminum toxicity led to improvements in water purification and the use of calcium-based phosphate binders. As a result, the incidence of aluminum toxicity and its associated bone histologic characteristics of osteomalacia has declined in recent years. However, the development and widespread use of newer vitamin D analogues, with the concurrent use of calcium-based phosphate binders, have led to a greater proportion of renal disease patients with suppressed circulating PTH levels and an increased incidence of ABD. Osteomalacia persists in patients with renal disease, suggesting that factors besides aluminum may play a role in its pathogenesis.

Patients with osteomalacia tend to experience a greater degree of both bone pain and fractures compared to those with osteitis fibrosa. Skeletal deformities, such as scoliosis and kyphosis, are seen and are predominantly localized to the thoracic and lumbar spine. There is also an increased incidence of anemia, which is thought to be due, in part, to an impaired response to recombinant human erythropoietin in patients with renal disease and aluminum toxicity. Neurologic signs, including dyspraxia, asterixis, seizures, and dementia, have been noted in cases of severe toxicity.

In contrast to those with osteomalacia, patients with ABD are less likely to complain of muscular pain and weakness. Joint stiffness is also less common than in patients with osteitis fibrosa.

The risk of vertebral and hip fractures is increased in patients with ABD compared to patients with other types of ROD. In a retrospective review of 1270 ESRD patients observed during a 10-year period, the risk of hip fracture was greatest in those with lower serum PTH levels. Furthermore, patients with PTH values >195 pg/dl did not have an increased risk of hip fracture. In this study, bone biopsies were not systematically performed. In a different study, the effects of circulating iPTH levels on bone mineral density (BMD) were examined in 187 male hemodialysis patients. Patients in the lowest tertile for serum iPTH (mean, 32.9 ± 16.4 pg/ml) had a 2.4-fold increase in vertebral fractures compared to patients in the middle tertile group (mean iPTH, 116.2 ± 40.9 pg/ml). Again, bone histology was not examined.

However, the optimal modality for determining BMD in patients with renal disease is unknown and remains a topic of intense debate.

Serum calcium concentrations in patients with low-turnover bone disease are often normal but may be elevated, primarily due to the sometimes large prescribed amount of daily calcium ingestion in patients with renal disease. Despite the presence of vitamin D deficiency in uremia, passive or diffusional calcium transport across the intestinal membrane exists in relation to the amount of ingested calcium. Coupled with the use of vitamin D analogues in the presence of adynamic bone, this often leads to the development of hypercalcemia (Table I). Serum alkaline phosphatase levels are often normal or slightly elevated. Serum PTH levels are usually <150 pg/ml and may be <100 pg/ml (normal range, 10–65 pg/ml) (Table I). In fact, the combination of a serum PTH level <150 pg/ml and a serum calcium concentration >10 mg/ml has at least an 82% positive predictive value for ABD.

Serum aluminum concentrations poorly reflect the quantity deposited in bone and are mostly a measure of daily ingestion. In a study of 258 peritoneal dialysis and hemodialysis patients, a poor correlation between serum aluminum levels and histologic findings on bone biopsy was observed. Only 50% of patients with serum aluminum levels >40 µg/liter were found to have histologic evidence of low bone turnover associated with at least 25% bone surface aluminum staining. Due to the shortcomings of noninvasive screening for aluminum bone toxicity, other measures such as the deferoxamine infusion test have been used diagnostically. Deferoxamine is a chelating agent that mobilizes and binds aluminum, and in the setting of bone toxicity it will produce dramatic increases in serum aluminum levels after its infusion. However, the sensitivity and specificity of this test have been questioned.

Radiologic features of low-turnover bone disease are less specific than those for osteitis fibrosa. Rib and vertebral fractures are the most common abnormalities. Low skeletal uptake of tracer is observed on nuclear bone scintigraphy.

TREATMENT STRATEGIES

The primary goal of minimizing the severity of ROD involves the following general approaches: control of serum phosphate, maintenance of normal levels of serum calcium, and the prudent use of vitamin D analogues. Promising therapeutic agents, such as the calcimimetic agents, have been evaluated in patients with renal disease. In advanced cases of secondary

hyperparathyroidism, parathyroidectomy may be indicated.

Control of Serum Phosphate

The most important intervention in the management of bone disease in uremic patients is the strict adherence to a low-phosphate diet (400–800 mg/day). In uremic rats, dietary phosphate restriction prevented the development of parathyroid hyperplasia, independent of serum ionized calcium or calcitriol concentrations. Avoidance of foods high in phosphorus content, such as dairy products, corn, whole-grain breads and cereals, broccoli, legumes, nuts, beef or chicken liver, and dark colas, is recommended. Consultation with a dietician is often beneficial.

In addition to a low-phosphate diet, use of phosphate binders is often necessary. Phosphate binders decrease intestinal phosphate absorption. Calcium-based binders, such as calcium acetate and calcium carbonate, are ingested with each meal or snack and can be dosed depending on the phosphate intake of a particular meal. The total daily dose of the phosphate binder is highly variable from patient to patient and must be titrated accordingly. It is a reasonable approach to target high-normal levels of serum phosphate while avoiding the development of hypercalcemia. The efficacy and the number of tablets required daily are equivalent for both drugs. Use of aluminum-based phosphate binders should be avoided.

Sevelamer hydrochloride (RenaGel), a relatively new synthetic nonabsorbable phosphate binder that is both calcium and aluminum free, binds phosphate in the intestinal tract and prevents its absorption. Sevelamer has been shown to be as effective as calcium carbonate and calcium acetate in suppressing serum phosphate levels in ESRD patients. Furthermore, the incidence of hypercalcemia, as determined from several clinical trials, is reduced with the use of sevelamer. In addition to its use as a phosphate binder, sevelamer has been shown to decrease total cholesterol and low-density lipoprotein cholesterol and increase high-density lipoprotein cholesterol levels in ESRD patients. Its high cost is a drawback to its widespread use.

Maintenance of Normal Levels of Serum Calcium

Due to the reduction in serum levels of 1,25-dihydroxyvitamin D₃, hypocalcemia is often seen in patients with renal disease. In addition to strict control

of serum phosphate levels, it is equally important to maintain normal serum calcium levels in an attempt to minimize oversecretion of PTH and the development of parathyroid hyperplasia. This is achieved in a variety of ways, such as by use of calcium-based phosphate binders, adjustment of the dialysate calcium concentration in hemodialysis patients, and use of vitamin D analogues. If hypocalcemia becomes problematic, it may be necessary to at least temporarily use calcium supplements given in between meals (rather than with meals as a phosphate binder).

Vitamin D Analogues

The use of vitamin D analogues has been primarily limited to the treatment of osteitis fibrosa in patients with renal disease. The PTH-lowering effect of intravenous administration of calcitriol three times per week in hemodialysis patients was first described in 1989. In the 1990s, second-generation vitamin D analogs [19-*nor*-1,25-(OH)₂D₂ (paricalcitol, Zemplar) and 1 α -(OH)-vitamin D₂ (doxercalciferol, Hectorol)] became commercially available and were developed in an attempt to decrease intestinal calcium and phosphate absorption. Although these agents have dramatically affected the treatment of secondary hyperparathyroidism in patients with renal disease, their overzealous use in the ensuing years has led to the emergence of ABD.

Given the deficiency of calcitriol in patients with renal disease, the use of calcitriol and other vitamin D analogues is almost universally employed in the treatment of secondary hyperparathyroidism. Vitamin D analogues are often prescribed intravenously during dialysis treatments, improving patient compliance; however, oral forms are commercially available for use in patients with chronic kidney disease.

Due to the deleterious effects of secondary hyperparathyroidism on bone mineral metabolism, treatment with vitamin D analogues is primarily undertaken to lower circulating PTH levels and facilitate calcification of osteoid. The primary objective is suppression of both PTH gene transcription and PTH secretion. However, therapeutic doses of calcitriol and other vitamin D analogues promote intestinal calcium absorption, increasing the propensity to develop hypercalcemia and metastatic calcifications. Furthermore, intestinal phosphate absorption is increased, primarily with the use of calcitriol, leading to the development of hyperphosphatemia. Thus, the therapeutic index for these agents is relatively narrow,

requiring the clinician to closely monitor the levels of serum PTH, calcium, and phosphate.

In general, the use of vitamin D analogues is recommended when the level of circulating PTH is higher than 200–250 pg/ml. In the setting of hypercalcemia or an elevated calcium phosphate product (usually >60–65), the use of these agents is contraindicated. The target level for circulating PTH is unknown; however, most clinicians seek a value of approximately 150–200 pg/ml.

The use of vitamin D analogues has been shown to decrease bone pain while improving both muscle strength and posture in patients with uremia. Furthermore, abnormal bone histology may be reversed with such therapy. A recent observational study of ESRD hemodialysis patients suggests improved survival of these treated with paricalcitol compared to those on calcitriol. To our knowledge, however, the use of vitamin D analogues has not been shown in a randomized controlled trial to improve mortality in patients with renal disease.

Calcimimetic Agents

The CaSR, located on the parathyroid cell membrane, regulates the release of PTH in response to changes in serum ionized calcium concentration. Calcimimetic agents have similar effects as calcium on parathyroid gland physiology. Currently being investigated as potentially beneficial in patients with renal disease, calcimimetic agents diminish the effect of decreases in serum ionized calcium concentration on the release of PTH by the parathyroid glands. Thus, in patients treated with calcimimetic agents, there is the potential for the development of hypocalcemia, thought to be due to a decrease in PTH secretion and altered calcium flux between bone and the extracellular space. The use of calcimimetic agents has been proposed in the setting of hyperparathyroidism and hypercalcemia, when vitamin D analogues cannot be employed. However, the variable bioavailability of the agents and the propensity of patients to develop hypocalcemia present difficult challenges regarding their widespread use in patients with renal disease. Further studies on the clinical application of calcimimetic agents in patients with renal disease are needed.

Parathyroidectomy

Parathyroidectomy is usually reserved for patients with severe secondary hyperparathyroidism in whom both dietary and medical treatments fail to improve

either clinical or biochemical parameters. Newer techniques, such as percutaneous ethanol ablation of the parathyroid glands, have been described. Patients in need of surgical treatment of secondary hyperparathyroidism usually have extremely high circulating PTH levels and often complain of intractable pruritis and bone pain. Profound hypocalcemia often develops in the postoperative period and requires close observation.

CONCLUSION

The presence of renal disease evokes complex alterations in mineral metabolism. Such alterations lead to the development of ROD, increasing morbidity for this patient population. The use of aluminum-based phosphate binders and vitamin D analogues has led to an increased prevalence of osteomalacia and ABD, respectively. Definitive diagnosis of the type of ROD present depends on the evaluation of bone histomorphometric parameters; however, because of the limited use of bone biopsy, the clinician must rely on both clinical and biochemical parameters to make a provisional diagnosis. In general, treatment strategies involve the control of both serum phosphate and calcium, in conjunction with the appropriate use of vitamin D analogues. Parathyroidectomy is reserved for patients with severe secondary hyperparathyroidism for which medical management is ineffective. Promising therapeutic agents, including the calcimimetic agents, are being evaluated in patients with renal disease.

of sodium reabsorption that occurs as a result of both the direct tubular effect of Ang II and the aldosterone secretagogue effect of the peptide, tends to reduce renin secretion back toward normal values. Furthermore, the profound effects of Ang II in inducing small artery hypertrophic remodeling, e.g., by increasing the wall-to-lumen ratio in these vessels, enhance the pressor effect of Ang II. From the clinical standpoint, all of these facts indicate that the chances of detecting an activated renin-angiotensin system and high plasma renin are high when the patient is seen soon after a given renal artery obstructive lesion has become hemodynamically relevant, but tend to wane afterward. This may explain why at the time of diagnosis as many as one-third of patients with renovascular hypertension (RVH) do not have high plasma renin, either in the peripheral blood or in venous blood from the affected side.

METHODOLOGY

Patient Selection

Measurement of RVR is an invasive procedure and therefore patients should be selected for this test based on a high degree of suspicion (pretest probability) of RVH, which can be established by using the criteria of Mann and Pickering or recommendations from updated guidelines such as those from the European Society of Hypertension–European Society of Cardiology.

Preparation of Patients for RVR Measurements

Several conditions can profoundly affect RVR levels (Table I). Therefore, the patients selected to undergo this invasive test should be adequately prepared in order to achieve the best diagnostic accuracy. The patient should be on a normal sodium intake and this should be verified by measuring 24 h urinary sodium excretion on the day of the test. Furthermore, since renin secretion is under the control of the sympathetic nervous system, which follows a circadian pattern of activity, ideally RVR studies should be performed between 8:00 A.M. and 12:00 P.M., after the subject has fasted overnight and has been kept lying quietly in the supine position for at least 1 h before and during the test.

Several drugs (listed in Table I) alter renin secretion and therefore must be withdrawn for at least 2 weeks prior to the RVR testing. If there is concern that the patient may be put at high risk by temporarily

Table I Preparation of the Patient for RVR Studies

1. Allow a normal Na⁺ intake for at least 7 days (100–200 mmol/day) prior to the study
2. Measure Na⁺/K⁺ excretion (24 h urine collection) the day of the RVR study
3. Perform the test between 8 AM and 12 PM
4. Keep the patient supine for at least 1 h prior to and during the test
5. Try to avoid causing any stress to the patient during the test
6. Withdraw for at least 2 weeks prior to the RVR study:
 - Diuretics^a
 - Beta-blockers
 - Direct vasodilators
 - Angiotensin-converting enzyme inhibitors
 - Ang II type 1 (AT-1) receptor antagonists (sartans)
7. Use a long-acting calcium entry blocker and/or an α 1-adrenoceptor blocker, if necessary

^aDue to their long half-life, aldosterone antagonists (spironolactone, kanrenone, and kanrenoate) must be withdrawn for at least 6 weeks before the RVR study.

withdrawing his or her antihypertensive treatment, as is often the case in patients with suspected RVH that can be resistant to therapy, it is wise to allow the use of a long-acting calcium entry blocker, such as verapamil, a long-acting dihydropyridine compound, or an α 1-adrenoceptor blocker. Under chronic conditions, these agents negligibly affect renin secretion. If necessary, they can be combined together to achieve adequate blood pressure control before and during the test.

Catheter Placement

It must be pointed out that several factors, which are listed in Table II, can lead to inaccurate findings in RVR studies, thus increasing the number of false-negative and false-positive results. Utmost care should, therefore, be exercised in obtaining blood selectively from the renal vein, a task that can be challenging since radiographic demonstration of venous anatomy is difficult to obtain because blood flows toward the catheter lumen, often leaving uncertainty as to the exact positioning of the catheter tip. Accordingly, it is not uncommon to draw diluted renal blood, e.g., blood not draining solely from the kidney. Additional problems relate to the fact that (1) multiple renal veins are present in a substantial proportion (20–28%) of patients on the right side and in much lower (1–3%) proportions on the left side, thus setting the stage for the collection of less “pure” renal vein blood on the right side than on the left side; (2) the

right renal vein is shorter than the left renal vein and thus the catheter will more commonly collect an admixture of blood from the vena cava on the right side than on the left side; and (3) plasma drawn from the lower pole vein might not identify an upper pole (segmental) ischemia.

Nonsimultaneous Sampling

The use of a single catheter for the sampling of both renal veins can run the risk of detecting an artifactual gradient between the two kidneys if an abrupt change in renin secretion occurs between the time of sampling on the first side and the time of sampling on the contralateral side. Therefore, bilateral catheterization with simultaneous sampling seems to be advisable unless the time elapsing between sampling from the two sides can be kept within 5 min. Furthermore, any maneuver that can abruptly increase renin secretion, such as stressful stimuli, should be avoided.

Assay Variability

There is no question that the measurement of plasma renin, either as a direct immunoradiometric assay of active renin or, even more so, as plasma renin activity, shows some variability (ranging between 8 and 20%), even in the same laboratory and in experienced hands. Obviously, this should be kept in mind when interpreting the results of RVR measurements. However, it has been estimated that an RVR ratio greater than 1.4

Table III Recommendations for RVR Studies

- Meticulous labeling of specimen
- Placement of catheter tip selectively (deeply) into the renal vein
- Collection of segmental venous blood, when clinically indicated
- Performance of the test during steady-state renin secretion
- Simultaneous renal vein sampling (use of separate catheters)
- Proper consideration to renin assay variability in interpretation of results
- Frequent interaction between clinician and interventional radiologist

would almost never occur simply on the basis of within-assay variability.

Summary of Recommendations

In summary, to gain maximal diagnostic information from RVR studies, protocols should take into consideration the principles listed in [Table III](#).

CRITERIA FOR INTERPRETATION OF RESULTS OF RVR MEASUREMENTS

Four different indexes derived from RVR measurements can be used to evaluate the results of RVR studies, as shown in [Table IV](#).

According to seminal studies from Dr. J. H. Laragh's group, typically, if a patient with unilateral hemodynamically relevant renal artery stenosis is seen during the first stage of the disease, e.g., when renin is high, the renal venous–arterial plasma renin activity (PRA) difference relative to arterial levels from the affected kidney $[(V_{\text{isch}} - V_{\text{iive}})/V_{\text{iive}}]$ would range between 0.24 and 0.50; furthermore, values >0.50 would indicate reduced renal blood flow. Conversely, values of the renal venous–arterial PRA difference relative to arterial levels from the unaffected kidney $[(V_{\text{ctl}} - V_{\text{iive}})/V_{\text{iive}}]$ close to 0 would indicate an absence of renin secretion, e.g., contralateral suppression. Importantly, a value of $[(V_{\text{isch}} - V_{\text{iive}})/V_{\text{iive}}] + [(V_{\text{ctl}} - V_{\text{iive}})/V_{\text{iive}}] < 0.50$ should suggest either incorrect sampling or a segmental disease. Therefore, it should mandate a repeat of the study with segmental sampling.

These important studies have provided a framework for the proper interpretation of RVR studies. However, it should be understood that there are several situations in which this simple scheme cannot be applied, such as in those patients with bilateral hemodynamically relevant renal artery obstruction and

Table IV Indexes Derived from RVR Studies

Indexes of lateralization of renin secretion

- RVR is the ratio of the PRA^a level on the affected side to that on the unaffected side, e.g., the PRA value in renal vein blood from the ischemic kidney/PRA value in renal vein blood from the contralateral kidney
- $(V_{isch} - V_{iivc})/V_{iivc}$ is the renal venous-arterial PRA difference relative to arterial^b levels from the affected kidney

Indexes of contralateral suppression of renin secretion

- V_{ctl}/V_{iivc} is the ratio of the PRA level on the unaffected (contralateral, ctl) side to the PRA level in the infrarenal inferior vena cava blood, e.g., the PRA value in renal vein blood from the contralateral kidney/PRA value in renal vein blood from the inferior vena cava
- $(V_{ctl} - V_{iivc})/V_{iivc}$ is the simultaneous renal venous-arterial^b PRA difference relative to arterial levels from the unaffected kidney

^aDirect measurement of active renin can be used instead of PRA to calculate these indexes.

^bThe values measured in the inferior vena cava blood V_{iivc} are usually taken as a surrogate measure of the level in arterial blood.

those with segmental renal artery stenoses. Furthermore, as discussed below, the usefulness of the $(V_{isch} - V_{iivc})/V_{iivc}$ and $(V_{ctl} - V_{iivc})/V_{iivc}$ indexes did not provide better diagnostic information than the simpler renal vein renin ratio (RVR).

It must also be acknowledged that the usefulness of the indexes derived from the measurement of RVR has been prospectively investigated by up-to-date statistical procedures, such as the receiver operator characteristics (ROC) curve analysis, in large populations of patients only in a study by the authors' group in 2002. Until that study, this lack of information resulted in some confusion regarding the optimal cutoff values. As an example, even the popular cutoff value of 1.5 for the RVR was empirically derived and never tested with the ROC curve analysis. Furthermore, only limited information existed on the usefulness of RVR measurements in patients with total renal artery occlusion and with bilateral renal artery stenoses. Thus, it remained unclear which of these indexes furnishes the best diagnostic accuracy and at which cutoff values the optimal combination of sensitivity and false-positive rate can be achieved.

CLINICAL RELEVANCE

The measurement of renin in renal vein plasma was introduced in the clinical arena 3 decades ago to demonstrate a unilateral overproduction of renin and thus to establish a pathophysiological link between ischemia-triggered activation of renin synthesis and high BP. The usefulness of RVR for predicting the blood pressure response to angioplasty or stenting has been also confirmed; nonetheless, most investigators would support the concept that lateralization of renin secretion is not a prerequisite for the cure of hypertension on revascularization. There is, indeed, a general consensus among experts that RVH can be

diagnosed only retrospectively, e.g., on demonstration of either normalization of a significant fall of BP values after correction of renal ischemia, due to the lack of accuracy of all tests that have been proposed over the years to predict the outcome of renal revascularization. For RVR, this might be due to the fact that at least one-third of patients with proven RVH do not have evidence of an activated renin-angiotensin system at the time of diagnosis.

It should also be noted that PTRAs and stenting are being used as effective alternatives to surgery for the treatment of RVH, because they incur substantially lower risks and lower costs than surgery and can be performed on the same occasion when diagnostic angiography is carried out. Furthermore, they can be effective and safe even in patients for whom they were formerly deemed to be contraindicated, such as those with atherosclerotic ostial renal artery stenosis. It has also been pointed out that avoidance of RVR measurements would result in a substantial savings of time and money due to cutting of catheters and assay costs. Accordingly, RVR measurements have largely been abandoned.

Yet there are patients, such as those with unilateral small kidney due to total renal artery occlusion and those with renin-producing tumors, in whom this issue is still relevant. In the former patients, nephrectomy remains the best therapeutic option and RVR measurements might be useful to pose the indication to surgery, as discussed below. In the latter patients, a clear-cut gradient of renin secretion may be the only clue to the identification of a small tumor. In truth, these tumors can be quite small and therefore may escape detection with computed tomography, magnetic resonance imaging, and even angiography. Thus, in patients with biochemical evidence of secondary (renin-dependent) aldosteronism and no renal artery stenosis, RVR studies with segmental sampling are mandatory.

RECOMMENDATIONS FOR USE OF RVR TESTS IN CLINICAL PRACTICE

Several relevant issues concerning RVR were investigated in a prospective study by Rossi and colleagues (2002) in consecutive patients undergoing both digital subtraction angiography and RVR measurements because of a high pretest probability of RVH. The specific aims of the study were to establish the diagnostic accuracy of these indexes in the subsets of RVH patients with and without total renal artery occlusion and with unilateral and bilateral renal artery disease. Based on this study, answers to the following questions can be put forward.

Which Is the Best Index Derived from RVR Measurements?

The RVRR, e.g., the ratio of PRA in the ischemic side to that in the contralateral side, is the index that provides the best discrimination between patients with and without RVH. The ratio $(V_{\text{isch}} - V_{\text{iivc}})/V_{\text{iivc}}$, albeit on average significantly different between patients with and without RVH, shows a greater overlap of values. In contrast, the two indexes of contralateral suppression, $(V_{\text{ctl}} - V_{\text{iivc}})/V_{\text{iivc}}$ and V_{ctl}/A , do not provide satisfactory discrimination between patients with and without RVH. When the usefulness of the RVRR index for diagnosing RVH by ROC curve analysis was examined, it was found that the area under the ROC curve is significantly ($P < 0.0001$) different from the identity line, thus confirming that RVRR provides an incremental gain for the diagnosis of RVH.

Can RVRR Identify RVH Due to Total Renal Artery Occlusion?

Approximately one-fourth of RVH patients who are seen at hypertension clinics can have a totally occluded renal artery. Practically all of them also have markedly elevated PRA levels in the renal vein plasma of the affected side, which translates into a significantly higher ratio of the affected side to the unaffected side (RVRR), compared to both the nonoccluded RVH and the non-RVH patients. Thus, a totally occluded artery is consistently associated with unequivocal evidence of renin lateralization. Accordingly, RVR could be useful not only for distinguishing vascular (occluded) from nonvascular unilateral small kidney, information also attainable by echo-color Doppler assessment of intrarenal artery blood flow, but also for establishing the indication to nephrectomy.

Can RVRR Identify RVH without Total Renal Artery Occlusion?

The incremental diagnostic value of RVRR for diagnosing RVH was mostly due to the contribution of the minority of RVH patients with total renal artery occlusion. The authors examined this hypothesis and could show a clear-cut shift to the left of the ROC curve, thus unequivocally confirming the usefulness of RVRR for diagnosing RVH due to total renal artery occlusion. The authors also demonstrated a shift to the right, e.g., a decrease in the urea under the curve (AUC), when patients with angiographic evidence of renal artery occlusion were excluded. These findings indicated that RVR identified far more accurately RVH with renal artery occlusion than RVH without renal artery occlusion.

Can RVRR Identify RVH in Patients with Bilateral Renal Artery Lesions?

The authors investigated this question using the ROC curve analysis in the subsets of patients with unilateral and bilateral renovascular disease. It was found that RVRR, as well as the other indexes, was more accurate in the former patients than in the latter patients, particularly for the identification of RVH caused by total occlusion of the renal artery. Of note, the AUC of the ROC curve for all indexes did not differ significantly from the identity line when patients without total occlusion of the renal artery were excluded. This finding indicates that, in the presence of bilateral lesions, lateralization of renin secretion is detectable by RVR measurements only if there is total renal artery occlusion.

What Is the Best Cutoff Value of the RVRR?

With the ROC curve analysis, it was also found that the optimal cutoff value, e.g., the value providing the best tradeoff between sensitivity and specificity, for the identification of RVH, was 1.55, e.g., close to the empirically derived value of 1.50. However, even in a selected population with a high prevalence of RVH, this cutoff value corresponded to a low degree of sensitivity (54%) and a relatively high false-positive rate (15%).

In contrast, for identification of RVH due to total renal artery occlusion, the cutoff value of RVRR that warranted the best combination of sensitivity (87%) and false-positive rate (22%) was 1.70, e.g., higher

than that for the identification of RVH. Accordingly, it can be concluded that (1) RVR measurements provide an unequivocal diagnosis in the vast majority of patients with RVH due to total renal artery occlusion and (2) a higher cutoff value is needed to optimize the diagnostic accuracy of RVR measurement-derived indexes in these patients. The fact that, even with a cutoff value that is higher than the commonly used value of 1.5, there is a 22% false-positive rate is certainly not reassuring from the clinical standpoint and mandates some caution, particularly when the RVR is just above this value. This is of interest because the detection of a unilateral small kidney on abdominal ultrasound or renal scintigraphy in hypertensive patients is not uncommon. These patients pose a special challenge from the therapeutic standpoint because, compared to nephrectomy, surgical revascularization of a totally occluded renal artery can provide a better preservation of renal function when undertaken in cases with angiographically demonstrated distal reconstitution of the vessels and evident nephrogram. However, when associated with a unilateral small kidney, total renal artery occlusion is usually best treated by nephrectomy. The latter normalizes blood pressure in the vast majority of such patients, whereas both PTRAs and surgical revascularization are often unsuccessful and lead to a high rate of secondary nephrectomy, because of the coexistence of marked obliterative changes in the intrarenal vascular bed at microangiography. Thus, prior knowledge of the RVR measurements can help to establish the indication for nephrectomy.

CONCLUSIONS

Evidence indicates that RVR measurements are most useful for identifying patients with a small unilateral kidney due to total renal artery occlusion and those with renin-producing tumors. In contrast, RVR measurements are of limited value for deciding on whether to revascularize a kidney with renal artery stenosis. Since nephrectomy provides the best chances of cure of hypertension in patients with a totally occluded renal artery, RVR measurements are useful for deciding on the indication for nephrectomy. Therefore, they should be performed whenever the clinical picture is indicative of a small unilateral kidney due to total renal artery occlusion and/or of a renin-producing tumor.

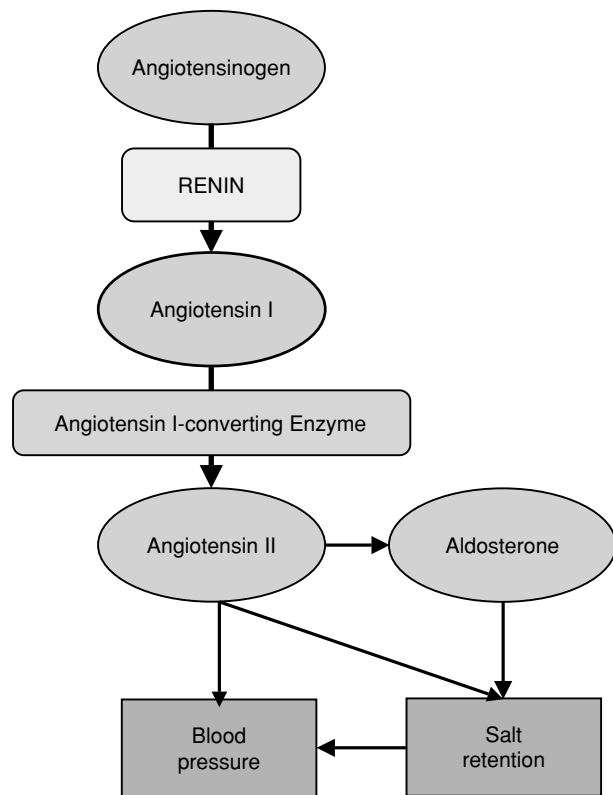

Figure 1 Schematic illustration of the renin–angiotensin–aldosterone system.

the juxtaglomerular portion of the preglomerular arteries. In response to prolonged stress situations, renin expression in vascular smooth muscle cells in renal arterioles can be reactivated.

In human, a single-copy gene on chromosome 1 encodes the enzymatically inactive prorenin. After cleavage of the leader presequence, prorenin is packaged into storage granules, which mature to secretory granules. During vesicle maturation, the enzymatically inactive prorenin is shortened by proteolysis to active renin, which is released from the JGE cells by regulated exocytosis. Some of the prorenin escapes packaging into secretory granules and is constitutively secreted into the circulation. Therefore, plasma contains both prorenin and active renin, with prorenin dominating over active renin in human plasma. Renin is variably glycosylated and has an average molecular weight of approximately 40 kDa. The renin concentration in the plasma can be estimated directly by radioimmunoassay or more indirectly through its enzymatic ability to generate angiotensin I, which in turn can be measured by immunoassay. Plasma renin activity in human is in the range of 1–5 ng angiotensin I per milliliter of plasma.

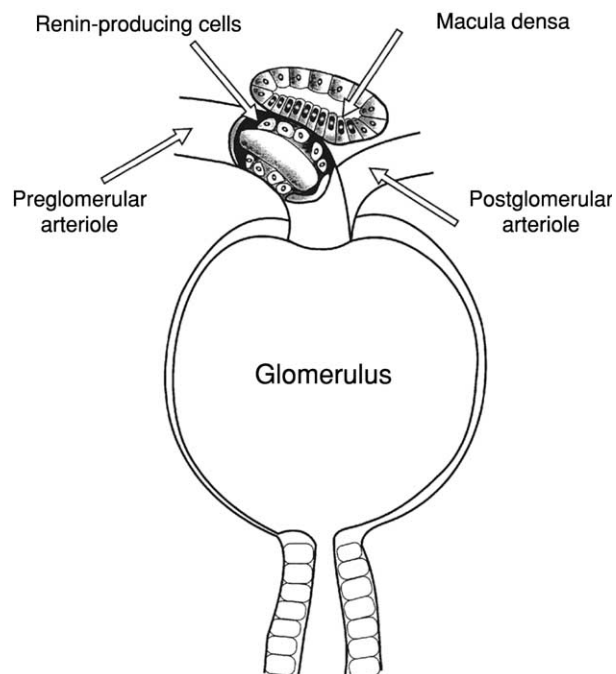

Figure 2 Localization of renin-producing cells within the kidney, which are the main source of renin.

PARAMETERS REGULATING RENIN SECRETION AND RENIN SYNTHESIS

Renin secretion and renin synthesis are coordinated, but they are regulated on different time scales. Whereas renin secretion from the kidneys can change within seconds, changes in renin synthesis require several hours. This time gap creates no problem, however, since the kidneys contain enormous stores of renin, sufficient to maintain a normal renin secretion rate over days, even if *de novo* synthesis of renin ceased.

Renin secretion and synthesis are essentially triggered by sympathetic nerve activity with noradrenaline as the main stimulatory transmitter acting via β_1 receptors on JGE cells. Renin secretion and synthesis are further controlled by several negative feedback loops (see Fig. 3). A very short feedback loop mediates an inhibitory action of angiotensin II via AT1 receptors. Furthermore, the sodium content in the body, which is determined by the activity of the RAAS, exerts a negative effect.

Finally, the blood pressure, which is influenced by the activity of the RAAS, exerts an inhibitory effect by a direct action on renal preglomerular vessels. Apart from these systemically acting factors, locally generated signals influence the function of JGE cells. Thus,

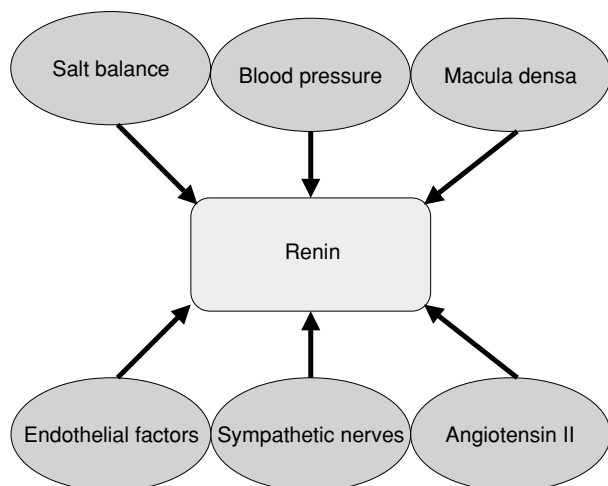

Figure 3 Factors controlling renin synthesis and renin secretion in the kidney.

the tubular macula densa cells, which are directly adjacent to the JGE cells, influence renin secretion in an inverse fashion to their salt resorption rate, establishing the so-called macula densa control of renin secretion. Renin secretion and synthesis are also influenced by endothelial factors, such as prostaglandins, nitric oxide, and endothelins. Furthermore, pro-inflammatory cytokines inhibit renin synthesis.

At the cellular level, renin secretion and synthesis are controlled by the cyclic AMP pathway, which acts in a stimulatory manner, and by the calcium pathway, which acts in an inhibitory manner.

ORGANISMS WITH GENETIC DEFECTS OF COMPONENTS OF THE RAAS

Mice, in contrast to humans, can possess two renin genes (*ren-1* and *ren-2*) and become hypotensive if the *ren-1* gene, corresponding to the human renin gene, is disrupted. Mice lacking functional angiotensinogen as the substrate for renin have low blood pressure and problems in the development of a normal urinary tract system. Mice lacking ACE also display hypotension and the males exhibit a markedly reduced fertility, due to the occurrence of ACE in sperm cells. A novel ACE isoform (ACE-2) is essential for heart function, since mice lacking ACE-2 develop a severe cardiac contractility defect. Mice lacking AT1 receptors have low blood pressure values and show changes in kidney structure. Mice lacking functional AT2 receptors are more sensitive to the hypertensive effect of angiotensin II mediated via AT1 receptors. Mice lacking the

mineralocorticoid receptor mediating the effect of aldosterone have severe problems with sodium balance and blood pressure regulation. These animals die early after birth.

RENIN FOR PATHOPHYSIOLOGY AND DISEASE

The clinical observation that inhibitors of the RAAS have a positive blood pressure-lowering effect in hypertensive patients suggests that the RAAS is critically involved in the development and maintenance of hypertension. However, renin plasma concentrations are often low during hypertension, suggesting that a hypersecretion of systemic renin is not as often the cause of hypertension. It is possible that local renin-angiotensin systems could be relevant in this context. A clear causal role for renin in pathophysiology is seen in the course of renal hypoperfusion or during ischemic kidney disease, which are associated with hyperreninemia. In addition, perturbations in sodium balance and extracellular volume (sodium accumulation and volume expansion) after prolonged stimulation of sympathetic outflow, such as during chronic heart failure, are causally related to the hypersecretion of renin.

Activation of the local renin-angiotensin system in particular is believed to contribute to changes in blood vessel wall structure, such as media thickening, and is also believed to contribute to the development of cardiac hypertrophy.

DRUGS INTERFERING WITH THE RAAS

A variety of drugs are able to interfere with the activity of the RAAS. Renin inhibitors have been developed to directly inhibit the enzymatic activity of renin. The frequently used ACE inhibitors block the processing of angiotensin I to angiotensin II, thus lowering the circulating levels of angiotensin II and reducing its biological actions. Similar effects are achieved with the commonly used AT1 receptor blockers. The effects of aldosterone can be inhibited by spironolactone, which is a structural antagonist for aldosterone at the mineralocorticoid receptor.

TH Regulation

Several mechanisms are responsible for modulating the supply of TH to tissues: (1) the hypothalamus–pituitary–thyroid axis controls TH synthesis and release from the thyroid gland via stimulation by TSH; (2) the generation of T3 from T4 at the tissues via the action of deiodinases may modulate tissue responsiveness to TH; and (3) autoregulation of the expression of the TH receptor (TR) can also modulate the effect that TH has on a tissue, e.g., the more receptor, the larger the response, and the less receptor, the smaller the response, for a given amount of hormone. TSH synthesis and secretion are stimulated by TRH, a tripeptide derived from the hypothalamus. TSH originating from the pituitary gland in turn stimulates TH synthesis and secretion. Although T4 is the predominant form of TH released from the gland, and T3 generated at the tissue level is the biologically active hormone, T4 can also bind to the TR, but with 100-fold less affinity. T3, generated from the conversion of T4 in the pituitary and hypothalamus by type II deiodinase, controls the synthesis and secretion of TSH and TRH through a negative feedback loop (Fig. 1).

The signs, symptoms, and laboratory abnormalities observed in RTH are due to reduced peripheral tissue and pituitary responsiveness to TH, resulting in impaired negative feedback of T3 on TSH/TRH and impaired peripheral tissue action of T3.

Mechanisms of TH Action

TH enters the cell by a process of concentration-dependent passive diffusion after dissociation from the serum hormone-binding proteins. Several molecules have been identified as putative TH transmembrane transporters, but none have been shown to be unique for TH. TH action, for the most part, is mediated through specific TRs in the cell nucleus, although pathways of nongenomic action of TH have been described.

TRs are members of the nuclear hormone receptor superfamily together with the retinoic acid receptors (RXRs), 9-*cis*-retinoic acid receptors, vitamin D₃ receptors, and peroxisome proliferator-activated receptors. TRs act as ligand-dependent transcription factors that increase or decrease the expression of target genes depending on whether the gene promoters contain, respectively, positively or negatively regulated TH-response elements.

There are two genes, *TRα* and *TRβ*, located on chromosomes 17 and 3, respectively, that encode TRs.

Figure 1 Schematic representation of the hypothalamic–pituitary–thyroid axis. Under normal conditions, the hypothalamus secretes TRH, which stimulates the pituitary to produce TSH, which stimulates the thyroid to produce mainly T4. T4 is metabolized in the peripheral tissues to T3 and, in turn, THs feed back in an inhibitory fashion on the hypothalamus and pituitary. Thyroid hormone action on pituitary and peripheral tissues occurs when T3 binds to its receptor; in RTH, the feedback is inhibited due to decreased sensitivity of the pituitary to TH, resulting in elevated TSH with increased T4 secretion. The peripheral tissues also have decreased sensitivity to TH in RTH.

TRs are cellular homologues of the viral oncogene *erb A*. Each gene generates at least two proteins by alternative splicing: TR α_1 , TR α_2 , TR β_1 , and TR β_2 .

The relative expression of the two TR genes and the distribution of their products vary from tissue to tissue and during different stages of development. Furthermore, TH differentially regulates the expression of the two TR genes and their isoforms.

The α and β TR isoforms have a well-conserved DNA-binding domain (or C domain) separated from the ligand (T3)-binding domain (or E domain) by a hinge domain (D domain). TR α_2 , due to a carboxyl-terminal sequence difference, does not bind TH and the molecule does not function as a TH receptor (Fig. 2).

TRs form homodimers (TR/TR) or form heterodimers with RXRs (TR/RXR) and bind to specific DNA sequences termed TH-response elements (TREs), which are located near the transcription start point of TH-regulated genes.

On genes up-regulated by TH, the unliganded TRs suppress basal gene transcription activity by interacting with a class of nuclear proteins known as

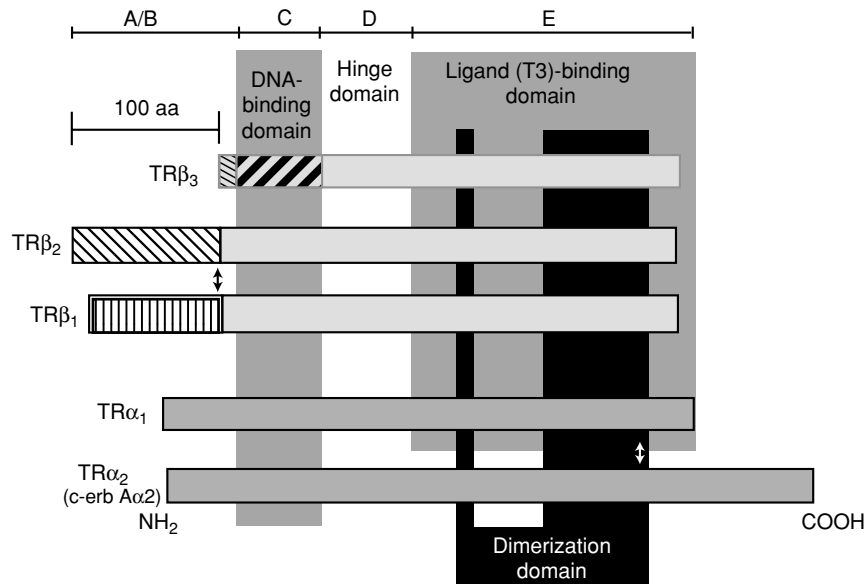

Figure 2 Schematic representation of the principal TR forms and their functional domains. Each of the two TR genes (*TRα* and *TRβ*) expresses two major protein forms (1 and 2) by alternative splicing (arrows). The shading pattern of the bars corresponds to the degree of amino acid sequence similarity (identical, similar, or completely different). Differences are most marked in the amino termini (NH₂) of the TRs. The different carboxyl terminus (COOH) of the α2 form completely abolishes T3 binding and this product is not considered to be a proper TR. The functional domains are also identified by a letter code and by the striped backgrounds.

corepressors, such as the nuclear receptor corepressor and the silencing mediator for retinoid and TH receptor. Conformational changes in TR, produced by T3 binding, enhance the occupation of TREs by TR/RXR heterodimers, release the corepressor complex, and recruit coactivators such as steroid receptor coactivator 1 (SRC-1), among others, all exhibiting histone acetyl transferase activity. SRC-1 modifies the structure of the chromatin and, by loosening the nucleosome at the site of the promoter, activates gene transcription (Fig. 3). The mechanisms involved in the genes that are down-regulated by TH, such as TSH, are less well understood, but are likely to involve the same classes of molecules on a different TRE that causes corepressors to become “activators” and coactivators to become “repressors.”

MOLECULAR BASIS OF RTH

Location of Mutations Associated with RTH

Eighty to 85% of subjects with RTH have mutations in the *TRβ* gene, whereas no mutations have been described in the *TRα* gene. One hundred fourteen mutations have been described in 261 different families. The majority of mutations have occurred in three “hot spots” located in the ligand-binding

domain (exons 8–10) of *TRβ* (Fig. 4). Whereas the majority of these mutations are single nucleotide substitutions, 5 families had nucleotide insertions and 7 families had from one to three nucleotide deletions. Eleven mutations were present in 5 or more families and the R338W mutation was reported to occur independently in 23 different families (Table I). The mutations commonly occur in a guanine immediately following a cytosine in 73% of the cases of frequently appearing mutations compared to only 5% of the other 81 point mutations described in 1 to 4 families each. This finding suggests that the “GC” regions are mutational hot spots in the *TRβ* gene.

The RTH index family had a homozygous deletion of the *TRβ1* allele, representing the only example of recessive inheritance of RTH. In all other cases, the inheritance pattern of RTH is autosomal-dominant, involving a single nucleotide substitution or small deletions. RTH is sporadic in 15% of cases, when a mutation has arisen *de novo*, where neither parent has the abnormal phenotype.

The mutant receptors either cannot bind TH or have reduced affinity for TH. As a result, the corepressor is not released and the gene is not activated. Other receptor mutants have been found that do bind T3 but release the corepressor more slowly than normal or have a weaker interaction with the coactivator.

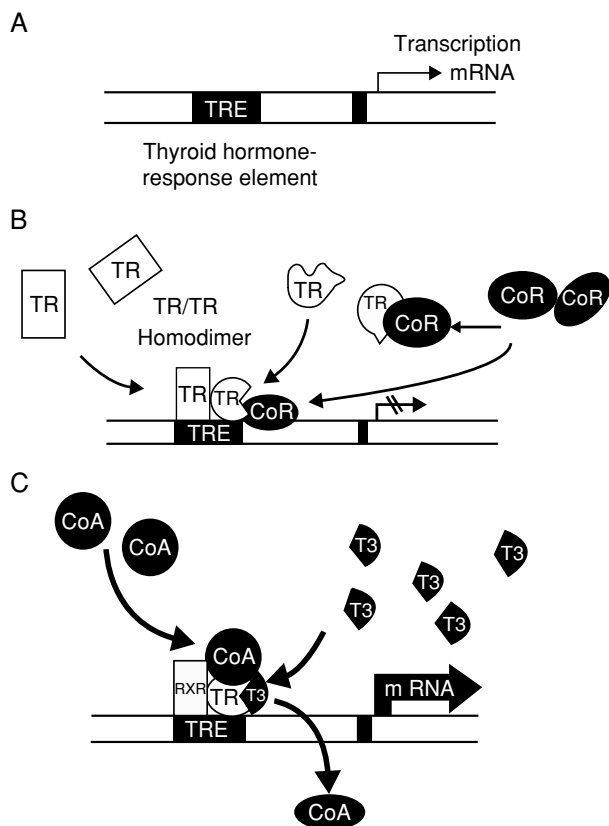

Figure 3 The mechanism of TH action. Schematic representation of the elements involved in the mediation of TH action through the regulation of T3-responsive gene expression (A). The unliganded TR homodimerizes with TR, associates with CoR (corepressor), and exerts a suppressive effect on genes positively regulated by TRE (B). Formation of a TR/T3 complex resulting in disassociation of CoR, occupation of TRE by TR/RXR heterodimers, and recruitment of CoA (coactivator) to enhance the transcription of genes positively regulated by TRE (C).

Ten to 15% of families with RTH do not have mutations in the TR β . These non-TR RTH subjects have a phenotype similar to those with TR β mutations including baseline thyroid function tests as well as metabolic and TRH responsiveness to exogenously administered TH. Since non-TR RTH also has an autosomal-dominant mode of inheritance, it is believed that another transcriptional cofactor involved in TH action could be responsible for the hormone resistance. In support of this notion are studies of the hypothalamic-pituitary-thyroid axis in knockout mice lacking the SRC-1 (coactivator) or the RXR that show that the absence of a cofactor can cause RTH. Further work is required to determine whether there are other forms of hormonal resistance in the non-TR RTH subjects in which the same cofactor may be responsible for mild, but multiple types of hormone resistance.

Table I TR β Codons with Five or More Families Having the Identical Mutation

| Codon mutation | No. of families | Nucleotide substitution |
|----------------|-----------------|--------------------------|
| R243W | 6 | CGG \rightarrow TGG |

| P453T | 10 | CCT \rightarrow ACT |
| P453S | 9 | CCT \rightarrow TCT |

Dominant Negative Effect

Mutant TR β s interfere with the function of the wild-type TRs, a phenomenon termed the dominant negative effect (DNE). Mutant TR β receptors are still able to bind to TRE and dimerize with normal TRs or RXRs, interfering with the function of the normal TRs. There is a strong correlation between the DNE measured *in vitro* and decreased release of transcriptional corepressor from TRs.

For a DNE to occur, the TR mutant must bind to TRE, which may explain why no mutations have been identified in the DNA-binding domain and why in a family with a deletion of all coding sequences of the TR β gene the heterozygotes did not manifest the phenotype of RTH. Interestingly, one subject with a homozygous deletion of TR β Thr-337 (amino acid deletion) with a dominantly inherited RTH pattern manifested the most severe form of RTH.

PATHOPHYSIOLOGY

The lack of negative feedback of T3 on TSH results in persistent TSH secretion and thyroid gland stimulation, resulting in an increase in TH synthesis and secretion. The normal or slightly increased TSH usually responds by a further increase in the release of TRH, distinguishing this from subjects with a TSH-secreting pituitary adenoma.

The serum TSH of RTH patients is identical immunologically to the serum TSH of normal controls. It does not contain an excess of glycoprotein α -subunits (TSH α) that are typically found in the serum of patients with TSH-producing pituitary tumors. However, the TSH has an increased biological

Figure 4 Location of natural mutations in the *TRβ* gene associated with RTH. Schematic representation of the *TRβ* and its functional domains for interaction with TREs (DNA-binding domain) and with hormone (T3-binding domain). The mutations that have been found in *TRβ* cluster in three areas of the T3-binding domain. The amino acid positions between which the mutations are found are indicated below the boxes (A, B, and C). Note the “cold regions” of 28 and 75 amino acids, devoid of mutations associated with RTH.

potency *in vitro*, perhaps explaining how normal TSH levels produce goiter and hypersecretion of TH by the thyroid gland. Another possible, albeit unproven, explanation of the goiter in RTH subjects with normal serum TSH could be augmented thyrocyte sensitivity to TSH through increased density of TSH receptor units.

Several of the clinical features encountered in some patients with RTH may be the manifestation of selective tissue deprivation of TH during early stages of development. The severity of symptoms is related to the relative expression of the mutant allele (and perhaps cofactors) in the particular tissue. For example, cardiac tissue predominantly expresses *TRα*. Most RTH subjects present with tachycardia: because of RTH subjects' abnormal *TRβ*, they overproduce TH, but since the heart has *TRα*, which is normal, tachycardia results.

Thyroid tissue obtained by biopsy or at surgery revealed various degrees of hyperplasia of the follicular epithelium, supporting the idea of structural heterogeneity of the follicles. Little can be said about the pathological findings in tissues other than the thyroid because of the unavailability of autopsy data from patients with RTH. Metachromasia in fibroblasts is present in patients with RTH as well as in patients with myxedema due to TH deficiency, although treatment with the hormone failed to induce the disappearance of the metachromasia in fibroblasts from patients with RTH.

CLINICAL FEATURES

Clinical Classification

The clinical presentation of RTH is highly variable both between families and among family members with identical *TRβ* mutations. The majority of

individuals appear to be euthyroid and therefore they are asymptomatic. Some may manifest symptoms suggestive of TH deprivation, such as growth retardation, impaired cognitive ability, and hypercholesterolemia, whereas others show signs of TH excess, such as tachycardia, advanced bone age, or hyperactivity. Not uncommonly, individuals have symptoms of both TH deficiency and excess.

Subjects with RTH that appear to be eumetabolic and maintain a near normal serum TSH concentration have been classified as having generalized resistance to TH (GRTH). In such individuals, the defect seems to be compensated for by the high endogenous levels of TH. In contrast, patients with equally high levels of TH appear to be hypermetabolic because they are restless or hyperactive or have a rapid heart rate. Such individuals have been classified as having selective pituitary resistance to TH (PRTH). Subdivision of RTH into GRTH and PRTH is an artifact arising from the subjective nature of symptoms and poor specificity of signs. Subjects harboring the same mutations, and even belonging to the same family, have been classified as having GRTH and PRTH. Furthermore, clinical studies have shown that the responses of peripheral tissue markers to TH action were equally attenuated. The classification of RTH into GRTH and PRTH can therefore be viewed as opposite ends of the spectrum of a single disease.

Clinical Findings

The phenotype of RTH is variable, with most patients presenting with mild to moderate symptoms. In children, investigations leading to diagnosis have been undertaken because of goiter, hyperactive behavior, learning disabilities, or developmental delay.

Most adults seek medical attention because of goiter or rapid heart rate. RTH is being diagnosed in infancy owing to routine neonatal screening programs that measure both TSH and T4 and to hormonal and DNA analyses performed in infants born to parents known to have RTH. In adults, abnormalities found on routine thyroid testing, in the absence of clinical findings, have been responsible for the diagnosis of RTH.

The majority of untreated subjects are eumetabolic at the expense of high levels of TH. The degree of this compensation for the tissue hyposensitivity to the TH is variable among individuals as well as in different tissues. As a consequence, there is clinical and laboratory evidence that TH deficiency and excess often coexist.

Many attempts have been made to demonstrate tissue hyposensitivity *in vitro*. The common finding of paradoxical responses to TH is difficult to explain. They are possibly due to: (1) variable interaction of the mutant TR with the α and β isoforms of the normal TRs; (2) variable expression of the *TR α* and *TR β* genes in different tissues; and (3) differences in the regulation of expression of the *TR α* and *TR β* genes by the hormone-activated TR, which in some tissues may be in opposite directions.

On physical examination, goiter is the most common abnormality, occurring in 85% of cases. Tachycardia occurs in 80–90% of subjects with RTH and is caused by excess TH acting on the *TR α* gene. Careful evaluation of subjects with RTH has shown that 50% have learning disabilities, often associated with attention deficit hyperactivity disorder (ADHD) and, on the average, lower intellectual quotients (IQs). However, frank mental retardation (IQ <60) occurs in only 3% of cases. RTH can present with mild to moderate growth retardation and delayed bone maturation in 25% of cases. Hearing defects have been detected in almost 25% of patients (Table II). Other features, such as frequent ear, nose, and throat infections, decreased bone mass, deafness, hypotonia, and seizures, have been recognized.

The course of the disease is as variable as its presentation. Some subjects have normal growth and development and lead a normal life. Others present variable degrees of mental and growth retardation. There is some evidence that the severity of resistance tends to improve as the subject gets older as determined by thyroid function tests. This has been shown in the *TR β* knockout mouse model of RTH and is supported from some published studies in humans.

Table II Clinical Features of the RTH

| Laboratory findings | Normal ^a | RTH ^b |
|--|---------------------|------------------|
| T4 Levels (pmol/liter) | 12.8–24.4 | 41±2.1 |
| T3 Levels (pmol/liter) | 3.8–8.4 | 11.4±1.5 |
| TSH Level (mU/liter) | 0.5–4.5 | 3.15±0.3 |
| Clinical findings | Frequency (%) | |
| Goiter | 65–95 | |
| Tachycardia | 50–80 | |
| Emotional disturbances | 70 | |
| Recurrent ear, nose, and throat infections | 50 | |
| Attention deficit hyperactivity disorder | 40–60 | |
| Hyperkinetic behavior/learning disability | 20–50 | |
| Low IQ (IQ <85) | 35–50 | |
| Delayed bone age | 30–47 | |
| Hearing loss | 10–22 | |
| Short stature | 18–26 | |
| Mental retardation (IQ <70) | 4–16 | |

^aNormal denotes normal range in the general population.

^bRTH denotes mean values of the thyroid function tests in patients with RTH.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Serum Levels of THs and TSH

Increased levels of free T3 and T4 in combination with nonsuppressed TSH in serum are indicative of RTH. One should rule out any condition that can give rise to spuriously elevated T3 and T4 levels with normal or elevated TSH, such as abnormalities in TH transport, drugs, and the presence of antibodies that can interact with the assays.

Serum T3 and T4 values range from just above the upper limit of normal to a severalfold increase in the upper limit of normal. The degree of T3 and T4 elevation is usually congruent, resulting in a normal T3 to T4 ratio. Reverse T3 concentration is also high in patients with RTH. The concentration of serum thyroglobulin reflects the level of TSH-induced thyroid gland activity. The extrathyroidal pool and absolute daily production of T4 and T3 are increased by approximately two- to fourfold. The extrathyroidal conversion of T4 to T3 has been found to be normal.

The fractional uptake of radioiodide by the thyroid gland is high. The iodide appears to be normally organified since no discharge of trapped iodide has

been observed following the administration of perchlorate.

TRH Testing

A diagnostic feature of the syndrome is the presence of normal or slightly elevated serum TSH levels and preservation of its response to TRH despite elevated TH levels. The TSH response to TRH is either normal or exaggerated; the latter is more common in patients receiving anti-thyroid drug therapy or with a history of prior surgery or radioiodide therapy. The bioactivity of secreted TSH is normal or increased and the concentration of its free α -subunit is not disproportionately high. In contrast, the α -subunit to TSH ratio is elevated in TSH-secreting tumors.

Responses to the Administration of TH and Other Drugs

Because resistance to TH plays a principal role in the pathogenesis of the syndrome, patients have been given exogenous TH in order to observe their responses and thereby establish the presence and degree of insensitivity to the hormone. A standardized diagnostic protocol, using short-term administration of incremental doses of L-T₃, is recommended. The three doses given in sequence to an adult are a replacement dose of 50 μ g/day and two supraphysiological doses of 100 and 200 μ g/day. The hormone is administered in a split dose every 12 h and each incremental dose is given for 3 days. Doses are adjusted in children and in adults of unusual weight to achieve the same level of serum T₃. L-T₃, rather than L-T₄, is used because of its direct effect on tissues, bypassing the potential defects of T₄ transport and metabolism. In addition, the more rapid onset and shorter duration of T₃ action reduce the period required to complete the evaluation and shorten the duration of symptoms that may arise in some individuals.

The administration of supraphysiological doses of TH suppresses TSH secretion, resulting in the decrease and eventually the abolition of the TSH response to TRH. Various responses of peripheral tissues to the administration of TH have been quantitated. Most notable are measurements of the basal metabolic rate, pulse rate, reflex relaxation time, serum cholesterol, lipids, enzymes, sex hormone-binding globulin, and urinary excretion of hydroxyproline, creatinine, and carnitine. Either no significant changes were observed or they were much reduced relative to the amount of TH given.

Family Studies

Once a diagnosis of RTH is suspected, testing of thyroid function in siblings and parents can be helpful. Confirmation of the same phenotype in other related individuals makes the diagnosis of RTH more likely than a diagnosis of a TSH-secreting adenoma as the latter has not been reported to be familial. Also, identification of an abnormal phenotype in an asymptomatic family member will allow for a correct diagnosis and may prevent unnecessary diagnostic testing and treatment. From a practical standpoint, a physician may find it difficult to arrange for thyroid testing on asymptomatic relatives; however, considering the cost of magnetic resonance imaging (MRI), documentation of an inherited disorder is more cost-effective.

Imaging Studies

Imaging studies are not necessary for the diagnosis of RTH. Although an MRI of the pituitary is often ordered to satisfy the physician that a TSH-secreting adenoma is absent, it cannot be justified as routine in the work-up for RTH due to the fact that a small microadenoma may be missed by the MRI and 10% of normal individuals may have some abnormality that may not have any clinical significance.

Genetic Studies

The use of genetic testing in a new family with RTH for mutations in the *TR β* genes is limited to research laboratories. In light of the 114 mutations that have been described, "screening" would be useful only if it were to involve sequencing of at least the last five coding exons of the *TR β* . Once a mutation has been identified, screening of other family members for the mutation can be more sensitive than screening for the phenotype, due to the mild and variable nature of the RTH phenotype. Confirmation of the mutation in a newborn may eliminate the need for treatment. Confirmation of the mutation in a fetus at some point may allow clinicians to prescribe intrauterine treatment, if necessary.

Summary of Recommended Diagnostic Evaluation

1. The usual presentation is high serum levels of free T₄ and T₃ with nonsuppressed TSH.

2. Confirm the elevated serum levels of free thyroid hormone (T4 and T3) and exclude TH transport defect or antibody interference in the assays.
3. Measure thyroid function tests in other family members.
4. In sporadic cases, exclude the presence of a pituitary adenoma by measurement of the α -subunit in serum.
5. Demonstrate a blunted TSH suppression and metabolic response to the administration of supra-physiologic doses of TH.
6. Perform genetic studies when indicated.

TREATMENT

General Considerations

No specific treatment is available to fully correct the defect. Fortunately, in most cases of RTH, the partial tissue resistance to TH appears to be adequately compensated for by an increase in the endogenous supply of TH and no treatment is necessary in these cases.

In cases where previous erroneous diagnosis has occurred resulting in postsurgical or postradiation hypothyroidism, treatment with TH can be started. The serum TSH level can be used as a guideline for hormone dosage; required T4 doses can be as high as 1000 $\mu\text{g}/\text{day}$.

Some patients with RTH present with peripheral tissues that are relatively more resistant than the pituitary. Thus, compensation for the defect at the level of peripheral tissue is incomplete. In such instances, administration of supra-physiologic doses of TH is indicated. Since the dose varies among affected subjects, it should be individually determined by assessing tissue responses.

Patients without prior anti-thyroid treatment but with more severe thyrotroph resistance and symptoms of thyrotoxicosis may also require therapy. Common symptoms are hyperactivity, tachycardia, and, less commonly, diarrhea. Usually symptomatic treatment with a β -adrenergic blocking agent would suffice.

Treatment with L-T3 may improve the symptoms of ADHD in a significant proportion of children who also have RTH.

Although RTH is a relatively rare condition, the physician should be aware that common diseases, such as autoimmune-mediated hypothyroidism and hyperthyroidism, can occur in subjects with RTH. Concurrence of Grave's disease and RTH would significantly alter the therapeutic and diagnostic approach to the care of these patients, but the overall

goal would be to obtain clinical euthyroidism with a normal serum TSH.

Pharmacologic Therapy

TRIAAC has been used successfully to decrease the serum TSH and TH levels, to reduce goiter size, and to alleviate some of the symptoms attributed to the effect of TH on peripheral tissues. However, the concomitant effects of TRIAC on markers that measure TH action on peripheral tissues, as well as on heart rate, are minimal, probably because the decrease in TH levels is offset by the intrinsic specific thyromimetic effect of TRIAC. The ability of TRIAC to suppress TSH without an increase in the thyromimetic effect on peripheral tissues is due to the following properties of this TH analogue: its higher affinity for TR β but not TR α as compared with T3 and its more rapid degradation. The mechanism mediating a similar effect attributed to D-T4 is less well understood. TRIAC was used to treat *in utero* a fetus harboring a TR β mutation in order to reduce fetal goiter. Although treatment was successful up to a point, some controversy has arisen due to the fact that repeated chordocentesis was necessary and that there is a lack of information about placental transport and fetal metabolism of TRIAC.

Dopaminergic drugs and somatostatin analogues have had limited use because of side effects and a low success rate in maintaining TSH suppression.

General guidelines for treatment with TH, usually L-T4, are as follows: (1) elevated serum TSH levels; (2) failure to thrive that cannot be explained on the basis of another illness or defect; (3) unexplained seizures; (4) developmental delay; and (5) history of growth or mental retardation in affected members of the family.

The future direction for the treatment of RTH will be the use of "designer drugs" that have been formulated to interact with a specific mutant TR β . Such a TH analogue would have a strong affinity for the mutant TR β and could eliminate the DNE. Such an analogue has already been reported, although no human studies have been reported. The rarity of the syndrome, the fact that RTH is not a life-threatening illness, the expense of the drug, and the cost of the necessary trials to obtain approval, even as an orphan drug, make the widespread availability of these drugs a prospect for the future.

Another set of compounds that are TR β isoform-specific agonists has been developed. These drugs, which would not stimulate TR α and therefore be cardioprotective, have also been reported and include medications such as CG-1.

Management of Pregnancy and RTH

Little is known about the ideal management of a pregnant mother with RTH. Different considerations may need to be made depending on whether the fetus also has RTH. In such an instance, one may predict that an increased level of maternal TH is necessary for the early development of a similarly affected fetus, but could be detrimental to a non-RTH fetus. Conversely, it is unknown whether a normal mother would be able to provide the appropriate amount of TH to an RTH fetus (for example, when the father is affected). Analysis of the limited amount of clinical data available indicates that there is no further morbidity in children and adults with RTH from affected or nonaffected mothers. However, there are no data on the outcome of normal children of RTH mothers. Further investigation is necessary for the evaluation of these important questions.

principal forms of premature ovarian failure: premature menopause, with complete follicular depletion of the ovaries, and the resistant ovary syndrome, with the presence of primordial follicles. Resistant ovary syndrome is occasionally associated with autoimmune disease. Possible etiologies of resistant ovary syndrome also include antibodies against the FSH receptor or mutations in the FSH receptor gene.

Ovarian reserve may be evaluated by the following assessment: basal serum FSH levels, basal estradiol levels, basal inhibin B levels, and autoimmune and genetic evaluation; ovarian volume and ovarian biopsy are less important.

Basal Serum FSH Levels

Once the ovary is more or less exhausted, increased pituitary production of FSH follows. It is accepted that the FSH level on day 2 or 3 of the cycle is the best marker for assessing ovarian reserve and for predicting the response to superovulation, with a good correlation with pregnancy rates. However, lack of a clear cutoff point, large variations among different laboratories, and monthly variations in FSH secretion in the same patient mean that FSH measurement is of only limited value in assessing the prognosis of IVF treatment.

Once the FSH levels start to fluctuate, it is probably too late. A decreased ovarian reserve can already be observed, and it is not clear whether starting stimulation during a later month with "normal" FSH levels will give a better result. It could be useful if each fertility center defined its cutoff point, depending on that center's experience. Furthermore, it could be very important to have another FSH evaluation in a different cycle and to test the pituitary response to the gonadotropin-releasing hormone (GnRH) test. In fact, in women with imminent ovarian failure, the pituitary is more sensitive to GnRH. This leads to higher FSH and LH pulse amplitudes, which underlie the elevated FSH concentrations during the early follicular phase.

Basal Estradiol Levels

Measurement of basal estradiol levels, in addition to FSH levels, might improve the ability to predict fertility potential compared with measurement of basal FSH and chronological age alone. The gold standard is to evaluate estradiol levels on day 3 of the cycle. A concentration of less than 80 pg/ml with a normal

FSH level in women between 38 and 42 years of age gives a good prognosis of successful treatment.

Basal Inhibin B Levels

Inhibin B is heterodimeric glycoprotein released by the granulosa cells of the follicle. One study showed that women with a low day 3 inhibin B level (<45 pg/ml) and a poorer response to superovulation for IVF were less likely to conceive a clinical pregnancy. It also showed that a decrease in inhibin B probably precedes the increase in FSH levels.

Inhibin is secreted mostly by granulosa cells and has a role in regulating the pituitary secretion of FSH. Therefore, inhibin is a potential marker for ovarian function and follicular content. The main function of inhibin in women is regulation of pituitary FSH secretion. One study showed that a decrease in serum inhibin concentrations could be observed when the ovarian follicular reservoir begins to diminish.

On the other hand, Petraglia and colleagues found that low levels of circulating inhibin B reflect ovarian failure in women with premature ovarian failure (POF), whereas women with hypogonadotropic hypogonadism have normal levels of inhibin B. The role of inhibin B in the pathogenesis of the resistant ovary syndrome has not been investigated in full, but inhibin B levels may be a helpful diagnostic tool.

Autoimmunity

To diagnose the resistant ovary syndrome occasionally associated with autoimmune disease, the first important step is to think about it. If a young woman presents an autoimmune disease, the ovarian function must be checked and the antiovary antibody must be tested. Furthermore, if a young woman presents hypergonadotropic amenorrhea, it is very important to evaluate her immunological asset to exclude a concomitant silent immunological disease.

Genetic

Several findings lean in favor of genetic control of the follicles decreasing during genital life by apoptosis. Ovarian insufficiency can occur by follicular maturation blocking (e.g., modification of genes GDF-9 and GDF-9B, null mutation of the FSH receptor gene, autoimmune polyglandular disease). Even if the etiology of premature ovarian insufficiencies in women remains unknown in more than 90% of the cases,

genetic studies on the family cases should make it possible to identify new genes involved in ovarian control.

Ovarian Volume

Increased age is associated with a decrease in ovarian volume. Transvaginal measurement of ovarian volume is quick, accurate, and cost-effective. Decreased ovarian volume is a sign of ovarian aging that may be observed earlier than a rise in FSH levels. Small ovaries are associated with poor response to superovulation and a high cancellation rate in IVF.

Ovarian Biopsy

Ovarian biopsy is more useful when attempting to obtain a correct diagnosis of the ovarian failure than when testing the ovarian response to the stimulation for an IVF protocol. The laparoscopic approach is preferred because it is less invasive.

THERAPEUTIC STRATEGIES

Genes acting at later stages of oocyte or ovarian follicle function, such as gonadotropin hormones and receptors, are responsible for POF in some women. POF has been found to be a heterogeneous disorder, the dissection of which offers promising insights into mechanisms governing germ cell origination, migration, and proliferation; meiotic mechanisms; and factors governing oocyte maturation and survival. Unfortunately, for these reasons, the genetical resistant ovary syndrome is far from being “solved.”

Identifying patients with autoimmune premature ovarian failure presents the opportunity to restore ovarian function by treating these patients with the proper immune modulation therapy. On the other hand, potent immune modulation therapy can have major complications. Corticosteroid therapy for autoimmune premature ovarian failure should be limited to use in placebo-controlled trials designed to evaluate the safety and efficacy of such treatment.

For the remaining women with an idiopathic resistant ovary syndrome, standard treatment protocols are not available. The most important thing is to have an early diagnosis because only in this way can the assisted procreation procedure be used to attempt to achieve a pregnancy. In fact, if the ovarian resistance become definitive, the only hope is to use donor oocytes for assisted reproduction technology (ART).

Based on our experience starting with evidence-based medicine, we have tried to treat these women with a regimen of low estrogen, using the negative feedback on hypophysis. The gonadotropin ovarian receptors are for some time free and able to respond to new stimuli.

When the ovarian response is restored, even if only for a few cycles, the final decision as to whether to follow these women in their physiological cycle and only monitor their ovulation or to stimulate with human menopausal gonadotropin (hMG) or recombinant FSH (r-FSH) for an insemination or for IVF/intracytoplasmic sperm injection (ICSI) is a decision also related to the age of the patient, the other hormonal parameters, and the quality of seminal fluid.

cancer, clinical trials showed that tamoxifen increased the risk of endometrial cancer in the uterus by 0.1%. These results strongly indicated that tamoxifen was not a pure anti-estrogen but had selective functions depending on the target tissue.

SELECTIVE ESTROGEN RECEPTOR MODULATION

In the 1980s, the concept of selective estrogen receptor modulators (SERMs) was recognized from research studies that investigated the pharmacological properties of tamoxifen at diverse tissue sites. For example, tamoxifen has estrogen-like effects on bone in ovariectomized rats. However, in the uterus, tamoxifen is both a partial estrogen and an anti-estrogen, but in the rat mammary gland, tamoxifen is an anti-estrogen/antitumor agent. Most importantly, observations in the mouse, where tamoxifen is predominantly an estrogen, were used to illustrate the target site specificity rather than the species specificity of tamoxifen. When athymic mice are bi-transplanted with both human breast and endometrial tumors, tamoxifen inhibits the growth of breast tumors while simultaneously stimulating the growth of endometrial tumors. Thus, the concept of the selective actions by nonsteroidal compounds was first recognized in the laboratory and then applied to clinical drug development. Tamoxifen maintains bone

density and lowers circulating cholesterol levels in postmenopausal women. It was known that tamoxifen lowers the recurrence of ER-positive breast cancer and decreases the incidence of contralateral breast cancer by 50% but causes a modest increase in the risk of endometrial cancer by 0.1% in postmenopausal women. The beneficial effects of tamoxifen at various sites in a woman's body were used to justify the evaluation of tamoxifen as a preventive in high-risk pre- and postmenopausal women. Predictably, tamoxifen reduces the incidence of invasive breast cancer and ductal carcinoma *in situ* by 50%.

The discovery that tamoxifen was a SERM has provided an opportunity for the development of new drugs with tissue selectivity. Multifunctional compounds that provide the potential positive effects of estrogen on the skeleton and cardiovascular system and prevent postmenopausal-related hot flashes, but avoid the negative effects on the breast and the uterus, are in high demand, particularly since it has been reported that hormone replacement therapy (HRT) increases a woman's risk of developing breast cancer and coronary heart disease but has only modest beneficial effects on bone density. One of these new SERMs, raloxifene, is similar in chemical structure to tamoxifen (Fig. 1) and has been shown to be an estrogen-like agonist on bone with a reduction of fractures, but with protective effects on the reduction of breast cancer incidence and little detrimental effect

on the uterus. Unfortunately, raloxifene does not decrease the incidence of hot flashes. Raloxifene is being tested as a chemopreventive for breast cancer in the Study of Tamoxifen and Raloxifene trial and because raloxifene lowers circulating cholesterol levels it is also being tested in the study of Raloxifene Use for the Heart trial as a preventive for coronary heart disease.

Development of new SERMs as multifunctional medicines is of growing interest to the clinical community. Thus, discovery of the mechanism of action of SERMs would greatly enhance the development of new agents. Some progress has been made in understanding the function of the SERM-ER complex *in vitro*. However, the exact mechanism of action in various tissues has not been discovered. Therefore, the future of SERM development in the clinic will depend on identifying new target sites for SERM action in the laboratory.

MECHANISM OF ACTION

ER- α and ER- β

An understanding of the selective nature of SERMs in patients first requires an understanding of the function of the ER at the molecular level. The human ER is a member of the nuclear receptor family of ligand-inducible transcription factors. The classical model of ER function is that estradiol binds to the ligand-binding domain (LBD) of the nuclear ER in target tissues to induce a conformational change in the three-dimensional structure of the complex. The ER dimerizes and subsequently binds to DNA sequences referred to as estrogen-response elements (EREs). These EREs are *cis*-acting enhancer elements located within regulatory regions of target genes. The DNA-bound ER contacts the preinitiation transcriptional machinery either directly or indirectly by coregulatory proteins (Fig. 2). In contrast, the nonclassical or tethered pathway for ER activity is the indirect interaction of the ER with regulatory elements in the promoter of target genes through direct interaction with transcription factors, such as jun/fos, or activator protein-1 (AP-1) and the subsequent activation of AP-1-driven genes. Thus, the ER can regulate the transcription of a wide variety of genes by both classical and nonclassical pathways.

The identification of different receptor isoforms is one recognized pharmacological method for developing tissue-selective drugs. The discovery of two genetically distinct ERs, ER- α and ER- β , provides a possible explanation for the tissue-selective nature of SERMs. The two receptors have some degree

of homology as both receptors have a LBD and a DNA-binding domain (Fig. 2). However, there are notable differences in the two activating functions (AFs). First, ER- β does not have an AF-1 region but does retain an AF-2 region. These differences in the AF regions alter the activity of the SERM-ER complex, resulting in increased or decreased estrogenic activity. For example, tamoxifen is more anti-estrogenic when it is complexed with ER- β . However, little is known about the role of ER- β in estrogen and SERM action. What is known from mRNA expression profiles is that ER- β is expressed in a wide variety of tissues—including the breast and uterus. However, the existence of significant levels of ER- β protein in all mRNA-expressing tissues has been more difficult to interpret and requires further investigation. Studies *in vitro* indicate that both ER- α and ER- β activate transcription in response to estradiol at ERE-containing promoters, with ER- α being a more efficient transcriptional activator than ER- β . However, when both receptors are expressed in cells, ER- β decreases the activity of ER- α and decreases the overall sensitivity of agonists. The mechanism is not known and there are few *in vivo* data showing competition between the two receptors for the same DNA sequence and/or heterodimerization of ER- β with ER- α . In cells where tamoxifen activates ER- α -mediated, ERE-driven transcriptional activity, coexpression of ER- β completely suppresses this activity. Thus, expression levels of ER- β might regulate the magnitude of the tamoxifen-ER- α complex on ERE-driven genes but only if the ratio of receptors was appropriate. In AP-1-containing elements/ER- α systems, where ER- α binds indirectly to AP-1 promoters by interaction with AP-1, estrogens activate transcription and SERMs display a range of activities from partial to full agonists. In contrast, estrogens antagonize and all SERMs tested activate transcription in cells expressing AP-1-ER- β systems. However, demonstration of the physiological significance of the AP-1-ER interaction *in vivo* has yet to be shown. What is known from *in vitro* studies is that tamoxifen appears to inhibit estradiol-activated transcription by both ER- α and ER- β . However, in some cell and promoter contexts, the tamoxifen-ER- α complex manifests partial agonist activity. Therefore, it remains to be explained how the same ER- α -ligand complex can be recognized differently in different cells.

ER Coregulators

Another explanation for the selective activities of SERMs in different cell types is the expression pattern

Figure 2 Function of estrogen receptors (ERs) α and β in a cellular context. The human estrogen receptor proteins α and β share identity. The major difference between the two receptors is that ER- β is truncated by 118 amino acid residues and contains no activating function 1 (AF-1) region. Both receptors contain DNA- and ligand-binding domains. Both bind one molecule of estradiol, dimerize, and recruit coactivators (CoAs) and/or corepressors (CoRs). If more CoAs are present than CoRs, transcription of target genes driven by estrogen-responsive elements (EREs) is activated, followed by a cellular response, such as cell division.

of coregulatory proteins. Estrogen receptors directly or indirectly activate or repress target genes by binding to hormone-response elements in promoter or enhancer regions (Fig. 2). Modulation of transcription by ERs requires the recruitment of coregulators. Coregulators are transcription modifiers that can either activate or repress the activity of the ER complex. A basic mechanism for the switching of target genes from off to on requires a ligand-dependent exchange of corepressors for coactivators. Members of the family of steroid receptor coactivators (SRC-1, -2, and -3) complement the activity of the ER. Ligand-dependent recruitment of coactivators is dependent on the AF-2 region within the C terminus of

the LBD of both ER- α and ER- β . The precise region of the coactivators that interacts with the AF-2 region of the ER is an LXXLL domain, where L represents a leucine and X represents any amino acid. The ER-coactivator complex functions to stabilize the preinitiation transcriptional machinery and promotes chromatin remodeling at the promoter region of the target gene. Thereafter, transcription of the target gene is either activated or repressed depending on the promoter and cellular context. SRC-1 has been shown to recruit CBP/p300, an acetyltransferase that acetylates histones bound to chromatin, facilitating remodeling. More than 30 additional putative coactivators have been identified. Thus, expression levels of

coactivators might explain the actions of SERMs in different cells. The estrogen-like activity of the tamoxifen-ER complex has been shown to be due to higher levels of SRC-1 in endometrial cancer cells versus MCF-7 breast cancer cells, where the tamoxifen-ER complex is mostly anti-estrogenic.

ER- α and ER- β also exert critical roles by repressing gene transcription. They function as ligand-independent repressors on some target genes or ligand-dependent repressors on others. Corepressors are coregulators that repress the activity of both ER- α and ER- β . The known co-repressors are N-CoR, SMRT, and REA. These coregulators contain multi-independent repressor domains that interact with histone deacetylases to mediate the deacetylation of histones and promote the condensation of chromatin, repressing the transcription of the target gene. The ER-corepressor complex prevents the interaction of the ligand-less ER with the transcriptional machinery, resulting in transcriptional repression. Transcriptional repression of target genes by SERM-ER complexes may depend on the structure of the SERM, the three-dimensional structure of the SERM-ER complex, and the availability of corepressors versus coactivators.

Structure-Function Relationship

The ligand that occupies the LBD of ER- α programs the external shape of the ER complex. Estradiol is a small, planar, and lipophilic steroid molecule (Fig. 1) that is able to fit into the LBD with high affinity. Estradiol binding to ER- α controls the activity of the AF-2 region, which is located in the LBD. The activity of the AF-1 region of ER- α is regulated by phosphorylation. These two activation domains can function either independently or synergistically, depending on the cell type and the target promoter of a particular ER-responsive gene. Numerous molecular models of estrogen, partial estrogen, and anti-estrogen action were developed in the 1980s based on structure-activity relationships of the ligand-bound ER- α . The model suggests that sealing an estradiol molecule in the LBD controls the intrinsic activity of the ER- α complex. Anti-estrogens block the binding of estradiol to the LBD by competitive inhibition. It has been shown that the length of the anti-estrogenic side chain regulates the anti-estrogenicity of the SERM. Partial agonist activity results from a mixture of diverse-shaped SERM-ER- α complexes, depending on the structure of the SERM. The identification of a single point mutation in the LBD, D351Y, of ER- α in a tamoxifen-stimulated breast tumor model and the finding that the D351YER α converts raloxifene from

an anti-estrogen to an estrogen demonstrated that a specific region in the ER controls the estrogen-like actions of a SERM. The crystal structures of both the tamoxifen-ER- α LBD and the raloxifene-ER- α LBD complexes show that the anti-estrogenic side chains of SERMs directly interact with D351, located on the surface of the LBD of the ER. The data demonstrate that raloxifene interacts tightly with the aspartate residue, resulting in neutralization of the carboxylate anion. However, tamoxifen is not able to shield the aspartate residue completely and thus is unable to neutralize the anion so that the tamoxifen-ER- α complex is more estrogen-like at target genes. Numerous other mutants of D351 were subsequently generated to address the hypothesis that the D351 residue in the LBD regulates the estrogen-like actions of tamoxifen. A D351G (aspartate to glycine) mutation, transfected into ER-negative MDA-MB-231 breast cancer cells, allosterically converts tamoxifen from an estrogen to a complete anti-estrogen, suggesting that the charge at position 351 of LBD is critical for the estrogenic activity. In contrast, expression of a D351E (aspartate to glutamate) or a D351Y (aspartate to tyrosine) mutation restores the estrogenic activity of the raloxifene-ER complex. The same result is seen when the anti-estrogenic side chain of raloxifene is changed from a piperidinyl ring to a cyclohexanyl ring (Fig. 1). Conversely, the D351F (aspartate to phenylalanine) mutation completely negates the agonist activity of raloxifene. The results, taken together, suggest that the interrelationship of the anti-estrogenic side chain of the SERM and residue D351 of the ER is critical for the estrogenic activity of SERM-ER complexes at specific target sites.

DRUG RESISTANCE

The activity of the SERM-ER- α complex is also regulated by phosphorylation of either the AF-1 domain at the amino terminus of ER- α or coactivators. Numerous *in vitro* studies demonstrate that the p42/44 mitogen-activated protein kinase (MAPK) pathway phosphorylates ER- α or SRC-3 and enhances the estrogenic activity in a ligand-independent and/or-dependent manner. Due to the fact that cell surface receptors activate intracellular phosphorylation cascades such as the MAPK pathway, one hypothesis to explain the differential activities of SERMs in different tissues is crosstalk between the ER- α and the surface receptors (Fig. 3). Evidence to suggest that crosstalk between surface receptors and the ER- α alters the activity of the SERM-ER- α complex came
