About the Editor-in-Chief

James E. Birren's many awards include the Award of the President of the American Society on Aging (1996), the Brookdale Foundation Award for Gerontological Research, the Sandoz prize for Gerontological Research, and the Award for Outstanding Contribution to Gerontology by the Canadian Association of Gerontology. Dr. Birren is currently Associate Director of the Center on Aging at the University of California, Los Angeles, and serves as an adjunct professor in medicine, psychiatry, and biobehavioral sciences. He is also Professor Emeritus of Gerontology and Psychology at the University of Southern California. Dr. Birren's previous positions include serving as the chief of the section on aging of the National Institute of Mental Health, the founding executive director and dean of the Ethel Percy Andrus Gerontology Center of USC, the founding director of the Anna and Harry Borun Center for Gerontological Research at UCLA, and as the president of the Gerontological Society of America, the Western Gerontological Society, and the Division on Adult Development and Aging of the American Psychological Association. Author of more than 250 scholarly publications, Dr. Birren's research interests include how speed of behavior changes with age, the causes and consequences of slowed information processing in the older nervous system, the effect of age on decision-making processes, and the role of expertise in skilled occupations. He has served as a delegate to several White House Conferences on Aging and continues to develop national priorities for research and education related to issues of aging. Currently he is teaching about autobiography and has received a Mind Alert award from the American Society on Aging to conduct study groups throughout America.

About the Editorial Advisory Board

Gloria M. Gutman developed and directed the Gerontology Department and Gerontology Research Centre at Simon Fraser University in Vancouver, Canada, from 1982 to 2005. Currently she is a professor in the department and the Director of the Dr. Tong Louie Living Laboratory. She is the author/editor of 20 books and monographs and over 150 scholarly articles, reports, and chapters on seniors' housing, long-term care, epidemiology of dementia, health promotion, and aging and technology. She was the founding president of the Gerontology Association of British Columbia, served two terms as the President of the Canadian Association on Gerontology, was the President of the International Association of Gerontology and Geriatrics from 2001 to 2005, and as an immediate past president, will serve on the IAGG Executive until 2009. She is a fellow of the Gerontological Society of America, a director of the International Institute on Ageing United Nations-Malta, a member of the World Health Organization's Expert Advisory Panel on Health and Ageing and serves on the editorial boards of six journals in the area of gerontology and geriatrics. In 2001, Dr. Gutman was named "one of 130 who make a difference" by the *Vancouver Sun* newspaper and was the recipient of the Canadian Association on Gerontology's Distinguished Member Award. In 2005, she was presented with the prestigious Rosalie Wolf award by the International Network for Prevention of Elder Abuse.

Victor W. Marshall is Professor of Sociology at The University of North Carolina at Chapel Hill, and director of the UNC Institute on Aging. Prior to that, he served as director of the Institute for Human Development, Life Course and Aging at The University of Toronto. From 1990 to 1995 he was the director of the Canadian Aging Research Network, a federally funded nationwide network of Centers of Excellence. Professor Marshall is a fellow of the Gerontological Society of America and a founding member and former Vice President of the Canadian Association on Gerontology. He currently serves on the editorial boards of *Ageing and Society*, *Journal of Aging and Health*, and *Social Forces*. Marshall's published research has covered such diverse aspects of aging as the family, long-term care, migration, and death and dying, but more recently he has focused on the aging workforce, the changing retirement transition, healthy aging, aging and public policy, and social theory in aging and the life course.

K. Warner Schaie is the Evan Pugh Professor of Human Development and Psychology at the Pennsylvania State University. He also holds an appointment as Affiliate Professor of Psychiatry and Behavioral Sciences at the University of Washington. He received his Ph.D. in psychology from the University of Washington, an honorary D.phil. from the Friedrich-Schiller University of Jena, Germany, and an honorary Sc.D. degree from West Virginia University. He received the Kleemeier Award for Distinguished Research Contributions from the Gerontological Society of America, the MENSA Lifetime Career Award, and the Distinguished Scientific

Contributions award from the American Psychological Association. He is the author/editor of 51 books, including the textbook *Adult Development and Aging* (5th edition, with S. L. Willis), and the *Handbook of the Psychology of Aging* (6th edition, with J. E. Birren). He has directed the Seattle Longitudinal Study of Cognitive Aging since 1956 and is the author of more than 275 journal articles and chapters on the psychology of aging. His current research interests are the life course of adult intelligence, its antecedents and modifiability, the early detection of risk for dementia, as well as methodological issues in the developmental sciences.

Edward J. Masoro was the recipient of the 1989 Allied-Signal Achievement Award in Aging Research. In 1990, he received the Geriatric Leadership Academic Award from the National Institute on Aging and the Robert W. Kleemeier Award from the Gerontological Society of America. In 1991, he received a medal of honor from the University of Pisa for Achievements in Gerontology, and in 1993, Dr. Masoro received the Distinguished Service Award from the Association of Chairmen of Departments of Physiology. In addition, he received the 1995 Irving Wright Award of Distinction of the American Federation for Aging Research and the 1995 Glenn Foundation Award. He served as President of the Gerontological Society of America from 1994 to 1995, as Chairman of the Aging Review Committee of the National Institute on Aging (NIA), and as Chairman of the Board of Scientific Counselors of the NIA. Dr. Masoro has held faculty positions at Queen's University (Canada), Tufts University School of Medicine, University of Washington, and Medical College of Pennsylvania. From 1973 through May of 1991, he served as the Chairman of the Department of Physiology at the University of Texas Health Science Center at San Antonio. He currently continues his duties as Professor Emeritus in the Department of Physiology and is the director of the newly created Aging Research and Education Center. He currently is a Professor Emeritus in that department and a member of the Barshop Institute for Longevity and Aging Studies of that institution. He continues to serve on the editorial boards of five journals: *Aging Cell*; *Experimental Gerontology*; *Journal of Gerontology*: *Biological Sciences*; *Growth, Development and Aging* and is also editing books (e.g., *Handbook of the Biology of Aging*, 6th edition) and writing books (e.g., *Caloric Restriction: A Key to Understanding and Modulating Aging*).

Thomas R. Cole is the Beth and Toby Grossman Professor and director of the McGovern Center for Health, Humanities, and the Human Spirit at the University of Texas Health Science Center in Houston. He is also the Chavanne Visiting Professor in the Department of Religious Studies at Rice University. Cole graduated from Yale University (BA in Philosophy, 1971), Wesleyan University (MA in History, 1975) and the University of Rochester (Ph.D. in History, 1981). Dr. Cole has published many articles and several books on the history of aging and humanistic gerontology. His book *The Journey of Life: A Cultural History of Aging in America* (Cambridge University Press, 1992) was nominated for a Pulitzer Prize. He is a senior editor of *What Does It Mean to Grow Old?* (Duke, 1986), the *Handbook of Humanities and Aging* (Springer, 1992, 2nd edition, 1999) and *Voices and Visions: Toward a Critical Gerontology* (Springer, 1993). The *New Yorker* noted his co-edited *Oxford Book of Aging* as one of the most memorable books of 1995. His most recent co-edited book is *Practicing the Medical Humanities* (2003). Cole's interest in the life stories of older people has taken him into biography and film making. In 1984, he encountered Eldrewey Stearns, a hospitalized psychiatric patient who claimed he was the "original Texas integration leader." Their collaboration resulted in a book *No Color is My Kind: the Life of Eldrewey Stearns and the Desegregation of Houston* (1997) and an accompanying film, *The Strange Demise of Jim Crow*, broadcast nationally on over 60 PBS stations and internationally by the State Department. The documentary received numerous awards and was nominated for a regional Emmy and a National Humanities Medal. Cole's film *Still Life: The Humanity of Anatomy* was an official selection at the Doubletake Documentary Film Festival in April 2002. This work explores the special yet unstated relationship between medical students in the anatomy lab and the people who donate their bodies for dissection. In 2001, Cole's writing workshop program for elders was featured in the PBS documentary *Life Stories*. Both films probe relationships between present and past, the living and the dead as crucibles of moral and spiritual development. Most recently, Cole co-produced *Living with Stroke*, a film about the invisible world of stroke survivors, which will be broadcast and distributed in 2007. Cole's work has been featured in the *New York Times*, National Public Radio, Voice of America, PBS, and at the United Nations. He serves as an advisor to the United Nations NGO Committee on Ageing, the Union for Reform, Judaism's Department of Family Concerns, and various editorial and foundation boards. In 2004–2005, he served as a consultant to the project on aging conducted by the President's Council on Bioethics, which was recently released in print as *Taking Care*.

David H. Solomon, MD, has been one of the leaders in the renaissance of geriatrics, which began in the late 1970s. In the American Geriatrics Society, he has been a member of the Board of Directors of AGS, editor of the *Journal of the American Geriatrics Society,* and a recipient of the Milo Leavitt Award, the Edward Henderson Award and the Award for Distinguished Service from AGS, as well as the Freeman Award of the Gerontological Society of America. A new award of the AGS has been named for him, the David H. Solomon Distinguished Public Service Award. For over 25 years, his focus has ranged from endocrinology and academic administration (Chairman of the Department of Medicine at Harbor-UCLA Medical Center and Executive Chairman of Medicine at UCLA) to geriatric medicine, where he has been the Associate Director of the Multi-campus Programs in Geriatric Medicine and Gerontology, a Founding Director of the UCLA Center on Aging and an active teacher, researcher and clinician in the field of geriatrics. He has played a key role nationally in the introduction of geriatrics education and training into the residency programs of surgical and related medical specialties and in research in the ACOVE project at the RAND Corporation on the measurement and attempted improvement of the quality of health care received by vulnerable older people.

FOREWORD

Efforts to assemble a comprehensive reference of universal knowledge date back to Aristotle, and some consider the work *Natural History* of Pliny the Elder to be the first encyclopedia. By the nineteenth century, encyclopedias had become more specialized, in line with expanding knowledge that required many sources. The *Encyclopedia of Gerontology,* second edition, is illustrative of the character of gerontology itself, universal by its capacious nature, while at the same time specialized. That is one reason, among many, that makes the field so extraordinary and inviting. The growth of aging populations and the advance of longevity, after all, reflect one of the great universal historic demographic shifts of all time. And with this revolution in longevity have come numerous challenges – social, economic, political, ethical, and personal – requiring a range of special adjustments. This fine encyclopedia reflects both the challenges and the adjustments.

Conventional knowledge notes that as societies increase in wealth, they are in a better position to provide social, health, and other benefits for their citizens. But based upon recently acquired knowledge, the reverse is also true, that health and longevity promote wealth. Svanborg, Manton, and others have found that as a result of social, medical, and public health advances, people not only are living longer but also are more likely to enjoy more disability-free years. These two facts strengthen the prospectus for increasing years of productive engagement. This demographic shift constitutes a great human achievement, compelling, in turn, the transformation of our culture and the personal experience of growing older that is at hand. It will lead to a body of new concepts and data concerning old age – and to an expanding encyclopedia.

Robert N. Butler, M.D.
President and CEO
International Longevity Center
Professor of Geriatrics and Adult Development
Mount Sinai School of Medicine

PREFACE

This second edition of the *Encyclopedia of Gerontology* reflects the dramatic growth of research and scholarship about aging. The study of aging has emerged as not only an area of scientific and scholarly effort but also an area of practical concern, as people are living longer and are more active, and the societies in which they live are changing. Aging is a complex process of change, involving influences of a biological, behavioral, social, and environmental nature. As the content of this second edition of the *Encyclopedia of Gerontology* reveals, aging is one of the most complex topics facing science in the twenty-first century.

Parallel with the expansion of research on aging, there has been an increased interest in issues relating to older persons in developed and developing countries. Evidence from new studies of aging is replacing long-standing stereotypes about older persons and the causes of change. How change is brought about in individuals over the life span results from many influences that range from genetics to physiology, sociology, psychology, and anthropology. Human life is influenced by physical, social, and economic environments as well as the traditions of families and religion. The articles in this encyclopedia have been selected to reflect both the depth and the breadth of influences on the living organism.

The second edition of the *Encyclopedia of Gerontology* includes both new topics and advances in areas included from the previous edition. In some cases, the updated articles are written by the same author, and in other cases, they are written by new authors with fresh perspectives. An international editorial advisory group was consulted in developing both the list of contents and the contributors for each article. The efforts of the authors, editors, reviewers, and publishing staff have been very important in the completion of this volume and are greatly appreciated.

The encyclopedia provides updates and summaries about what is known about the many processes of aging. As before, the topics are arranged alphabetically. Readers are encouraged to use the comprehensive index at the end of the encyclopedia, since a topic of interest may be dealt with under different terms by different authors.

James E Birren

How to Use the Encyclopedia

The *Encyclopedia of Gerontology*, second edition is intended for use by both students and research professionals. Articles have been chosen to reflect major disciplines in the study of gerontology and adult development and aging, common topics of research by professionals in this realm, and areas of public interest and concern. Coverage includes five major areas: the biology of aging, the psychology of aging, aging and the social sciences, health sciences, and the humanities and aging. Each article serves as a comprehensive overview of a given area, providing both breadth of coverage for students and depth of coverage for research professionals. We have designed the encyclopedia with the following features for maximum accessibility for all readers.

Articles in the encyclopedia are arranged alphabetically by subject. Complete tables of contents appear in both volumes. Here, one will find broad discipline-related titles such as "Demography" and "Pharmacology," research topics such as "Dementia" and "Creativity," and areas of public interest and concern such as "Abuse and Neglect of Elders" and "Ethics and Euthanasia."

The Index is located in Volume 2. Because the reader's topics of interest may be listed under a broader article title, we encourage use of the Index for access to a subject area, rather than use of the Table of Contents alone. For instance, Alzheimer's Disease is covered under the title "Dementia: Alzheimer's", "Dementia," and olfaction is covered in the article "Smell and Taste." Because a topic of study in gerontology is often applicable to more than one article, the Index provides a complete listing of where a subject is covered and in what context.

Each article contains a glossary, cross references, and a list of recent and seminal primary and secondary sources for further reading on the topic. The glossary contains terms that may be unfamiliar to the reader, with each term defined *in the context of its use in that article*. Thus, a term may appear in the glossary for another article defined in a slightly different manner or with a subtle nuance specific to that article. For clarity, we have allowed these differences in definition to remain so that the terms are defined relative to the context of each article.

Each article has been cross-referenced to other articles in the encyclopedia. Cross-references are found within the body of the article and at the close of the article before the further reading suggestions. We encourage readers to use the cross-references to locate other encyclopedia articles that will provide more detailed information about a subject.

The further reading section lists sources to aid the reader in locating more detailed or technical information. Review articles and research articles that are considered of primary importance to the understanding of a given subject area are also listed. The further reading section is not intended to provide a full reference listing of all material covered in the context of a given article, but is provided as a guide to additional sources of information on the subject.

A

Abuse and Neglect of Elders

L McDonald, University of Toronto, Toronto, ONT, Canada

Glossary

Elder Abuse – Intentional actions that cause harm or create a serious risk of harm, whether or not intended, to an older adult by a formal or informal caregiver who has a trust relationship with the elder, or failure by a caregiver to satisfy an older person's fundamental needs or to protect the elder from harm.

Formal Caregivers – Professionals and semi-professionals, such as social workers, physicians, lawyers, homecare providers, and nurses, who care for older persons in a wide variety of settings.

Informal Caregivers – Family members or close family associates who care for the older person, either in the older person's own home or in the caregiver's home.

Neglect – Intentional or unintentional harmful behavior on the part of an informal or formal caregiver in whom the older person has placed his or her trust. Unintentional neglect is the failure of the caregiver to fulfill a caretaking responsibility, but without the intention to harm the older person; intentional neglect occurs when the caregiver consciously and purposely fails to meet the needs of the older person, resulting in psychological, physical, or material injury to the older person.

Self-neglect – An act of omission on the part of the older person, such as the failure to take care of personal needs, that may result in psychological, physical, or material injury. The problem can often be attributed to the older person's diminished physical or mental capabilities to care for him- or herself. There is some question as to whether self-neglect should be included in a consideration of elder neglect and abuse, since no abusive caregivers are involved.

Introduction

Elder abuse, also called mistreatment or maltreatment, is harmful behavior directed toward older persons by informal or formal caregivers who the older person loves or trusts, or on whom they depend for assistance. The destructive behavior can cause physical, psychological, or material injury to the older person, resulting in unnecessary distress, suffering, and sometimes death. Historically, there has been no generally accepted definition of elder abuse, but there is a growing international consensus about the types of actions to be included in the definition. There are usually five agreed-upon categories of abuse, with some disagreement about whether self-neglect and abandonment are forms of elder abuse. Physical abuse includes any act that involves the intentional infliction of physical discomfort, pain, or injury. Examples of physical abuse include such behaviors as restraining, slapping, kicking, cutting, or burning. Medical maltreatment is sometimes considered an example of physical abuse. Sexual abuse or assault covers any kind of nonconsensual sexual contact with an older person, such as unwanted touching, all types of sexual battery, such as rape, or coerced nudity. Psychological abuse, sometimes referred to as verbal or emotional abuse, involves the intentional infliction of mental anguish or the provocation of fear of violence or isolation in the older person. Psychological abuse can take various forms, such as name-calling, humiliation, intimidation, or threats of placement in a nursing home. Material abuse, often referred to as financial abuse, involves the intentional, illegal, or improper exploitation of the older person's material property or financial resources by the abuser. Material abuse can include fraud, theft, or use of money or property without the older person's consent. Neglect generally refers to the intended or unintended failure of a formal or informal

caregiver to fulfill any part of a caregiving obligation. Examples include failure to provide an older person with the necessities of life such as food, water, clothing, shelter, medicine, or comfort. Acts such as theft, physical assault, rape, or burglary by a person outside of a trusting relationship with the older person usually would not be classified as elder abuse, but rather as crimes. Crimes against the elderly include some, but not all, forms of elder abuse.

These categories of abuse have been strongly influenced by research in Canada, the United Kingdom, Europe, and the United States. Studies conducted in other countries such as China, India, and South Africa have used different definitions that reflect the values within their societies. In China, where harmony and respect are core societal values, neglecting the care of an older person is considered elder abuse. In one of the first attempts to classify abuse in a developing country, focus groups held in South Africa added to western definitions such categories as accusations of witchcraft, loss of respect for elders, and abuse by systems such as health clinics and pension offices.

The abuse of older people by family members did not come to light until after child and wife abuse had entered the public domain in the mid-1960s. Elder abuse was first described as late as 1975 in British scientific journals as 'granny battering' but rapidly came to be regarded a significant social problem in developed countries in the 1980s. With the realization of the dramatic increases in the aging populations in developing countries in the 1990s, elder abuse became a global issue. This article reviews the extent of elder abuse in domestic and institutional settings, the risk factors for mistreatment, the theoretical frameworks used to explain abuse, and global responses to the problem.

The Extent and Social Context of Elder Abuse

Elder Abuse in Domestic Settings

Although many studies have documented the existence and nature of elder abuse and neglect, only a few international studies have collected data on the prevalence (total number of occurrences in a given time period) and the incidence (number of new occurrences within a specific time) of the problem among the non-institutionalized elderly. Reliable data have been difficult to obtain because definitions of elder abuse and neglect vary, the problem is recurrent, methodologies and time frames for the occurrence of abuse differ, and samples sometimes do not accurately represent older people. In light of these difficulties, rates from international sources range from 2 to 10% and should be interpreted with some caution.

In the United States, one of the first prevalence studies was carried out in the greater Boston area in 1985–86 based on a representative sample of 2020 persons, all 65 years of age or older. The study found that 3.2% of the elders had experienced some type of abuse. About 2% of the sample were physically abused, 1.1% were chronically verbally abused, and about 0.4% were neglected. Material abuse was not considered in this investigation, resulting in a generally lower prevalence rate than in other studies. In contrast, telephone surveys in Sweden and Denmark indicated that 8% of elders reported abuse, but theft was included as a type of elder abuse. A study done in a small town in Finland found that 5.7% of a representative sample had been abused since the time they retired. A study in Canada used a representative sample to conduct a national telephone survey in 1989 of 2008 randomly selected older persons. This investigation found that about 4% of the sample reported some type of abuse. Approximately 2.5% of the sample experienced material abuse, 1.4% experienced chronic verbal aggression, and 0.5% suffered physical abuse. About 0.4% reported neglect. A more recent study, reported in 1998, was a study in Amsterdam of a representative sample of persons 69 years of age and older. It found that the 1-year prevalence of elder abuse was 5.6%.

The prevalence rates appear to be relatively low, but they may also be misleading. Although these studies represent the best prevalence studies currently available, they all suffer from flaws in design and implementation; they are subject to cultural and contextual differences; and, more than likely, they provide low estimates because the cognitively or hearing impaired have been excluded from at least two of the investigations. There is little doubt that better prevalence data using large-scale random samples on either locally or nationally representative samples are required.

Incidence rates for elder abuse are still virtually unknown in most countries. However, attempts at estimates have been made by the National Center on Elder Abuse at the American Public Human Services Association. In the National Elder Abuse Incidence Study, data on domestic elder abuse, neglect, and self-neglect were gathered through a nationally representative sample of 20 counties in 15 states. Using reports from local Adult Protective Agencies and from 'sentinels' who are specially trained individuals at a variety of agencies, the study uncovered approximately 450 000 adults age 60 and over who were newly abused or neglected in domestic settings in

1996. The study also estimated that for every reported incident of elder abuse and neglect, approximately four incidents go unreported. Female elders were abused at higher rates than males, and in almost 90% of the cases, the perpetrator was a family member; two-thirds of the perpetrators were adult children or spouses. The incidence study has been questioned on methodological grounds to the extent that many older vulnerable people do not have contact outside of their homes and thus are often reluctant to take action against their abuser, so are not identified as mistreated.

Elder Abuse in the Institution

Institutional abuse is the mistreatment of older persons living in facilities such as nursing homes, hospitals, or long-term care institutions; it is perpetrated by the formal caregiving staff, and sometimes by other patients or visitors. There is, however, some indication that an abusive relationship at home may not necessarily end once an older person has entered institutional care. Elder abuse and neglect by formal caregivers fall into the same categories as that committed by informal caregivers, but the victims are likely to be more vulnerable to abuse because they require the protective environment of the facility. Some researchers have added violations of basic rights to the list of abuses that can occur in institutions. Such violations include denying elderly people the right to make personal decisions or the right to privacy. Another form of abuse that has been considered is systemic abuse, which refers to abuses resulting from unquestioning regimentation, such as routine use of incontinence briefs instead of helping the person to the bathroom.

There are no reliable data on the prevalence of maltreatment or neglect in hospitals, nursing homes, day care, or residential long-term care facilities. There is enough anecdotal evidence (case studies, governmental reports, ethnographic studies, personal histories) in every country where these institutions exist, however, to suggest that abusive behavior is a widespread, regular aspect of institutional life. There have been reports of material abuse, including the theft of patient's funds and fraudulent therapy and pharmaceutical charges; physical abuse, including rough handling, hitting and slapping, and inappropriate medical treatment such as chemical and physical restraint; and psychological abuse, including social isolation, yelling in anger, and threats. Neglect often reflects deficiencies in the provision of nursing care such as inadequate nutrition and hydration and poor oral and physical hygiene.

The first prevalence study of abuse in nursing homes was carried out in the United States. In a random survey of 577 nurses and nursing home aides in 1989, staff were asked to report on abuse perpetrated by others and to report on their own abusive actions. Only physical and psychological abuse were considered. The researchers found that, overall, 36% of the sample had seen at least one incident of physical abuse in the preceding year. The most frequent type of physical abuse observed by the staff was the excessive restraint of patients. A total of 81% of the surveyed staff had witnessed at least one psychologically abusive incident in the preceding year. Ten percent of the nurses reported that they themselves had committed one or more physically abusive acts, the most common being the excessive use of restraints (6%). Forty percent of the nurses admitted to psychological abuse, the most common form being yelling at a patient (33%). A more recent training project conducted a non-random survey of 77 certified nurses aids (CNAs) about whether they had witnessed abuse. Their reports supported the first American study. Fifty-eight percent of the CNAs said they had seen a staff member yell at a resident; 36% had seen residents insulted, 11% had witnessed threats to hit or throw something at a resident, and 21% had seen a resident grabbed, pushed, shoved, or pinched in anger.

In a random telephone survey of 804 nurses and nurses aids in Ontario, Canada, 20% reported having witnessed abuse of patients in nursing homes, 31% witnessed rough handling of patients, and 28% witnessed yelling and swearing at patients. A study of workers in Sweden (which included a few home-care workers) revealed that 11% of workers knew of at least one incident of abuse in the last year.

As in the analysis of domestic abuse, several North American scholars identified a number of factors that they believe contribute to the abuse of elderly residents by staff in nursing homes. These factors include the lack of comprehensive and consistent policies with respect to the infirm elderly, the fact that the long-term care system is characterized by built-in financial incentives that contribute to poor-quality care, the poor enforcement of nursing home standards, the lack of highly qualified and well-trained staff, the powerlessness and vulnerability of the elderly residents, especially those with some type of dementia or memory loss, and the tendency of staff to avenge patient aggression.

In a partial test of a model developed to explain abuse in institutions, the researchers found evidence that the maltreatment of nursing home patients appeared to be a response to highly stressful working conditions rather than a consequence of the characteristics of the nursing home such as the size or ownership status of the institution. Staff who were

younger, who were burned-out, and who experienced aggression from patients were more at risk of becoming abusive toward their elderly patients.

Risk Factors for Elder Mistreatment

Accurate research on risk factors for abuse is critical for the development of effective screening tools and intervention protocols, for reducing or eliminating contributing factors to deter mistreatment, and for the development of policy for those populations at heightened risk of mistreatment. As is the case with incidence and prevalence rates, the risk factor literature on elder mistreatment is both limited and inconsistent.

The first wave of research on elder abuse, beginning in the late 1970s, concluded that the typical victim at risk for abuse was a female over 75 years of age, with debilitating physical and psychological impairments and dependent upon a family caregiver, usually a daughter. Research at the end of the 1980s, based on sounder methodologies, cast some doubt on these observations and indicated that the situation was far more complex than was originally presumed. The focus shifted from the classification of the at-risk victim to the classification of the perpetrator, and to profiles of different combinations of victims, perpetrators, and types of abuse. In the early twenty-first century, mounting research evidence emphasizes the interactive aspects of elder abuse and supports distinctions between patient-directed, patient-generated, and mutual abuse.

Two decades of careful research can be distilled into five major observations. First, several studies, primarily done in North America, indicated that a shared living situation is a major risk factor for abuse, and, conversely, older adults living alone have the lowest risk of mistreatment. Shared housing and, in some countries, over-crowded quarters can increase interpersonal contacts and the possibility for mistreatment. There is the likelihood that there is a differential role of living arrangement according to type of mistreatment, but this requires further investigation. Second, family violence research has consistently discovered some degree of social isolation in almost all violent situations. Similarly, several empirical studies in North America and Scandinavia have found that abused elders were significantly more likely to have fewer contacts with friends and family members than were non-abused elders. This finding was interpreted to mean that there is less likelihood for violence when an older person has strong and active family and social ties. The presence of involved family and friends not only might deter violent behavior but also could provide additional support that would modify the caregiver's sense of burden and stress. Third, a number of studies have found higher rates of physical abuse in older adults with dementia when compared with the abuse rates in the general older population. Several findings, however, suggested that dementia itself is not the risk factor but rather the behavior that results from the caregiver violence. Fourth, the personality traits of the perpetrator, also referred to as the intra-individual characteristics of the abuser, are based on observations from a number of studies that discovered that an inordinately high proportion of abusers had histories of psychiatric illnesses and problems with drugs and alcohol. Depression appeared to be a common characteristic, and alcohol the most frequently used drug. Last, several research studies showed that abusers are more dependent on their older victims for financial support and for housing than are comparable groups of non-abusers.

There is only mixed or limited support for the views that older women are more likely to be abused, that adult children are the primary abusers, and that victims show higher levels of aggression. There is very limited support for the idea that race is a risk factor for elder abuse. Research has generally failed to find support for the view that frailty or dependency of the older adult is a risk factor for abuse, and, most importantly, there has been no support for the view that greater caregiver stress leads to mistreatment. The only two studies that examined the transmission of intergenerational violence as a risk factor for elder abuse found no evidence to support this hypothesis, contrary to research findings on other forms of family violence.

Theoretical Explanations

Much of the literature on elder abuse does not make the important distinction between theoretical explanations and the individual factors related to abuse. A theory provides a general, systematic explanation for observed facts; in the elder abuse literature, particular factors, such as stress or dependency, are often treated as complete theoretical explanations even though they are only factors and could be incorporated in any of a number of theories. The specific relationships between the various factors and elder abuse form propositions upon which theories are built. Over the course of the brief history of elder abuse, different accounts of the relationships among the factors have led to at least four distinct theoretical perspectives. Their variations are of particular import, since each theory determines what actions should be taken to ameliorate the abuse and neglect.

The Situational Model

Probably the first and most widely accepted perspective is the situational model, which has its roots in the mainstream perspectives on child abuse and family violence. The basic premise of the situational model is that stressful situations cause the caregiver to abuse the older person, who is usually viewed as the source of the stress. This approach suggests that mistreatment is an irrational response to stressful situations. The situational variables that this theory links to abuse include factors related to the caregiver and the elder as well as social and economic conditions. Interventions grounded in this perspective attend to reducing the stress of the caregiver. One major flaw of this perspective is that it fails to account for the fact that many caregivers, who experience the same stresses as abusers, do not mistreat their elderly. The perspective has also been criticized for being dangerously close to blaming the victim, since it identifies the older person as the source of the stress. As of mid-2005, there is no support for this theory.

Social Exchange Theory

Social exchange theory is based on the assumptions that social interaction involves an exchange of rewards and punishments between people, and that all people seek to maximize rewards and minimize punishments. In most relationships, people have different degrees of access to resources and different capabilities to provide services to others, which makes some people more powerful than others. In the social exchange perspective it is argued that, as people age, they become more powerless, vulnerable, and dependent on their caregivers, and it is these characteristics that place them at risk for abuse. There are many problems with this perspective, not the least of which is its basic ageist assumption: people do not automatically become dependent and vulnerable as they age. As noted previously, it is the abuser's sense of powerlessness that leads to maltreatment. Interventions prompted by a social exchange analysis would first have to identify the dependent party. If the older person was assessed as the dependent one, then services aimed at increasing his or her independence would be in order, whereas a dependent adult child might need help from mental health services or require vocational training or job placement in order to become self-reliant.

Social Learning Theory

There is some evidence to suggest that children learn through observation and participation that violence is an acceptable response to stress. Having learned violent behavior, a significant number of children are violent toward their own children and spouses in adulthood. This transmission of violent behavior may be reinforced by a family subculture that accepts and condones violence. While this a popular hypothesis in the literature on family violence, very few elder abuse studies have actually found evidence to support the idea that children who were mistreated by their parents went on to abuse the parents in later life. In fact, several studies have clearly found no basis for the relationship. The small number of studies of this theory (approx two) indicates that further research is required to test this hypothesis.

Political Economy Theory

Research has been preoccupied with the abused and the abuser at the expense of exploring the wider implications of the structure of the economy, the impact of social policy, or factors that systemically organize society such as age, gender, race, ethnicity, and class. All of these societal factors influence people's position in the social structure and their opportunities in life. Some theorists have focused on ageism as a possible factor leading to what some consider a weak political response to elder abuse in various countries and as one of the factors leading to elder abuse (*see* Ageism and Discrimination). For example, older people can be subject to discriminatory attitudes and actions that are based on negative perceptions about their chronological age. Experts have proposed that such ageist attitudes toward older people may contribute to the development of elder abuse. Misconceptions and distortions about aging dehumanize older persons, making it easier for them to be victimized and easier for the abusers to feel little or no remorse. At the same time, elderly people may even view the maltreatment as deserved, since they too may have adopted society's negative attitudes. The feminist models also supply an account of the structural factors: gender determines a set of positions in society that facilitate, and even justify, the abuse of women. Other crucial factors that are known to influence the aging process, such as race, ethnicity, and socioeconomic status, are only now attracting modest attention. As would be expected, the few investigations that do exist show that elder abuse is viewed quite differently by different cultures.

Overall, most scholars have realized that there is a broad diversity in the manifestations of elder abuse and neglect and have abandoned their search for a comprehensive, all-inclusive explanation of the phenomena. In the future, new theories of elder abuse may explain different dimensions of elder abuse and

neglect, and theoreticians will probably cast their net wider, including gerontological theories alongside the family violence theories that have been, so far, the mainstay of the elder abuse literature. As a consequence, practitioners will have a wider array of interventions at their disposal, which will facilitate the provision of more effective care for mistreated elders.

Responses to Abuse and Neglect

National Responses to Elder Abuse and Neglect

Efforts to spur social action to eradicate elder mistreatment at a national level and to develop national polices and legislation are at varying stages of growth around the world. While the United States has developed a full-blown national response to elder abuse at the state level that allows for the funding and reporting of elder abuse and has instituted at least three national organizations (the National Center on Elder Abuse, the National Committee for the Prevention of Elder Abuse, and the National Association of State Adult Protective Services Administrators); other countries have been less proactive.

In Australia and Canada, various states and provinces have created mechanisms for dealing with elder abuse, but there are no firmly established federal policies about elder abuse. At the federal level, both Canadian and Australian national clearing houses on family violence are maintained, while New Zealand has run pilot projects across the country. All three countries have national organizations dedicated to the amelioration of elder abuse that were established in the 1990s. In the United Kingdom there is a national body called Action on Elder Abuse that has stimulated government responses to elder abuse. Norway has had parliamentary approval for services and a resource center for research and information. France, Germany, Italy, and Poland are at the point of recognizing the legitimacy of elder abuse and neglect.

The Latin America Committee on Elder Abuse has been active in drawing attention to the problem within Latin America and the Caribbean. In Buenos Aires, the organization Proteger, a government department, deals exclusively with elder abuse cases and provides staff with training in gerontology. In Brazil, the Ministry of Justice, Health and Welfare supports official training about elder abuse. In Chile, a law against family violence was passed in 1994 that clearly addressed abuse of the elderly.

In Asia, there have been several studies by researchers in Japan, India, and the Republic of Korea about elder abuse and the beginnings of national organizations to fight the problem.

South Africa established a preventive program on institutional abuse that was jointly sponsored by the government and the private sector in 1994, while the Nigerian Coalition for the Prevention of Elder Abuse facilitates the meetings of professionals working with the elderly.

Given this rapid global expansion of activities on elder abuse, the International Network for the Prevention of Elder Abuse (INPEA) was formed in 1997 with representations from six continents. Most recently, the World Health Organization (WHO) recognized the need to develop a global strategy for the prevention of elder abuse. Working with INPEA and HelpAge International, the WHO carried out a study of eight countries (Argentina, Austria, Brazil, Canada, India, Kenya, Lebanon, and Sweden) that used focus groups with older persons in the community and health-care workers to explore their views on elder abuse.

Legal Responses to Elder Abuse

Most countries have not introduced specific legislation on elder abuse. Abuse is often covered under criminal law, or by laws dealing with property rights, civil rights, and family violence or mental health, and varies widely from country to country. In all countries, however, a key issue is whether and under what circumstances criminal charges should be filed against alleged perpetrators. There is a concern as to whether appropriate assistance and support services will be made available after authorities have intervened in a mistreatment case, and considerable concern as to whether the older person will press charges, especially against a family member. A few western countries have introduced special adult protection legislation at the state or provincial level in response to the problem of elder abuse and neglect. The goal of the legislation is to protect the mistreated person, help the abuser, and marshal health and social services.

Adult protection legislation has been largely borrowed from child protection legislation, which called for the mandatory reporting of suspected cases of abuse. This legislation generally falls into three categories: (1) adult abuse legislation with mandatory reporting; (2) elder abuse legislation with mandatory reporting; (3) adult or elder abuse legislation with no mandatory reporting. Adult abuse legislation is applied to persons over the age of 18, but is often restricted to those suffering from physical and cognitive impairments. Elder abuse legislation is directed specifically to older people, usually defined as individuals over the age of 60 or 65. While all 50 states of the United States have legislation authorizing

the state to protect and provide services to vulnerable or incapacitated adults, other countries have been slower to enact special legislation. For example, in Canada only five provinces and one territory have enacted adult protection legislation, while the United Kingdom and Australia have no provisions at all.

Mandatory reporting, the legal obligation to report cases of elder abuse, is the standard in the majority of jurisdictions in the United States, in the Atlantic provinces of Canada, and in Israel. The obligation is usually imposed on certain individuals, such as nurses, doctors, the police, and social workers. The purpose of the legislation is to deter elder abuse and neglect and also to provide a mechanism for collecting data and monitoring prevalence and incidence rates. The legislation frequently grants the reporting individual immunity from civil and criminal liability in order to encourage individuals to report. Failure to comply with mandatory reporting laws can result in fines, civil liability for damages, reports to professional licensing boards, and short jail terms.

The few research studies on mandatory reporting (all done in North America) have cast doubts on the contribution the process can make to the prevention of elder abuse and neglect. Several studies have shown that cases reported under mandatory provisions were already known to the authorities, implying that there is no significant increase in the reporting of cases. In contrast, several studies have shown an increase in the number of cases reported, but also an increase in the number of unsubstantiated cases. Other studies have shown that the statutes failed to ensure the consistent collection of information that would aid in the tracking of the types and extent of abuse and neglect. There is confusing research as to what types of cases mandatory reporting is likely to uncover. Several studies have found that mandatory reporting is more likely to be associated with cases of neglect and self-neglect; others, however, established that mandatory reporting is more likely to be associated with cases of physical abuse. The few studies that examined the relationship between mandatory reporting and institutionalization of the older victim indicated that mandatory reporting could result in increased rates of institutionalization of the abused, although contact with protective services was the more plausible explanation. Finally, the passage of a mandatory reporting law does not necessarily mean that those who are required to report will be aware of the law or be motivated to comply. The general conclusion in the research literature is that mandatory reporting systems in existing jurisdictions need further investigation as to their effectiveness.

Program Responses

A program provides a blueprint for service delivery, establishes resources, and coordinates the delivery of service through government and/or private and public agencies. Three major programs have emerged in response to elder abuse: the statutory adult protection service programs, programs based on the domestic violence model, and advocacy programs for the elderly. A fourth model now appearing in many communities is the interdisciplinary team model. Institutions have been slow in their responses to elder abuse, but promising approaches are appearing, at least in North America. It is not useful to categorize the various health and social services available to older persons, since each program ultimately makes use of them all, depending on need.

Adult Protection Programs The adult protection legislation provides the legal framework for protective services for vulnerable adults. The mandated services are provided in approximately three-quarters of the states in the United States by special adult protection units in state social service departments and, in most of the remaining states, by state units on aging. In Canada, there are at least three different models for service delivery, depending on the provincial jurisdiction. As would be expected, there are great variations in responses, depending on the financial commitment of the state and other organizational and political factors.

The legislation confers a wide range of powers of intervention, which vary from jurisdiction to jurisdiction. The usual procedures for the state or provincially designated units are to receive reports of suspected cases of abuse, to screen the cases for potential seriousness, to conduct an investigation if mistreatment is suspected, to develop a care plan that will resolve the abuse, and then to transfer the case to other community agencies for case management and the delivery of services. The protective services program represents a mixture of legal, health, and social services that allows for the widest array of interventions and for considerable coordination and interdisciplinary team work. Many adult protection workers have had specialized training in the substantive area of elder abuse and neglect. New and innovative learning initiatives are increasing: for example, the creation of a special student training unit within adult protective services was recently instituted for the first time in the United States with considerable success.

In recognition of the fact that not all clients will voluntarily accept protective services, the protection workers may implement guardianship or

conservatorship to ensure that the older person receives the necessary services. Some jurisdictions in the United States have created special court procedures to secure court orders for protective services, to place the client in a nursing home, to provide emergency treatment when the client is in danger, and to enter a client's home against the client's wishes. Proponents of these wide-ranging interventions argue that the rights of the older person are always safeguarded; the goal is to enhance the individual's level of functioning while protecting them from injury. They also maintain that because little can be done for the victim who refuses services (about 36 to 40% of elders refuse services), only mandated interventions ensure that the victim receives at least the minimum help. In addition, such interventions are limited by prudence: few practitioners are willing to risk intervention unless they are on solid legal ground.

Those against an enforcement-oriented approach to service provision dispute these claims. They observe that the vagueness of the legislation in many jurisdictions places adult protection workers in a quandary the moment they try to decide whether abuse has occurred. It is almost impossible to use legal powers to force oneself into an older person's home and at the same time respect the person's basic rights; the protection worker can easily come into conflict with both the older person and the abuser. In addition, adult protection workers have been accused of being 'trigger-happy' in placing older persons in nursing homes and in treating older people as if they were children – an unavoidable occupational hazard given the child welfare roots of the adult protection programs.

Domestic Violence Programs The domestic violence model for program delivery is an adaptation of the programs that have been instituted to combat woman abuse. This approach is gaining momentum in North America, because it does not violate people's civil rights, nor does it discriminate on the basis of age. The domestic violence response to elder abuse involves crisis intervention services, such as telephone hotlines; a strengthened role for police when pressing charges; court orders for protection; the use of legal clinics, emergency, and secondary sheltering; support groups for both the abused and the abuser and individual and family therapy; and the use of a whole range of health, social, and legal services. An integral component of domestic violence services is public education, especially the education of the abused about their rights. Almost all of these services have been adapted specifically for elder abuse victims, and sometimes for their abusers. For example, existing shelters have been modified to accommodate older abused women, and new shelters have been established to accommodate both men and women. Along with shelters, there are support groups, hotlines, special legal clinics, and family and individual counseling programs. An example of each type of service can be found in North America; however, most attempts at service delivery have been scant and sporadic and have shown little evidence of coordination. Whether the model is effective in helping the older victim is still a moot question.

The domestic abuse model is not without its critics, who quickly point out that the flaws in the model equally apply to elder abuse. Problems with police response, restraining orders, poorly managed shelters, and the shortage of follow-up services are but a few of the issues. Gerontologists have also cautioned against the singular use of crisis intervention, since older persons' problems tend to be multiple and interrelated, take a long time to solve, and need to be monitored closely. They also have drawn attention to the inadequacy of the model when applied to cases of neglect. Police intervention or education about rights are inappropriate in the face of family or self-neglect.

Advocacy Programs Advocacy includes all actions performed on behalf of an individual or group in order to ensure that their needs are met and their rights are respected. Like the domestic violence model, this approach recognizes that the older person is an adult in a potentially dangerous situation. Advocates for the abused use the least restrictive and intrusive interventions into the older person's situation. In practice, advocates advise clients of their rights and the alternative services available, and they can assist them in carrying out agreed-upon plans. The most important feature of the advocacy model is the advocate's independence from the formal delivery system; this distance allows the advocate to establish a positive relationship with the older person. Formal and informal advocacy programs are used in a number of states and provinces in the United States and Canada; they operate in the community or in institutions and nursing homes. Although advocacy may appear to be non-intrusive, some social scientists have suggested that, in practice, it can be quite intrusive, especially if the advocate is immune from liability and is not accountable.

The Multidisciplinary Team Model An observable trend at the community level has been the development of multidisciplinary teams made up of workers from a broad array of agencies that represent all of

the programs described previously. These community-based teams or committees provide consultations on atypical and difficult cases of abuse, help to resolve agency disagreements, identify system improvements, and provide services, such as legal and medical consultations not readily available in the community. In some instances specialist teams have been developed, such as the financial abuse specialist teams (FASTs) to investigate financial abuse and the fatality review teams to review deaths brought about by elder abuse and to determine how to prevent further deaths from abuse. Initial assessments of this approach have been very positive: service providers become familiar with one another, resources are organized and dispersed in a single initiative, and more comprehensive care plans are produced. The main drawback reported by team members is that the committees spend more time per case than professionals acting alone.

Residential Care Facilities While residential care settings in most countries are subject to different regulations and enforcement strategies such as unannounced regulatory visits, video recorders in key locations, and ombudsmen, several avenues for intervention have been identified to prevent institutional maltreatment. Interventions that address hiring and the supervision of staff, staff training, and staff skill development, including the problems of burnout and the creation of specialized treatment programs for the abused in an institution, could serve as the basis for managerial initiatives. To date, however, there are few programs and very little research as to what is effective.

Services

It is evident from the literature that the services already available to older persons provide the bulk of the resources used in response to elder abuse, regardless of what approach is utilized, and that new or uniquely designed services are not always required. Most elder abuse practitioners face difficulties in accessing limited resources, especially in critical emergency situations, and they must deal with the challenges of coordination and collaboration in the existing patchwork of services. They also must deal with the reality that there is a paucity of well-researched intervention studies to inform the identification and management of elder mistreatment.

Accelerated Aging

F Sierra, National Institute on Aging, National Institutes of Health, Bethesda, MD, USA

Published 2007 by Elsevier Inc.

Glossary

Accelerated Aging – Characteristic of animals in which the first inflexion on the mortality curve occurs at the same age as in wild-type individuals, but whose mortality after that point occurs at a faster rate.

Free Radical Hypothesis – Proposes that aging is the result of damage to macromolecules, including DNA, occurring because of continuous exposure to free radical species, primarily reactive oxygen and nitrogen species (ROS and RNS, respectively).

Mutation Hypothesis – Proposes that aging is the result of irreparable and irreversible damage to DNA, by whatever means the damage might occur.

Premature Aging – Characteristic of animals in which the first inflexion on the mortality curve occurs earlier than in wild-type animals, but the mortality after that point occurs at a normal rate.

Progeria – A disease causing premature appearance of a significant number of age-associated phenotypes, and usually leading to premature death.

Progeroid – A disease causing premature appearance of a significant number of age-like phenotypes, and usually leading to premature death.

Introduction

In the last few years, much knowledge about aging has been gained from the study of genetically altered organisms, ranging from yeast to mice. Most of the progress has been made by focusing on long-lived mutants, which has allowed the identification of several longevity assurance genes (LAGs). Recently, there have been a handful of publications extolling the virtues of short-lived mutants. These are much more controversial, but when analyzed carefully, they may be just as informative as the long-lived ones. This article describes some of these mutants and discusses their potential uses and pitfalls. The discussion is limited to mice, for which there is enough pathological data, and the mutants are divided into three (subjective) categories: (1) mouse models of segmental progeroid syndromes, (2) mice created to prove or disprove a given hypothesis of aging, and (3) mice that display apparent acceleration of the aging process, but that were created without that expectation in mind.

The golden rule of genetic models of aging (*see* Models of Aging: Vertebrates) is that experimental manipulations that result in an extension of health span are likely to be more informative about the aging process than those that reduce life span (**Figure 1**). This argument is difficult to dispute. However, this article brings forth the argument that short-lived mutants can also be very informative about the aging process, if used and analyzed judiciously. Of course, judiciousness is also a must when dealing with long-lived mutants, since not all longevity-prolonging manipulations are necessarily informative to the aging researcher. Nevertheless, it is recognized that this is even more true in the case of short-lived mutations or manipulations, since many genetic alterations will result in shortened life spans, or even mortality *in utero*, without being informative about the aging process. In fact, most alterations will not be informative. However, in a few cases, it can be argued that such mutants could indeed be useful, as long as the short life span is accompanied by an earlier or faster appearance of a significant subset of the pathologies and age traits characteristic of the species in question. This precludes the use of an important part of the bestiary currently used in aging research, since in the case of *Drosophila melanogaster, Caenorhabditis elegans*, yeast, and other such lower species, we lack sufficient knowledge of their pathology and causes of death, and thus, it becomes impossible to ascribe the short life span of any given mutant to true age-related phenomena. However, in the case of mice, humans, and other higher vertebrates, the pathology and causes of death are better understood, and thus, the use of mutants with shorter life spans becomes a possibility. For the rest of this article, the discussion is limited to genetically modified mouse models, and although very relevant to aging research, the focus is on models that are believed to affect the aging process as a whole, and not the development of specific diseases, even if they are age dependent, such as Alzheimer's or Parkinson's.

There are three main categories in which short-lived genetic variants might be useful for understanding the phenomenon of aging (**Table 1**). First, mouse models of human progerias allow investigators to dissect the molecular mechanisms behind the disease phenotype. There is an argument about whether or not human progeroid syndromes are informative of normal aging, and in that sense, the mouse models

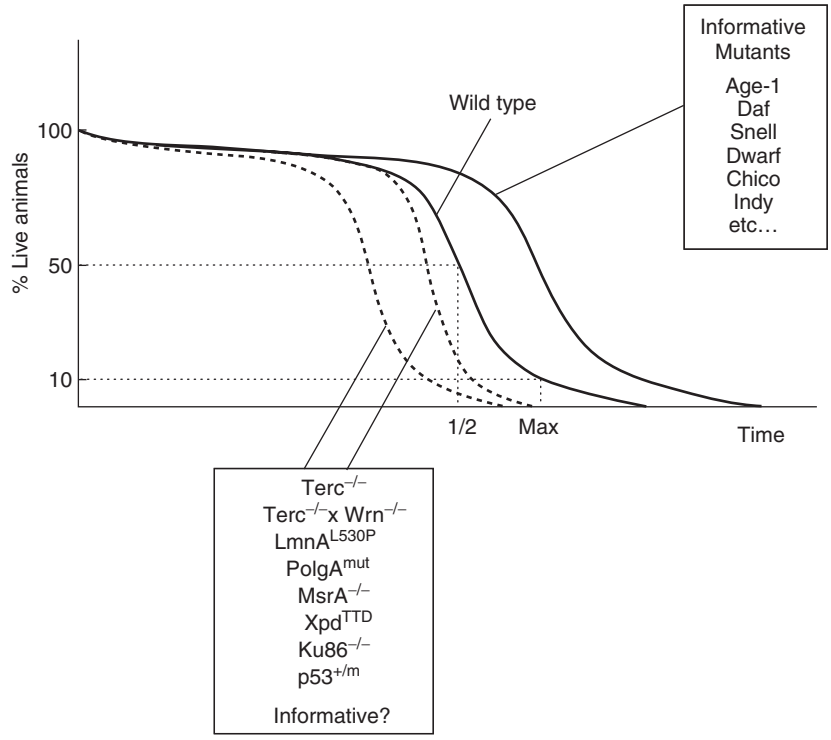

Figure 1 The golden rule of genetic studies of aging. Genetic manipulations believed to affect the aging process usually begin by measuring a surrogate marker of aging, namely, time of death. By measuring survival of a cohort as a function of time, a curve can be drawn from which the mean (50%) and maximal survival (often 10%, but in many cases, the actual longevity of the record holder is reported) can be derived. Mutants that increase both mean and maximal life span have traditionally been automatically considered to be informative of the aging process. Short-lived mutants (broken lines) can be of two types: accelerated aging occurs when the slope of the mortality curve is increased, while premature aging occurs when the curve is displaced to the left without changing the slope. Of course, mixed phenotypes can also be observed.

represent a circular argument. However, most researchers agree that useful information can be derived from these studies, and the mouse models at hand generally confirm this suspicion. Second, several mouse models have been produced in order to test a particular hypothesis of aging. While such mutants might not represent the final answer (and theories of aging have been historically hard to completely dismiss), it is reasonable to suspect that in this case, short-lived mice should be as informative as long-lived ones. Third, there are a few mice in which an accelerated aging phenotype was not expected, yet was observed. To the extent that these can be validated, they are probably the most exciting models.

Mouse Models of Human Segmental Progerias

In 1979, George Martin coined the term segmental progerias to define a series of pathologies characterized by shortened life spans, but most importantly, accompanied by a plethora of early signs of aging, both externally and at the pathological level (*see* Premature Aging). The relevance of these diseases to the study of aging has been challenged, primarily because of the segmental nature of the phenotypes. Conversely, it can be argued that this segmental feature is precisely what makes the models particularly useful, as it allows the dissection of some of the many components that together comprise the complex aging phenotype. Furthermore, the segmental argument also applies to simple models that are either primarily postmitotic (*C. elegans*, *Drosophila*) or unicellular (yeast). The effects of individual genes on longevity must by necessity also be segmental in these cases, since it is extremely unlikely that all features of vertebrate aging can be reproduced in a model organism that either does not contain replicative cells or is unicellular. Furthermore, as is true for all models to be discussed here, it is highly unlikely that aging is controlled by a single or even a small handful of genes. Thus, it is to be expected that specific mutations might have segmental effects, thus affecting some of the aging phenotypes, but not all. And yet, most researchers will agree that models of increased longevity have been very useful, and their usage has outlined the importance of several pathways (the IGF

pathway and sirtuins, for example), as well as the importance of stress resistance to longevity. Importantly, further experimentation has shown the validity of several of these observations in higher vertebrates including mice. In these examples, therefore, the segmental argument loses its validity.

There are multiple diseases that, to varied extents, can be classified as segmental progerias, and recent research has identified the culprit genes in most of them (**Table 2**). In all cases, they turned out to be genes involved in nucleic acid metabolism, thus lending strong support to the so-called mutation hypothesis of aging. The most dramatic is childhood progeria, or Hutchinson-Gilford syndrome (HGS). In this case, the mutation affects the structural nuclear envelope protein Lamin A (LmnA), and the defective processing of this molecule leads to significant changes in nuclear morphology and function. Thus, cells from these patients are very prone to apoptosis and are also resistant to immortalization by telomerase. Accordingly, affected children die in their early teens, usually of cardiovascular disease. A mouse model of defective LmnA shows a comparable extremely short life span as well as a considerable set of age-related diseases and phenotypes (**Table 3**). Thus, even though the mutation present in this mouse is not exactly the same as in HGS, the mouse does recapitulate many aspects of this most dramatic progeria. Several laboratories have produced true HGS mice, but their characterization is still very incomplete and unpublished.

Mouse models of several other progeroid syndromes, including Werner, Bloom, ataxia telangiectasia, and several members of the xeroderma pigmentosa pathway, have also been produced. Interestingly, with the exception of the *Xpd*^{TTD} mouse (a model for the disease trichothiodystrophy [TTD], discussed later), all of the others failed to present any phenotype, including accelerated aging. At least in the case of Wrn, Blm, and Atm, the cause for this lack of phenotype has been established after further scrutiny. Both *Wrn* and *Blm* code for DNA helicases, while Atm plays a critical role in the activation of the stress response after DNA damage (**Table 1**). All three

proteins are at least partially found in association with telomeres, and it was therefore surmised that the lack of a phenotype might be due to the excessively long telomeres present in mice, as compared to humans. Interestingly, like the others just mentioned, *Terc*$^{-/-}$ mice also failed to show any immediate phenotype. However, upon repeated cross-breeding, *Terc*$^{-/-}$ mice did show accelerated age-related pathology and shorter life spans, albeit at the fifth or sixth generation, supposedly because their telomeres had been humanized by shortening (**Table 3**). By crossing *Wrn*$^{-/-}$, *Blm*$^{-/-}$, and/or *Atm*$^{-/-}$ mice with *Terc*$^{-/-}$ mice, the resulting double and triple animals did display accelerated aging phenotypes at much earlier generations (usually the third), and furthermore, some of the phenotypes observed were not present even in later generation *Terc*$^{-/-}$ mice. These data indicate that mutations in these genes can indeed give rise to an accelerated aging phenotype, as long as the telomeres are not excessively long. The data also suggest that the proteins participate in protecting cells from the effects of dangerously short telomeres.

Werner is the best characterized of the human progeroid syndromes, and so are the double (*Wrn*$^{-/-}$ x *Terc*$^{-/-}$) and triple (*Wrn*$^{-/-}$ x *Atm*$^{-/-}$ x *Terc*$^{-/-}$) knockout mice, so the rest of the discussion will focus on these models and how they have demonstrated their usefulness in aging research. Mutations in the *Wrn* gene lead to two major effects: a mutator phenotype (given primarily by stalling at replication forks) and accelerated cellular senescence. Clinically, Wrn patients show a rather dramatic skin atrophy phenotype in the presence of a normal immune system (*see* Premature Aging). Further analysis indicates that while the mutator phenotype of *Wrn*$^{-/-}$ is observable in both skin fibroblasts and T lymphocytes, accelerated senescence is observed only in fibroblasts, not in lymphocytes, which have higher telomerase levels, at least in young individuals. These observations suggest that cell senescence, rather than mutations, might be more closely related to the agelike phenotype of the skin of Wrn patients, but further confirmation is difficult in the absence of a tractable genetic model of the disease in a lower organism. Thus, the mouse models have helped: fibroblasts from *Wrn*$^{-/-}$ mice (which, as we have seen, do not show any pathology) do not show premature cellular senescence either. In contrast, fibroblasts derived from third-generation *Wrn*$^{-/-}$ x *Terc*$^{-/-}$ mice (which do show age-related pathology) do undergo premature cell senescence and are also more sensitive to apoptosis. In fact, both of these phenotypes have also been observed *in vivo* in later generation double- or triple-mutant mice. These observations further confirm that it is cellular senescence (or at least a DNA transaction occurring at telomeres) that is responsible for the observed phenotypes. It should be pointed out that conversely, Wrn patients suffer from other pathologies that are not age related, such as increased mesenchymal tumors, rather than the epithelial tumors most commonly found among the elderly. This effect might be the result of the mutator phenotype of *Wrn*$^{-/-}$ cells. Such an explanation would predict that in a normal subject, the Wrn protein might protect the mesenchymal cells more efficiently than the epithelial cells. Taken together, these observations suggest that (1) the DNA transactions that involve Wrn, Blm, and Atm are most relevant at the level of the telomeres, (2) telomere biology indeed seems to be important in aging, as previously suggested by research on cellular senescence, and (3) the lack of a phenotype in the earlier generation mice, or in mice with wild-type Terc, suggests that the mutator phenotype conferred by mutations in proteins such as Wrn is not relevant for aging.

Mouse Models that Test Hypotheses of Aging

The field of aging has been prolific in producing theories that are elusive to prove, but also difficult to disprove. Genetics provides a powerful means to test hypotheses, and such an approach has indeed been used by researchers in the aging field. In simple terms, if a gene or a process is hypothesized to play a role in aging, then overexpression of that 'bad' gene should result in accelerated aging, while knocking the gene out or inactivating it should result in increased longevity and/or less age-related disease. Of course, the opposite is true for a 'good' gene.

Two of the most pervasive theories of aging are the free radical hypothesis and the mutation hypothesis. To an extent, these are intimately connected, because one of the central tenets of the free radical hypothesis is that free radicals, produced either intrinsically or extrinsically, will ultimately damage the DNA, leading to some nebulously explained molecular catastrophe that results in tissue deterioration, disease, and finally death. Both of these theories have been tested rather extensively in mouse models. Most notably, with the possible exception of mitochondrial-directed catalase, overexpression of several enzymes involved in scavenging free radicals failed to provide an extension of life span, as did the overexpression of enzymes involved in DNA repair. The proponents of these theories offer many arguments to explain these disappointing results, including an already available overabundance of protection against free radicals, or the enormous complexity and potential for functional redundancy in DNA repair systems. Some of these arguments might be true, and some researchers have therefore turned to the opposite approach: deletion of these protective and/or repairing genes should produce a shorter life span.

Testing the Free Radical Hypothesis of Aging

More than 40 years ago, Clark and Rubin showed that radiation leads to a shortening of the life span. This is a manipulation that in many respects is akin to a genetically short-lived mutant mouse. However, instead of being dismissed as irrelevant to aging, such experiments spawned what is currently the most accepted hypothesis of aging: the free radical hypothesis. The hypothesis was originally proposed by Denham Harman in 1956. It predicts that aging results from the accumulation of damage to macromolecules produced by reactive oxygen species (ROS) or other free radical species. ROS are produced both intrinsically, primarily in the mitochondria and the plasma membrane, and extrinsically, by reactive compounds present in the diet and the environment. Because of their enormous potential for damage, cells have evolved powerful means of neutralizing free radicals, primarily through scavengers, both cellular and from the diet. The best characterized cellular ROS scavengers are the superoxide dismutases (SODs). Because most of the free radical generation appears to arise from mitochondrial respiration, and both free radicals and their associated damage appear to increase with age, much effort has been focused on the mitochondrial MnSOD. Overexpressing the enzyme did not result in an extension of life span, and the knockout is embryonic lethal. Thus, further studies have been done on heterozygous mice. These animals indeed display a 50% reduction in MnSOD activity, without a compensatory upregulation of other scavengers, including the peroxysomal Cu/ZnSOD, catalase, or glutathione peroxidase, Gpx. They show increased ROS production in several tissues analyzed, and this does indeed lead to increased oxidative damage to both nuclear and mitochondrial DNA and to lipids, as well as increased pathology (primarily cancer). Surprisingly, however, the mice displayed absolutely no changes in life span. Similar results have been observed for $Gpx^{-/-}$ mice. Together with the data on SOD and catalase overexpression, these data strongly question the validity of the free radical hypothesis of aging, and in this case, it is the lack of a short-lived mouse model that proved to be informative. However, there is a mouse that has a defect in a gene related to free radicals and that is short lived: the $MsrA^{-/-}$ mouse (methionine sulfoxide reductase knockout; see **Table 1**). This mouse appears to be significantly short lived, though the survival study lacked enough statistical power to be conclusive. MsrA is not involved in scavenging free radicals; rather, it reverses the damage that these compounds produce in proteins. Many proteins have an abundance of methionines exposed in their surface, and because all cells have MsrA, which can reverse the oxidative damage caused by ROS on this particular amino acid side chain, this might represent a last line of defense against ROS. If this mouse can be shown to be short lived, it would rescue the free radical hypothesis of aging, but based on all other data available, the hypothesis would need to be revisited.

Testing the Mutation Hypothesis of Aging

The mutation hypothesis of aging assumes that aging is the result of progressive accumulation of damage to DNA, eventually resulting in loss of tissue functionality and the aging phenotype. The hypothesis implies the importance of defense mechanisms in attaining a long life, and indeed, many long-lived

mutants in several animal models are characterized by an increased ability to withstand stress. An emerging generalization is that the ability to either defend the organism against stress or repair the damage effectively after it is produced is a central feature of long-lived individuals, be it at the level of mutants within a species or at the level of comparative biology (i.e., comparison of different species with different life spans). A corollary to this observation is that no specific damage can be blamed directly for the age-related decline. Rather, any damage, if not repaired, will do it.

Several mice with reduced DNA repair mechanisms have been produced. Most of these animals display no change in life span. Among them, most relevant are the $Xpa^{-/-}$ and $Xpc^{-/-}$ mice, because a closely related family member, *Xpd*, does produce an accelerated aging phenotype when mutated (see later). All Xp proteins are involved in base excision repair, and in some cases, their mutation leads to the segmental progeroid syndrome, xeroderma pigmentosa, or to trichothiodystrophy (TTD), also characterized as a segmental progeria. Xpd is primarily involved in transcription coupled repair, a subclass of base excision repair, and it has been proposed that it is this activity that is mainly affected in the mutant mice. A similar situation applies to genes involved in nonhomologous end joining repair (NHEJ) of double strand breaks. This pathway involves several proteins, including Ku70, Ku86, Xrcc4, and DNA ligase IV. Of these, only $Ku86^{-/-}$ mice display premature aging, but such a phenotype has not been observed in any of the other mutants, in spite of the fact that all these mice display premature cellular senescence. Clearly, all of these mice need to be investigated further, maybe in conjunction with $Terc^{-/-}$ mice, as has been done in the case of *Wrn, Atm,* and *Blm*.

As mentioned previously, however, there are two exceptions that deserve discussion, the Xpd^{TTD} and the $Ku86^{-/-}$ mice. In both of these cases, the mice live shorter than wild-type controls (significantly so in the case of $Ku86^{-/-}$ and only marginally in the case of Xpd^{TTD}). Most importantly, the mice display several symptoms of premature aging, including small size, lordokyphosis, and skin and bone deficiencies (see **Table 3**). Thus, like in the $MsrA^{-/-}$ mice, the data suggest that under certain circumstances, failure to repair DNA damage can indeed lead to premature aging.

At first glance, the general inability to obtain short-lived mutants when DNA repair pathways are incapacitated suggests that damage to DNA might be important in certain pathologies, such as cancer, but irrelevant to aging. An alternative possibility is that the integrity of the genome is so important that sufficient defense mechanisms are in place, so that elimination of any repair pathway is efficiently corrected by a backup mechanism. However, in several of these strains, significantly increased levels of DNA damage (up to 30-fold) have been observed, an observation that weakens this second proposition. Similarly, mice that have reduced free radical defense mechanisms, such as $Sod2^{+/-}$, $Cat^{-/-}$, and $Gpx^{-/-}$, show increased levels of DNA damage but no effect in life span. In contrast, the short life span of the $MsrA^{-/-}$ mice, defective in an enzyme responsible for repair of oxidatively damaged proteins, suggests that it is not the ROS-driven damage to DNA that causes a shortened life span but, rather, the damage to proteins. This is contrary to firmly entrenched current beliefs, but the data can be harmonized by proposing that it is not damage *per se* that causes aging, but damage to specific proteins that can act as sentinels and induce a cellular response that is at the center of the action. Some possible targets have been proposed, such as mitochondrial *cis*-aconitase, but experimental testing is still lacking.

One other mouse model that was produced with the intent of testing a hypothesis of aging is the $PolgA^{mut}$ mouse. These animals express a proofreading deficient form of the nuclear encoded catalytic subunit of mitochondrial DNA polymerase. As expected, the mice suffer a severe increase in mitochondrial DNA mutations (3- to 5-fold), and indeed, the mice are significantly short lived and display an early onset of age-related phenotypes (see **Table 3**). This model suggests that unrepaired DNA damage can indeed affect the process of aging, and since the affected DNA is the mitochondrial genome, it neatly links mitochondrial-derived ROS to the DNA damage hypothesis. The discrepancy with other models of DNA repair prompts two alternative explanations: (1) it is the mitochondrial (but not the nuclear) DNA that is important for the aging process, or (2) the redundancy of the repair machinery available in the nucleus (but not the mitochondrion) prevents the other mice from developing a phenotype. As discussed earlier, the fact that most of these mice do display vastly increased levels of DNA damage argues against the second hypothesis, and thus the mitochondrial DNA emerges as a strong candidate.

In summary, mice produced with the purpose of testing specific theories of aging have yielded mixed results. Because the research has been hypothesis driven, well-done experiments are informative even if a short-lived mouse is not obtained. Indeed, the inability to obtain such mice informs us about the validity of the hypothesis, and the negative result, if

well obtained, begs for a revision of the hypothesis in order to properly accommodate the data.

Mouse Models with an Unexpected Accelerated Senescence Phenotype

In 2002, a paper by Tyner *et al*., showed that a serendipitously obtained p53 mutant in mice, dubbed $p53^{+/m}$, confers a shorter life span accompanied by a considerable premature aging phenotype that includes the usual small body size, lordokyphosis, and skin and bone deficiencies, as well as several other symptoms of aging (see **Table 3**). The mouse was obtained by a fortuitous incorrect recombination event that led to the deletion of several genes upstream of p53, but most notably, it also produced a deletion of the amino terminus of the p53 protein, which contains the transcriptional activator domain. The truncated carboxyl fragment contains the polymerization domain, and thus, it is expected to form heterotetramers with wild-type p53. In fact, the *m* mutation only produces the phenotype in the presence of a wild-type p53, suggesting that it is the heterotetramers that are the active species. p53 is a very important tumor suppressor and regulator of cell fate. In response to DNA damage, p53 activation leads to a cell cycle arrest that gives the cell a chance for repair. If that does not occur, then p53 can induce one of two pathways that remove the affected cell from the potentially proliferating pool: it can induce either apoptosis or cell senescence, two well-described mechanisms of tumor suppression. Accordingly, overexpression of p53 results in a reduced tumor burden, while mice heterozygous for this gene display a dramatic increase in tumors (and a correspondingly short life span). Most surprisingly, the *m* allele of p53 also reduces tumor incidence (to 6%, from the 45% observed in wild-type mice), but instead of living longer, they live shorter (by 20%) and display accelerated aging. Thus, the mutant appears to act as a hypermorph, increasing the basal activity of wild-type p53. In fact, there is precedence for this, since it has been shown that the p53 mRNA can give rise to two different proteins, p53 and p44, the second being the product of an alternative initiation site for translation, located at an AUG in the fourth exon. p44 has been shown to act as a hypermorph, and mice expressing this alternative protein (in addition to the wild-type p53) have been produced. Like the *m* mutation, these mice also display a shortened life span, accompanied by a plethora of age-related characteristics. Because p53 is involved in cell proliferation, apoptosis, and cell senescence, it was interesting to ascertain the causes for the small size of the animals, a non-aging-related feature common to all accelerated models that might also give a clue as to the causes of early death. In both strains of mice, it was found that several tissues show early atrophy. This is not due to a smaller size of the existing cells; rather, the tissues display a reduced cellularity. Furthermore, embryonic fibroblasts from $p53^{+/m}$ mice display premature senescence and a decrease in the growth burst usually observed during the first passage *in vitro*. Together, the data suggest that the accelerated aging phenotype might be related to the decreased cellularity in a variety of organs, as well as decreased regenerative ability. Consequently, it has been hypothesized that this might be due to p53's ability to reduce cell proliferation, particularly in the stem cell niche, and indeed, the $p53^{+/m}$ mice display a reduced number of hematopoietic stem cells, even at an early age.

While the hypermorphs seem to accelerate aging, simple overexpression of p53 does not. The so-called super p53 mice do indeed show an increased resistance to tumors, but they do not live shorter (or longer, for that matter). It has been hypothesized that the reason for this difference lies in the pulsatility of p53 gene expression. In response to a genotoxic stress, p53 is rapidly induced and rapidly turned off. This mechanism is still in place in super p53 mice, which were generated by insertion of large BACs supposedly containing all relevant regulatory elements normally present in the p53 locus. Thus, super p53 mice contain a supernumerary normal allele, capable of normal but increased pulsating activity. In contrast, it is possible that the presence of hypermorphic variants in both the *m* and the *p44* models leads to a stabilization of active p53 tetramers, resulting in a sustained response. This inability to turn off the signal might be what leads to the decreased longevity, since all cells in the animal are exposed to high levels of p53 activity even after the genotoxic assault has subsided. As mentioned, both $p53^{-/-}$ and $p53^{+/-}$ mice live shorter, but their increased tumor burden (and death from these tumors) makes them poor models of aging. However, a similar argument can not be made for the $p53^{m/+}$ or the *p44* mice. It will be interesting to learn what these mice can teach us about cellular homeostasis and its relation to normal aging.

Accelerated Aging in Mouse Models with Less Defined Genetics

In addition to the models described previously, there are at least two additional models of premature aging in mice, in which the functionality of the gene responsible for the phenotype has not been positively identified. These are the *klotho* mutation and the

senescence accelerated mice (SAM). Mice born with the autosomal recessive mutation *klotho* live less than 100 days and display several age-related characteristics (**Table 3**). Conversely, overexpression of *klotho* in mice extends life span. The mutated gene has been cloned, and a recent report indicates that its product functions as a circulating hormone that binds to a cell surface receptor and represses the intracellular signals derived from insulin or IGF1.

SAM mice are actually a group of several inbred strains, developed from AKR/J mice and selected for accelerated senescence. It has been proposed that these mice might represent better models for progerias than for normal aging. Each strain displays a unique but reproducible subset of aging phenotypes, affecting different organs and functions. In none of them has the culprit gene(s) been identified, although microsatellite marker analysis has indicated the presence of four loci that appear linked to the senescence acceleration. Because the onset of senescent phenotypes is not significantly earlier than controls, these mice appear to represent a model of accelerated senescence rather than premature senescence, as in the case of the human diseases Werner or Hutchinson-Gilford.

Conclusions

Several short-lived mouse strains have been developed recently. The important questions are the following: Are they useful models for studying aging? What can we learn from these mouse models? (Or, perhaps, what have we already learned?) Several researchers have argued that these models are not useful, because there are a myriad of ways of shortening life span without affecting the aging process, and thus, it is extremely difficult to select which ones might be informative from among all these short-lived mice. In contrast, it is often argued or assumed that, for an organism to live longer than the average of the species, the entire aging machinery needs to be modified. Thus, the argument goes, mutations that increase life span must be informative of the aging process as a whole. This is obviously a fallacy. In captivity, the life span of female fruit flies is limited by the accumulation of toxic byproducts present in the male's seminal fluid. Restriction of intercourse or genetic manipulations that decrease such toxicity would greatly increase the life span of female flies, but such manipulations are utterly uninformative about the process of aging. Thus, similar caution is required on both ends of the spectrum, though it is conceded that more caution is required in the case of short-lived models.

One subject that has not been brought up in the previous discussion is the Gompertz curves. It has been frequently argued that mutations that alter life span in any way must conform to Gompertzian traits. That is, the slope of the mortality curve (which represents the age-specific mortality) must be affected in order for the model to be called a true model of accelerated aging. Not all researchers agree with this criterion, and indeed, the Gompertz equation accepts as valid only those models that display accelerated aging, but it precludes the use of models in which aging occurs prematurely but with the same mortality slope (see **Figure 1**). The arguments in both directions are beyond the scope of this article, but nevertheless, the discussion would not be complete without at least mentioning this fact. Gompertz curves have proved very useful in aging studies based on population genetics (primarily *Drosophila*). However, with some exceptions, in most of the models described here the size of the cohorts (dictated by the price of raising mice to an old age) is relatively small, and a proper Gompertz curve can not be confidently derived. Nevertheless, a recent review attempted to distinguish which of these models might be useful to study aging, according to this particular criterion. Based on their analysis, the authors concluded that most of the models described here do not display a change in the slope of the Gompertz equation. The exceptions are the PolgA^{mut} and the MsrA$^{-/-}$ mice. Surprisingly, however, the authors also failed to observe age relevance in several well-established long-lived models, including Prop 1, IGF1R, GHRHR, and InsR. In contrast, they do find a relevant relationship in the cases of GHR, Pit1, and Shc. Given the close relationship between these many models, it seems likely that this criterion might be too stringent, and/or some of the data were derived without sufficient numbers of animals. This is certainly the case for the MsrA$^{-/-}$ mouse.

One potentially useful analysis of the various models involves contrasting the characteristics, at the cellular level, of short-lived mutants and mutants affecting similar pathways, but that do not live shorter. **Table 4** lists a limited number of such comparisons. The pairs (first- vs. third-generation *Wrn*$^{-/-}$ x *Terc*$^{-/-}$; *Xpa*$^{-/-}$ and *Xpc*$^{-/-}$ vs. *Xpd*^{TTD} and *Ku86*$^{-/-}$; *SOD*$^{+/-}$ and *Gpx*$^{-/-}$ vs. *MsrA*$^{-/-}$; and *super p53* vs. *p53*$^{+/m}$ and *p44*) were chosen from those discussed previously. The cellular features compared were limited to DNA damage, cellular senescence, and apoptosis. The table shows that there is little if any correlation between the ability of a given genetic manipulation to increase damage to DNA (or increase ROS production) and shortening of life span. As discussed earlier, one important

Table 4 Comparison of selected phenotypes in accelerated vs. not-accelerated aging mice

nr, not reported.

exception not included in **Table 4** concerns the *PolgA*^{mut} mice, which do live shorter, apparently as a result of increased damage to their mitochondrial DNA. In contrast, there is good agreement between the increased capacity to undergo either cellular senescence or apoptosis and a shortened life span. In the case of the *Sod*$^{+/-}$, *Gpx*$^{-/-}$, and super p53 mice, increased apoptosis or cell senescence is only observed after appropriate challenges, but not when measured under resting conditions.

Thus, the emerging picture points in the direction of a significant role for basal cellular turnover (under basal conditions) in controlling life span. Indeed, any manipulation that leads to increased cell turnover seems to culminate in accelerated aging. Thus, if cells are suffering a chronic increase in stress loads, be it because they cannot repair their DNA (*Wrn*$^{-/-}$, *Ku80*$^{-/-}$, *Xpd*^{TTD}, *PolgA*^{mut}), or because of structural defects (*LmnA*^{L530P}) or reduced defenses (*MsrA*$^{-/-}$), the end result will be a chronic increase in apoptosis and/or cell senescence. Indeed, further support for a role of apoptosis both in aging and in the accelerated aging phenotype of the *PolgA*^{mut} mouse has recently been published. Thus, the short-lived models are teaching us that it may not be the origin of the damage that is critical, but rather whether or not that damage can be repaired in a way that precludes the functional loss of the cell, be it via apoptosis or cell senescence. Both of these outcomes might lead to an increased pressure on the replicative capacity of stem cells, as was suggested by studies on *p53*$^{+/m}$ mice. If in turn this capacity is also taxed, and/or if the process of stem cell proliferation and differentiation is further affected by the aging milieu, then the end result will be increased aging of the tissue. Because of the effect of surrounding tissues, this process is self-renewing, giving rise to the exponential deterioration observed in aging organisms. Naturally, different tissues will be affected at different rates, and the effects will also be idiosyncratic within the population under study.

Achievement

D K Simonton, University of California, Davis, CA, USA

Glossary

Career Age – The number of years an individual has been active within a given domain of achievement. Also called professional age.

Equal-Odds Rule – The empirical generalization that the ratio of successful works to total output stays more or less constant across an individual's career.

Last-Works Effects – The tendency for creative products conceived toward the end of life to exhibit qualitative and quantitative changes. These changes suggest a resurgence and transformation of creativity in the final years.

Introduction

Achievement is a generic concept that can cover a tremendous range of human activities. These activities may have little in common and may require rather distinctive biological, psychological, and sociological conditions. To offer some obvious examples, the Nobel laureate in physics may have little in common with the Olympic athlete, just as the founder of a successful business enterprise may share nothing at all with a movie star. However, close examination of these and other cases does reveal that all instances of achievement tend to feature the same four characteristics.

First, achievements are behaviors or products that make an individual stand out from the majority of individuals who are active in the same endeavor. Not every author wins the Nobel Prize for Literature; not every tennis player becomes a singles champion at Wimbledon; not every entrepreneur manages to build from scratch a Fortune 500 company. As these instances show, some individuals may attain distinction by offering something unique to the world, such as an artistic masterpiece, whereas others may make a name for themselves by performing some well-defined task better than any competitors, such as sprinting 100 meters faster than anyone else in the world.

Second, achievements are behaviors or products that reflect favorably on the skill or talent of the person under view. Only a tiny percentage of the population has the mental or physical capacity to make a serious bid for a major honor, award, or prize. It is for this reason that lottery winners are not credited with achievements; the skill needed to purchase a lottery ticket is of a very ordinary kind that everybody possesses.

Third, we usually associate achievement with motivational characteristics, such as effort, persistence, drive, and determination. As a consequence, individuals who enjoy a certain natural talent at some task but who make no attempt to develop their native skills further are most likely to be called underachievers. So important is this third characteristic of achievement behaviors that we will sometimes label an activity an achievement even when it requires far more motivation than ability or skill. For instance, many of the achievements listed in the *Guinness Book of Records* are of this variety. Someone who holds the world record for the number of days spent sitting atop a pole is going to earn admiration more for persistence than for talent. Nevertheless, those achievements that seem to require both

ability and effort seem to elicit the most widespread and profound esteem.

Fourth, the word achievement is normally assigned to behaviors or products that have positive social value. Accordingly, notorious assassinations or infamous crimes are seldom considered accomplishments. Unfortunately, this component of the concept is not always easy to evaluate. Not only may value judgments vary from culture to culture, but these assessments may also vary from individual to individual within the same culture. In some nations, assassination for political or religious reasons may be actually encouraged. And for some pacifists, a general's victories on the battlefield may constitute criminal acts of institutionalized homicide. Nevertheless, nothing prevents us from adopting a relativistic conception of societal norms. If an activity tends to earn praise from the majority of those living within a given sociocultural system, it can be counted as a notable accomplishment.

In this article, the focus is on those achievements that exemplify all of the central characteristics. The key question then becomes how this level of achievement varies as a function of a person's age. At what point can it be safely inferred that a particular individual is 'over the hill' or 'past his or her prime'? Does there exist an age beyond which we should not anticipate further accomplishments of the kind witnessed earlier in the career? To address this question, we first review the empirical findings on this subject. Next we can examine some of the possible theoretical interpretations of those results.

Empirical Findings

The scientific study of the relation between age and achievement is one of the oldest research topics in the history of the behavioral sciences. The earliest such investigation was conducted in 1835 by Adolph Quetelet, who examined how the production of notable plays varied as a function of the dramatist's age. This was the first study to demonstrate how creative productivity often declines in the later years of life. However, the first truly thorough research on this subject was conducted by Harvey C. Lehman, especially as summarized in the 1953 book *Age and Achievement*. Lehman investigated virtually every possible domain of achievement, including both creativity and leadership. He also attempted to introduce much more systematic and rigorous methods in his quest for the typical age curves for various intellectual, aesthetic, political, and economic endeavors. Although subsequent investigators have identified several methodological flaws in Lehman's work, many of the central results have been replicated in studies that use more advanced analytical techniques. In particular, the literature tends to support the conclusion that the odds of significant achievement usually tend to decline after a career peak that most often appears around mid-life. In addition, the specific nature of this descent tends to vary according to many other factors, such as the specific domain of achievement. These and other complications will become apparent in the following sections, where we examine the longitudinal changes in three broad domains: leadership, creativity, and entertainment.

Leadership

Of all categories of achievement, leaders may occupy the highest place. Political, military, economic, and religious leaders all define the world in which we all inescapably must live. A nation's material and emotional well-being closely depends on the politicians who write its laws, the generals who are responsible for defending its boundaries, the entrepreneurs who introduce new products and create new industries, and the religious figures who guide a people's moral and spiritual life. It should not be surprising, then, that of all forms of achievement, leaders tend to be the most prominent. The average person on the street may not know who most recently received the Nobel Prize for Literature or for Physics, but few would not be able to identify the individual who serves as the nation's current head of state. Even the historical reputation of leaders tends to exceed that of individuals active in different domains of attainment.

Given the significance of leadership, the relation between age and achievement assumes great practical importance. When is a person too old to occupy such a critical position in society? This question can be best addressed by looking separately at political, military, religious, and economic leadership.

Politicians When we speak of the relation between age and political achievement, we must recognize that leadership can be assessed many different ways. The most commonly used definition in research is simply to note the age at which individuals are most likely to ascend to a particular political position. At what age do individuals become president, prime minister, senator, governor, member of parliament, secretary of state, ambassador, and so forth? Research shows that the leaders that enter such established political roles tend to have entered their more mature years, most commonly being in their 50s or 60s. Moreover, it is not rare to see status quo political leaders who are even older. At the same time, it is clear that the age distributions tend to vary according to the nature of the political position. Among

politicians in the United States, legislators who serve in the Senate tend to be older than those in the House of Representatives, while among chief executives, those who serve as President tend to be older than those serving as state governors. Of course, some of these contrasts can be attributed to differences mandated by law. Nonetheless, this cannot entirely explain the age differences, because the most typical age ranges tend to be older than those set down by law. For example, most presidents exceed the minimum by about 20 years. In fact, successful presidential candidates tend to be clustered fairly closely around 55 years of age, whereas most losing candidates tend to be either much younger (as young as 36) or much older (as old as 85).

So far we have considered only established political roles. Other political leaders achieve distinction by heading revolts, rebellions, or revolutions against the established government. These revolutionaries and rebels are far more prone to be much younger than their contemporaries who occupy status quo positions. For example, among politicians of the twentieth century it was rare for a status quo politician to attain power before the age of 40. In contrast, almost half of eminent revolutionaries were younger than 35 at the onset of their involvement, and almost 80% were younger than 45. Interestingly, as a political system matures, the average age of its leadership tends to increase as well. This trend is seen in the history of the United States since its inception at the end of the eighteenth century. Members of Congress in the twentieth century are about a decade older than those at the beginning of the nineteenth century. Furthermore, the average ages of those serving as Speaker of the House have increased from the 40s to the 70s. These upward trends cannot be entirely attributed to shifts in mean life span. In fact, for some political positions the trends go in the opposite direction. The governors of the American colonies were actually about 20 years older than the governors of the various states of the union after the revolution. Colonial governors, as subordinates of the British crown, had to more strongly represent the status quo. Hence, the same principle applies. Youth challenges the powers that be, while maturity defends those institutional powers.

These findings all focus on the age at which individuals fill certain leadership roles. Although this is certainly a reasonable criterion of achievement – given the difficulty of attaining these positions – it cannot be our sole criterion. Indeed, a more critical gauge of achievement would be some indicator of the leaders' actual performance during their tenure in office. For example, one investigation looked at the relationship between the age at which a US president is inaugurated and his subsequent performance as an executive, legislator, and diplomat. Absolutely no relationship was found. Older chief executives are no better or worse than those who are much younger, and there exists no peak age for maximum success.

Nevertheless, it is necessary to point out a serious methodological problem with many of these studies. For most political offices in democratic systems, the length of tenure is rather restricted. In the US presidency, for instance, only one chief executive has served more than 8 years, and many have served 4 or less. This is too little time to calculate longitudinal trends. What is required is an analysis of leaders who have served throughout their adult lives. The only political institution for which this is feasible is hereditary monarchy. Because monarchs may then ascend to the throne at a young age and may remain enthroned until death, analyzing these leaders allows us to scrutinize changes in performance over three decades or more. One empirical inquiry that examined a large sample of long-tenured monarchs in fact discovered a tendency for performance to peak around 42 years old. After that peak, there was a gradual decline in the monarchs' ability to expand or maintain their political power and influence. Thus, age decrements can be found when the observations are truly longitudinal in nature.

Military Commanders The study of military leadership presents some of the same problems as seen in the study of politicians. For example, we must be careful to distinguish between the age at which an individual is most likely to occupy the role of general or admiral and the individual's performance in that role. One early investigation, for instance, looked at the age at which commanders led armies in historic battles without noting whether the battle was won or lost. As a result, the information obtained was very limited in its implications. Another difficulty is even more severe than that seen in the study of political leaders: although military careers can last a long time, the central function of those careers, namely, fighting wars, usually has a much shorter duration. It is rare for a major war to last for more than 5 years, and a very large proportion last for only a year or two. Seldom can we trace a commander's tactical success over a long period of time. As a consequence, we often have no other choice but to examine cross-sectional rather than longitudinal data. We must ask whether the age of two opposing commanders in a battle allows us to predict who will be mostly likely to emerge the victor. The answer to this question is affirmative. For instance, one empirical study looked at the winners and losers in 326 land battles. The older a general was in comparison to his opponent,

the less likely he was to take the offensive by attacking first. In other words, older commanders tend to adopt more conservative, defensive tactics. This age trend is important because taking the initiative on the battlefield is a key predictor of tactical victory. In addition, there was evidence of a curvilinear relationship between age and military success. The commanders who were closest to the peak age of 45 years were most likely to be those with the most career victories and the longest winning streaks. Together, these findings suggest that military achievement, at least as defined by battlefield victory, may decline in the later years of a commander's life.

Entrepreneurs Economic leaders are extremely important to the material well-being of any capitalist society. After all, these are the leaders, the businessmen and -women, who market the new products and create the new jobs that are essential to a high standard of living. Yet research on these figures is relatively limited. Most studies indicate that entrepreneurial leadership may peak somewhat late in life. Typically, the most distinguished leaders first reach the high point of their financial power in their late 50s. Moreover, these individuals do not actually attain wide recognition for their economic accomplishments until somewhere in the 60s. Thus, this form of achievement may require more maturity and experience in the business world. At the same time, we must recognize that these age curves are not easy to interpret. The income and influence of entrepreneurs are largely based on decisions made earlier in their careers. The seeds of the wealth of an Andrew Carnegie, John D. Rockefeller, Henry Ford, or other corporate giant were often planted in their 30s. It takes time for the risky investments of youth to make an impact on an industry. Even so, these entrepreneurs usually manage to continue their money-making abilities until quite late in their lives. Only in rapidly changing markets might they find themselves suffering from younger competitors. In this sense, economic leadership is similar to what tends to hold for diplomats and other forms of political leadership in which accumulated expertise is at a premium.

Religious Leaders The life span development of those who lead religious movements and institutions follows a pattern that closely parallels what has been observed for political leaders. On the one hand, some figures attain distinction by becoming the head of some established religious group, whether a church, denomination, or sect. These status quo religious leaders tend to be quite advanced in years. The history of the Roman Catholic papacy provides a typical illustration. Almost all popes were older than 50 years old at the time they were elected, and around two-thirds were well over 65. Furthermore, the optimal age range for becoming pope lies roughly between 80 and 90. On the other hand, the founders of new world faiths are often much younger. It is extremely rare for a founder to be older than 60. Most tend to be between 35 and 38, and many are much younger than that optimum interval. For example, from the history of Christianity, John Wesley founded Methodism at age 35, Martin Luther launched the Protestant movement at 34, Ignatius Loyola wrote the 'Spiritual Exercises' at 30, John Calvin wrote the *Institutes* at 27, Joseph Smith begun Mormonism at 25, and George Fox founded the Quaker faith at 23. Jesus himself was probably around the age of 30 at the height of his mission. Similar statistics hold outside the Christian faith. For example, Buddha was probably in his mid-30s when he began teaching the fruits of his enlightenment. Of all the world's major faiths, Islam had the oldest founder, and even he, Mohammed, was only 40 when he became the Prophet. Facts such as these support the conclusion made by G. Stanley Hall that "men in their prime conceived the great religions, the old made them prevail" (Hall GS (1922) *Senescence: The Last Half of Life*, p. 420. New York Appleton). Curiously, when exceptions to this rule seem to appear, the underlying principle persists upon closer examination. Thus, Popes Innocent III and Leo X, for instance, entered the pontificate in their late 30s. Yet both were extreme activists, the former in the political sphere and the latter in the cultural.

Creativity

The subject of the relationship between age and creative productivity has already been treated at length in the article on creativity in this encyclopedia. Therefore, here we need only to summarize the six central findings.

Typical Age Curve When we plot the number of contributions individuals make as a function of their age, we discover a single-peaked, inverted-U curve. More specifically, the output of works first increases up to a certain optimum, after which productivity gradually declines. By the 80th year of life, output is about 50% of the level reached at the career peak. Although this might seem a substantial drop, we must note two extenuating facts. First, even a creator who is well advanced in years can expect to maintain a respectable level of creative productivity. Second, the output rate seen by individuals in their 70s is about the same as that seen by those in their 20s.

In this sense, septuagenarians can hold their own against the youngest members of their discipline.

Interdisciplinary Differences The typical age curve varies substantially according to the specific domain of creative achievement. In some fields, the peaks may appear relatively early in life, and the post-peak declines can be relatively rapid. This is the situation for lyric poetry and abstract mathematics, for example. In other fields, however, the productive optima usually occur much later in life, even as late as the 50s. Such delayed peaks are common in history and philosophy. Furthermore, those creative domains that feature later productive maxima also tend to exhibit gradual, even negligible, declines. Thus, in these late- and slowly maturing disciplines, aging has minimal impact on creative achievement. Moreover, even in those disciplines characterized by early peaks and rapid declines we do not expect the output rate to drop to zero. In fact, the typical creator in these domains will maintain a level of productivity by age 80 that will equal about 10% of that observed at the career peak.

Career Versus Chronological Age Although most researchers have tended to view the longitudinal changes in terms of chronological age, this practice is not really correct. Instead, the curves expressing changes in creative productivity are better defined according to career or professional age. Those who begin their careers earlier in life will tend to exhibit earlier peaks as well. By the same token, those whose careers get a very late start will normally enjoy later peaks. This means that it sometimes happens that late bloomers will actually attain their career high points in the last one or two decades of life. In addition, it is perfectly possible for a person to exhibit two career peaks. This can happen when an individual already successful in one field decides to make a mid-life career change and thus develops a second successful career in later life.

Individual Differences We should not overlook the fact that individual differences in creative achievement are quite substantial. Not all creators are created equal; rather, some produce considerably more creative ideas than their less-accomplished colleagues. In most disciplines, the top 10% who are the most productive are usually responsible for 50% of all contributions in the field, whereas the bottom 50% who are the least productive account for only about 15% of the total achievement. This cross- sectional variation explains more variance in output than the longitudinal changes attributed to career age. Accordingly, highly prolific creators who are in their 70s or 80s will equal or even exceed the output levels of other, less productive creators who are in their 30s or 40s.

Equal-odds Rule There are two ways we can count output across the career. On the one hand, we can simply tabulate the total number of works produced, regardless of whether the pieces are successful or not. For example, we might count the number of scientific papers produced per decade without regard for whether these papers made any contribution to the field. On the other hand, we might restrict our counts to merely those creations that can be considered genuine achievements. For instance, we could tabulate those scientific papers that receive a specified number of citations in the publications of other scientists working in the same discipline. The first kind of measure gauges quantity, or pure productivity, while the second kind of measure assesses quality, or real creativity. Obviously, if our standpoint is one of achievement, the exclusive quality measures are superior to the inclusive quantity measures. This distinction also has interesting repercussions for understanding how aging affects creative achievement. In the first place, the age curves for quantity and quality are essentially the same. Those periods in an individual's life in which the most works are produced are also those in which the most influential products are most likely to emerge. Furthermore, if we calculate the proportion of successful works to total output, we find that this quality ratio fluctuates more or less randomly throughout the career. This means that older members of a creative enterprise will have roughly the same success rate as those members at their supposed creative prime. In other words, even though the elder creators may be producing fewer masterpieces, they are also generating fewer neglected works. This equal-odds rule suggests that from the perspective of the quality ratio, we cannot realistically speak of an age decrement at all. Age is simply unrelated to the probability of success.

Last-works Effects We can advance a step beyond the last point. Highly creative individuals will frequently undergo a resurgence of creative activity toward the end of life. This upsurge in total output, as the equal-odds rule maintains, will correspond to an increased production of important works. More importantly, as death draws near, the creativity of these individuals will often undergo a qualitative transformation that renders their final works quite distinct. In the visual arts, for example, it is not uncommon for master painters to enter into a phase in which their works exhibit a notable 'late style.'

In addition, creators will often devote considerable effort to the production of a single piece that successfully serves as an artistic last testament or career capstone. In classical music, for instance, this creative shift has been called the swan song phenomenon. What makes these achievements especially significant is that they often appear when the individual's health has been undergoing chronic and debilitating deterioration, such as blindness, deafness, arthritis, and other infirmities. Thus, the age curves notwithstanding, the aging process need not prevent exceptional creators from maintaining their creative powers right to the end.

Entertainment

In this final category are placed several miscellaneous forms of achievement that cannot be classified as either leadership or creativity. Because the number of potential domains is extremely diverse, we review only three representative areas of accomplishment, sports, chess, and film.

Athletes Among all the principal domains of achievement, accomplishments in sports are almost exclusively the province of youth. Sports championships, such as the Olympics, are predominantly populated by athletes in their 20s. Indeed, for some events, like swimming, it is the teenagers who are most likely to prevail. Moreover, the various age optima for athletic competitions tend to be quite stable over long periods of time. For instance, the mean age of Olympic gold medalists in track and field events has stayed relatively constant since the first Olympics were held. In addition, the variation around these means is usually rather small. For most athletic activities, the top athletes will be no more than 5 years apart in their ages.

On the other hand, it is also true that the ages of peak achievement tend to vary systematically according to the particular sport. In swimming and track, for example, there appears a fairly consistent tendency for the longer events to be won by older athletes, the differences sometimes exceeding 5 years. More importantly, the age optima are even greater for those competing in sports in which skill is more important than speed, strength, or stamina. Thus, champions in shooting, golfing, bowling, and billiards are most frequently in their early 30s. Even so, there exists no regular sport in which the championships are most commonly held by athletes in their 40s or older. So, the main generalization stands: older adults cannot be expected to compete at the same level as younger athletes.

However, this last remark should not blind us to another fundamental truth. There always exist substantial individual differences in athletic performance, differences that tend to be relatively stable across time. Consequently, a top athlete past his or her prime may still be competitive with lesser athletes who are at their prime. Whenever we focus on those who receive the gold medals or most valuable player awards, we tend to forget that there are older competitors that came in third or fourth in the event, match, or ballot. One classic illustration is the baseball pitcher Nolan Ryan, who went from a record-breaking player in his late 20s to a still highly competitive player in his late 30s. In fact, he was still breaking records shortly before injury forced his long-delayed retirement.

Chess Masters In the previous section we observed that those sports that place the most emphasis on skill are most likely to be those with older champions. This tendency may lead us to ask: what about those competitive activities in which the skill is entirely mental rather than physical? For example, because card and board games do not require any extraordinary proficiency in eye–hand coordination, we might anticipate that the premiere players who win championships can do so at older ages than is typical in sports. There is indeed evidence that this expectation fits the facts. For instance, Arpad Elo devised an objective measure of the performance of chess masters, which he then used to gauge how expected performance changed over the career course. The average age for peak competitiveness was around 36, and the range of maximal to near-maximal performance was between the late 20s and the late 40s. Furthermore, a player at about age 63 could expect to play as well as a player at around age 21. Hence, the assets of youth are much less conspicuous for a competitive activity that is almost entirely intellectual in nature.

Finally, what was said of athletes holds equally well for chess grandmasters. The strongest players in the later stages of their careers are superior to lesser players in their prime. Individual differences in skill are so pronounced as to often overwhelm longitudinal changes in competitive ability. A prime example is a player like Emanuel Lasker, who became world champion in 1894 and successfully defended his title when he was 53 years old. Significantly, even in his 60s Lasker was able to pull off some classic victories in chess competition.

Movie Stars The final domain of achievement in entertainment concerns actors and actresses in film. Acting may seem far removed from the preceding

two domains, yet in certain respects they are actually comparable. In the first place, the movie business is extremely competitive, so that only a small percentage of aspiring actors and actresses can expect to attain star status. Second, like chess, acting largely represents an intellectual skill that is acquired and developed. Third, like athletics, success in films requires certain physical attributes, even if these characteristics are not usually of the same kind demanded in sports. In particular, it is rare for an actor or actress to rise to stardom without emanating an unusual amount of physical attractiveness. Whether we call them handsome or beautiful, most project in their performances a certain amount of sex appeal. This latter attribute raises an intriguing question: might not the relation between age and achievement within this domain vary according to gender? After all, the sexual attractiveness of men and women may change in different ways as a function of the aging process. Indeed, whereas women might quickly lose sex appeal, men might actually gain as their appearance grows more masculine and distinguished. Only if the skill component of great acting predominated would we expect the accomplishments of actresses and actors to follow the same life course.

Research on this question supports the conclusion that gender contrasts are in fact quite conspicuous. For example, one inquiry looked at the ages of the actors and actresses who were the top money makers. The curves for the two sexes were dramatically different. The women began to make big money earlier, around their late teens, reached the peak of their careers in their late 20s, and were largely finished as box office attractions by their late 30s. The men, in contrast, did not really take off until their early 20s, attained their peaks in their early 30s, and, most significantly, continued to enjoy some box office success until they attained their late 60s. Curiously, largely the same age curves appeared for stars who turned in best performances, as judged by movie critics. The best performance of an actress most often appears in her late 20s, that of an actor in his early 30s. Furthermore, whereas the women have little chance of such an accomplishment beyond age 40, the prospects for actors remain good into their 60s. Hence, physical attractiveness may be far more crucial than performance skill in determining the achievements of movie stars. Not only must women be younger than men to maximize success, but also women experience a more precipitous drop in their opportunities for stardom. Admittedly, these curves represent only statistical averages, and accordingly exceptions do exist. Katherine Hepburn is a classic illustration of a woman whose achievements as an actress survived the deterioration of her physical beauty. Nonetheless, for the vast majority of movie stars, the aging process harms the careers of women much more than those of the men.

Theoretical Explanations

The previous section emphasized the empirical findings on the connection between age and achievement. No attempt was made to discuss the theoretical explanations for these diverse results. In this section, this deficiency is rectified. The available substantive interpretations may be grouped into three categories: biological, psychological, and sociological.

Biological Processes

It is perhaps too common to explain any age decrements in achievement in terms of the adverse effects of the aging process on individual health. Older persons almost invariably experience marked declines in physical vigor. Aging also brings about a slowing down of mental functioning due to changes in the central nervous system. In addition, it may take increasingly longer to overcome the disabilities resulting from injuries and infections. No doubt these biological consequences of aging take their toll on an individual's capacity for achievement. Yet these interpretations are incomplete. For example, a purely biological explanation cannot account for why career age is more predictive of creative productivity than chronological age. Those who get a late start on their careers may actually be attaining their career peaks when they are well advanced in years. Nor can the physical repercussions of aging help us understand the basis for interdisciplinary contrasts in creative output. It takes far more physical exertion to write a novel than to write poetry, and yet novelists peak much later in life than do poets. In all, we must realize that biological interpretations have to be applied with extreme caution. Otherwise, we may overlook the fine details regarding the relation between aging and achievement.

Nonetheless, in some domains biological processes can carry most of the explanatory weight. This is most evident in sports. As pointed out, the optimal ages for top performance in various athletic competitions have remained rather stable for at least a century. The age at which an individual is most likely to become an Olympic champion depends almost entirely on the nature of the athletic event and the gender of the participant. All the medical advances of the twentieth century have not significantly modified these age curves. This temporal stability suggests that there are fundamental physiological bases for the age curves. Sprinters will be younger than long-distance runners for purely physical reasons.

Biological explanations may take another form as well. According to sociobiologists, some patterns of human interaction are the products of standard evolutionary processes. Since the beginning of our species, individuals have been engaged in the business of optimizing their reproductive success, and this preoccupation has favored the dominance of certain types of social behaviors. For example, if individuals select mates according to fertility, then the attractiveness of men and women should exhibit very different age curves. Whereas women are maximally fertile in their 20s and early 30s, men maintain their fertility until much later in life. This contrast may help explain the dramatic difference between the career trajectories of actors and actresses. Because a woman's fertility declines so precipitously, her sex appeal on the silver screen suffers a drastic drop as well, until the actress is no longer seen as a box office attraction.

Of course, this sociobiological principle alone cannot explain why actors get a slower start than actresses. After all, young men can prove to be quite fertile. However, here we can evoke another explanatory principle from sociobiological theory, namely, that the sexual attractiveness of men is influenced by their success in life's competition. Attractive males are supposedly survivors who have endured the tests and have emerged victorious, as evinced by their control over power and resources. By this account, then, an older male holds the edge over the younger male. This would explain not only why actors peak later than actresses, but also why the decline is so much more gradual. Men in their 60s can display an attractiveness only enjoyed by women in their 20s. Incidentally, this same phenomenon may also account for why status quo political and religious leaders tend to be older. Social animals increase their reproductive success by selecting the best individuals to lead their group. These are going to be the individuals with the most experience and success. As a consequence, whereas successful actresses tend to be much younger than successful actors, women leaders tend to rise to power at about the same age as men.

Considerably more research must be undertaken before we can have full confidence in sociobiological explanations. Even so, these accounts indicate that the impact of biological processes can be far more subtle and complex than simply attributing achievement decrements to the infirmities of age.

Psychological Processes

Many have proposed that the linkage between aging and achievement reflects more fundamental changes in the psychological processes that underlie the attainment and maintenance of success. Perhaps the single most common explanation is cast in terms of a possible age decrement in intellectual functioning in the later years of life. Particularly provocative is the distinction between two varieties of intelligence, namely, crystallized and fluid. Crystallized intelligence concerns knowledge, information, and expertise, whereas fluid intelligence concerns flexible problem-solving ability. Whereas the first may increase or at least stay relatively constant across the life span, the second may exhibit fairly sharp declines in the later years of life. This contrast in developmental trends may help us understand the interfield differences in career trajectories, because each domain of achievement probably requires a different optimal mix of crystallized and fluid intelligences. For instance, diplomats, historians, or heads of established churches probably need more crystallized than fluid intelligence, and thus their career peaks appear in advanced maturity. On the other hand, revolutionaries, poets, and founders of new faiths may need more fluid than crystallized intelligence, thereby pushing the career optima toward more youthful ages.

However, we must acknowledge that motivational factors may also play a role, perhaps even the most important role. For example, one investigator has proposed that achievement is a function of two components: experience and enthusiasm. While experience continuously increases with age, according to this theory, enthusiasm first increases up to a peak sometime in the early 30s and thereafter decreases. The career optimum then appears where the sum of these two curves maximizes, which occurs around the late 30s. Yet different domains may require a characteristic mix of experience and enthusiasm. Revolution and poetry, for instance, may require greater zeal, whereas diplomacy and history may demand more wisdom. The career peaks will appear at different ages accordingly.

The foregoing explanations operated under some kind of age-decrement assumption. Either intellectual ability or enthusiasm underwent an age-related decline in the processes that underlie achievement. Nonetheless, other psychological explanations do not presume the occurrence of such inexorable age decrements. For example, some researchers have proposed psychoeconomic theories that presume that achievement operates in a manner similar to business investment. Achieving individuals are trying to optimize their long-term assets, and to do so they must invest in their human capital. The utility of these investments may diminish in the latter part of any life for the simple reason that an individual is less likely

to be around to reap the profits. Nonetheless, this choice to redirect effort may be reversed if at any time the person perceives an altered cost–benefit ratio. Such calculations may result from modified family circumstances, career changes, and more optimistic perceptions of probable life spans. The important point here is that the achievement potential of individuals may not necessarily decline just because the observed levels of achievement may appear to fall off. At different stages of their lives, people must adjust their priorities according to considerations that are unrelated to inherent capabilities.

Sociological Processes

We must not ignore the often extremely powerful impact of larger societal forces on the relationship between age and achievement. Sometimes these influences may take a rather explicit form. Political institutions, in particular, will often possess constitutions or by-laws that specify the acceptable ages at which certain positions of authority may be occupied. The US Constitution, for instance, states that an individual must be at least 25 to serve as a member of the House of Representatives, 30 to serve as Senator, and 35 to serve as President of the United States. This means that the age curves are automatically truncated at the lower end and that the occupants of the various federal positions will exhibit a certain amount of age stratification. Although other political systems have been successfully governed by very young heads of state, such a possibility is constitutionally prohibited in the US system. Of course, the legal restrictions can just as well go in the other direction. For many years, and in many places, organizations both private and public practiced mandatory retirement. We will never know how many potential achievements never saw the light of day because individuals at age 65 suddenly found themselves denied the resources to continue their work.

These institutional constraints cannot tell the whole story, however. Other social realities have a part to play as well. The US presidency provides another illustration. Why is it that successful presidential candidates tend to be in their mid-50s, whereas unsuccessful candidates tend to be either younger or older? One could argue that this age function reflects a fundamental necessity of presidential politics. In order to get elected to the White House, one must build a political base, a foundation that relies most heavily on a candidate's own cohort. Those who are much younger than 50 probably have not yet managed to construct the necessary broad support. Furthermore, those who are much older than 50 will likely see their political base erode as members of their cohort retire or die and as younger politicians recruit support from the younger generations. Hence, the career trajectory here may represent nothing more than the pragmatics of coalition formation. A candidate's intrinsic capacity for leadership may have relatively little impact on this process.

Although these examples all focus on leadership, social influences may determine the career trajectories for other forms of achievement as well. For instance, the optimal age for creativity in scientific disciplines tends to increase as a discipline matures. It takes more time for individuals to acquire the necessary expertise, and it requires more time to work out the implications of any given idea. Moreover, we have by no means discussed all the sociological processes that affect the location of the age peak and the magnitude of the post-peak decline. It should suffice to say that the amount of achievement that we can legitimately expect of older achievers is a complex function of biological, psychological, and sociological factors. Under the right combination of these factors, the amount of achievement that we can anticipate from even octogenarians is truly substantial.

Adaptation

S K Whitbourne, University of Massachusetts, Amherst, MA, USA

Glossary

Adaptation – The ability to maintain a consistent view of the self over time, facilitated by the use of coping strategies, that enhance the individual's emotional state and present the individual with viable ways of making practical changes that compensate for losses in physical and mental functioning.

Competence Adaptation Model – A model in which optimal adaptation is theorized to occur when the individual's functional abilities are matched to the degree of stimulation and challenge presented in the environment.

Defense Mechanisms – Emotion-regulating strategies through which individuals attempt to minimize feelings of anxiety.

Identity Process Theory (IPT) – Theory that conceptualizes identity as a biopsychosocial entity that encompasses the individual's self-representations and experiences encountered in the realms of physical, psychological, and social functioning.

Introduction

The search for the key to satisfactory adjustment in old age is the basis of a significant body of work within the fields of psychological and social gerontology. Some of the earliest research on personality and social development in later life addressed the enormously complex issue of trying to identify the 'best' or most 'successful' way for the individual to age. These empirical attempts involved the description of different personality types who varied in their approach to the aging process, from 'disengaged' to 'active.' Whether it was beneficial for the older individual to take a passive or an active approach to the aging process served as the touchstone for considerable controversy and debate among gerontologists. A now-discredited view of psychological aging, 'disengagement theory,' proposed that older adults become increasingly oriented toward internal preoccupations as they face the inevitability of death, and that this movement inward was psychologically adaptive. Despite the theory's lack of support, there still persisted the idea in the gerontological literature that with age, individuals become more preoccupied with their own psychological concerns and less oriented toward other people.

The notion of a radical alteration in personality in response to the aging process is not substantiated by research. Instead, it is becoming recognized that the challenges presented to the individual's personality by the aging process are adapted to according to that individual's personality. Successful adaptation to the aging process is seen, in these terms, as involving the ability to maintain a consistent view of the self over time. In addition, the individual must adjust to the normal physical changes brought about by aging: increases in chronic health problems, alterations in social and community roles, and, ultimately, the proximity of death. These adjustments are facilitated by the use of coping strategies that enhance the individual's emotional state and present the individual with viable ways of making practical changes that can compensate for any losses in physical and mental functioning.

Contemporary researchers are directing their efforts, on the one hand, to this search for the optimal path of adaptation to the demands and challenges presented by the aging process and, on the other hand, to the factors that increase the risk of depressive reactions in later life. It is recognized that adaptation in later adulthood reflects a biopsychosocial process reflecting the multidimensional influences of biological, psychological, and social forces that have operated throughout the individual's life course.

Coping and Adaptation in Later Adulthood

The adaptational demands presented to the older individual can be seen as challenges to the individual's ability to cope. Cognitive models of coping define stress as the perception of threat. In later life, such threats can come from events related to bereavement, poor health, caregiving, fears of aging, risks to personal safety, threats to self-esteem, and uncertainty of life beyond death. Often, these threats are of a chronic nature. Coping, in turn, can take one of two forms. In emotion-focused coping, individuals alter their perceptions of a stressful situation; in problem-focused coping, by contrast, individuals take actions designed to change the situation itself. Passive, emotion-focused coping strategies appear to characterize the reactions of elders who are less successful in managing stress. These strategies include self-blame, wishful thinking, avoidance, fantasy, and escape into

drugs and alcohol. Unfortunately, people tend to attribute mild, short-term symptoms to aging, leading them to adopt more passive coping strategies, and it is these strategies that ultimately can reduce health status even further.

By contrast, successful elders use active, problem-focused coping strategies, including sport and physical recreation, interacting with others for social support, and keeping busy by participating in social groups and learning new skills. Successful copers see themselves as being in control of their experiences, view themselves positively, and take a confrontive, optimistic, and self-reliant approach to stressors. In cases of chronic illness, they accept restrictions, but still look for new possibilities in life. An active, problem-focused coping style seems, then, to be positively associated with handling adversity in later life. However, this style of coping does not necessarily involve close self-scrutiny, introspection, or an intensive process of life review. A positive orientation to one's past life based on involvement with family and a focus on past successes may help the older adult view the future more positively. For some individuals, prayer may prove beneficial as a coping strategy that allows them to feel in control of, for example, health-related stresses.

Defense mechanisms, emotion-regulating strategies through which individuals attempt to minimize feelings of anxiety, are closely related to coping in that they help the individual manage stress. Age differences in defense mechanisms and related coping processes were the focus of two major cross-sectional investigations. In general, older adults were better able to manage their emotions through the use of what were considered the 'mature' defense mechanisms of controlling negative emotions or trying to put the situation into perspective. Similarly, in their coping strategies, older adults showed less of a tendency than younger adults to react in self-destructive or emotional ways. Aging individuals were more likely to attempt to understand the situation and figure out a way around it, through both problem-focused coping and use of other strategies such as suppressing their negative feelings or channeling those feelings into productive activities. Younger people, including adolescents and young adults, were more likely to react to psychologically demanding situations by acting out against others, projecting their anger onto others, or regressing to more primitive forms of behavior. Consistent with these findings, a longitudinal study of over 2800 adults studied from 1971 to 1994 revealed that aging was associated with a decrease in negative affect.

Consistent gender differences have also emerged in studies of defense mechanisms and coping. Regardless of age, women are more likely to avoid unpleasant or stressful situations, to blame themselves when things go wrong, and to seek the support of others. Men are more likely to externalize their feelings and to use reaction formation.

There are significant ethnic and cultural variations in coping strategies. Those older African Americans who have had a lifetime of rehearsal in using social support during times of stress and developing flexible ways to seek help are in some ways better prepared to cope with stress. Furthermore, while people in many ethnic groups may experience a lifetime of poverty and adversity African Americans who do so may be better able to handle uncertainty. However, they may face additional demands that tax their adaptational resources, for example, when they become caregivers to their grandchildren. Although they may have strong support networks, they are economically overwhelmed when they must take on this role, as the majority of them live below the poverty level. Nevertheless, African American caregivers as a group, despite the economic and physical strains they experience, have lower levels of depression and caregiver burden than White caregivers. In contrast, Hispanic and Asian American caregivers report higher levels of depression than Whites. Apart from their reported emotional states, all racial and ethnic minority caregivers are in poorer physical health than their White counterparts, indicating that lack of resources and feelings of filial obligation ultimately take a higher toll.

Another strategy for adapting to stress involves the process of social comparison, a mechanism that can be used to assess one's position in terms of the stereotypes regarding age-related changes. Older individuals may use social comparison to help negotiate potentially stressful transitions, such as having to relocate their place of residence. In this sense, the stereotypical view of the changes that come with aging can serve to function in the adaptation process. This view of aging can provide a set of 'normative' experiences and losses to which individuals can compare and accept their own experiences. Also, such stereotyped views of aging provide a buffer that can protect one's sense of well-being because one's actual experiences will, by comparison, appear more successful and adaptive. The result of social comparison is that older adults are able to maintain or even expand their degree of life satisfaction even as they experience real age-related changes in functioning.

Religion also plays a role in adapting to difficult life circumstances, serving as another important coping resource for many older adults. Through involvement in community religious activities, the individual can access important social network resources as well as

receive verification of his or her role as contributing members of society. Belief in the values and teaching of one's religion can also provide the individual with a source of inner strength and sense of purpose in life. The sense of burden that elders may feel in attempting to cope with their own health problems or those of family members can be alleviated when viewing these demands in terms of fulfilling a higher purpose in life.

It appears that successful agers find ways to adapt their coping strategies to reduce the stressors they encounter in their daily lives. They also take advantage of the principle 'use it or lose it,' by finding ways to compensate for physical and psychological changes associated with the normal aging process that can potentially interfere with the ability to perform daily activities and to cope successfully with environmental stressors. These compensatory activities may include regular and consistent involvement in physical exercise, the seeking of intellectual stimulation, and the willingness to take advantage of commercially available prostheses such as proper hearing aids and eyeglasses. Going beyond the concept of coping, which implies a responsiveness to externally produced events, some elders seek new levels of personal growth and development through constant searching for new opportunities to learn and stay involved in the world around them. Furthermore, elderly adults with a lifetime of experiences with stress have developed unique strengths to aid them in this coping with the aging process.

Adaptation to the Environment

The quality of the physical and social environment must also be considered in understanding adaptation to changes associated with later life. Theoretical models relating the individual's adaptation to the quality of the environment point to the need for a match or 'fit' between the characteristics of the individual and the demands of the environment. Perhaps the most well-known of these approaches to person–environment interaction is the competence adaptation model. In this model, optimal adaptation is theorized to occur when the individual's functional abilities are matched to the degree of stimulation and challenge presented in the environment. Another aspect of person–environment fit involves the matching of the individual's motives and needs with the 'press' of the environment. An individual with a high need for autonomy, according to this model, would be optimally adjusted in an environment that promotes and supports the independence of the individual. If that environment fosters dependence, the individual's adaptive ability will be reduced. In other words, using one's personal resources proactively will result in greater well-being than passively reacting to the demands of the environment. This dynamic interplay influences adaptation on the emotional or physical level. Furthermore, without stimulation or reinforcement for independent, autonomous behavior, it is likely that the individual will enter a downward spiral of accelerated deterioration and dependence.

Adaptation to Physical and Cognitive Changes

Physical and cognitive changes associated with aging place demands on the individual's ability to adapt to the environment. When age-related changes create difficulties in physical mobility, social interaction, and everyday decision making, the individual's quality of adaptation to the environment is compromised. This reduced adaptive ability creates more problems in daily life, as the individual finds it more difficult to go about his or her daily routine. Equally important is the effect of the individual's lowered adaptability on feelings of competence. Psychologists have long argued that feelings of competence play a major role in self-concept and identity. If the aging individual is and feels less able to handle daily tasks, he or she will begin to suffer losses in sense of self-esteem and feelings of self-efficacy. Furthermore, this loss of competence invades the individual's sense of stability and continuity over time, as the individual is forced to redefine the self as less capable than in earlier years. The overlay of negative social attitudes toward the aging process further contributes to the potential erosion of the individual's identity as a competent and worthwhile individual. All of these changes may be reflected in a variety of psychological symptoms and a further reduction of competence, as the individual begins to live out a fatalistic self-fulfilling prophecy in which he or she simply gives in to the inevitability of the aging process.

Countering the downward spiral is the natural spirit that many elders have as they approach the aging process, in which they regard the changes with age as a challenge not unlike the many others they have faced in their long lives. Rather than become demoralized by the awareness of a progressive deficit in functioning, they seek ways to reverse or at least slow down this manifestation of the aging process and spontaneously compensate for loss of functioning in one area by building strengths in others. Although these behaviors promote their adaptation to the environment and maintain their sense of identity and self-efficacy, individuals who take this active approach to the aging process run the risk of becoming demoralized and frustrated when they are faced with changes that they cannot overcome. They are

particularly vulnerable to rapid-onset diseases that negate their prior efforts to remain healthy and active.

Adaptation to Changes in Social Roles

In western society, great value is placed on the individual's economic productivity, which traditionally is linked to worth. Due to the social and cultural emphasis on economic worth, retirement presents the potential for an individual to feel devalued and stripped of social importance. Furthermore, given the assumption that autonomy and independence are desirable qualities, the reliance of older individuals on the government or private pension plans for subsistence can challenge their sense of well-being as contributors to society. Added to these difficulties are views of the older generation as a financial drain. The news media's coverage of the national debt portrays elders as a drain on the budget due to the vast funding needs of Medicare and Social Security. Discussion of the health-care needs of the aging population often focuses on dilemmas regarding prolonged treatments of terminally ill patients on life support. As health-care costs skyrocket, older adults are seen as presenting even more of a threat to overtaxed public and private health-care insurance companies. These negative attitudes can affect not only people's expectations about the process of aging, but also the self-perception and affective experiences of the older people who are at the heart of these frightening scenarios.

Individuals may be expected to vary, however, in the extent to which they incorporate society's negative views about aging and older adults into their identities and sense of well-being, particularly with regard to the economic and psychological transitions to retirement. For older adults socialized in the importance of the work ethic, loss of their occupation through retirement can be a major blow to their sense of well-being. They may feel useless and regard their lives as devoid of meaning. Other individuals, however, may be able to draw upon their previous identities within the world of work, defining themselves as retired 'Xs,' where 'X' represents the individual's primary past occupation. Development of involvement in leisure and recreational activities prior to retirement may also moderate the individual's response to retirement. An individual who maintains an active lifestyle can adjust more readily to the disappearance of work from daily routines than an individual whose work completely determined the activities of his or her daily life.

Changes within the context of the family represent another challenge to adaptation for the aging individual. Married couples experience a number of changes associated with the aging process that can pose significant threats to the later-life relationship and, ultimately, each individual's sense of well-being. The task of caring for a married elder who becomes infirmed due to physical changes or Alzheimer's disease typically falls to the spouse, and can be a source of unending stress and burden. Another set of challenges pertains to the area of sexuality. There are many common stereotypes and misconceptions regarding the potential for enjoyment in the later years. Older couples can sometimes be affected by these negative, and usually inaccurate, beliefs. For example, some individuals might think that it is abnormal, or even morally wrong, to maintain an active sexual life into their later years. But for most couples, sexual intimacy does remain an important component of the relationship over the years of marriage. Even if this intimacy does not consist of sexual intercourse, the expression of affection and loyalty can become very important in the later years. It is worth noting that although older couples still view sexual intimacy as important, they also place a greater value on qualities that develop over time, such as security and level of commitment to each other.

The exit from and reentry to the home by grown children is increasingly becoming an adaptational challenge due to economic changes affecting the job options for young adults. Changes caused by the movement of children into and out of the home affect not only the physical space and privacy of the older couple, but also their intimate relationships. The return of adult children can require the older couple to reestablish interaction patterns within the household that are more characteristic of their middle adult years, leading to an exacerbation of potential stresses existing at that time.

Traditionally, households had only one person who retired from the workplace, but here again, patterns are changing so that there are increasing numbers of households in which both partners are employed. In this case, the couple may chose to retire at different times or plan their retirement together. Choosing to retire in an unsynchronized fashion can have a major impact on intimacy due to the fact that each partner in the relationship faces role changes at different times, making the adjustment to a new lifestyle as a couple potentially more challenging. After retirement, the daily lives of both members in the relationship change drastically. Time once occupied by the requirements of work no longer presents a restriction, and other activities must be found to take its place. As a result of this transition, couples find that they are able to spend a considerably greater amount of time on the growth of their relationship,

perhaps narrowing their interactions increasingly to each other and a few close friends. This increased time together may have favorable effects. Couples who remain together can become more accepting, tolerant, and respectful of their partners, and behave in ways that are more affectionate and loving. The increase in free time may lead some couples to spend some of that time interacting with friends, an activity that can bolster marital satisfaction through strengthening the partners' identity as a couple.

There can be benefits, then, as well as challenges, as the married couple ages. Personal differences, which for many years may have been held in abeyance due to the competing demands of children and work, often come back into focus at this time. In learning to interact as a dyad once again, the couple is often faced with the challenge of developing new ways to communicate and make decisions. By identifying and working out solutions to marital difficulties, the couple can often maintain a satisfying relationship as well as develop an even greater level of enjoyment from the partnership. This is an especially challenging task in the postretirement years, because the couple will be not only working on their relationship together, but also learning to restructure their own personal time.

The Role of Identity

The process of adaptation may also be seen as involving psychosocial factors relating to the quality of the individual's investment in relationships, understanding of one's place in the life course, and resolution of issues related to mortality. These factors are best understood in the context of Erikson's (1963) eight-stage psychosocial model of the life cycle, in which it is assumed that change occurs systematically throughout the years of adulthood. Erikson proposed that after adolescence, with its often tumultuous search for identity, adults pass through three psychosocial crisis stages. The stages corresponding to the early and middle adult years focus on the establishment of close interpersonal relationships (intimacy vs. isolation) and the passing on to the future of one's creative products (generativity vs. stagnation). In the final stage (ego integrity vs. despair), the individual must resolve conflicted feelings about the past, adapt to the changes associated with the aging process, and come to grips with the inevitability of death. Erikson's ideas, although difficult to operationalize, have provided a major intellectual inspiration to workers in the field of personality development in adulthood and old age.

In Erikson's model, each psychosocial crisis is theorized to offer an opportunity for the development of a new function or facet of the ego. However, the crisis involving identity has special significance, as it establishes the most important functions of the ego: self-definition and self-awareness. Following the development of identity, according to Erikson, additional functions of the ego, including love, care, and wisdom, can evolve. In old age, according to Erikson, the individual engages in a process of reviewing past experiences and incorporating those into a cohesive and positive identity. The sense of identity that emerges from this process, which Erikson called 'existential' identity, plays an important role in adaptation to the changes experienced in later life and the ability to meet death without fear. For some elders, this process might involve a reassessment of past goals and expectations to meet future needs; for others, it might mean taking the time to examine their sense of self and to conform their identity to the life that they have actually lived.

Models of coping tend to focus on ways in which individuals appraise and attempt to reduce stress by adopting particular interpretations of themselves in relation to threat. However, traditional models of coping do not incorporate the notion of the self in the sense of examining how individuals interpret events as reflections of or challenges to their sense of identity. This failure to address the role of identity ignores an important component of the stress–environment appraisal equation in two important ways. First, successful coping can be seen as a self-enhancing process that can improve the individual's well-being. Second, many events are appraised as stressful if they challenge the individual's self-conceptions or are seen as threats because the individual believes that he or she lacks important coping skills. Older adults may find even a seemingly innocuous event, such as a friendly bridge game, highly stressful if they feel that their ability to count the cards that have been played has suddenly vanished.

Adding identity to the stress and coping formulation brings in this crucial dimension. Erikson's framework provides a starting place for examining identity in adulthood, but it stops short of postulating how identity may continuously develop throughout a life of experiences that can lead to the growth and differentiation of the individual's basic sense of self. Identity process theory (IPT) conceptualizes identity as a biopsychosocial entity that encompasses the individual's self-representations and experiences encountered in the realms of physical, psychological, and social functioning. Using IPT, we can expand and deepen our understanding of adaptation throughout the years of adulthood.

As a biopsychosocial entity, identity includes multiple dimensions of self-schemas. These are physical

(able to lift a heavy weight), cognitive (able to remember a telephone number), and social (holding valued roles in the community). The majority of individuals tend to have positive self-schemas in which they view themselves as competent, effective, and important to others in their social network.

IPT proposes that individual development in adulthood can be best understood according to the relative use of three identity processes: identity assimilation, identity accommodation, and identity balance. Although individuals rely on all three sets of processes, they do so to differing degrees. Identity assimilation refers to the interpretation of identity salient experiences in terms of previously established schemas that include thoughts and feelings about the self. When individuals use identity assimilation, they tend to minimize the impact of age-related experiences that might challenge their self-schemas as able and competent, such as forgetting an important fact or a relative's birthday.

Because identity assimilation serves to protect the individual from potentially negative feedback about the self, it helps to bolster the individual's well-being. Unfortunately, there may be risks involved in using identity assimilation to the point where protection becomes denial of potentially important information about the self. For example, by using identity assimilation to an undue degree, an older adult with arthritis may injure an already ailing joint by overexertion.

In contrast to the minimization of potentially negative information associated with identity assimilation is the process of identity accommodation, which involves changes in identity in response to new experiences. On the positive side, the individual does not suffer from the denials and distortions that can lead to negative consequences in people who use identity assimilation. In terms of adaptation, it is identity accommodation that accounts for making necessary changes in the self in response to experiences that demand change. The cost of identity accommodation, however, is the tendency to become prematurely 'old' from a psychological point of view. People who rely heavily on identity accommodation overreact to even small and seemingly unimportant changes, such as assuming that a small error of memory is a sign of impending senility. Instead of using the experience as an instigation to learn new memory strategies, when the problem reoccurs, the individual who overuses identity accommodation simply gives up and concludes that there is no point to fighting the inevitable. Thus, what is essentially an adaptive process becomes twisted into a process that cascades toward even greater losses and further negative changes in identity.

As adaptive processes, identity assimilation and identity accommodation both have virtues, but they also carry significant dangers. The ideal adaptive approach incorporates both processes, and is called identity balance. Individuals who use identity balance maintain a stable sense of self in confronting age-related changes while nevertheless findings ways to make necessary changes that ensue from these changes. This dynamic balance or equilibrium between assimilation and accommodation is associated with positive self-esteem.

Cultural factors may also play a role in affecting the individual's use of identity processes and the impact of these processes on self-esteem. Older Americans may be particularly likely to use assimilation, which is, in many ways, the kind of 'can-do' stoicism predominant during their formative years of early adulthood in the Depression and World War II years. By contrast, older adults who spent their youth in war-torn Europe may have adapted to the constant levels of stress associated with living under constant siege by developing a more pessimistic approach, in which accommodation becomes the predominant mode of adapting to negative experiences.

In general, positive affect toward one's life is related to a lack of preoccupation with the past, involvement with family, and a turning outward rather than inward. In contrast, a focus on the past and involvement in one's own personal losses rather than involvement with family is a feature of poorer adaptation and lower levels of well-being. These findings counter what we examine next in relation to adaptation: the role of reminiscence, life review, and development of a sense of ego integrity.

Ego Integrity and Adaptation in Old Age

In addition to the development of an existential identity in later adulthood, Erikson proposed that the end of life brings with it concerns regarding ego integrity – the achievement of a sense of wholeness and completion in one's life and self. According to Erikson, the optimally adjusted older adult is one who has achieved a state of ego integrity and who can look at the past without regrets and the future without fear. Such an individual experiences a positive attitude toward life, accepts life for what it was, has a sense of accomplishment, and feels that if life could be lived over again, it would be done so without major changes. This sense of accomplishment and completion allows the individual to face death and not see it as a premature ending or even something to be dreaded. By contrast, older adults who feel that they did not fulfill their potential or who have a weak and fragmented sense of self are in

a state of despair. Such individuals constantly regret past decisions and wish they could live their lives over again. They fear death because it will occur before they have corrected their past errors.

At the intersection of identity with ego integrity can be seen very different sets of reactions to the aging process. The individual characterized by despair views each physical, cognitive, and social loss as a constant reminder of impending death. This individual will be constantly subjected to new threats and will need to resort to identity assimilation as a way of protecting the self from these threats. Conversely, the individual who has achieved ego integrity does not fear aging or the future and is able to respond to aging changes in a more balanced manner.

The state of ego integrity is one that is not easily achieved, particularly in a society that is characterized by an emphasis on materialistic and individualistic values. For older adults who have successfully adapted to prior life crises, the sheer number of losses and changes in old age presents a far greater challenge. A stable but flexible identity as well as a sense of acceptance of the life that has been lived appear to be the major factors involved in successful adaptation to the aging process. However, there may be multiple paths to adapting to the changes associated with the aging process. For some older adults who are more philosophically inclined (and perhaps who have the benefits of being more highly educated), a critical examination of the self in relation to past experiences may provide the impetus for movement into a final stage of self-integration. Other older adults may adapt successfully by taking a more active approach – engaging in behaviors that maintain their physical and cognitive functioning while giving little thought to the larger implications of the aging process for the sense of self (accommodation in the service of assimilation). Finally, there are those elders whose involvement in issues external to the self, such as family, religion, or other formal and informal roles, helps maintain their sense of optimism and purpose in life. In helping older individuals achieve a state of optimal adjustment, it is important to remember that there are multiple paths to successful adaptation, reflecting the continuity of the individual's lifelong personality patterns, social context, and adaptational demands.

Addiction: General

B Segal, University of Alaska, Anchorage, AK, USA

This article is a revision of 'Substance Abuse' in *Encyclopedia of Human Behavior,* volume 4, pp 335–345,

Glossary

Drug – Any substance, neutral or synthetic, that by its chemical nature alters structure or function in the living organism.

Drug Addiction – Chronic and relapsing drug-taking behavior characterized by compulsive drug seeking and abuse and by long-lasting chemical changes in the brain. Drug seeking becomes compulsive, in large part, as a result of the effects of prolonged drug use on brain functioning and on behavior.

Drug-Taking Behavior – A neutral term that describes drug use, inferring that use of drugs can be explained in the same terms as any other form of behavior.

Psychoactive Drug – Any chemical substance that alters mood, perception, or consciousness.

Substance Abuse – Inappropriate or excessive drug-taking behavior to produce pleasure, to alleviate stress, or to alter or avoid reality (or all three); such use may be dangerous or undesirable to the individual or community.

Tolerance – A diminished response to the same dose of a drug as a result of prior use of the drug. Once tolerance sets in, more of the drug is required to achieve its initial effects.

Introduction

This article provides an overview of the nature of psychoactive drugs and their actions. It also describes advances in understanding of how drug addiction occurs, emphasizing that drug addiction is the function of chemical changes in the brain following drug use that alters functioning in a manner that results in dependence on a drug. The article concludes with a discussion of elder drug abuse, specifically focusing on prescription drug abuse/misuse and on drinking among the elderly.

Understanding Addiction as a Brain Disease

Addiction is more than frequent drug use. Recent scientific research provides strong evidence that drugs not only interfere with normal brain functioning but also have long-term effects on brain metabolism and activity. Those addicted to drugs experience compulsive drug craving and cannot quit by themselves. Treatment is necessary to end this compulsive behavior.

Repeated use of a drug results in chemical and molecular alterations in the brain, and such changes have become equated with drug dependence. Although a person can initially be introduced into using drugs because of genetic, psychological, and sociocultural

factors, once a drug is taken, the drug-taking behavior itself may promote continued drug-seeking behavior via the changes caused in the brain. Continuous drug use leads to a cascade of intracellular events that changes the excitability of cells and ultimately alters neuronal circuit activity. These alterations are believed to elicit changes that provoke acute positive reinforcing effects because of drug interactions with individual transmitter systems within the general reward circuitry of the brain (i.e., the limbic system). Long-term drug effects include tolerance, sensitization, dependence, and withdrawal. Because these changes in reward circuitry are neuroadaptations, drug addiction may be defined as a brain disease.

It is as if there is a switch in the brain that turns on at some point during a person's drug-taking behavior. This switch flips on at different points for different drugs and different individuals, but once it is on, it fundamentally changes the user from a drug user/abuser to a drug addict.

Drugs and Drug Effects

A scientific definition of a drug is any substance, natural or synthetic, that, by its chemical nature, alters structure or function in the living organism. This broad definition encompasses many chemical compounds, some of which have the capacity to induce an altered state of consciousness. A psychoactive drug is any substance that alters consciousness, mood, or perception. Psychoactive drugs can be grouped into five categories based on their behavioral effects: (1) sedative-hypnotic compounds, (2) behavioral stimulants, (3) narcotic analgesics (opiates), (4) antipsychotic agents, and (5) psychedelics/hallucinogens.

Drug effects, however, vary widely and are often unpredictable, depending on such factors as mood, expectations of what the drug will do, previous experience with the drug, the route of administration, the nature and potency of the drug used, and the setting in which it is used. What follows is a very brief description of some of the major psychoactive agents that are used to alter mood, perception, or consciousness.

Central Nervous System Depressants (Sedative-Hypnotics)

Sedative-hypnotic drugs depress the functioning of the central nervous system (CNS), resulting in a reduction of neural activity and level of awareness. They include barbiturates and non-barbiturate hypnotics, antianxiety agents (minor tranquilizers such as Valium or Librium), and alcohol, which is classified as a sedative-hypnotic because of its behavioral effects, but it is not structurally related to the barbiturates or other such compounds. Some of the better-known barbiturates are secobarbital (Seconal), pentobarbital (Numbutal), and methaqualone (Quaalude).

Physiologically, CNS depressants lower blood pressure and respiration, slow speech, and alter consciousness. Tolerance develops from use over a lengthy time period, and physical dependence may also occur. Most CNS depressants act on the brain similarly – they affect the neurotransmitter γ-aminobutyric acid (GABA). Neurotransmitters are brain chemicals that facilitate communication between brain cells. GABA works by decreasing brain activity. Although different classes of CNS depressants work in unique ways, ultimately it is their ability to increase GABA activity that produces a drowsy or calming effect.

Discontinuing prolonged use of high doses of CNS depressants can lead to withdrawal. Because they work by slowing the brain's activity, a potential consequence of abuse is that when one stops taking a CNS depressant, the brain's activity can rebound to the point that seizures can occur.

Central Nervous System Stimulants

CNS stimulants consist of a variety of chemical agents that vary in mechanisms of action and chemical structure. There are four categories of CNS stimulants: (1) behavioral stimulants, which include cocaine and amfetamines; (2) clinical antidepressants; (3) convulsants such as strychnine; and (4) general cellular stimulants, which include caffeine and nicotine.

Behavioral stimulants include amfetamines and cocaine. There are three chemically similar types of amfetamines: (1) amfetamine (racemic amfetamine sulfate, formerly Benzedrine), (2) dextroamfetamine sulfate (Dexedrine and Obetrol), and (3) methamfetamine hydrochloride (Desoxyn).

Amfetamines cause an increase in heart rate and body temperature and can raise both systolic and diastolic blood pressure, increasing respiration and circulation. Pupils, blood vessels (vasodilation), and the air passages of the lungs (bronchodilation) are dilated.

Methamfetamine is a CNS stimulant chemically related to amfetamine, but its CNS effects are greater. Usage of methamfetamine has increased in recent years. Crystal meth is an extremely pure form of methamfetamine (between 98 and 100%). Methamfetamine releases high levels of the neurotransmitter dopamine, which stimulates brain cells. It also appears to have a neurotoxic effect, damaging brain cells that contain dopamine as well as serotonin.

Over time, methamfetamine appears to cause reduced levels of dopamine, which can result in symptoms like those of Parkinson's disease.

Methamfetamine causes increased heart rate and blood pressure and can cause irreversible damage to blood vessels in the brain, producing strokes. Other effects of methamfetamine include respiratory problems, irregular heartbeat, and extreme anorexia. Its use can result in cardiovascular collapse and death.

Cocaine is an alkaloid obtained from the coca plant. Cocaine is a short-acting but powerful stimulant similar in many ways to amfetamines. Crack is cocaine mixed with non-volatile chemicals to create a 75% cocaine paste.

Cocaine's physical effects include constricted blood vessels, dilated pupils, and increased temperature, heart rate, and blood pressure. It is known to produce its effects by acting on structures deep in the brain associated with experiencing pleasure (i.e., the limbic system, which is rich in receptor sites for dopamine, a neurotransmitter). In the normal communication process, dopamine is released by a neuron into the synapse, where it can bind with dopamine receptors on neighboring neurons. Normally, dopamine is then recycled back into the transmitting neuron by a specialized protein called the dopamine transporter. If cocaine is present, it attaches to the dopamine transporter and blocks the normal recycling process, resulting in a buildup of dopamine in the synapse. As cocaine abuse continues, tolerance often develops. This means that higher doses and more frequent use of cocaine are required for the brain to register the same level of pleasure experienced during initial use.

Narcotic Analgesics (Opiates or Opioids)

The term narcotic has generally been used to refer to opium and opium derivatives that are obtained from the oriental poppy, but it has also come to include other drugs that are semisynthetic or wholly synthetic opiates. There are three types of opiates: (1) natural opiates, which are obtained directly from opium, such as morphine and codeine; (2) semisynthetic opiates, which are chemically prepared derivatives of morphine or codeine, such as Dilaudid (dihydromorphine), heroin, and Metopon (methyldihydromorphine); and (3) synthetic opiates, which are chemically synthesized analgesics whose effects are similar to morphine, such as propoxyphene (Darvon), methadone (Dolphin), meperidine (Demerol), and pentazocine (Talwin).

One of the major effects of opiates and opiate derivatives on the body is nausea and vomiting. Opiates stimulate a part of the brain called the chemoreceptor trigger zone (CTZ), which senses impurities in the blood and stimulates a center that causes vomiting. Opiates constrict the pupils, depress reflexes, and may lower blood pressure due to dilation of peripheral blood vessels. Flushing may be experienced and sweating usually occurs. Continued use of opiates is known to reduce sexual functioning, thought to be associated with a decrease in the level of sex hormones in both genders. Opium and its derivatives can remain in the body for 2–3 days.

The CNS contains specific receptor sites for natural opiate-like chemical substances (endorphins, enkephalins, etc.) that specifically abound in the limbic system, and opioids interact with these receptors. These receptor sites are not the normal postsynaptic receptor sites involved in synaptic transmission – they are special proteins to which narcotic drugs are attracted, and it is postulated that these sites can also be occupied by heroin, morphine, and other opiate derivatives. The binding of a narcotic drug to these receptor sites, which is believed to cause an inhibition of the release of dopamine, norepinephrine, serotonin, and other neurotransmitters, seems to be the preliminary step in the initiation of both physiological and behavioral effects, but exactly how these effects occur remains to be discovered.

Hallucinogens (Mind-Altering Drugs)

Hallucinogens or psychedelics refer to the different classes of drugs that involve visual, auditory, or other hallucinatory experiences, and that create a sensation of feeling separated from reality. They achieve their effects chiefly by disrupting the interaction of nerve cells by interfering with the transmission of serotonin. Distributed throughout the brain and spinal cord, the serotonin system is involved in the control of behavioral, perceptual, and regulatory systems, including mood, hunger, body temperature, sexual behavior, muscle control, and sensory perception. Common hallucinogens include lysergic acid diethlamide-25 (LSD), psilocybin and psilocin, mescaline, and phencyclidine (PCP).

Marijuana

Marijuana is derived from the dried and chopped-up leaves, flowers, stem, and seeds of the hemp plant. More than 400 closely related chemicals have been isolated from the cannabis plant, which are collectively called cannabinoids, of which THC (delta-9-tetrahydrocannabinol) is believed to be the primary psychoactive or mind-altering compound. Today's marijuana is much more potent than that used in the early 1970s, up to greater than 30% more potent in some instances, and as the potency of the plant

increases there is a corresponding increase in its psychopharmacological effects.

Volatile Solvents (Inhalants)

Volatile solvents or inhalants are chemicals whose vapors, when inhaled, can produce psychoactive effects. Many of these chemicals are industrial solvents or aerosols, not pharmacological remedies. The pharmacological chemicals included in this category are anesthetics and other compounds that are inhalable. Volatile inhalants are grouped into three categories: organic solvents (hydrocarbons), volatile nitrates, and nitrous oxide.

The effect of these chemicals is a rapid general depression of the CNS. Chemical solvents can be highly toxic, and death or severe physical damage can result from their use. Death occurs from liver, kidney, bone marrow, or other organ failure; asphyxiation; paralysis of breathing mechanisms; or accidents as a result of being inebriated. Continued use of these drugs can lead to kidney, liver, lung, and brain damage.

Look-Alike Drugs

Look-alikes are psychoactive drugs whose name or appearance suggests psychoactive effects similar to another psychoactive drug. Many look-alikes are sold as drugs of deception and do not contain the drugs they are represented to be. Look-alikes generally consist of three substances: caffeine; ephedrine (or pseudoephedrine), a CNS stimulant; and phenylpropanolamine (PPA), a bronchodilator and respiratory decongestant. The substitute or look-alike drugs can cause serious side effects, ranging from sleep disturbances to psychotic episodes.

Club or Designer Drugs

Designer drugs mimic the effects of illegal drugs. Thirty-five variants or analogs have been synthesized from PCP. Several dozen analogs of methamfetamine have also been produced. Ecstasy, MDMA (3-4 methylenedioxy-methamfetamine), is a synthetic, psychoactive drug chemically similar to the stimulant methamfetamine and the hallucinogen mescaline. Research suggests that chronic MDMA use can lead to changes in brain function, affecting cognitive tasks and memory. MDMA can also lead to symptoms of depression several days after its use. These symptoms may occur because of MDMA's effects on neurons that use the chemical serotonin to communicate with other neurons. The serotonin system plays an important role in regulating mood, aggression, sexual activity, sleep, and sensitivity to pain.

Prescription Drug Abuse and Addiction: The Elderly at Risk

The non-medical use or abuse of prescription drugs is a serious and growing public health problem. According to the Center for Substance Abuse Treatment, "substance abuse, particularly of alcohol and prescription drugs, among adults 60 and older is one of the fastest growing health problems facing the country. Yet, even as the number of older adults suffering from these disorders climbs, the situation remains underestimated, underidentified, underdiagnosed, and undertreated" (2001: 1).

Prescriptive drug abuse or misuse occurs when people, purposely or accidentally, use medications in a manner that deviates from the recommended prescribed dose or instruction. Misuse may include overuse because of a belief that more is better, as well as underuse due to cost issues or as a method to avoid side effects. Abuse of prescribed or over-the-counter (OTC) drugs occurs when a person continues to use the drug even when it is not required for the primary purpose for which it was recommended, or when the person takes it in greater than recommended amounts because of its psychotropic effects.

The elderly are particularly vulnerable to prescription drug abuse or misuse because they tend to be prescribed more medications than necessary to treat their conditions than younger persons. Additionally, the onset of dementia in its various forms contributes to confusion about what, when, and how much medication needs to be taken. Many elderly people need help to take their medications correctly.

Although many of the prescribed drugs have the potential to be abused or misused, three types of drugs are chiefly involved in elder abuse: opioids, frequently provided for pain relief; CNS depressants, prescribed for anxiety and sleep disorders; and stimulants, prescribed to treat sleep disorder narcolepsy and attention-deficit hyperactivity disorder (ADHD). These three drugs, as described earlier, have the capacity to alter the brain's activity, leading to addiction.

Older people may be prescribed more drugs than they require because of the way drugs are now marketed (i.e., advertised in a manner that guides persons to ask their physician to prescribe a specific drug for a given condition), resulting in doctors writing scripts to satisfy their patient's demands. Additionally, the increasing number of medicines being prescribed for a variety of health problems, many of which can easily be obtained from online pharmacies, also contributes to elder misuse of prescriptive drugs. Most of these online pharmacies are legitimate businesses that provide an important service, but

some dispense medications without a prescription and without appropriate identity verification.

A variety of other factors also influences the use and potential for misuse or abuse of psychoactive prescription drugs and OTC medications by older adults. The aging process, with its physiological changes, accumulating physical health problems, and other psychosocial stressors, makes prescription drug use both more likely and more risky.

Further, older people are more likely to be prescribed long-term and multiple prescriptions that can lead to unintentional misuse. The elderly are also at risk for prescription drug abuse because they may unintentionally take medications that are not medically necessary. In addition to prescription medications, a large percentage of older adults also use OTC medicines and dietary supplements. Because of the high rates of comorbid illnesses in the elderly, changes in drug metabolism with age, and the potential for drug interactions, prescription and OTC drug abuse and misuse can have more adverse health consequences among the elderly than are likely to be seen in a younger population.

Elderly persons who take benzodiazepines are at increased risk for cognitive impairment associated with such use, leading to possible falls (causing hip and thigh fractures), as well as vehicle accidents. However, cognitive impairment may be reversible once the drug is discontinued.

A variety of health-care system-related and environmental factors helps to place older adult users of psychoactive prescription drugs at risk for misuse of these substances, serious adverse effects, or abuse and dependence. Potentially dangerous prescribing practices include ordering medications without adequate diagnoses or other documented indicators of symptoms, prescribing them for too long a time without appropriate medical monitoring of drug reactions and patient compliance with the prescribed regimen, selecting drugs known to have a high potential for side effects in older adults at the doses given, ordering drugs without knowing or reviewing whether they interact adversely with other medications the patient is taking, and failing to provide adequate and comprehensible instructions for patients regarding how and when to take medications and what side effects to expect and report. Drug misuse also includes failure to consider the influence of aging on the effects of drugs in the body.

Alcohol and Aging

Drinking is continuing to be recognized as a problem among the elderly. Although there are similarities in the drinking practices of older and younger drinkers, the problem presents a specific difficulty because there is a difference in the way older and younger people respond to alcohol. This difference stems from the physiological changes associated with the aging process. Additionally, people 65 and older tend to be affected by at least one chronic disorder that makes them more vulnerable to the adverse effects of drinking than younger people.

Risk factors for alcohol abuse include the following:

1. Gender: Research has indicated that older men, compared to older women, tend to develop drinking problems. Older women are less likely to drink, and among those who drink, they tend to drink less heavily than older men.
2. Loss of spouse: Drinking has been found to be more prevalent among older adults who have been separated or divorced and among widowed men.
3. Other losses: Other types of losses that contribute to drinking among older people are the loss of family members and friends to death, the loss of a sense of self-worth due to retirement, diminished mobility, impaired sensory capabilities, and declining health. Drinking, in many instances, may be a way to cope with the grief associated with such losses. Loss of independence, when the need to be placed in a caregiving facility arises, is also a factor related to the onset of drinking.
4. Earlier drinking and/or drug abuse: Having experienced a drinking or drug-related problem earlier in life presents a significant risk factor to resumption of former drinking or drug use. Such resumption may be related to the stress associated with aging, exacerbated by one or more of the types of losses noted earlier.
5. Family history of alcoholism: Research clearly indicates that drinking behavior is genetically influenced, thereby placing a person with a history of family drinking at risk for drinking-related problems throughout life.

Concluding Remarks

Drugs, in one form or another, have been available since the dawn of civilization, and they have been used for different purposes in different cultures. Many of the substances were, and continue to be, employed for their medicinal qualities. Today, however, because of the pharmacological revolution that is taking place, many more drugs are available. It is important to be aware of the nature of drugs, their psychopharmacological effects, and the adverse reactions that they can induce, especially among the elderly.

Adult Education

A Kruse and E Schmitt, Institut für Gerontologie der Universität Heidelberg, Heidelberg, Germany

Glossary

Education – The process of acquiring abilities, skills, experiences, and knowledge systems as well as the results of this process.

Formal Learning – Learning in institutional contexts, with structured objectives, contents and methods, and which evaluated, documented, and certified.

Informal Learning – Learning that results from daily activities in the context of work, family, and leisure time, and which does not have structured objectives, contents, methods or evaluation.

Life Competencies – Experiences, strategies, and knowledge systems that people have acquired in earlier phases of their life span that enable them to maintain or reestablish a personally satisfying perspective on their life when confronted with serious problems, tasks, and challenges, in later years.

Introduction

The term education describes the process of acquiring abilities, skills, experiences, and knowledge systems as well as the results of this process. Specific contents of education reflect general cultural values and preferences of social environments and milieus, social change, and societal progress. Analyses of social environments and milieus confirm marked differences in formative educational experiences during childhood and youth, expectations and subjective conceptions of education, interests and barriers in extended vocational and general education, demands for methods and atmosphere, interest in educational content related to personality, health and key qualifications, competence, and informal learning, and the subjective attractiveness of alternative providers of education. Since the contents of education necessary for success in a given culture change continuously – it is assumed that the knowledge of mankind doubles approximately every 40 years, and in some economic sectors as often as every 6 months – educational activities can neither be concentrated in nor restricted to a single phase of the life span.

Interest in individual educational activities in adulthood is determined by lifelong interactions between opportunities and the necessity to learn new things and by the degree of openness to new experiences and knowledge systems. A comprehensive understanding of education is not confined to the acquisition of knowledge systems, but considers explicitly the abilities, skills, and experiences essential for creative ways of using knowledge to cope effectively with actual and (potential) future tasks and challenges. Moreover, the significance of education for the development of the individual is confined neither to his or her working life nor to the occupational sphere. In addition to occupation-related aims such as economic growth, maintenance or enhancement of innovative potentials, and individual employability, independence, self-determination, and social participation are principal aims of education in adulthood and old age to support the realization and perfection of a multitude of individual leisure activities and interests.

A comprehensive understanding of education should consider formal, non-formal, and informal learning. Formal learning typically refers to institutional contexts and is structured in terms of educational objectives, contents, methods, and evaluation. Formal learning is regularly documented and certified. By contrast, non-formal learning results from

daily activities in the context of work, family, and leisure time and is not structured by learning objectives, contents, methods, and evaluation. The main difference between non-formal and informal learning is that the latter refers to unstructured learning processes outside educational institutions, but is not systematic or intentional.

Education also comprises exchange processes among equal partners in social interaction in everyday life. On the condition that the experiences of older people are taken seriously, even apparently incidental intergenerational contacts might offer opportunities for the younger generation to benefit from older people's creative modes of successful coping with tasks and challenges. Accordingly, the possibilities and limits of a more effective use of the potentials of intergenerational learning are related to the socialization of old age in society. In this regard it is of particular importance whether old age and aging are constructed and represented as a social problem and whether negative stereotypes of old age and aging are salient in intergenerational contacts.

Life Span Development and Education

From an educational perspective, life span development can be described as a continuous and active process of coping with developmental tasks, i.e., demands, challenges, and chances that depend on people's environment and life situation in given phases of the aging process. Specific developmental tasks are conceptualized as a consequence of the interaction between biological maturity, normative conceptions of successful aging, or development in society and individual plans, aims, needs, and values. The significance of environment and life situation for life span development is twofold: first, coping successfully with demands of the environment and life situation increases the potential for coping with future demands and initiates further development; second, chances offered by environment and life situation contribute to the realization of specific developmental gains.

Aging implies different processes of change in different dimensions of the person. In each dimension, gains and losses can be observed simultaneously; changes in one dimension are a poor predictor of changes in other dimensions. Accumulated and organized experiences, knowledge systems, and strategies for coping effectively with familiar problems and tasks are important developmental gains (in the sense of psychological growth) in older adulthood. Important developmental losses do occur in physiological and neurophysiological functions and processes, e.g., cognitive flexibility, ability to cope with unfamiliar problems and tasks, and speed of information processing. Education is a precondition for reaching developmental gains, for the opportunity to compensate for developmental losses (e.g., via the process of selective optimization with compensation), and for individuals to maintain or reestablish a satisfying perspective on life in old age.

Four conclusions regarding education in old age can be drawn from the results of life span developmental psychology:

1. Accumulated and organized experiences, differentiated knowledge systems, as well as effective strategies for coping with tasks and problems and for taking the chances offered by environmental conditions and life situation must be understood as a consequence of education in earlier phases of the life span, i.e., active coping with tasks, demands, challenges, and chances in younger years. In this context, the continuity of lifelong development becomes clear, since achievements in earlier years extend to later years as long as they are used sufficiently.
2. The use and further improvement of experiences, knowledge, and strategies for effective action are essential for the realization of developmental gains in old age. This fact emphasizes the importance of education in old age. Generally, there is a sufficient amount of plasticity, i.e., capacity to learn and change. As a consequence, education in old age, aiming to contribute to the use and further improvement of experiences, knowledge, and strategies for effective action, should be able to contribute to effective coping with developmental tasks and successful aging. There is a demand for education in old age, since people cannot cope successfully with developmental tasks or realize the potentials offered by cultural innovation (e.g., in technical fields) in old age without engaging in a process of coping with self, life situation, and environment.
3. Education in old age must not be analyzed only in terms of possible gains, depending on development in earlier phases of the life span; possible developmental losses are of equal importance. In this context, two aspects should be considered. First, gerontological research could show that cognitive training has an impact on the decline in the mechanics of human intelligence, i.e., the basic processes underlying intellectual performance. Moreover, through cognitive training, compensation for specific impairments and losses can be encouraged. Intellectual performance and everyday competence can be improved by new learning and memory strategies that compensate at least in part for deficits in sensory and motor functions. The selective optimization with compensation, i.e., the choice

(selection) of well-developed functions, skills, and strategies and their differentiation (optimization) with the aim of compensating for losses in other functions, skills, and strategies, forms an important basis of successful aging.

4. In the context of possible developmental losses, especially in very old age, decreases in health status and social integration as well as limitations of life expectancy should be mentioned. However, empirical findings show that even in the very old, most people are able to cope effectively with developmental losses and to maintain or reestablish a personally satisfying perspective on their life, exemplifying resilience in old age. It should be noted that resilience is established through personal and environmental resources. Concerning environmental resources, gerontological studies show that participating in cultural and social activities that offer stimulation and support promotes effective coping with developmental losses. These findings support an educational perspective that points to the significance of education for coping with critical life events, e.g., via providing information about effective coping strategies or institutional services. In the case of losses in certain functions and skills (e.g., visual impairment as a result of macular degeneration), compensation (e.g., use of audio cassettes or touch typing) as well as increased engagement in interests and activities that do not require these functions and skills can be interpreted in two ways: as a process of education and as encouraged by educational activities. Several intervention studies show the possible impact of educational opportunities on the effectiveness of individual coping processes. From the understanding of education and its effects, the close relationship between education and competence becomes clear. The latter is defined as the skills and abilities to maintain or reestablish an independent, task-oriented, and personally meaningful life in a stimulating, supportive (physical, social, and infrastructural) environment that encourages self-responsible coping with problems, developmental tasks, and challenges.

Education and Employability of Older Employees

The principal findings of international studies on working performance and possible training gains in older workers can be summarized in the following 10 points.

1. Most studies find an inverted-U relationship between chronological age and working performance. The peak of performance is reached between the ages of 30 and 40 years, and performance in old age converges to the performance of 20-year-olds. Similar findings are reported for driving, for which perceptual losses account for decline in performance.

2. Age differences in occupational performance are small. Training measures can compensate for age-related slowing. Training is a better predictor of performance than chronological age. In many cases age effects prove to be reversible through adequate training measures.

3. Age differences can be observed in less-experienced workers. If any age differences are found between experienced employees, the differences are only of a small magnitude.

4. However, in the cognitively most challenging professions, experience cannot compensate for age-related deficits. Complex tasks that require extended information-processing capacity regularly show some age-related deficits.

5. Previous knowledge can effectively compensate for losses in working memory. The working memory resources required for the process of thinking ahead can be assisted by using previous knowledge to structure information processing.

6. The performance of older experts regularly reflects successful compensation for age-related decline in some components through improvement in other components (knowledge, strategies). Experience with occupational tasks and challenges can be used to compensate for age-related decline, particularly in complex tasks. In some tasks the peak of performance is reached only in older years because accumulation of relevant knowledge and expertise requires long learning processes. By contrast, the performance of simple tasks often cannot be improved upon by using acquired strategies and knowledge systems. Leadership is a prototypical example for the particular potentials of older employees. Older managers are often more successful in comparison to younger managers because they take more time for important decisions, which reflects a more extensive use of relevant information, flexibility, prudence, and self-criticism.

7. Practice is an essential precondition for development and maintenance of expertise over the life span. For supreme performance, musicians need at least 10 years or 10 000 hours of practice. Professional pianists show only some age-related decline under conditions of highly complex requirements on motor abilities. The same is true for older pianists who reduced their amount of practice in comparison to younger pianists.

8. Transfer of training gains depends on task-specific requirements. High specificity in content, personal relevance, and long-term time investment

are the general conditions of a successful training program. The development of a cognitive ability should be oriented toward those special strategies and detailed knowledge systems that underlie expert performance (cognitive engineering). Training gains are similar for guided and self-initiated learning.

9. The relationship between chronological age and performance follows different developmental paths; some kinds of performance even increase with age.

10. High levels of performance can be maintained when occupational tasks are adapted to the employees' individual preferences and working rhythms. As a consequence, changes in job placement and job profiles are promising strategies for companies to ensure continued employability of older workers.

Their expert knowledge often qualifies older employees for overseeing important tasks within the company. In the late 1980s in the United States, some companies attempted to motivate retired senior executives to return to work and take responsibility for some tasks. This corporate strategy developed from the insight that the retirement of older employees often leads to a loss in expert knowledge for the company. This expert knowledge is seen as an important basis for successful reorganization of operating sequences and improvement of internal communication, as well as for familiarizing younger employees with their work.

Education, Health, and Competence

Numerous studies confirm a close relationship between health and education. Educational status proved to be a predictor of life expectancy and morbidity. Survey data indicate that as early as in younger adulthood, people with higher education – women somehow more than men – have an extended life expectancy and suffer less often from headaches, sore throat, stomach pains, and backache. Low social status correlates with morbidity and health-related stress. The aforementioned relationships are ascribed to different opportunities for leading a healthy life, occupational stress, competencies for coping with disease, habits in using health insurance, and communication with representatives of public health. Such explanations point to education as a mediator of possibilities to exert influence on one's own health status or to establish a relationship with medical practitioners that allows for codetermination in medical treatment in cases of disease. Intervention studies show that enhanced knowledge and patient training contributes to a lessened and more effective use of the health insurance system and improved compliance in people suffering from chronic disease.

Developing competences for maintaining health and effective coping with disease means acquiring the ability to express one's needs, wishes, and expectations, to catch up on relationships and opportunities, to choose, to decide, to judge, to codetermine, and to control.

For older women and men, staying healthy is one of the most important aims in life. Analyses indicate that the subjective importance of health steadily increases over the life span and that there is no sphere of life in old age in which people are as engaged as in the maintenance and improvement of health. Consistent with this finding of empirical research, contemporary cohorts of older people in Western societies in comparison with previous cohorts more often claim their rights for self-determination and self-responsibility with regard to the health insurance system. Lack of codetermination and self-management, deficits in the enforcement of patient rights, deficits in information and explanation and in transparency of services, bureaucratic structures and procedures, and being considered a patronized patient instead of a partner in medical treatment are aspects of the health insurance system that have been criticized empathically. The need for more self-determination and self-responsibility in dealing with the health insurance system is based on six principal findings:

1. Competent users of the health insurance system are able to soundly exhaust self-help potentials before making use of professional treatment.

2. Competent users of the health insurance system are able to cope effectively with their own disease, particularly chronic disease, and any necessary treatment in the sense of case management.

3. Competent users of the health insurance system are cooperative with regard to the consensually determined treatment and contribute to the prevention of misdirected medical resources due to a lack of compliance.

4. Competent users show a sense of responsibility toward the supportive society.

5. Competent users of the health insurance system develop a better understanding of medical and professional decisions as necessarily reflecting a scope of discretion. They are able to consider that in the light of medical progress and the competences and experiences of the individual practitioner, different decisions and judgments do not always imply a lack of quality in the health insurance system.

6. Competent users of the health insurance system develop a detachment from the public health system in the sense of minimized rates and length of contact by simultaneously keeping constant or improving outcomes in terms of morbidity, mortality, quality of life, and health costs.

The aforementioned competence in the use of the health insurance system is influenced by a magnitude of factors. These factors comprise personal resources such as the health-related self-concept and the experiences that people have had in coping with disease. Moreover, competence is influenced by environmental and social factors, such as which living and life conditions are available for leading a healthy life, how a given health insurance system is organized, and on which kinds of social and familial support people can rely when suffering from disease. Last but not least, educative, communicative, and informative factors play a role in individual coping with disease and in perceptions of internal control over maintenance or improvement of health.

Today, training programs to support a self-determined and self-responsible disease management have been developed for many chronic diseases. In addition to the acquisition of specific techniques, the establishment of consensually determined control of use of the health insurance system is another important part of such training programs. The patient is intended to learn what is relevant for the course of his or her disease, what he or she can do on his or her own, and in which cases it is necessary to consult a medical practitioner. Experiences from campaigns in the Netherlands and Germany show that educational programs can contribute to reduced consultation of medical practitioners in cases of coughs and sneezes.

Adequate communication is an indispensable precondition for participation and competence improvement. Difficulties in the communication between patients and medical practitioners are the most frequent reason mentioned for the consultation of patient-initiated counseling. Patients regularly have the impression that their concerns are not taken seriously and that medical practitioners do not offer enough information and explanation of medical treatment and potential alternatives. Older and disabled people in particular suffer from this impression, indicating that professionals often tend to assume a lack of competence and dependency from physical disablement.

With regard to health and competence, information comprises all measures to support the patients' acquisition of knowledge necessary to understand his or her own health status. Today, such information is available from numerous resources. This increase in the quantity of available information goes hand in hand with the risk of a decrease in quality of that information, implying a reduced usefulness of this additional information. The problem of receiving health-related information is increasingly replaced by the problem of adequately evaluating the quality of the available information. In Western societies patients are able to make use of the progress in information technology to access a vast amount of information on their diseases, alternatives in medical treatment, or preventive measures that makes them at least to some degree independent from medical practitioners' previous monopoly on providing information as well as from a costly investigation of literature for experts and laymen. Clear information about diseases, diagnostics, alternatives in treatment, and prevention could substantially strengthen patient sovereignty. According to data from the 1999 American Internet User Survey, 36% of all adult American Internet users (42% of female users) regularly look for information in the sphere of health and medicine. However, the quality of the information can seldom be assessed. The same is true for much health-related information available from the print media. As a consequence, services intended to strengthen patients' role as competent partners in the health insurance system must be offered by independent institutions on the basis of quality assurance.

Life Competencies of the Old as Human Capital

The term life competencies refers to experiences, strategies, and knowledge systems that people have acquired in earlier phases of the life span (i.e., understanding of education as a result of active coping with challenges and demands of environment and life situation in a given period of life). Life competencies are built up in the context of effective coping and enable people to maintain or reestablish a personally satisfying perspective on their life when confronted with serious problems, tasks, and challenges in later years. Building up life competencies in earlier years is a basic requirement for successful development in advanced age, i.e., effective coping with the demands of life in old age. Such demands include practical and psychological as well as interpersonal and ethical demands. Consequently, our understanding of life competencies is not limited to the experiences, strategies, and knowledge systems acquired in the context of occupational activities. Life competencies are also reflected in ethical judgments, voluntary activities, as well as the willingness and readiness to take responsibility for oneself, for others, or for society. Empirical findings show that active

coping with developmental tasks and the chances and limits of life can lead to the establishment of expert knowledge or wisdom with respect to questions of life. Expert knowledge or wisdom is not limited to old age but can be developed in earlier years as well. The only prerequisite for the development of expert knowledge or wisdom is the conscious and responsible preoccupation with a multitude of problems, tasks, and challenges in different periods of life and different contexts of development. Therefore, empirical findings support a perspective on lifelong educational processes that accentuates the development of the person rather than the cultivation of specific knowledge and skills.

The term human capital refers to the significance of life competencies for society and culture, i.e., processes of initiating societal and cultural change and the extent to which societal and cultural change is determined by life competencies of the old. Societal and cultural development depends on the possibility of using individual life competencies. It is here necessary to establish the infrastructural conditions, e.g., opportunities for volunteers to qualify and to use given experiences, strategies, and knowledge systems effectively.

Proceeding from a comprehensive understanding of productivity, several possibilities for leading a productive life in old age can be distinguished. Being interested in the development, living conditions, and vital interests of younger people, the transmission of information to younger generations, and the responsible reflection on experiences and knowledge systems of younger generations are examples of intellectual and emotional productivity in old age, since intergenerational discourses can initiate emotional and intellectual differentiation in older and younger participants. Moreover, by leading an independent and responsible life, even when confronted with serious problems or borderline situations, older people can give a good example to younger people of how to cope with problems and difficulties, i.e., build a productive context for others: an illustrative example of emotional and motivational aspects of productivity. Even the dialogue between young and old can be understood as an educational process in which young and old people can enrich each other by exchanging specific experiences and knowledge as well as general life competencies. For our understanding of education in old age, two conclusions can be drawn. First, older people are able to fulfill educational functions for others by offering skills, experiences, and knowledge or by leading an independent and responsible life that can be regarded as exemplary for younger generations. However, it should be mentioned that for fulfilling educational functions for others it is essential that the transmission of experience and knowledge is free from prejudiced beliefs that presuppose that one's own knowledge is superior to the knowledge of other people and that, therefore, others have to be instructed to adopt one's own experiences and knowledge systems. Second, dialogue and discourse with younger people can initiate further development. Intergenerational discourse is an important means of realizing potential for development. From the reports of services and institutions concerned with education in old age, it seems obvious that intergenerational encounters – either informal or in the context of formal educational settings – do have a great impact on the developmental processes of both the young and the old and therefore should be promoted intensively. Stimulating an exchange between the young and the old by inviting older people to visit schools, participate in specific lessons (e.g., on history), and engage in the transmission of experiences and knowledge is appreciated equally by the young and the old. The challenge for educational practices in establishing intergenerational contact that enables people to realize and use their specific life competencies is twofold: first, experiences, strategies, and knowledge systems must be explored and integrated systematically, and second, discussion or discourse must be initiated and guided with methodological competence.

Lifelong Learning

In past decades, the traditional understanding of education, which was exclusively oriented toward formal learning in childhood and young adulthood, has been broadened to the concept of lifelong learning. Different versions of this concept have in common the idea that learning in different phases of the life span, learning in formal, non-formal, and informal contexts, as well as learning in the context of a variety of personal experiences are indispensable components of lifelong learning. However, there may be changes in form, content, and motivation. In childhood and young adulthood, formal learning in school and professional training are most common. Decisions concerning the course of education are during childhood primarily made by the parents, whereas independent decisions continuously increase during the transition to adulthood. Inequalities in educational opportunities are determined by differences in social status. In the context of professional training, education focuses on aspects of utility for future working activities, whereas in school there is a focus on general education. In working life, non-formal and informal contexts become more

important as compared to formal contexts, admittedly not for all workers in all jobs. Employees in positions with many opportunities for independent and self-responsible decisions benefit from opportunities for further learning. By contrast, the competence of employees who must perform unchallenging, repetitive, and monotonous activities without opportunities for independent and self-responsible decision making decreases due to a lack of stimulation and deficits in extended vocational training. Because individual resources are restricted and tied to diverse obligations in adulthood, these employees cannot evade decreases in employability. The pressure of immediate utility, which is characteristic not only for learning during working life but also increasingly for learning in young adulthood, is no longer important in retirement. However, retirement implies the loss of the learning contexts of working life. This loss can admittedly be compensated for by activities of civil engagement. On the one hand, there is the opportunity in old age to use the new freedom to study further in accordance with personal hobbies, interests, and aspirations. This kind of learning might open up new areas of activity. On the other hand, maintenance of health and independence requires continuous learning processes.

Proceeding from the aforementioned aspects of lifelong learning, the 1972 Faure report suggested a comprehensive definition of educational aims, i.e., the establishment of a physical, mental, emotional, and moral human entity. The previous definitions of lifelong learning are a good starting point for a more comprehensive understanding of learning in occupational contexts and retirement. However, they focus too much on professional training and working life by accentuating aspects of utility and job mobility. The concept of lifelong learning can be explicated by seven points:

1. Lifelong learning encompasses the totality of all formal, non-formal, and informal learning over the entire human life cycle.
2. Lifelong learning implies different educational paths that are simultaneously permeable and interconnected.
3. Lifelong learning implies independent and responsible learning, and independence and responsibility themselves must be learned.
4. Lifelong learning implies learning in a manifold and transparent landscape of opportunities.
5. Lifelong learning implies enabling learning by the provision of sufficient resources.
6. Lifelong learning implies an investment of individuals, companies, and society.
7. Lifelong learning implies transparency, counseling, and quality management.

The necessity of lifelong learning in adulthood becomes particularly evident in the context of changes in life that can be described as discontinuities, e.g., parental leave, changes in occupation, and unemployment. In comparison to earlier phases of the life span, learning is less determined by institutional contexts. Due to occupational and familial commitments and obligations, there is a higher demand for programs that allow for a flexible adaptation of learning times, such as correspondence courses or computer-assisted learning. Qualifications and competences that were acquired via informal learning in occupational and familial contexts should be made exploitable by means of documentation and certification. The benefit of learning for the learner should be made obvious. Usage of modules from formal educational programs facilitates the development of individual profiles of competence. Moreover, a successful strategy of lifelong learning requires that companies and institutions responsible for education and job placement cooperate in a way that meets the challenges of transparency and counseling in the context of obligations and commitments in adulthood. Similarly, counseling must take into account the magnitude of professions as well as the variety of individual talents, interests, and life situations.

The necessity for intensifying the investment in lifelong learning follows from four principal aims: (1) the elevation of economic growth and improvement of competitiveness, (2) the support of individual employability, (3) the promotion of independence in old age, and (4) the strengthening of societal cohesion.

Aim 1: Due to demographic change and globalization of markets, the economic growth and competitiveness of Western societies increasingly depend on the innovative potential and qualifications of employees. As a consequence, there is a need to enhance the investment in education, including investment in extended vocational training for older workers.

Aim 2: Rates of employment and unemployment differ according to the level of qualification of the employee. In particular, those who reached a higher level of qualification and who continuously used opportunities for further education remain employed until retirement. This relationship has been no real problem for Western societies as long as losses in employability of older workers could be compensated for by opportunities for early retirement. However, demographic change limits the ability of younger

generations to guarantee economic competitiveness and Social Security benefits. For Western societies there is no alternative to an increased investment in the employability of older persons.

Aim 3: Good health and mental flexibility are central preconditions for leading an independent and personally satisfying life in old age. Numerous studies confirm that everyday competence as well as physical and mental capability can be improved by adequate training programs. Moreover, programs proved to be effective regardless of the age or mental and physical capacity of the participants. Results from empirical studies suggest that people suffering from dementia might benefit from a combination of psychomotor and memory training. The protective effects of physical activity are well supported, even in the oldest age groups. The significance of lifelong learning is apparent from the fact that healthy lifestyles have a lifelong protective effect. Consequently, educational programs for younger age groups that contribute to the awareness of the relationship between health status in old age and health-related behavior in earlier phases of the life span should be regarded as an important contribution to prevention for old age. In addition to such prevention for old age, prevention in old age also has considerable effects. As a consequence, the implementation of educational programs designed primarily for older people is a central part of a strategy of lifelong learning. Educational programs supporting health and capability (not exclusively for older people) are offered not only by traditional institutions but increasingly also by health insurance companies or sports clubs. Moreover, self-help groups are also important in this respect. Furthermore, the influence of the media should be considered. The media contribute, via mediation and accentuation of age stereotypes, to the endeavors that people undertake to shape their own aging process. In addition to this motivation or demotivation, a major function of the media is to enlighten people on medical relationships, health products, and health programs. Social inequalities in morbidity and mortality also reflect the significance of lifelong learning. A strategy of lifelong learning points to the necessity of promoting educational activities among members of underprivileged social strata. In this regard more group-oriented opportunities and contexts should be established.

Aim 4: General political and cultural learning mediates basic orientations and competences that are a precondition for social participation in a continuously changing complex society. The contents of learning are essential for civil engagement in all phases of the life span. Without this engagement, social cohesion and security in modern societies would be impossible. A general education is a precondition not only for occupational training and extended vocational training, but also for independent and responsible decisions concerning professional and private life. Personal responsibility for participation in lifelong learning opportunities, including the financing of this participation, cannot simply be presupposed. Instead, personal responsibility for lifelong learning develops from successful participation and positive experiences. In multicultural and multi-ethnic societies, belonging to a cultural minority regularly goes along with inferior educational opportunities. A large proportion of illiterates among foreigners might be a minor problem in industrial societies where blue collar jobs are essential for the gross national product. However, in modern societies, a lack of education mortgages access to the labor market, precludes people from social participation, and therefore implies a serious risk for social cohesion.

A principal challenge for a future-oriented educational system is to develop attractive services for the oldest age groups and for people from underprivileged social status groups. Moreover, the special interests of those older people who have been already engaged in lifelong learning activities must not be neglected. This is particularly important with regard to higher educational status in later-born cohorts of older people. In addition to senior academies and universities, other initiatives that try to integrate older people into regular courses of universities are promising. Finally, an efficient educational system considers the continuity of individual motivation for education over the life span. The successful realization of a strategy of lifelong learning depends on society's ability to motivate younger people to continuously invest in general education. The establishment of a broadened spectrum of interests in the younger years is seen as an important part of prevention for old age. Numerous studies suggest that establishing and maintaining life satisfaction in old age is supported by opportunities for new or extended engagement in interests and activities that have been built up and developed in earlier phases of the life span.

Glossary

Age – Refers to both people and their social structures. For people, age marks how much of their lifetime has so far been lived. In social structures, age denotes criteria both for performing in roles and for entering and leaving them. It operates in complex ways to locate people of every age in society.

Age-Graded Roles – Positions in social structures (e.g., work or nursing homes) for which age (or some substitute for age such as physical strength) is used as a criterion for permitting or proscribing role occupancy, entry, or exit, or for defining role expectations or sanctions for performance.

Age Strata – The rough divisions by age of people from younger to older within a society or group. Age strata reflect socially significant aspects of people and are only partly defined by biology.

Aging – Interacting biological, psychological, and social processes that start with birth (or conception) and end with death. The term is widely used to refer to the biopsychosocial changes in later phases of the life course.

Birth Cohort – A set of people born at approximately the same period of time. Members of a cohort in a society thus experience a common slice of history. Through cohort succession (or cohort flow), new members are continually born into a society, move up through the age strata as they grow older, and eventually die. As one cohort exits an age stratum, it is replaced by members of an oncoming cohort.

Demographic Transition – The transformation a society experiences as it moves from high birth and death rates to low birth and death rates. This transition in vital rates is generally associated with economic development. During this transition the population age structure shifts from one dominated by children to one in which old people comprise a large proportion.

Easterlin Effect – The hypothesis, first developed by the economist Richard Easterlin, that cyclical changes in demographic and social behavior are produced by fluctuations in cohort size. It is posited that large cohort size reduces economic opportunities for its members and that small cohort size offers advantages to its members.

Structural Lag – The situation in which the roles available to members of an age stratum are mismatched with the needs and preferences of individuals in the age stratum. In aging research, this involves a situation in which social structures (firms, schools, families) do not provide rewarding roles for the growing number of healthy, well-educated, long-lived people entering later life.

Introduction

Age stratification is a conceptual framework for exploring both how individuals age over the life course and what meaning is given to age in a society. This framework was developed by Matilda White Riley and her associates in the 1970s, and the term is still identified with her name. As a conceptual orientation, age stratification gives attention both to the individuals who occupy the various age strata in a population and to the social structures that use age to shape the behavior of those individuals. It gives special attention to changes over time in the experience of aging and to changes over time in relationships between age strata. This perspective insists that we recognize that human aging is, to a large extent, socially constructed. An important implication of this perspective is that the ways in which individuals age can and do change over time. In view of the breadth

of the perspective and also in view of the sometimes confusing and multiple connotations of the general concept of stratification, Riley later preferred to call it the aging and society perspective.

Age Strata in a Population

Age is a universal feature of individuals, and each population can be described in terms of its age composition. Although the meaning of age differs across societies, age is always socially significant. Therefore, the age composition of a population has social relevance.

Age Composition

The age composition of a population provides a starting place for discussing age stratification, and the population pyramid provides a simple way to picture the age composition of a population. Populations pyramids are shown in **Figure 1** (depicting the US population in 1900 and in 2000) and **Figure 2** (depicting the populations of Kenya and Spain in 2000). In each of the population pyramids, the percent of the population in the various age strata is shown by horizontal bars stacked on top of each other, with the youngest age category on the bottom and the oldest on top. This graphic depiction of a population

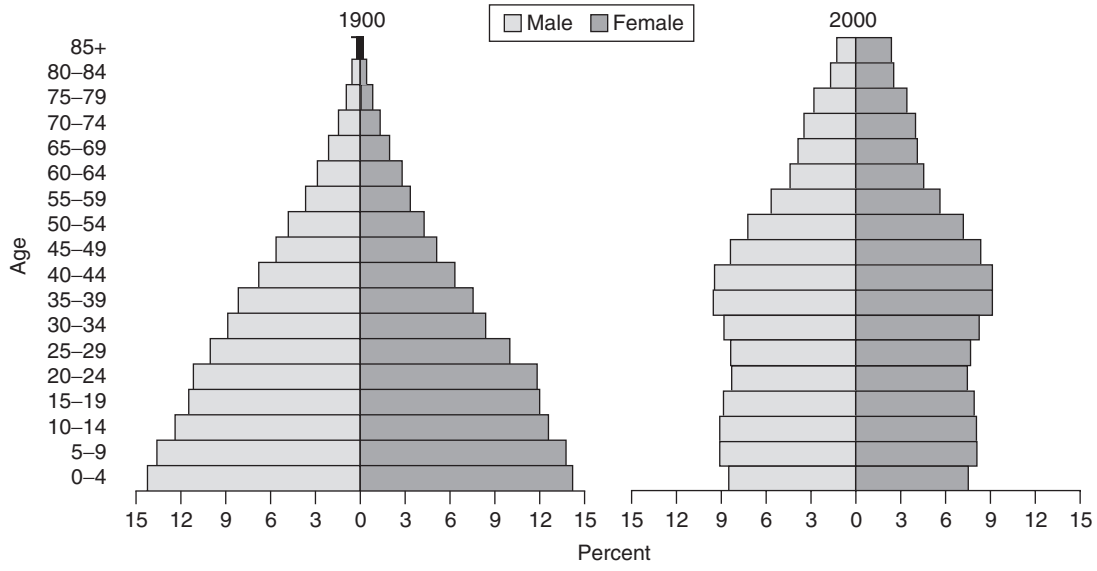

Figure 1 Age and sex distribution of the US population, 1900 and 2000. Source: US Census Bureau, decennial census of population, 1900 and 2000.

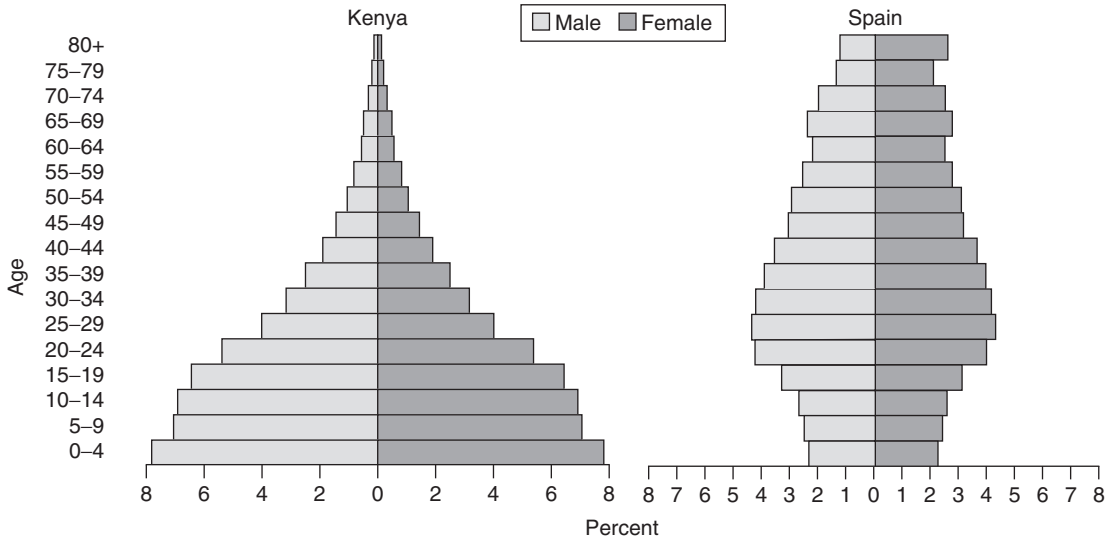

Figure 2 Age and sex distribution of the populations of Kenya and Spain, 2000. Source: US Census Bureau, International Database.

immediately suggests one aspect of age stratification in society – the population may be viewed as layers of people based on chronological age. By convention, each age stratum in the population pyramid is divided by sex, with males on the left and females on the right. The term pyramid clearly was derived from the typical shape of population age composition in high-fertility societies – the age composition of populations in low-fertility, late modern societies does not resemble a pyramid.

The dramatic changes occurring over time in the relative size of various age strata in populations of the economically more developed societies is well known. Using the example of the United States, the population over age 65 increased from 4.1% in 1900 to 12.4% in 2000, and is expected to exceed 20% by 2040. Equally dramatic is the contrast between contemporary societies that are at different stages of development (illustrated by Kenya and Spain). In Kenya's population, the ratio of children under age 15 to people over age 65 is 17.5; in Spain, this ratio is 0.9. Demographic analysis can explain why the age distribution of populations varies so much across societies and over time. At any point in time, the number of individuals in a population who occupy each age category is determined by past patterns of fertility, mortality, and migration. Migration patterns tend to have only a minor impact on the age composition of a population, so the large transformation in the age composition occurring over the past hundred years must be related to declining death rates and, especially, declining birth rates. In societies with sustained high fertility, young people dominate the population; in societies in which fertility has declined to near or below replacement level, old people comprise a significant proportion of the population. Past and future population aging, the increase in the proportion of the old and the decrease in the proportion of the young in a population, has profound implications for all societies that experience the demographic transition. However, as the age stratification perspective seeks to elucidate, what these implications are depends not only on the relative size of age strata, but also on the characteristics of the individuals in them and on the social meaning of age.

Characteristics of Individuals in Age Strata

Even a casual observation of a population reveals that age strata differ not only in size, but also in the social and physical characteristics of their members. For example, in the United States in 2000, younger males slightly outnumbered females, but at the oldest ages females greatly outnumbered males (**Figure 1**). Other examples of differences across age strata in the United States around 2000 are in the proportions of racial/ethnic minorities (24% of the population under age 5 years were minorities, compared to 13% of those aged 70–74), and in the average educational attainment level (12% of the population aged 35–34 had less than a high school education, compared to 33% of those aged 75 and older). Of course, the explanation for these differences between younger and older age strata cannot be attributed to intrinsic biological aging – individuals do not become whiter or less educated as they age. Some differences across age strata, such as intellectual functioning and physical ability, are generally assumed to be related to effects of biological aging. But a satisfactory explanation of the differential composition of various age strata at a particular time requires tracking the experience of birth cohorts as they age through unique historical contexts.

Differences between age strata can be illustrated by comparing those aged 75–79 in the United States in 2000 with those aged 45–49. Individuals in the age category 75–79 were born in 1921–25, were children during the Great Depression, and were becoming parents during the Baby Boom. Individuals aged 45–49 in 2000 were born during the Baby Boom years of 1951–55, were children during a period of economic prosperity, and encountered a tight labor market as they entered young adulthood. A comparison of several social and biological characteristics of these two age strata in 2000 is shown in **Table 1**. Why do these age strata differ so markedly in educational attainment, marital history, sex ratio, childlessness, prevalence of physical disability, and race and ethnic classification? The aging and society perspective argues that the answer to this question requires an examination of how social forces in the past differentially shaped the life course development of these cohorts. For example, the differences in educational attainment reflect differences in the educational institutions encountered by these cohorts as they moved through childhood. A variety of

Table 1 Percent of individuals aged 45–49 and 75–79 in 2000 with selected characteristics

Characteristic	*Percent aged 45–49*	*Percent aged 75–74*
Less than a high school education	11	29
Female	51	59
Ever divorced	35	18
Childless	16	11
With a disability	9	24
Non-white	18	11

Source: US Census Bureau.

historical, social, and economic forces affected the marital and childbearing experiences of these two cohorts. The differences in racial and ethnic composition and in sex ratios reflect, in part, the social conditions that led to differential survival experience of different segments of the population in the twentieth century.

It is quite apparent that the cohort born in 1950–54 experienced aging in the first half of its life course differently than the cohort born in 1920–24. Consequently, we can anticipate that when members of the younger cohort occupy the age category 75–79 in 2030, they will be substantially different from the cohort aged 75–79 in 2000. Even in terms of physical disability, it is unlikely that the older population in the future will replicate the experience of those who are currently old. When cohorts experience different lifestyles and different health-care systems as they age through life, their health status in old age is likely to be different.

Age and Society: Basic Social Systems Principles

The preceding discussion primarily focused on differences in the number and characteristics of individuals comprising various age strata. The age stratification approach further develops a model of aging and age differences by explicating the role of social structure in how individuals age.

Background: Age in Social Structure

As noted at the outset of this article, in gerontology the term age stratification remains largely synonymous with the extensive and influential work of Riley, who introduced the term in the early 1970s. Later, in the 1990s, Riley came to believe that the complex and multiple connotations of the general concept of stratification rendered the term confusing, and renamed her approach the aging and society perspective. Nevertheless, age stratification remains a widely used term, and it is largely synonymous with her approach and with her extensive and influential body of writings. The age stratification model played a significant role in stimulating researchers interested in aging to link theoretical and empirical analyses. It also has provoked critique and controversy, and these critiques are discussed after reviewing the basic model.

Before discussing the formulation of age stratification, it is important to understand the basic social science principles on which this approach is founded. In Riley's framework, aging as a property of individuals must be distinguished from the 'social fact' of age – that is, from the concept of age as a cluster of cultural representations and organizing principles of society. This analytical distinction that separates 'person' from 'role' is derived from Talcott Parsons' approach to social systems. Persons, of course, are individual human actors. In Parsons' framework, roles are not properties of persons; they are positions in social systems (e.g., families, communities, schools, corporations) that are occupied by persons. Especially when social systems are explicitly age graded, age is a feature not just of individuals, but also of the role structure and normative apparatus of a society.

Applied to the notion of age stratification, this differentiation has two important aspects, one that is static and one that is dynamic. In static terms, age stratification deals with the distinction between the age structure of roles and the age structure of a population. Its dynamic aspect highlights the contrast between age differences among individuals at a single point in time with the changes that occur to individuals as they develop and age over the life course.

Age Grading, Allocation, and Socialization

The population age structure refers to only one of the components of age stratification, the age-specific distribution of people. The age stratification framework also implies attention to the age-related aspects of the role structure of society and the problem of allocating or matching the available individuals with a finite number of available age-graded roles. When roles are rigidly age graded (as in the case of mandatory schooling for children, military conscription, or mandatory retirement), problems of mismatch or 'strain' can occur.

Age is built into the role structure of society when age is a criterion for occupying, entering, or relinquishing certain roles. Further, age can regulate how individuals are expected to perform their roles: the appropriate behavior in a role and rewards (or punishments) for performance may vary depending on the age of the person occupying the role. The most obvious use of age in social structures occurs when chronological age criteria are written into law, regulations, or contracts. For example, in contemporary US society, age regulates when it is legal for one to marry, drive a car, leave school, drink alcohol, vote, and become president. Further, chronological age is a criterion for receiving Medicare insurance, pension benefits, and selected tax benefits. There also are informal norms that use age to indicate what behavior is or is not acceptable, such as when one is judged as too old to become a foster parent, to enter a graduate program, or to participate in certain

sporting events. As with all norms, age norms are sometimes violated and can change over time. Nevertheless, the age stratification perspective calls attention to the importance of social definitions of age as forces that shape behavior and the aging of individuals.

The final component of the age stratification model deals with the processes by which the individuals in an age stratum are matched with the appropriate age roles in social structures. Allocation processes are used to assign people to age-appropriate roles and to continually reassign them as they age into different socially recognized phases of the life course. The mechanisms for allocating may be individuals in roles designed for this purpose (e.g., personnel managers or admission directors) or policies (e.g., pension plans or school attendance regulations).

This general phenomenon of allocation is closely related to several key theoretical ideas and research questions. For example, according to the Easterlin effect, the members of small cohorts have a broad-based advantage in that members of such cohorts will experience less competition for the finite number of age-graded roles as they enter particular age strata (e.g., admissions slots to elite colleges or choice entry-level jobs), whereas members of large cohorts will face greater competition. These differentials of advantages can carry on through the life course. In any pyramidal organizational structure (which describes not only corporations but also military, ecclesiastical, and educational organizations), the chance to be promoted to one of a few high-level managerial or executive slots will be enhanced if one has fewer competitors. On the other hand, it has also been suggested that under some conditions, individuals in an age stratum may benefit from being members of a relatively large cohort; for example, this might have applied to the male Baby Boomers who were in the draft lottery in the early 1970s. It has also been hypothesized that those retiring in the early twenty-first century may derive political advantage because they will comprise a larger relative size of the electorate.

Riley used the issue of the person–role mismatch to call for social change. She developed a critical analysis of inelastic, age-graded social arrangements that result in humanly destructive consequences. This critique led to the development of the concept of structural lag (discussed later).

The age stratification perspective also recognized that the concomitant process of socialization operates constantly, in parallel with allocation. That is, in everyday life experience, individuals are continuously internalizing the social practices and learning the skills that are integral to the roles that they occupy in the larger social system. The concept of socialization has been widely and effectively critiqued because of a number of conceptual and theoretical limitations that it imposes on the kinds of questions one would ask as a researcher. Nevertheless, the powerful processes through which individuals are shaped by the roles they occupy are a central feature of the reality that the age stratification model seeks to represent.

Age Structure and Cohort Flow

As a temporal snapshot, the age pyramid reveals virtually nothing about the actual aging of individuals. Rather, it describes the piling up at a single point in time of successive cohorts. Viewed over time, the movement of cohorts will produce shifts in the population age structure. Often, however, the age-graded role structure is relatively static, and Riley coined the term cohort flow to describe the movement of cohorts through it. As one cohort moves out of a particular age stratum, it is succeeded by another that enters that age stratum. This static–dynamic distinction highlights the dangers of the life course fallacy, which is the practice of inferring life course changes from cross-sectional age differences. This is a key point that researchers and consumers of research overlook at the peril of misleading interpretations of data. But this distinction also brings us back to the important substantive issue of strain: the dynamic movement of unevenly sized cohorts through a relative static and inelastic structure consisting of a finite number of roles is a source of strain.

Challenges and Criticisms of the Age Stratification Approach

Two basic types of criticism of Riley's formulation of the age stratification approach can be distinguished. First is a critique focusing on the lack of clarity and consistencies in its use of the concept of stratification. Second is a critique of the functionalist assumptions on which the model was built.

Age and the Concept of Stratification Influenced by the youth-driven social disruption of the 1960s, Norman Ryder recalled Mannheim's discussion of the role of generations in producing social change to elaborate the analytical importance of cohorts. Riley and her associates forged the concept of age stratification in the wake of the same set of real-world dynamics. Like the concept of cohort, the age stratification perspective turned out to have an intellectual value that was broader and more sustained than the social movements of the 1960s that initially inspired it.

Important ideas deserve critical scrutiny, and age stratification has been no exception. Using the term stratification to capture the cross-age tensions of that decade invited questions about the extent to which a homology with class or other forms of socioeconomic stratification was intended. For example, questions were raised about the choice of the term age stratification because of the important ways in which age stratification is fundamentally different from stratification in its traditional guises. Interestingly, in the past two decades new insights into aging have been gained by research that looks at the intersection of age with other bases of stratification, such as gender, race/ethnicity, and social class, utilizing concepts such as cumulative advantage.

Age Stratification and the Functionalist Perspective A second and more enduring line of critique of the age stratification perspective has focused on limitations associated with its Parsonian functionalist underpinnings. Clearly, the key strengths of the age stratification model derive from the analytical refinement and precision of the Parsonian framework, as described earlier. In particular, the person–role distinction and the conceptualization of age as a feature of social structure provide the basis for the social critique that Riley articulated as structural lag and the vision embodied in her writings of an age-integrated society. Yet critics of age stratification rightly note that serious limitations derive from its avoidance of issues of (1) power dynamics and (2) mechanisms of social change. Serious attention to these would have brought the issue of the interaction of age with other bases of stratification to the fore much sooner.

Much like Parsons, Riley dealt with the problem of reconciling human action and structure through a heavy reliance on voluntarism. Thus, Riley's discussions of how individual agency produces change in large-scale social systems focus on the aggregation of individual choices in processes such as cohort norm formation. In every case, she avoided examining the role of (1) social movements in shaping (rather than merely expressing individual aspirations), and (2) of institutional power as it operates in everyday life to organize individual opportunities, to limit choice, and indeed to shape individual taste and perception. These limitations derive directly from the underlying assumptions of consensus and voluntarism that are simultaneously hallmarks and limitations of the functionalist framework. It is thus a considerable irony that, in spite of these limiting aspects of functionalism, Riley used the analytical precision of that framework to generate a radically new and potentially liberating vision, exposing how age operates as an aspect of social systems (e.g., role structures as entirely separate from people and age as a property of social organization, value, and perception – not just of the chronological development of individuals).

Issues Related to Age Stratification

The age stratification framework has provided a basis for several critical assessments of how aging is socially constructed in modern societies. Three of these issues are discussed here.

Competition between Age Strata

The potential for competition and conflict to develop between age strata exists because each age stratum occupies a different position in the socially constructed life course. The self-interest of individuals may vary depending upon their life course location: older people may have different concerns than young people. For example, the well-being of older people in the United States in the early twenty-first century is directly affected by public pension and health-care policies, whereas the well-being of young people is directly affected by education and child-care policies. Given limited resources, one might expect competition between the old, who benefit from greater government spending on Social Security and Medicare, and the young, who benefit from greater spending on education and child care and greater tax relief for parents with young children.

A lively debate over the possible emergence of interest group politics based on age (the generational equity debate) developed after 1984, when an article by Samuel Preston in *Demography* called attention to recent trends in poverty for different age strata. The divergent trends between old and young are quite striking: between 1970 and 1995 the proportion of older people in poverty declined from 25 to 12%, while the proportion of children in poverty increased from 15 to 23%. An important reason for declining poverty among older people was the increase over this time period in government transfers to the older population. By 2000, per capita social welfare spending from all levels of government was three times larger for the population over age 65 than for the population under age 19 ($19 700 versus $6400). Some view this discrepancy in government spending on young and old, in combination with the divergent trends in poverty, as evidence that there was inequity in treatment of different age strata. Children were suffering because of excessive political power of the old, and this inequity might become even more severe as the large Baby Boom cohorts move into old age.

Despite what may appear to be a conflict of interests between young and old, empirical studies have

not found any significant age-based differences in political views among voters. Younger voters are as supportive of Social Security and Medicare as older voters, and there is no indication that voters become less supportive of local and state taxes to support public education as they grow older. There are two reasons why a polarization between age strata may not occur despite the forces that could push in that direction. First, in contrast to the relatively fixed statuses of sex, race, and even social class, upward age mobility is inevitable (unless one dies). Because younger adults anticipate moving into old age in the future, efforts to reduce the benefits going to the old would work against their own long-term interests. Second, many non-old adults either have parents or will have parents who are old. The large government transfers to the old are a major reason why few older people are dependent upon adult children for economic support. Thus, the collective strategy to keep older people economically independent serves to protect the assets of middle-aged adults. In fact, the current arrangement results in many older adults being able to transfer resources to their children and grandchildren. It is not clear, of course, how the possibility of age conflict in the future will play out, but recent history has been marked primarily by intergenerational support.

Structural Lag

A starting place for thinking about structural lag is the distinction between age as a property of individuals and age as a property of social systems. At any time, a given birth cohort will comprise that collection of individuals occupying a particular age stratum (e.g., 65–69). Because cohorts of varying size and composition are constantly moving through role structures that are relatively stable, it is always possible for a mismatch to exist between the capacities of the individuals in an age stratum and the places available for these individuals in social structures. This is especially likely when age is objectified as a property of the social system through various forms of age grading – making age a legal or normative criterion for role access. When such a mismatch develops in a particular historical context, it may be described as a structural lag. That is, social change has not occurred in a way that is congruent with changes in the aging of cohorts.

Why might an asymmetry develop between structures and lives? Although changes in patterns of aging and changes in social structures can affect each other, each process follows its own dynamics. The capacities of a cohort at a particular age are shaped by its past experience of aging through a unique slice of history, for example, the health and educational environment when the cohort passed through childhood, or the work opportunities and family norms existing as it moved through early adulthood. Social structures, with their age-graded roles, however, do not follow any rhythm analogous to human aging but are affected by political, economic, and social developments. Thus, the qualifications, expectations, or needs of individuals in a particular age stratum may not be compatible with the available places in social structures.

The most noted example of structural lag at this time involves the failure of social structure to accommodate the needs and interests of cohorts entering old age. Because of historical changes, people entering old age in recent years are healthier, better educated, and expected to live longer than the members of cohorts that preceded them. But in many advanced societies of the twentieth century, social structures imposed more restrictions on opportunities for older people to be productive than existed before the advance of modernity. For example, work organizations do not provide an adequate number of jobs with the flexible working conditions that would match the needs of older workers. Similarly, educational opportunities and volunteer opportunities for older people lag behind the needs of the resourceful people entering old age. Ways in which the lives of older people may lag behind structural changes can also be noted. Because opportunities and incentives for lifelong learning have been lacking, members of cohorts entering old age may not be equipped to participate in structures requiring new technological skills.

When structural change lags behind changed lives, or when lives lag behind structural changes, pressure for change may develop. Such changes do not come about randomly. They may result from scientific progress that leads to demographic change or complex cultural shifts that lead individuals to change their aspirations. When such initiatives lead to wide-scale change in values and perceptions, the result is cohort norm formation (discussed previously). A prime example is the impact of the women's movement of the late twentieth century on the life course aspirations of young and midlife women. Similarly, the media shape the thinking of elders, as well as nonelders, about the situation of older people. The media sustain ageist stereotypes, but also provide information about age discrimination and increasingly provide positive images of old age, especially as commercials target this growing demographic segment of the population. Organizations of senior citizens may lobby for the interests of older people. Policy makers in government and the private sector may recognize

areas of structural lag and initiate changes to reduce the mismatch between individuals and roles. It is also possible, however, that structural lags could persist and trigger conflict across age strata.

Age Segregation

Age stratification leads directly to the possibility for age segregation in a society. The existence of age segregation can be studied both at the structural level and at the individual level. There is extensive empirical evidence that a high degree of age segregation currently exists at both levels.

Age segregation at the structural level can be seen by the use of age as an eligibility criterion for participation in social activities. The clearest examples of age being used to direct people to enter or leave social structures are seen in the social institutions of education, work, and retirement. At a fixed chronological age, children are expected to enter a graded school system, and then, if 'normal,' to move lockstep with age peers through the system. Young adults are expected to finish school and move into work settings that exclude both the young and the old. Finally, as old age approaches and opportunities for participating in school and work sites are limited, adults are expected to move into the last phase of life – retirement.

Socially created separations between age groups are exacerbated by rules and practices in other institutions as well. Age criteria are used to control access to health-care institutions and welfare programs. Religious congregations frequently structure activities on the basis of age, sending children, youth, young adults, and older adults into separate programs. A pattern of residential segregation by age can also be seen, as is obvious in retirement communities and college dormitories.

At the individual level, age segregation occurs when there is an absence of social interaction between people of diverse ages. Studies of personal social networks reveal that very limited cross-age interaction occurs in modern society, particularly among nonkin. The linkage between age segregation of social institutions and the age segregation of personal social networks is straightforward. Institutional age segregation restricts the age range in the pool of persons from whom network members are typically recruited. Similarly, the lack of social interaction between individuals of diverse ages allows the perpetuation of age stereotypes that are then used to justify institutional age segregation.

Moving toward a more age-integrated society could potentially benefit people of all ages. First, through social interaction, older and younger people could provide mutually beneficial socialization. As Margaret Mead once argued, in a rapidly changing society in which youth have a greater mastery of new technology, the old need the young to be their teachers if they are to avoid becoming marginalized. It is also the case, however, that youth benefit from learning history from older people who have relevant life experiences. Second, through interaction, older and younger people can develop empathy for the challenges faced by those in different life course positions. This understanding offers an opportunity for reducing age stereotypes and for breaking the mutually reinforcing cycle of ageism and age segregation. Third, relaxing rigid age boundaries would allow individuals at all stages of life to more easily move between activities related to education, work, and leisure. Encouraging older people to engage in productive activities could lessen the burden of their dependency on younger adults, and allowing more diverse opportunities for younger adults could reduce the role overload associated with this phase of life.

In considering the possibility of reducing age segregation, it is important to recognize that human aging is alterable. The age-segregated life course that emerged in recent history was produced by social institutions that were constructed in particular ways. This suggests that changing these institutions could produce increasing age integration. And there are signs that structural barriers to age integration have abated in recent decades. Examples of recent changes encouraging greater age integration can be found in education, where lifelong education is receiving greater attention, and in work, where there is increasing job flexibility and increasing use of incentives to encourage working later in life. There is no reason to doubt that the aging experience of cohorts entering old age in coming decades will differ from that of the cohorts who preceded them. Whether or not this will bring about increasing age integration is an important but open question.

Conclusion

Age stratification is a model of aging that has profoundly affected how social scientists understand the process of aging and the meaning of age in society. It recognizes that although chronological aging is inevitable, the way in which individuals age from birth to death depends upon social organization and the social practices that derive from an individual's location in social structure. As the forces associated with modernity have transformed societies, the legal-bureaucratic use of age as an eligibility criterion has increased. The emergence of age norms that govern many aspects of life, the institutionalization of the

life course, gives social meaning to age and gives direction to how people 'ought to' age. There is no reason to assume, however, that the normative age-graded life course that shapes how individuals age in the early twenty-first century is either necessary or beneficial to human beings. The age stratification perspective addresses this issue because, in addition to providing a framework for examining how aging is socially constructed, it provides a basis for critically examining the human consequences of structuring age in particular ways.

Ageism and Discrimination

T D Nelson, California State University, Stanislaus, Turlock, CA, USA

Glossary

Ageism – Prejudice, discrimination, and stereotyping against someone based on his or her age.

Implicit Stereotyping – When a perceiver evaluates a member of an outgroup without realizing the influence of automatically activated stereotypes about the outgroup.

Terror Management Theory (TMT) – A theory suggesting culture and religion are creations of humans that put order and meaning on the world. Self esteem comes from the thought that our being in this world has a purpose. Fear of aging becomes a fear of having no purpose.

Introduction

Ageism refers to prejudice, discrimination, and stereotyping against someone based on his or her age. While it can refer to prejudice against younger persons, ageism, as the term is used by most researchers, typically refers to prejudice against older persons. Over the centuries, the nature of various societies has changed such that elders in a community have been displaced from a position of high status, commanding

respect, power, and deference, to a position of virtually no power, commanding little respect. The purpose of this article is to explore those changes, describe how ageism is manifest in the lives of its targets, and how those targets react to such treatment. Ageist behavior and ways to reduce ageism are also discussed.

Origins of Ageism

Historical Changes

In agrarian and pre-industrial societies, older people were held in high regard. They typically wielded the most political and economic power in their communities. Elders were valued for their life experience, wisdom, and knowledge of the history of their community. Older persons were the historians and libraries of their communities, so to speak. Those who wished to learn about the nature of their society or the workings of the world would need to consult an elder for that information. As a result of their great life experiences and their knowledge about their community history, older persons were the leaders of their communities. During this time, older persons were revered, respected, and admired by their community for their leadership, wisdom, and life experiences.

Three major developments heralded a major change in the way that younger adults viewed older adults. The first was the development of the printing press. A large part of the status that elders had in their societies derived from the fact that their lifetime of knowledge, information, and memories about the history of their community and the world beyond was far beyond that of others in their community. They had knowledge and expertise that no one else had. They represented an almost oracle-like, one-stop shop for the community members who desired to learn more about virtually anything they needed to know to survive and thrive in their community. However, the advent of the printing press meant that such information was no longer the sole province of the elders; instead, anyone could own that information. Moreover, in much the same way that the Internet brought the world closer together, the printing press at its inception brought information from all over the world to small, heretofore isolated communities.

The second major development was the industrial revolution. Prior to that period, it was quite common for a typical family structure to be extended in that grandparents would live with their children and grandchildren in the same house. Elders were revered, were respected for their wisdom and knowledge, and were valuable educators to their children and grandchildren. The industrial revolution created a boom in employment that resulted in the need for greater mobility, so that families could move to where the jobs were located. Smaller families were more mobile. Coinciding with this change in society was a change in the way that society regarded tradition. Attitudes toward elders changed in that the moral authority of older adults to dictate what happens to their extended family (by dint of their land ownership, financial, or other political power) was replaced with ideals encapsulated in the American and French revolutions. The idea that all men are created equal and all are on the same footing for their own families' welfare took a strong hold in the hearts and minds of Europeans and Americans. Moreover, the industrial revolution emphasized a value on innovation, rather than tradition. To be successful and thrive in this new world, young people needed to value new, creative ideas, and because older people represented tradition and were seen as unwilling or unable to adapt to new, creative ways of doing things, older people were devalued and even seen as an obstacle to the success of younger persons. Forced retirement was created as a way to legitimize this increasing bias in favor of the young, so that after a worker reached a certain age, he or she was no longer a part of the workforce.

This period heralded great advances in medicine, which was the third major historical factor that led to the rise in prejudice against older persons. In pre-revolutionary America, only about 2% of the population lived beyond age 60. As medicine allowed people to live longer, however, society and families were faced with finding a place and a role for older people in society. Unfortunately, with the diminished status and power of older adults in society, the rights and welfare of older adults were often regarded as unimportant. Younger adults tended to not want the burden of dealing with older adults and their health concerns or the financial and time demands of caring for their older family member. Older people were seen no longer as sage teachers, but as non-productive relics of a bygone era who should be marginalized to the fringes of society. If younger adults did not want their elderly parents living with them, preferring that someone else manage their parents' care, a place such as a nursing home could fill that need. Indeed, nursing homes have grown in popularity in the United States ever since President Roosevelt signed the Social Security Act in 1935. It should be noted that prior to that time, most states did not have nursing homes, but rather alms houses (sometimes known as poor farms) where poor older adults were sent. They had inadequate facilities, and older adults there were treated miserably. States encouraged the stigma regarding these houses in an effort to

discourage people from relying on them. Though today's nursing homes are vast improvements from these earlier institutions, there is a definite stigma that surrounds nursing homes, in terms of how older people regard them and how society regards older people living in them.

Theoretical Perspectives

Terror Management Theory An interesting theory that has been put forth to account for the origin of ageism is terror management theory (TMT). TMT suggests that culture and religion are creations of humans that put order and meaning on the world, and this keeps at bay the scary thought from childhood that the world is chaotic and random. According to TMT, we derive our self-esteem from the thought that our being in this world has a purpose. The fear of aging then becomes a fear of having no purpose (i.e., when one retires from a job). Since older people are a reminder to the young of their mortality, older people become a salient symbol of a feared future self. Experiments have shown that people deny the reality of their mortality by denigrating and stereotyping older people as bringing about their diminished or lower-status situation onto themselves. People fool themselves into believing that such a fate will not befall them. Research on the theory has shown consistently that when people are reminded of their mortality, they are more likely to stereotype others (as a way of enhancing their self-esteem and thereby denying anxiety of their own mortality).

Researchers studying TMT have argued that because death anxiety is so powerful in the United States, the TMT effects on prejudice and stereotyping of older adults are unlikely to diminish unless a concerted effort is made to educate the public about death. If death is demystified, reframed as a natural part of the life cycle, and generally normalized, perhaps anxiety about death (and about people, such as older adults, who are reminders of mortality), will diminish. When that happens, even though older people will always remind the young about their mortality, they may be less likely to evoke anxiety in younger people, who then may be less likely to stereotype older adults.

Ambivalent Attitudes Toward Older Adults Decades ago, research indicated mixed evidence for the existence of ageism. Some studies suggested that people had very positive attitudes toward older adults, while others suggested that society regarded elders in a negative light. Upon closer inspection of the research methods in these studies, it is clear why this discrepancy exists. Studies that yielded positive attitudes toward elders tended to ask about attitudes toward specific older adults in the respondent's life, such as his or her boss or grandparent. In those cases, the personal relationship is likely what dominates the person's attitude toward the older adult, and that may be the basis upon which the respondent answers the question. However, when people are asked about their attitudes about older people in general, their responses are often much more negative. Over the decades, then, much research has confirmed that, indeed, there is a pervasive, negative view of aging and, by association, older adults. These negative attitudes give birth to stereotypes and prejudice about elders.

Recent research indicates that older adults are regarded by younger people as incompetent but warm. In other words, older adults are viewed as having little to offer or contribute to society, but they are valued almost on a sentimental level for what they represent (values, tradition, family). The dependent relationship that often emerges between elders and their adult children often contributes to the tendency to treat elders as though they were childlike. Younger people tend to not want to discuss complicated, serious matters with their elderly parents, fearing that such topics will either be too upsetting or too sophisticated or intellectual for the older person. The insidious nature of this stereotype (i.e., that older people are like children) is that it influences the beliefs and behavior of the older adults about themselves. Many start to buy into this stereotype and foster the dependent relationship by acting in ways that they are expected to act, according to society's age grading and stereotypes held by younger persons (this point is discussed later in the section on experiencing ageism).

Implicit Ageism In recent years, researchers have discovered that overlearned links between people and characteristics in our memories can have significant effects on the way we think, feel, and behave toward those people. Specifically, strong stereotypes about a group will lead a person to be especially likely to automatically think about members of that group in terms of those stereotypes. When the individual is aware of the fact that he or she is stereotyping the person he or she is thinking about, that process is referred to as stereotyping (or prejudice, or, if the person is acting negatively toward the stereotyped target, discrimination). However, when the perceiver is unaware of the influence of the automatically activated stereotypes about the outgroup when he or she is evaluating a member of the outgroup, that process is referred to as implicit

stereotyping. Implicit stereotyping is all the more difficult (but not impossible) to control and remedy because the perceiver is unaware of its activation and influence.

Implicit ageism originates when children learn, from a very young age, that older people are not highly regarded in society. Research on children's books, school books, and fairy tales shows that these books are highly biased against older people. Older people are rarely featured in books for children, and when they are, it is usually as problem creators or dependent characters. One study found that the portrayal of older persons in children's books mirrors the ambivalence of society toward elders, in that the older characters were most often described as poor, sad, wise, and dear. These stereotypes, conveyed in innumerable ways from various sources throughout a person's life, become quite strongly associated with older persons, to the point that the mere mention or perception of an older person automatically evokes those stereotypes, often outside of conscious awareness. Implicit ageism can be unlearned, but research shows that doing so requires a tremendous commitment of motivation and effort to recraft default concepts about elders and to break the association between negative characteristics and the category of older adults. This is discussed further in the reducing ageism section.

Variations of Ageism

Ageism in Health-Care Professionals

Surprisingly, ageism is also found among those whose careers revolve around promoting the physical and mental health of others. For example, one study of medical students' recommendations concerning breast-conserving strategies found that medical students were significantly more likely to recommend breast conservation procedures for younger (86%) than older women (66%). Those students were also significantly more likely to recommend mastectomy for older patients (95%) than for younger patients (65%). The authors of the study suggest that, given the similarity in diagnosis, the difference in treatment recommendations reflects a clear ageist attitude on the part of the medical students. Other researchers have written extensively about the implicit (and sometimes explicit) ageist attitudes that are communicated to med students (and which med students then internalize). For example, some physicians tend to view older adults as lonely, depressed, or inflexible. Some physicians regard treating older adults as an exercise in futility, given the cognitive and physical limitations of elders. In other words, some regard treating the health issues of older adults as less important than treating the same medical conditions in young persons. As a result, physicians may be much less likely to prescribe aggressive medical interventions to alleviate the problem of older adults and are more likely to prescribe medicine to help older adults manage their pain.

Among mental health professionals, ageism is also frequently in evidence. Some therapists are reluctant to treat older adults, due to their misconceptions and stereotypes about older adults as merely lonely people in need of someone with whom they can talk. Some stereotype older clients as grumpy, suspicious of psychology, too talkative, or non-talkative. It may also be the case that these stereotypes are fueled by a healthism, or a stereotype about people who are in poor physical health. That is, some therapists are more likely to rate the psychological prognosis of older clients less optimistically compared to younger clients with the same presenting concerns.

Communication of Ageism

Based on their stereotypes of elders as dependent, and childlike, younger people tend to communicate with older adults in a negative fashion. One type of communication is termed overaccommodation; it describes the situation in which a younger person is overly polite, exaggerates his or her intonation, speaks louder, and speaks in simple sentences when talking to an older adult. Another type of negative communication has been termed baby talk; this refers to an exaggerated intonation, high pitch, and, sometimes, non-words or baby-speak that one would use when talking to a baby. Research indicates that older people differ in how they react to such communications. Those older persons who are higher in social, physical, and cognitive functioning find such speech degrading and insulting. However, those who are lower in those capabilities tend to actually prefer such speech, because it seems to communicate a secure, nurturing quality in the speaker, which the older person (who needs someone to attend to his or her needs) finds comforting. Younger people have also been shown to communicate their ageist assumptions via the way they interact with older adults. If younger people believe that elders are childlike, they will be less likely to treat the opinions of older adults seriously and will tend to restrict their conversations with elders to simple, pleasant topics.

Institutionalized Ageism

One of the major reasons why research on ageism lags far behind the volume of empirical interest

generated by racism and sexism is the institutionalized nature of ageism. That is, age prejudice is so pervasive throughout society, that virtually everyone knows about the stereotypes, and yet few regard the stereotypes as on the same par as prejudice based on sex or race. In other words, most people do not recognize age prejudice within themselves or in others. Of course, if people do not recognize ageism, reducing or eliminating it becomes that much more difficult.

That American culture is youth-oriented is not news. There is a multibillion dollar industry built around promoting products that help people conceal signs of age (antiwrinkle and age spot removal creams, wigs, etc.). Cosmetic plastic surgeries have increased in popularity over the last two decades. Advertisers cater their marketing to what they believe is their most desired demographic (those most likely to spend money on the sponsors' products), those who are 18–40 years old. Indeed, it is strange that advertisers do not specifically focus on those with even more disposable income: older adults aged 40 to 65 (those older than 65 may be restricted by a fixed income from Social Security, pensions, etc.). These older adults are more likely to be financially secure and are more likely to have money to spend on themselves and on products for their loved ones. Older adults are portrayed in television shows and movies as forgetful, grumpy (or mean), asexual, and silly and are frequently the punch lines of jokes made by younger persons. Due to the age grading of society, in which there are implicitly understood acceptable behaviors for people depending on their age, when older people engage in an interest or behavior that is age-inconsistent, they are regarded as cute or silly (e.g., skiing or running) or repulsive (e.g., having sex). Here again, stereotypes about aging needlessly restrict people's beliefs about what behaviors people can do and what interests they may have at various ages throughout their life.

One obvious example of the extent to which ageism is institutionalized in American society can be found in the greeting card industry. The prevailing message in the vast majority of birthday cards is a joke about how sad it is that the card recipient is another year older. Cards make fun of the recipient's age by pointing out (as indisputable fact) the recipient's deteriorating health, loss of worth or lessening contributions to society, and failing memory. A cottage industry has been built around the phrase over the hill, with black balloons, mock tombstones, hearing aids, and other ageist items available to purchase for the individual having the birthday. The public at large regards such messages and jokes as a harmless stretching of the truth.

Experiencing Ageism

The influence of age prejudice, stereotypes, and discrimination on the well-being of older persons is a topic that remains largely open for empirical inquiry. Like most research in prejudice, the examination of the influence of prejudice on the target of prejudice has only recently gained empirical and theoretical attention.

Treating older adults like they are children communicates the presumption of a dependent relationship of the older individual, and it can lead to self-fulfilling effects, in that the older adult may start to believe the validity of the stereotypes being communicated in the behavior and language of the younger person. Research has demonstrated that older people who start to believe stereotypes about aging tend to behave, think, and feel according to those stereotypes. This can have significant implications for their overall physical health. One study found that older adults with a more positive self-concept actually lived 7.5 years longer, on average, than their low self-concept counterparts. Older people who act according to stereotypes about older adults are regarded by other older people as less alert, helpless, and weak. A plausible explanation for this result is that it is due to a black sheep effect, predicted by social identity theory, which suggests that if a stereotyped group has a member acting in stereotype-consistent ways, he or she will be shunned by other group members, because that individual's behavior is tarnishing the group's efforts to overcome stereotypes about the group.

A useful distinction between two groups of older adults has been made in the research literature. Those who are between the ages of 55 and 74 are referred to as the young-old, and those 75 and older are referred to as the old-old. This distinction reflects the fact that most negative stereotypes about older adults tend to derive from assumptions about or distortions of characteristics sometimes found in those older than 75. When applied to those young-old persons, the mismatch between stereotype and reality is likely to be even greater. One recent survey of more than 850 older adults in California asked older participants to indicate whether they had ever been the victim of ageism, and if so, how they felt about and reacted to that treatment. Responses provided further support for the conceptual distinction between the young-old and the old-old. Those respondents who were 74 or younger indicated that yes, they had been the victim of ageism, and when it did happen (and each time it happened), they became angry. Those respondents 75 or older were significantly less likely to indicate that they had ever experienced

ageism, and saying that if and when it did happen to them, the ageist treatment did not bother them. The young-old in this survey became angry when stereotypes about elderly people (not them!) were applied to them. The old-old seemed to accept the validity of stereotypes about older people (i.e., themselves), and did not feel offended when those stereotypes were applied to them. Some researchers have speculated that the reason people in stigmatized groups are unwilling to acknowledge the prejudice against either their group or themselves personally is that if they did admit such treatment, the thought would be too unsettling or anxiety provoking for them. Specifically, the thought that no matter what one does, he or she will be regarded negatively by others due to his or her membership in a stigmatized group is discouraging, to say the least. Some research evidence supports this interpretation of findings such as these, but much more empirical attention is needed to be more confident in this explanation.

Though indirect, another way that older adults experience the negative attitudes of society about aging is through retirement. Voluntarily leaving the workforce, of course, usually does not carry with it negative experiences of ageist attitudes, compared to situations in which the employee is forced to retire or retirement in that position is mandatory. In these latter contexts, the older adult has a more difficult time transitioning to postwork life. These individuals struggle with the message that they have received from their forced retirement, that even though they may be capable and experienced, society still does not want their contributions. Much research supports a basic tenet of social identity theory that says that much of people's self-concept is rooted in their occupation. We are what we do. When an older person retires, that major part of his or her self-concept is no longer there, and the individual must find new ways to define him- or herself. That transition is a difficult one, even under the best of circumstances. However, it is especially problematic if the person was forced to retire.

Another problem with postretirement life is that American society has not thoughtfully considered and provided clear roles and opportunities for elders who still wish to contribute their expertise and wisdom to their communities (via the workforce, education, or other avenues). People have a strong need to feel that they are needed and that their contribution to their community is important. The culture at large, and communities in particular, need to pay more attention to making the postwork life of older adults a more community-connected, meaningful, enjoyable, and satisfying time of their life.

Workplace Discrimination against Older Persons

One of the most common types of discrimination against older persons is workplace discrimination. Employers tend to be unwilling to acknowledge age discrimination practices at their company, or they may be unaware that those practices constitute age discrimination. In one study, when employers were confronted with their company's lack of older workers in certain positions, they explained that age disparity as due to something about the older workers themselves (i.e., that older persons do not want that type of position) or due to external factors (population trends, dearth of older workers with job-specific skills, etc.).

When the work performances of older and younger workers are evaluated, it is found that older workers tend to receive more severe evaluations if they have performed poorly. Older workers who get poor job evaluations are less likely to be referred to remedial training than their young counterparts. This may be due to ageist beliefs about the ease with which older people can learn new information. The more ageist beliefs the employer endorsed, the more likely he or she was to call for the poor-performing older person to be fired (compared to the poor-performing younger worker). One study found that when older workers link their identity with the characteristics of their same-age peers, their self-esteem is reduced, and they feel a greater sense of relative deprivation when they compare their outcomes with those of younger workers.

Moreover, experiencing workplace discrimination influences people's well-being in retirement, in that those persons are less satisfied with their lives. Being an early retiree has its downside in another respect: these individuals feel like they are too old to rejoin the workplace, yet too young to join groups of retirees or senior citizens. Thus, they have a more difficult time navigating where they fit in the post-workplace world, and society has done little to accommodate such workers.

Ageism across Cultures

Ageism is not a universal phenomenon. There is great variability across cultures, and even within some cultures, in how older adults are treated. Some researchers suggest that the ageism of the United States represents a subtle form of abandonment. This has the ring of truth when considering policies such as forced retirement and the lack of attention that America gives to postretirement life. Not only are elders psychologically abandoned or forgotten, but also the message is communicated that when people

get old, they should not be a burden to their family, and thus, they ought to go to a retirement home, nursing home, or other facility. These messages tell older adults that they are not needed or valued and should stay out of the way of the younger adults.

Not all societies are as ageist as the United States. Traditionally, Eastern cultures are very reverent toward their elders. Much of this attitude is rooted in how these cultures view death. In contrast to the United States, Eastern cultures view life, death, and the self as intertwined. Death is seen as a welcome relief from the suffering of life, and as a way of joining one's revered ancestors. Interestingly, recent research shows that as Eastern cultures become more Westernized (adopting capitalist, democratic, market-driven economies and valuing individual freedoms and pursuits), their attitudes toward older adults have become more negative. The degree to which the values of cultures change from emphasizing tradition and experience to valuing change and innovation will influence how those cultures treat their elders. As TMT rightly shows, the strong fear of death is a powerful contributing force to ageist behavior, age prejudice, and age stereotypes.

Reducing Ageism

In order for discrimination, stereotypes, and prejudice against older adults to be reduced or eliminated, fundamental changes in the way society views aging need to occur. Researchers agree that if society enacts the following 10 changes, there will be a significant impact in reducing and eliminating ageism in the United States.

1. Information needs to be shared with media outlets and authors (notably of children's schoolbooks and entertainment books) that older adults have a great deal to contribute to other people and society.
2. Opportunities for older adults to contribute to their community should be created.
3. Conditions need to be created that allow older adults more control and independence in their lives.
4. Much more attention needs to be given to postwork life for older citizens. Their lives can be fulfilled with continuing opportunities to contribute, and they can grow and thrive mentally, socially, financially, and emotionally.
5. Contact between older adults and younger people (including, of course, children) should be increased and encouraged, so that children and young adults are exposed to the wisdom, history, and value of interacting with adults with so much experience. Doing this demystifies what older people are like, and it helps break down the stereotypes about older adults.
6. Stereotypes and myths about aging need to be confronted with actual figures and facts about aging.
7. Perspective taking should be used as an effective method for teaching empathy for other groups; some evidence suggests this is effective in significantly reducing ageism.
8. The way that society views death (currently with dread) needs to be directly confronted, such that death is reframed as a natural part of the life cycle that is not to be feared, but accepted as a normal part of life.
9. Efforts need to be made to address all explicit and implicit institutionalized ageist practices and traditions (e.g., hiding signs of aging, jokes about negative characteristics about older people).
10. Younger people need to be taught that older people should be treated with respect.

Over the last several decades and continuing to the present, much more empirical and theoretical attention has been devoted to understanding other types of prejudice. Little attention, however, has been devoted to understanding age prejudice. As a result, our understanding of the causes, maintaining factors, and consequences of ageism is nascent. Ageist beliefs and behaviors are so entrenched in American culture that they have become institutionalized; this may be a likely reason why researchers have not devoted much attention to the problem, and why everyday citizens do not perceive age stereotypes or ageist practices as a problem. The US Bureau of the Census projects that the number of people over age 65 will double by the year 2030. This graying of America represents a major change in the complexion of the demographic of the country, and with it will come a major demand on society's resources (economic, health, legal) that, at present, it is ill-equipped to handle. It is crucial that we devote much more research attention to understanding and eliminating ageism. In so doing, we can help policymakers, researchers, educators, and society at large make the changes needed to significantly enhance the quality of life for all older adults in society.

Alcohol and Drugs

E S Lisansky Gomberg, University of Michigan, Ann Arbor, MI, USA

Glossary

Alcohol-Related Problems – Medical, legal, occupational, family, and social problems.

Illegal or Controlled Substance – Schedule I drugs, defined as manifesting a high potential for abuse and no currently acceptable medical use, including heroin, LSD, and marijuana.

Medications – Any drug substance, prescribed or over-the-counter, taken for therapeutic purposes. This includes prescribed use of psychoactive drugs.

Pharmacodynamics – Physiological and psychological response to drugs; there are gerontological changes in drug response.

Pharmacokinetics – The time course of absorption, tissue distribution, metabolism, and excretion of drugs and their metabolites from the body.

Introduction

A drug is defined as any substance (not food), natural or synthetic, which by its chemical nature alters an organism's structure or function. Drugs may be found in nature or they may be produced in the laboratory. They may also be classified in terms of their chemical composition or, in the case of psychoactive drugs (e.g., alcohol, opiates, nicotine, etc.), in terms of their central nervous system action. A major classification is in terms of social acceptability; drugs vary from widely accepted (caffeine) to illicit substances, which often appear as 'street drugs' (heroin). Drug abuse and drug dependence may be defined as deviant usage. Diagnosis is usually made in terms of the American Psychiatric Association standards set forth in the *Diagnostic and Statistical Manual IV*.

There are several classes of drugs to be reviewed here. First, there is the use by older people of medications in general and psychoactive medications (anxiolytics, stimulants, etc.) in particular; there are likely to be prescribed, although there is a 'street' supply from non-medical sources. Second, there is the use of over-the-counter (OTC) drugs that need no prescription and may be bought in any pharmacy. Third, there is nicotine used by Americans of all age groups and by the elderly. Fourth, are the controlled

substances, banned by law. The best known controlled substances are marijuana, heroin, and cocaine; associated with crime and violence, these drugs get the most media attention. Fifth, there is the use and abuse of the legal drug, alcohol.

A major area of study is the biological change over the life span that occurs in the body's response to different drugs. Pharmacokinetics involves the study of the time course of absorption, tissue distribution, metabolism and excretion of drugs and their metabolites from the body, and the relationship of drug disposition to the duration and intensity of drug effects. Studying the effects of age on pharmacokinetics produces information about the mechanism of altered pharmacodynamics in the elderly. Pharmacodynamics is the physiological and psychological response to drugs. Pharmacodynamics is concerned with the greater or lesser response of older people to particular drugs, independent of pharmacokinetic effects. Different psychoactive drugs, for example, may produce different pharmacodynamic effects in the elderly (e.g., the response of older persons to some of the benzodiazepines appears to be an enhanced response).

Age Changes

Pharmacokinetics Although there do not appear to be significant age changes in drug absorption, with aging there are changes in body composition that influence drug distribution. There are age changes in drug elimination, particularly a decline in renal function.

Pharmacodynamics Age changes in sensitivity to some drugs and increased sensitivity to drugs acting on the central nervous system (CNS) are observed; the susceptibility to adverse drug reactions appears to be increased.

Adverse Drug Reactions Adverse drug reactions (ADRs) in the elderly can result from multiple drug therapy, drug overuse or misuse, slowing of drug metabolism or elimination, or to age-related chronic diseases, alcohol intake, and food–drug incompatibilities. ADRs in the elderly are more severe than among younger patients. Risk factors include being female, living alone, multiple diseases, multiple drug intake, and poor nutritional status (*see* Pharmacology).

Medications

The increase in acute and chronic illnesses that appears in older populations produces greater health-care expenditure and more medications for this subgroup of the population. Older people constitute approximately 12% of the general population, but estimates are that they receive a third of all prescriptions. Older people also buy and use a disproportionately larger number of OTC drugs. A list of the most widely used prescribed drugs includes general medications and psychoactive drugs; cardiovascular medication, diuretics, antibiotics, and analgesics are among the most frequently used drugs as are psychoactive drugs, such as sedative-hypnotics including benzodiazepines, and psychotherapeutic drugs, which include antidepressants and stimulants.

Although some treatment facilities report sizable patient intake of older persons with drug-associated problems and dependence on psychoactive drugs, this issue has never evoked much interest. It may well be that in the minds of legislators and the public, keeping older people sedated is an acceptable idea. Older persons frequently associated their intake of psychoactive drugs with problems like insomnia or depression, and almost half of those taking such drugs report that they could not perform their daily activities without the medication. The issue of prescribed psychoactive drug use and misuse among the elderly is complex and has psychological, societal, and policy components.

There are several questions related to the use of prescribed psychoactive medication. Nursing home use of such drugs is a problem, and it is questioned whether such medication is used for the benefit of the patients or for the benefit of staff to facilitate patient caregiving. Age differences in drug problems are reflected in the contrast of drug-associated emergency room (ER) use: younger patients are likely to present in ERs with emergencies relating to controlled substances like cocaine; older persons are more likely to present in ERs with problems associated with misuse of a psychoactive drug, usually prescribed. There are also gender differences. Up to age 65, women are prescribed and use more psychoactive drugs. From age 65 on, the differences become complicated, and data suggest that antidepressants are more widely prescribed for older men than for older women. This may be related to older men's utilization of medical resources, or possibility to a gender difference in psychiatric problems among older people. For older (white) men, the decline in power with aging is reflected in suicide rates. Although suicide rates remain low and stable with aging women, they rise with age among older men.

National surveys of elderly persons living in the community show a widespread usage of psychoactive drugs, and it has been noted by several investigators that older people receive a disproportionately high percentage of psychoactive drug prescriptions. The

question of abuse, misuse, and dependence is raised infrequently, usually as a caveat that a given drug (e.g., a sedative) should not be used continually for more than 2 weeks. In spite of that caution, approximately half the older persons queried in research studies report that they could not perform their regular daily activities without the medication. Societal concerns about older persons' use of substances seem to focus on alcohol.

The elderly have more health problems than younger people and therefore are more likely to be taking multiple prescriptions. Such multiple drug therapy means an increased risk of adverse drug reactions. Studies involving hospital patient monitoring have suggested a number of drugs of concern: dioxin, diuretics, aspirin, psychotropics, cytotoxins, and nonsteroidal anti-inflammatory drugs (NSAIDs). Adverse drug reactions may be a consequence of multiple drug therapy, drug interactions, changes in older persons' drug metabolism or elimination, noncompliance with prescribed drug use, incompatible food–drug combinations, or alcohol intake combined with medication use. It is estimated that the incidence of adverse drug reactions is two to three times more frequent among the elderly than among younger patients. To compound the difficulties, adverse drug reactions among older people are more severe, and there are those investigators who believe that drugs should be prescribed at lower initial doses for older patients. There are also investigators who believe that medications are over prescribed for the elderly and that some restraint in prescription would be helpful.

Data from the Drug Abuse Warning Network (reports from urban ERs) indicate that older people are most likely to present with problems relating to nonbarbiturate sedatives, tranquilizers, barbiturate sedatives, and antidepressants. On all of these, the percentage of women appearing in ERs is greater than the percentage of men.

Several classifications have been made of different usage of psychoactive drugs. One such classification distinguishes appropriate use, unintentional misuse, and purposeful misuse. Another differentiation is of benzodiazepine use: first, there is a low or therapeutic dose, the usual prescription pattern, and no withdrawal symptomatology when use ceases. There is also high-dose therapeutic use, which is again prescribed but usually produces withdrawal symptom when use ceases. Second, there is intake involved in multiple-drug use, frequently involving alcohol; here the aim is to achieve a "high" or some form of self-prescribed relief.

A problem relating to medical practice and prescription drugs is the question of non-compliance. Non-compliance is seen as a major problem, including the following:

1. Non-use: not obtaining the prescribed drug, perhaps because of cost.
2. Partial use: ceasing before course is complete, perhaps because of side effects, or combinations of prescribed drug with OTC drug not prescribed.
3. Incorrect dosage: more or less than prescribed.
4. Improper timing or sequencing of medication.
5. Shared medications.

A survey by the largest organization of older persons, the American Association of Retired Persons (AARP), found that 40% of the respondents experienced side effects; half of those said that side effects had not been discussed by health-care personnel. Although non-compliance is often attributed to cognitive limitations of older persons, a question has been raised as to whether the non-compliance is more likely to be linked to limited financial resources, a denial mechanism, issues of autonomy, and the quality of communication between patient and physician. Although it has been suggested that older people have the 'right' to make decisions about their drug intake, the extended life expectancy is related to pharmaceutical advances. What is needed is a balanced view in which patient and physician can arrive at a modus operandi and a rationale for medication intake.

Over-the-Counter Drugs

The most commonly used non-prescription drugs are analgesics, nutritional supplements like vitamins, laxatives, and antacids. Non-narcotic analgesics are the most commonly reported drugs of purchase by older persons both in the United States and in other countries. When the question is raised whether the elderly use more OTC medications than other age groups, there is disagreement. Some investigators believe that older people purchase and use disproportionately more OTC medication than other age groups; other investigators believe that elderly people do not use such OTC medications excessively.

The Food and Drug Administration has suggested that there be special labeling on prescribed drugs for persons over 65. The general response to the suggestion of special age-related labeling on OTC drugs has been negative, and consensus among investigators is that labeling by specific medical condition is preferable. It is of interest to note that more information is available to OTC drug consumers on packaging and package inserts than to consumers of prescribed drugs.

The question of home remedies and folk remedies may be raised here. Although herbal teas and chicken soup are not in the same category as drugs or medication, such folk remedies are widely used and probably more often by poor people. Perhaps studies of American eating habits could include such investigation. One suspects that self-medication with home remedies is the first line of health defense with most people.

Nicotine

Men are more likely to be smokers than women, although the percentage gap between the sexes has narrowed considerably in the last 20 years. The Public Health Service has tracked the marked increase in female smoking during and after World War II and by the 1960s, lung cancer deaths among women began to rise. Since 1985, lung cancer has passed breast cancer as the chief cause of cancer death among women.

A survey of people 65 and older in Massachusetts showed that those *less* likely to be current smokers included respondents living alone or with their children, those who reported their health as poor or fair, and 'the frail elderly.'

The relationship between smoking and a variety of diseases is well documented. A review of studies of the metabolism of drugs in older persons concluded that the effects of aging, nicotine, and alcohol are confounded.

Illegal Substances

The occasional social use of drugs like marijuana, hashish, and even cocaine probably does occur among older individuals, and there are apparently users of illicit drugs (e.g., heroin) who began drug use earlier in life and have survived into old age. One of the widely held beliefs about opiate addicts was that they did not survive to old age, that they either died or 'matured out.' There is, however, a small number of elderly heroin-dependent people who have managed to maintain their habits and live beyond their sixties. In the mid-1970s, people over 60 years of age constituted 0.005% of the methadone maintenance population in New York City; 10 years later, the proportion had risen to 2%. These are not drug-dependent people whose habit is of recent onset; they are long-term heroin addicts who have survived. Interestingly enough, the Michigan Department of Public Health reported that for treatment admissions in 1992–93, for those 60 and over, heroin was the primarily substances of abuse for 3%.

Study of the New York City methadone-maintained survivors showed a number of variables relevant to survival: the survivors had long-lived parents, they avoided violence, and were careful about the use of clean needles. They were able to hold some drugs in reserve, used other drugs – particularly alcohol – moderately, and were generally in reasonable health when compared with same aged people in the general population.

The use of banned substances is associated with younger rather than older persons. In Michigan, treatment admissions for those under 60 show twice the percentage of younger patients whose primary substance of abuse is heroin: 6% compared to 3%. The contrast is even sharper for those whose primary substance of abuse is cocaine or crack: 18% of those under 60 and 2% of those 60 and older. Data from the criminal justice system suggest a triadic relationship: youth, criminal activity, and illegal drugs. For older persons, the criminal justice system has traditionally been involved with the homeless skid row man. In recent years, however, arrests for public intoxication have diminished, and the homeless population has become more heterogeneous.

Alcohol

Alcoholic beverages are legal and socially accepted. As such, they are used infrequently or moderately, they may be consumed in large quantities, or they may produce alcohol abuse, alcoholism, or dependents for some users. We will examine briefly the moderate social use of alcoholic beverages by older persons and then move to alcohol-related problems as manifested in abuse or dependence.

To what extent is alcohol used by older persons? It has been generally accepted that moderate drinking declines with age, but some data challenge this. Perhaps there is a historic shift so that the older cohort of the 1990s behaves differently with alcoholic beverages than the older cohort of the 1950s or 1960s. There are National Health Interview Survey (NHIS) results that suggest an increase in alcohol intake among men 65 and older, and a small increase among the same aged women. A few community-based longitudinal studies have shown an increase over time; a Framingham, Massachusetts, study showed a large increase for women. Drinking is tied to laws and social customs, and there has been a trend in recent decades toward greater acceptability. Many small communities with local prohibition laws have shifted to acceptance, and women's drinking in particular is likely to be affected by social acceptability. Older people as well as younger people are affected by changing mores.

How much of a health risk is alcohol for older persons? It is certainly true that the older population is more likely to manifest both acute and chronic illness; it is also true that this population takes more medication than younger groups. The question of age changes in hepatic blood flow and the capacity of the liver to metabolize drugs is relevant. Older people show a decrease in body water content that produces higher peak serum ethanol levels for the same amount of alcohol, which would produce lower peak levels for younger people. There are other relevant age changes, and the increased vulnerability of the brain with aging raises questions about symptomatic behavior like confusion, depression, and dementia as they may relate to alcohol intake. The general consensus, however, is that light drinking is not particularly harmful to older persons, provided they are reasonably healthy and take no medications that interact with alcohol; one drink a day is considered prudent.

Drinking Problems

Although there may be a larger number of older adults with psychoactive medication problems, they are not likely to appear in substance abuse services. It is much more likely that older adults who drink heavily or frequently and who manifest alcohol-related health and other problems will appear, voluntarily or not, at such services. In Michigan, treatment admissions of patients under 60 years of age include 62% for whom alcohol is the primary substance of abuse; for people 60 and older, alcohol is the primary substance of abuse for 86%. In a study done at a veterans' hospital 65% of the younger alcoholic men and women 80% of the older alcoholic men in the study group chose alcohol as 'substance of first choice.'

The literature on elderly alcoholism is limited, and samples are drawn from hospitals, arrest records, out-patient clinics, and housing for older people, and from community and national surveys. The issue of how patients are screened is also relevant. Although standard screening instruments are widely used, there is a question about the meaningfulness of some of the criteria for diagnosis of alcoholism. Losing time from work may be irrelevant, falls and medical problems may be more relevant. Caution is needed: surveys show a relatively low percentage of problem drinkers among those 60 and over but the size of the problem may be larger. A recent study examined the records of all hospital inpatient Medicare Part A beneficiaries, 65 and older, and reported a high prevalence of alcohol-related hospitalizations. The highest rate of such hospitalization occurs in the 45- to 64-years-old age group (94.8 per 10 000 population) and the second highest rate was in the 65-and-over age group (65.1 per 10 000 population). The alcohol-related disorders included alcohol abuse and dependence, and alcoholic liver disease, psychoses, cardiomyopathy, gastritis, and polyneuropathy.

There is a vast literature on neuropsychological or cognitive loss which is a by-product of heavy or problem drinking. Such psychological deficits have been explored in terms of functions impaired, gender differences, and the relationship of age to cognitive impairment. The latter produced a 'premature aging hypothesis,' which posited premature senescence brought on by heavy drinking; evidence about this hypothesis has been mixed. Cognitive impairment may focus on specific functions: short-term memory, non-verbal abstracting, the ability to process new information, and so forth. There is a question about the reversibility of the cognitive loss, and it is generally believed that older problem drinkers may regain loss function, given time, although the process is slow.

One of the most interesting phenomena of elderly problem drinking is the subtyping: early onset versus late onset. Some authors have defined late onset as the beginning of problem drinking around age 40; this means that a group of problem drinkers are divided into those who began problem drinking in their twenties or younger and a group that began around age 40. There is a good deal of literature that indicates that the younger-onset group will show more positive family history, more comorbid diagnoses of antisocial personality, and poorer prognosis. If we are, however, to associate onset and old age, it would be better to differentiate problem drinkers at 65 or 70 into early onset and recent onset. That a group of late- or recent-onset problem drinkers exists has been verified by a number of reports that suggest that about one-third of older problem drinkers studied qualify as recent onset. There is an interesting question whether such recent or late onset is associated with experienced stress; several investigators studying stress and drinking have come up with support for stress-as-etiology and others with stress-as-irrelevant data. Stress may be a complex phenomenon that impacts differently depending on gender, general health, socioeconomic status, life experience, and so on.

There are drinking-related factors, and it seems a reasonable hypothesis that problem drinking is more likely to occur in someone who has had a history of intermittent heavy drinking. There are changes in role and status with old age and different coping mechanisms and ability to adapt among older people. There are also shifts in the social environment, particularly for the elderly who move to a different location.

By and large, the patterns of drinking and alcohol-related problems do not seem remarkably different for older and younger problem drinkers. Older alcoholics are less likely to get into fights and less likely to have work-associated problems. They may have more alcohol-related health problems, more accidents, more concern about income, and possibly more likelihood of binge drinking.

Information about elderly female alcoholics is sparse, but a recent report compares such men and women in their 60s. The women report more marital disruption than the men and that is consistent with other age group gender comparisons; martial disruption in this age group, however, is less likely to be divorce or separation for the women, of whom 51% were widowed (compared with 18% of the men). There is a striking difference in reported age at onset: more than a third of the women report onset in the last 10 years and only 4% of the men do. Another significant gender difference is heavy or problem drinking by a significant other; as occurs in all age groups' gender comparison, more women report the spouse as a heavy or problem drinker than do men. Also, true of all age group gender comparison is that women are more likely to drink at home and less likely than men to drink in public places. Effects of alcohol as reported by the women show more negative effects (e.g., feel miserable) than do the men, the men report significantly more often that they 'get along better with people' when drinking, and there are no gender differences in aggression as a result of drinking. A final gender comparison: women are significantly more likely to report dependence and tolerance in psychoactive drug use (e.g., minor tranquilizers) than are men. Again, this gender difference appears throughout the life course.

The Role of Ethnicity

An early study, conducted in an ER of a Florida hospital, gave some figures for admissions 60 and older: 3.5% were Hispanic elderly, 6.2% were black elderly, 20.3% were white elderly.

A study of aging and ethnicity, containing material from the United States General Accounting Office, 1992, shows the following: for the 65 and older groups, a third of Whites are defined as 'poor'; for Hispanics that proportion is 69%; for Blacks, 100%. Clearly older minority group members have benefited little from affirmative action programs designed to help people through school or business. Such programs have clearly helped younger African Americans (*New York Times*, June 24, 1995).

This relates to an interesting contrast within the Black–White comparison in relation to drinking: when low-income black men are compared with low-income white men, they report significantly more drinking consequences and drinking problems. When affluent black men are compared with affluent white men, the difference in drinking problems is diminished to insignificance. Comparisons of Black–White drinking problems must therefore include not only age and gender but income as well: Significant interactions have been observed of social class, race, drinking consequences, and total alcohol-related problems.

Researchers have reported a comparison of elderly alcoholic men in treatment. There were 142 white patients, mean age 64, and 27 black patients, mean age 62. Some interesting differences were found:

1. The black patients (although drawn from the same clinical sources) showed significantly less educational achievement, occupational status, income, and current employment status. This is the age group that has benefited little from recent affirmative action programs.
2. Compared on drinking behaviors and patterns, it appeared that the black alcoholics drank larger quantities, preferred high-alcohol-content beverages, and were significantly more likely to engage in drinking in public places.
3. The black alcoholics had used or abused drugs other than alcohol to a greater extent than reported by the white alcoholics; and though both groups were elderly, the black men reported earlier age introduction to and use of 'street' drugs. One may raise the question of availability of such drugs in the community.
4. Health consequences were reported more often by the black elderly alcoholics than the white and a regression model for health consequences showed that the variables of greatest relevance were educational achievement, lifetime daily drinking average, drinking in public, and dependence on drugs other than alcohol.

An array of social, community, and institutional consequences of the heavy drinking was reviewed, and on the job and with the police, the black men reported more trouble; they also reported more rejection from friends. A regression model for social, community, and institutional consequences found the variables of greatest relevance to be educational achievement, lifetime daily drinking average, drinking in public, and race.

The triple stigma of being black, elderly, and alcoholic presents formidable challenges in finding these people, motivating them, and working at rehabilitation.

Questions have been raised about the prevalence of heavy drinking or alcohol abuse in retirement communities. There are no controlled studies (e.g., a comparison of the drinking of retirees who move to retirement communities and those who stay in their own homes). It may very well be that moving to a different state, an excess of free time, and social facilitation may play a role for some elderly drinking, but that has yet to be demonstrated.

A half century ago, there was much research interest in the chronic drunkenness offender. A disproportionately high percentage of arrests for drunkenness and public intoxication was noted among men 60 years of age and older. Two major changes have occurred in what used to be called skid row: first, a Supreme Court decision which permits arrests for antisocial behavior (e.g., disorderly conduct) but not for intoxication *per se*; second, the character and locale of the homeless population has changed. The homeless population now includes many former mental hospital patients and may be found in many different locales (airports, train terminals, etc.). In some inner cities, there has also been a drift of African Americans and Native Americans toward the old skid row neighborhoods. At present, it is more likely that the elderly homeless alcoholic will be referred to a detoxification center, but little progress has been made in measures to help the rehabilitation process.

The question of whether those older persons who live alone are more likely to be heavy drinkers is not resolved. Older women are more likely to live alone than older men, and the rate of problem drinking is considerably lower for those women than for older men. There are certainly older alcoholics who live alone, but a review of their histories may show a lifetime of alcohol abuse and an alienation of family; living alone is therefore a consequence rather than a cause of the abusive drinking. Study of this question must take into consideration the gerontological fact of differences in subgroups of the US population: the elderly person living with family members is more characteristic of some ethnic groups than others and is clearly related to socioeconomic status, family location and relationships, state of health, marital status, and so on.

Treatment and Prevention

A great deal has been written about the elderly alcohol abuser, but there are really three major questions: First, how do older alcohol abusers get into treatment? Second, what kinds of problems in diagnosis and management do such patients present and are there unique patterns in their clinical histories? Third, having made the diagnosis of alcohol abuse with or without accompanying comorbid symptoms, what are the most effective ways to proceed in treatment?

Older patients may be referred or brought to a substance abuse facility by family members, ER personnel, policemen, physicians, social agencies, or law enforcement agencies. A major basis for referral is the presence of alcohol-related health problems. One Canadian program notes that clients rarely enter a program to deal with their addiction but rather for help with other problems (e.g., accommodations, health care and the like).

The manner in which an elderly patient enters a substance abuse facility is very much a matter of his or her social networks and support systems. It may be concerned family or friends who bring in a client, but it is at least as often police or medical authorities bringing a patient who has long since destroyed family contacts.

There is, however, the question of maintaining contact. We have been studying elderly persons, diagnosable by the *Diagnostic and Statistical Manual IV* (*DSM-IV*) as alcoholics or alcohol abusers. The subjects came from hospitals, Alcoholics Anonymous, community advertising, general hospital wards, senior citizen housing, and community centers. Interviews were conducted with 104 unremitted alcoholic men currently in treatment and with 67 men, diagnosable as alcoholic but not in treatment. The groups were demographically similar and differed only in the fact that significantly more of the not-in-treatment group was retired. The most striking differences between the two groups of men occur when they are asked for self-description about their drinking (e.g., asked if they could stop drinking without a struggle after one or two drinks). Fifty-four percent of the men in treatment answered no compared with 24% of the not-in-treatment group. Examined for the nine symptomatic behaviors necessary for a diagnosis of alcohol abuse or alcoholism (*DSM-IV*), the men in treatment responded positively significantly more often than the not-in-treatment men. Drinking patterns were quite similar, but the men in treatment reported significantly more alcohol-related health problems. Finally, there was a striking difference in help-seeking behavior. In summary, older alcoholic men in treatment show greater severity of alcoholism (*DSM-IV*) and are more likely to self-describe as problem drinkers or alcoholics. They are more likely to engage in help-seeking behaviors that may include the use of the ER in a local hospital, a chapter of the Alcoholics Anonymous, seeking out a friend or relative or a physician, and so forth.

Finally, are there more effective ways of working with the elderly alcohol-dependent person? One question that has arisen is the efficacy of elder-specific

programs (e.g., group therapy with a group made up of elderly patients). Reports are mixed, but as with other special populations, if feasible, it is probably wise to offer an elder-specific group. Working with elderly patients is not remarkably different from working with other groups, but the counselor must be patient because the tempo may be slower. A nonconfrontational therapist who encourages reminiscence as well as discussion about current problems is recommended.

A note on prevention: because we are not really on firm ground in describing the antecedents or etiology of alcohol problems among the elderly, effective prevention programs must wait upon more knowledge of etiology. Although there is disagreement among researchers about the role of stress in facilitating heavy or problem drinking among the elderly, it is wise to develop aid programs for those who are recently widowed, recently retired, or even recently removed from one residence to another.

Allergic Reactivity in the Elderly

T O Anderson, University of Illinois, Illinois, IL, USA

Glossary

B Lymphocytes – Cells of the lymphocyte lineage that migrate from the bone marrow, mature in the gut-associated lymphoid tissue (GALT), and are subsequently responsible for synthesis and release of specific antibody immunoglobulins. These soluble proteins are structurally configured to react with the foreign antigen that incites their production. The immunoglobulins constitute the humoral arm of the immune response.

Immunoglobulins (Ig) – The soluble protein products secreted by activated, B cell-derived plasma cells that carry combining sites specifically reactive with the inducing antigen or allergen. Immunoglobulins are produced in five variant forms designated IgM, IgD, IgA, IgG, and IgE. Antigen or allergen-Ig union presages foreign antigen removal and destruction by a variety of mechanisms.

Interleukins (IL) – A general term for cytokines, a special class of soluble leukocyte products that serve important intercellular communication and regulatory roles and thus profoundly influence the character of the immune response.

Isotype Switch – The mechanism by which B cells 'switch' from producing immunoglobulin M (IgM) to produce IgE, IgG, or IgA molecules that continue

to carry the structural (epitope) regions reactive with the inciting allergen, but combine it with a different Fc segment. This switch changes the nature of the secondary reaction characteristics of the Ig.

T Lymphocytes – Cells of the lymphocyte lineage that migrate from the bone marrow to the thymus gland where they mature and are programmed to subsequently carry out one of a number of vital effector or regulatory roles in the operation of the immune system. These roles include functions such as controlling B cell activation or effecting specific delayed hypersensitivity responses.

Introduction

The immune system has evolved to protect against infections and to eliminate any other foreign material from the body. Ordinarily it accomplishes this without causing significant physiologic or structural damage to tissues of the individual host. When an infection is persistent, however, or when the foreign material is difficult to eliminate, the stimulus to the immune system is intensified. Also, if the individual is genetically prone to respond immunologically to even very low concentrations of foreign material such as inhaled plant pollen, an allergic or hypersensitivity state develops. These intensifications of the usual immune reactions lead to associated or concomitant forms of tissue damage in the host that are manifest clinically. It is our purpose here to look at such reactions in the elderly and how they are influenced by the aging process.

Background

In immunologic parlance, allergies or hypersensitivity states are disorders in which immune responses, sometimes directed against otherwise harmless substances, result in inflammation and consequent tissue damage. Common clinical examples of such unfortunate hypersensitivities include hay fever, allergic asthma, hives, eczema, anaphylactic reactions to insect stings, serum sickness, farmer's lung, and contact dermatitis.

Under the right circumstances, hypersensitivity reactions can develop in anyone, but there are some individuals in whom there appears to be a genetic predisposition to develop allergic responses – particularly of the immediate type. Such persons are said to be atopic. Although classic allergic reactions most often first appear in the young, they can occur at any age and although they may persist for years, they tend to wane or even disappear in the elderly. The involution of allergic reactivity in particular and immune responses in general in the aged is our focus.

Immunological reactions are ordinarily protective and are designed to prevent or to overcome infection by viruses, bacteria, fungi, or other micro-organisms. When the system is operating vigorously, it may also play a key role in suppressing the formation and growth of tumors. Thus, an intact immune system is crucial for our survival in a biologically hostile and competitive world (*see* Immune System).

It is an old clinical observation that the elderly often die of infections or of tumors that they are simply unable to overcome. In the era prior to the advent of antibiotics, pneumococcal pneumonia used to be called 'the old man's friend,' because it was so often the gentle terminal event in an otherwise long and relatively healthy life. An elderly patient with an extensive multilobar pneumonia would often develop only a modest fever of perhaps 100°F to 101°F, an elevation of the white blood count of 8000 to 10 000 with a slight 'left shift,' (i.e. the appearance of a few immature white cells in the blood). Clinically, the patient would not seem severely ill. Shortly thereafter he would die. Give the same extent of pneumonia, a young adult would develop a fever of 105°F to 106°F, a white blood count elevation of 35 000, and show many young band cells in the blood. He would feel very ill, but he would live. It was apparent that the intensity, the vigor of the systemic responses to infection in the young adult and in the elderly individual were dramatically different. Clearly, very old people did not handle infections well. The suspicion arose decades ago that this might be because the capacity to mount an immune response becomes progressively impaired as the individual ages. And indeed it does.

To understand not only why resistance to infection is impaired, but why hypersensitivity or allergic responses involute in the aged, it is necessary to describe how hypersensitivity states develop in the first place. To this end, it may be useful to review some basic features and to list the major reactive elements of the immune system.

Basic Elements and Functions of the Immune System

Immunologic responses exhibit two singular characteristics. The first of these is that the reactions are specific (i.e., a given immunologic reaction is directed only against the foreign antigen or allergen that elicited the response – although there may be some cross-reaction with allergens that are structurally related). The second is that the system is able to distinguish self from non-self. Except under rare circumstances,

such as those that obtain in autoimmune disease, the immune system simply does not react against the body's own tissues. This makes good biologic sense, because the central objective for the immune reaction is to remove from the body macromolecules and life forms that are foreign to its own makeup and are potentially harmful.

Immunological specificity resides in the receptors or recognition structures on the surface of T and B lymphocytes. The capacity to discriminate self from non-self is largely a function of the T lymphocytes. As T cells from the bone marrow pass through the thymus gland, those with receptors having a strong affinity for self-antigens and hence might react with the body's own tissues are eliminated. Others are restricted to react to foreign antigens only in conjunction with self-defining structures called the class I or class II major histocompatibility complexes (MHCs). Thymic screening and programming of T lymphocytes is a complex and incompletely understood process, but it is central to direction and control of immune responses throughout the life of the individual.

The gut-associated lymphoid tissue (GALT) is probably to B cells what the thymus is to T cells in terms of the environment it provides for B cell maturation.

Although an intact, fully functional immune system is generally very adept at discriminating self from non-self, it does not readily distinguish between foreign substances that are potentially harmful and those that are chemically or biologically innocuous. To illustrate, in allergy-prone individuals the immune system may not only react to, neutralize, and remove life-threatening bacterial toxins in the course of an infection (an eminently useful response), but may also react vigorously to inhaled, harmless animal dander protein or to plant pollen. This latter kind of immunologic reaction may result in severe allergic rhinitis or asthma – a biologic response that is misdirected, probably protective, and carries with it more harm than good.

The varied and complex functions of the immune system are subserved by a number of cellular elements and by many soluble biologically active effector macromolecules. These include enzymes and other regulatory proteins that possess stimulatory and inhibitory properties. Chief among the cellular components are T and B lymphocytes, macrophages, polymorphonuclear leukocytes, mast cells, and basophils. Among the soluble, secreted regulatory or effector molecules are the macrophage or lymphocyte-derived cytokines or interleukins (ILs) and the proteins of the serum complement cascade.

T lymphocytes and their subsets of CD4 or T helper and CD8 or T suppressor cells are extraordinarily versatile. They serve vital regulatory roles by influencing B cell functions as well as themselves effecting cell-mediated cytotoxicity and delayed hypersensitivity responses. These latter two reactions are particularly important in destroying parasites, fungi, and intracellular bacteria as well as virus-infected cells and tumor cells. B lymphocytes (and their derivative plasma cells) are responsible for antibody-mediated immune reactions.

B cells produce and release soluble antibody proteins that are tailored to the tasks of neutralizing toxins and extracellular viruses as well as facilitating phagocytosis (cellular engulfment) and destruction of bacteria. Antibodies are structurally configured to conform to and react with the surface structure of the foreign allergen or antigen. A useful analogy often used is that antibodies fit the antigen much like a key fits a lock. Antibodies are made in five immunoglobulin (Ig) isotypes, IgM, IgG, IgA, IgD, and IgE. These proteins are alike in that they react specifically with the antigen or allergen that elicited their production, but differ in their secondary properties, properties that are manifest after they combine with the inciting antigen. The structures and special reaction characteristics of the immunoglobulins are shown schematically in **Figure 1**.

Most B cells initially carry and manufacture IgM antibodies. In the face of many kinds of allergen exposure or under conditions of persistent antigenic stimulation, B cells may undergo a process called class switching. They 'switch' from making IgM antibodies to making IgG or IgA or IgE antibodies of the same antigenic or allergenic specificity. The class switch is induced and controlled by T helper (CD4) cells through their formation and release of certain of the ILs or cytokines. Class switching is achieved by retention of the Fab segment carrying the site specifically reactive with the inciting allergen, eliminating the original Fc segment and replacing it with the Fc portion of the new isotype. This results in the production of antibodies whose secondary reaction characteristics, manifest after combination with the inciting allergen, are different from those of the original IgM isotype.

As described below, B cells are ordinarily activated and induced to form antibodies by T cells that have themselves been activated by prior contact with processed foreign antigen or allergen. Thus this process of B cell activation is termed T cell dependent. On rare occasions B cells may encounter what are termed thymus or T cell-independent antigens. These include lectins, polymeric proteins, and a good number of polysaccharides with structures that are able to activate B cells directly by cross-linking B cell surface receptors with little or no T cell help.

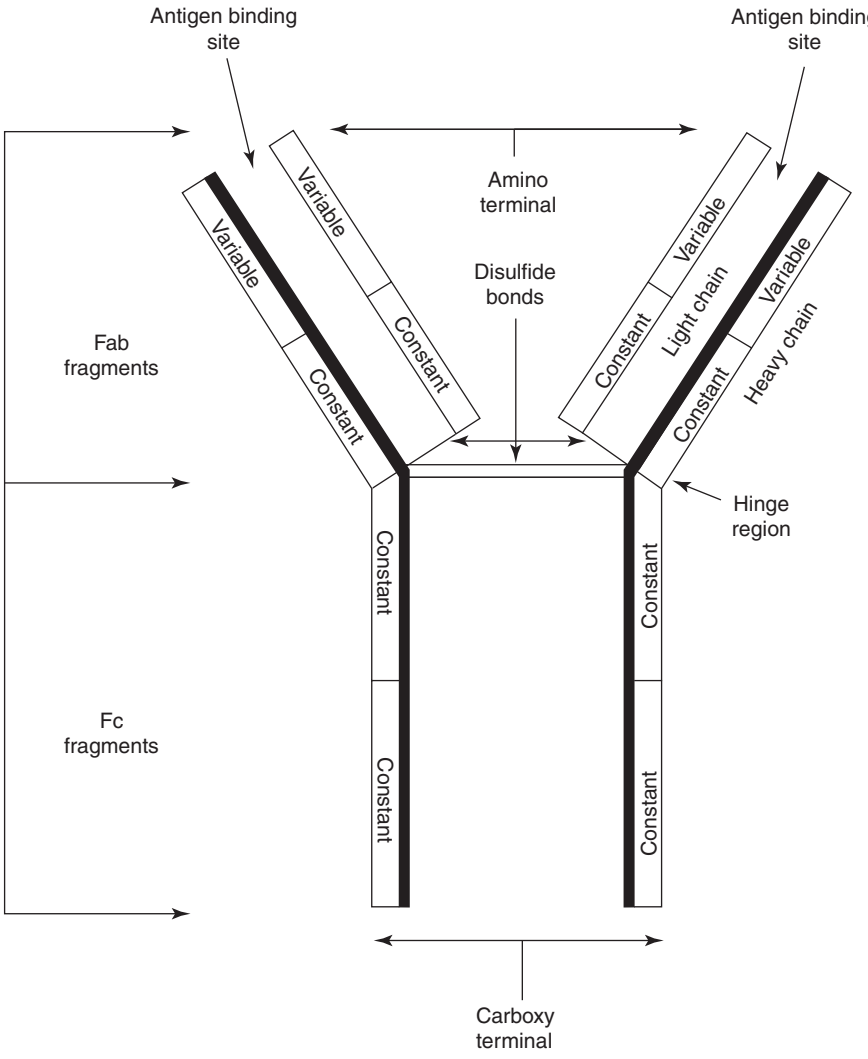

Figure 1 Basic structure of immunoglobulin antibody molecules. Variable regions of the light and the heavy chains constitute the epitope or antigen-combining site. Constant regions of the heavy chain in the Fc fragment hold structures responsible for the secondary reaction attributes of the particular antibody isotype (i.e., complement fixation and binding to cell surface receptors). Immunoglobulins differ in whether they are monomeric, dimeric, or pentameric expressions of this basic structure and in the differing chain lengths and nature of the receptors of the Fc segment of the heavy chains.

T-independent response produces mostly IgM, confirming that T helper cell lymphokines are required for class switching.

Immunologically mediated defense and hypersensitivity reactions also depend upon macrophages, phagocytic polymorphonuclear leukocytes, and metabolically active mast cells and basophils. The latter two cell types manufacture, store, and release a host of effector molecules. Acting in concert with the proteins of the serum complement cascade, the ILs, and other regulatory cytokines, these elements comprise a very intricate system that underpins immunologically triggered and directed inflammatory responses. Without these reactive capacities, humans could not resist infections or tumors and could not long survive.

Response to Allergens: Sensitization

How then do allergic or hypersensitivity states develop? The series of steps that follow and the attendant explanations identify the mechanisms that operate in the genesis and expression of the four classic hypersensitivity states as classified by Gell and Coombs. Sensitization to an airborne pollen will serve to illustrate the typical reaction sequence.

Pollen grains are breathed in through the nose and impinge on the nasal mucous membrane. The pollen is partially solubilized and a major sensitizing antigen is absorbed into the underlying tissues. Here the pollen antigen or allergen encounters and is engulfed by a macrophage. Within this remarkable cell, the allergen is dissembled into polypeptide fragments.

In association with a structure termed the class II major histocompatibility complex (MHC-II), these fragments are externalized and presented on the surface of the macrophage. By the time this allergen processing is complete, the macrophage has most likely migrated to the environment of a regional lymph node.

Next, the macrophage displaying the allergen fragment or MHC-II complex is perused by a series of helper T cells (CD4 cells). Then a particular T helper cell bearing a T cell receptor (TCR) with a structural configuration complementary to that of the pollen fragment locates and locks on to the pollen MHC-II complex through its receptor. At some point in this process, the pollen fragment is confirmed as foreign, and the T cell is activated.

This antigen-processing activity just described as a function of macrophages can also be carried out by B cells – particularly those whose surface receptors fit the foreign antigen or allergen especially well. The B cell may internalize the antigen, process it, couple it with the MHC-II complex, and present it to the appropriate T helper cell, much as does the macrophage.

The activated T helper cell undergoes clonal proliferation and differentiation. The derivative T helper cells produce and release a number of soluble substances called lymphokines, which activate those B cells that carry surface receptors akin to those on the T cell (i.e., those that are also structurally complementary and specifically reactive with the allergen). In addition, some of the activated T helper cells differentiate into effector cells that are destined to bring about delayed hypersensitivity (DH) reactions on subsequent contact with the inciting allergen (below). Some become memory T cells, cells poised for rapid mass reaction if they later again encounter the same antigen. This is termed a secondary or recall response and is more rapid than the initial or primary response.

The activated B cells in turn proliferate and differentiate into plasma cells that produce and excrete large amounts of antibody specifically reactive with the allergen. Almost invariably, several lineages of plasma cells develop, each of which manufactures and releases antibodies of differing isotypes. Thus stimulation by a single allergen, such as an airborne pollen, results in the production of IgG as well as IgE antibodies and also in the induction of a condition of delayed hypersensitivity mediated by special T helper cells.

There is one other variant of the allergic response that needs to be mentioned. Rarely, when some individuals are treated with a drug such as an antibiotic like penicillin, the drug or some metabolite of it may bind to the surface membrane of a cell (e.g., a red cell). In this attached configuration, the drug may prompt an antibody response with its own structure acting as the "foreign" determinant. The resulting antibodies will subsequently seek out and combine with any of the individual's red cells carrying the penicillin or penicillin metabolite. The combination between the antibody and penicillin determinant on the red cell may activate the complement system and the red cell may be lysed or ruptured.

Manifestations of Hypersensitivity States

Once initial contacts with an allergen have occurred and the foregoing reactions have ensued, the individual is said to have been 'sensitized.' The diversity of these responses to initial stimulation with a single allergen accounts for the different hypersensitivity reactions that result on subsequent contact with the allergen. These four kinds of reactions may be described as follows.

Type I or the immediate type of hypersensitivity, mediated by IgE antibody, is what most people recognize as classic allergies. IgE antibodies, formed after initial sensitizing contact with the pollen or other allergen, attach themselves by their Fc piece to the surface of submucosal mast cells and circulating basophils. When the pollen or other sensitizing allergen again gains access to the tissues, it reacts with the mast cell-bound IgE antibodies, cross-linking them and triggering the degranulation of the cells. This degranulation releases a series of biologically active mediators into the tissues, including histamine, leucotrienes, prostaglandins, and eosinophil chemotactic factor. These compounds cause an acute inflammatory response in the upper and/or the lower airways with vasodilation, itching, local tissue swelling, increased mucous gland secretion, smooth muscle contraction and eosinophilic infiltration. This is the mechanism behind hay fever or allergic rhinitis, allergic asthma, and the life-threatening anaphylactic reactions to bee or wasp stings or to penicillin administration in penicillin-allergic individuals.

Type II or cytotoxic hypersensitivity may be expressed in three forms. Each of the reaction sequences requires antibody. If the sensitizing foreign material is a drug or a drug metabolite that has been incorporated into a cell membrane, perhaps the membrane of a red blood cell, antibodies (most often of the IgG isotype) attach to the bound drug and attract and activate the serum complement system. This results in lysis of the red cells. If this process is sufficiently widespread, it can produce a serious hemolytic anemia. Alternatively, antibody attached to a membrane-fixed determinant may attract and

secondarily bind through its Fc receptor to what are termed natural killer cells (NK cells). These cells can, by a process not yet completely understood, also bring about lysis of the antibody-coated target cell. Finally, if the allergen-antibody-coated cell is not too large, it may be opsonized and destroyed by engulfment by a phagocytic cell, which also hooks on through a receptor on the Fc fragment of the antibody. It is worth noting that this same type of hypersensitivity reaction in its three variant forms is thought to operate in destroying tissue in a number of autoimmune states. In autoimmune diseases, the membrane-bound target is not a foreign drug or allergen, but is presumably a normal cell constituent mistakenly viewed as foreign by the immune system.

Type III or immune complex hypersensitivity is the immune reaction responsible for a number of clinical conditions, including hypersensitivity lung diseases, serum sickness, and immune complex kidney disease. Antigen exposure in this disorder is usually intense and protracted. This leads to a quantitatively impressive antibody response because the sensitizing antigen or allergen is often cleared from the body with difficulty. The allergen and the antibodies combine and then fix complement, which results in an inflammatory reaction. Vascular walls are damaged in the process and their permeability is increased. As a result of this initial damage, the deposition of the immune complexes in the vascular walls and tissues may then worsen and perpetuate the inflammatory cycle by attracting polymorphonuclear leukocytes that further accentuate local tissue damage. When such complexes deposit in renal glomeruli, kidney disease results. The presence of immune complexes in the circulation is not an uncommon event. Ordinarily they are rapidly removed by circulating red cells (picked up by red blood cell complement receptor) or by phagocytosis. It is when the complexes are formed in the presence of antigen excess that they deposit in tissues and tissue damage ensues.

The mechanism of Type IV hypersensitivity (also termed tuberculin, contact, or delayed hypersensitivity) is antibody independent and is mediated by T cells alone. The very descriptive term *delayed* hypersensitivity is employed because the reaction becomes manifest and reaches its peak only after about 48 hours following reexposure to the sensitizing antigen. A subset of T cells of the CD4 type especially programmed to secrete cytokines IL2 and interferon (IFN) gamma appear to be responsible for precipitating the Type IV inflammatory reaction and the consequent tissue damage. If it is sufficiently intense, a local delayed hypersensitivity reaction can result in vascular occlusion and tissue necrosis. Delayed hypersensitivity underlies the disease contact dermatitis, as in the reaction to poison ivy, and under such circumstances is clearly deleterious. Paradoxically, as noted earlier, this same hypersensitivity state is an absolutely crucial feature of the complex immune response, which serves to contain virus infections and to control mycotic and intracellular microbial infections such as tuberculosis. This is also the reaction responsible for the diagnostically useful tuberculin skin test.

Involution of Hypersensitivity States with Aging

Again, the vigor of immune responses, including allergic or hypersensitivity reactions, diminishes in the elderly. The nature of the impairment has been studied extensively over the past two decades, and we now know some of the bases for immunologic senescence. These changes are best understood in light of the mechanisms producing the hypersensitivity reactions just described.

Although there are some variations in published reports, the overall number of immunocompetent cells and their various subsets does not appear to change much with advancing age except very near the end of the individual's life. This phenomenon has been well documented in the Baltimore Longitudinal Study of Aging. In the majority of the subjects, the absolute peripheral blood lymphocyte count remained within the normal range into advanced age. However, a marked lymphopenia was found in men in the 3 years preceding their deaths. Although in most studies in humans, B cell and macrophage numbers appear to be maintained, and the total number of T cells may remain nearly constant, there seems to be an increase in the proportion of immature T cells in the elderly.

This release of immature T cells into the peripheral blood of the elderly may reflect changes in the thymus, the organ that consistently shows the most dramatic changes as humans grow older. This key structure, so important in the development and management of T cell activity, begins to involute at puberty and continues to do so until middle age. After the age of 50, the thymus contains less than 10% of its previous immunologically active cell mass – most of which is replaced by adipose tissue. As this process progresses, there is a concomitant decline in the synthesis and release of regulatory thymic hormones. These hormones are no longer even detectable after the age of 60 years. Some level of thymic activity, however imperfect, is probably maintained in the elderly because T precursor cells continue to leave the bone marrow and home in on the thymus. It appears that the positive and negative

selection, the maturation, and programming of the T cells in the thymic environment is impaired. This also may be a key factor that contributes to the increasing autoimmune activity seen in the aged.

Given the extensive involutional changes in the thymus, it is perhaps not surprising that the T cells more than B cells are the most directly and profoundly affected in the aging process. The extant, long-lived peripheral T cell population in the blood, the lymph nodes, and the spleen may also develop functional deficits over time. These are manifest in important ways. Cell-mediated immunity and delayed hypersensitivity, both manifestations of direct T cell effector activity, may be seriously compromised. It has been demonstrated that a group of individuals over 80 who became non-reactive or hyporesponsive in tests for delayed hypersensitivity showed a higher mortality over a 2-year period than did a comparable group who were not hyporesponsive. The loss of delayed hypersensitivity and impairment of specifically directed cytotoxic cell-mediated immunity opens the door for reactivation of latent viral, mycotic, or tubercular infections.

Furthermore, perhaps reflecting the repeated immunologic stimulation that accrues over the years, the elderly show increasing numbers of T cells committed to memory function.

T cells from the aged when placed in culture show a marked decrease in their ability to proliferate when exposed to phytohemagglutin (PHA) or concanavalin A, two potent mitogens (compounds that stimulate cell division). Among old T cells, only about half are able to respond to such stimulation. Furthermore, when they do respond old T cells show an impairment in calcium uptake, a decrease in enzyme induction, a decrease in protein synthesis, and a decrease in nuclear response to intracellular signals.

All these deficits in the efficiency of intracellular processes diminish the replicative capacity of the T cells. They also substantially decrease the T cell's ability to form and release those soluble regulatory substances so crucial to the T cell role in arousing and controlling the overall immune response.

In this regard, the decline in IL2 production has been extensively studied and the mechanism of the failure defined in some detail. Deficiency in IL2 production has broad ramifications. It affects not only T cells, but B cells and antibody production as well. Deficits in T cell synthesis and release of other ILs, of B cell differentiation factor, and of B cell growth factor decreases the effectiveness of intercellular communication and thus of immunoregulation.

Witness to this failure in immunoregulation in the aged is the decrease in B cell capacity to mount a vigorous specific antibody response to T cell-dependent allergenic or antigenic stimulation. It appears that the B cell response to T cell-independent antigens may be less compromised. The levels of such natural antibodies as isoagglutinins against blood group antigens also decline in the aged. Oddly, other elements of the B cell population show increases in the production of autoantibodies. Fortunately, although old people show an increase in autoantibody activity, they do not often show a concomitant increase in autoimmune diseases.

Defects in regulatory function are also manifest in the proliferation of single B cell lineages in the elderly, which synthesize and release large amounts of monoclonal 'antibody' of obscure specificity. These latter immunoglobulins are produced in such quantity that they are manifest as 'M' peaks on serum electrophoresis. They appear to be produced by a B cell clone that has escaped normal T cell suppressor or other dampening regulatory influences. Among 90-year-olds, as many as 15 to 20% may show M peaks. Such monoclonal 'gammopathies' not infrequently presage the onset of fatal lymphoproliferative malignancies in the elderly.

Macrophages seem to withstand the aging process relatively well, but are not entirely spared. Their number seems not to diminish much with time, and they appear to retain phagocytic and antigen processing and presentation processes fairly well. Importantly, however, their capacity to produce ILs and other soluble factors may be impaired as the individual ages.

It appears to be relatively well established that classic allergic or immediate (Type I) hypersensitivity reactions are far less frequent in old age. The reasons appear to be several. Serum IgE concentrations are significantly lower in the elderly than in the young, and the differences are most marked in males. The specific IgE response to administration of diphtheria toxoid has been found to be lower in the aged, and the intensity of the immediate skin test 'weal and flare' reaction is reduced in old people. It is suggested that these findings are not only because of a decrease in the ability to make IgE, but are also a reflection of impaired mast cell function.

Some particularly elegant work has shown a decrease in the production and the response to IL4, the cytokine that is key to controlling the synthesis and release of IgE. As previously noted, this Ig isotype is responsible for immediate hypersensitivity reactions or classic allergies. The impressive decline in IgE explains the disappearance or the diminished intensity of allergic rhinitis and allergic asthma in patients who are up in years. Severe IgE-mediated reactions such as anaphylaxis can occur in the elderly, but they

are rare. The involution of the atopic state ranks among the few comforts of growing older.

Serious impairment of immune responses including those in the realm of allergic or hypersensitivity states carries ominous portent. Thus, assessment of the condition of the immune system in the elderly can provide important prognostic insights.

Andropause

S M Harman, Kronos Longevity Research Institute, Phoenix, AZ, USA

Glossary

Anabolic – Tending to build up new tissue components and favoring growth and repair.

Dihydrotestosterone – A potent androgen made from metabolism of testosterone by desaturation (deletion of two hydrogens) of the A ring.

Estradiol – Main female sex steroid hormone that mediates breast and feminine body habitus development, supports female reproductive function, and helps sustain bone mass.

Gonadotropin – Protein hormone produced by the pituitary gland that regulates testis and ovarian function.

Receptor – Protein to which a hormone binds specifically and that mediates effects of hormone at cellular level.

Steroid – Fat-soluble molecule derived from cholesterol having four rings, three of six carbons and one of five carbons.

Testosterone – Main male sex steroid hormone that mediates masculinization of fetus and male puberty, and sustains male sexual function and body habitus.

Introduction

The major male sex steroid hormone, testosterone (T), is synthesized from cholesterol and secreted mainly by the Leydig (interstitial) cells of the testes in response to pituitary luteinizing hormone (LH). LH, a large glycoprotein hormone, is, in turn, produced in response to neurally timed episodic pulses of gonadotropin-releasing hormone (GnRH), a decapeptide secreted by neurons in the hypothalamus, which reaches the pituitary via a portal venous network. GnRH and LH secretion are controlled by a feedback system in which T and its aromatization product estradiol inhibit hypothalamic and pituitary secretory activity. T circulates about 40% bound to sex hormone-binding globulin (SHBG). Of the fraction of T not bound to SHBG, called the bioavailable T, most is loosely bound to serum albumin, leaving only 1–2% dissolved in plasma as free T. T acts mainly via the androgen receptor (AR), which participates in a nuclear receptor complex and stimulates or inhibits activity of specific genes by binding to upstream androgen regulatory sequences. In many androgen target cells, T is converted to dihydrotestosterone (DHT) by the enzyme 5α-reductase. DHT is a more potent androgen than T, having a higher binding affinity for the AR. DHT also circulates partially bound to SHBG, usually at about 10% of the concentration of T. In addition to stimulating maturation of male genitalia, body habitus, and hair patterns at puberty and maintaining male libido, T has important lifelong effects on body composition, especially skeletal muscle mass and fat distribution, bone metabolism, cognition, and affect.

Extensive clinical research has been conducted investigating whether a decline in male hormones with age (andropause) occurs in men. Yet the questions of the extent to which T decreases as a concomitant of the normal aging process and, more important, whether such decreases represent functional male hypogonadism remain open. Critical issues bearing on the advisability (or inadvisability) of T replacement in elderly men have not been resolved and require further investigation. The key questions to be answered in order for physicians to make appropriate clinical decisions are the following:

- Does T decrease with age in men and, if so, are levels consistent with hypogonadism in significant numbers of older men?
- To what extent are changes in T levels clinically significant?
- Are typical aging changes in physiology, body composition, and function consistent with hypogonadism?
- Do typical age-related changes correlate with endogenous androgen levels?
- Are there potential benefits from treating older men with T alone or in combination with other hormones?
- What serious adverse effects occur with androgen replacement in elderly men?

These questions have not been answered satisfactorily. However, some research results suggest that T replacement may be useful in a significant number of older men.

Is There a Decrease in T Levels with Age?

A few initial cross-sectional studies of T levels in men of various ages failed to detect significant decreases in older men. However, in the majority of cross-sectional investigations declines in circulating androgens with age have been observed (e.g., **Figure 1A**). In addition, SHBG levels appear to increase with age. Thus, for the same concentration of total serum T, the level of free or bioavailable T tends to be lower in old men than in young men, and the age-related decrease in free or bioavailable T is more pronounced than that for total T (**Figure 1B**). In addition, longitudinal studies have confirmed progressive linear reductions at fairly constant rates of about 1% per year for total T and 1–2% per year for non-SHBG-bound T with aging in healthy men, beginning by age 30. This change has been well defined in the Baltimore Longitudinal Study on Aging (BLSA) population and is shown in **Figures 2A** and **2B**. Estimates of the frequency with which T concentrations reach hypogonadal levels (i.e., two standard deviations below the mean for young men) in men of different ages vary from 30–40% in men over 65 to as high as 70% in men in their 80s. These estimates suggest that millions of elderly men have hypogonadal serum T levels as conventionally defined. This condition has been referred to as partial androgen deficiency of aging men (PADAM). The extent to which such men might benefit from hormone replacement is an extremely important, but as yet unanswered, question.

Is the Lower T in Aging Men Clinically Significant?

In apparently healthy men, there are significant age-related decreases in lean body mass and bone density. These changes in body composition are accompanied by diminished strength and VO_{2max} (fitness) and are caused in part by muscle loss (sarcopenia). Negative calcium balance and loss of bone mineral leading to

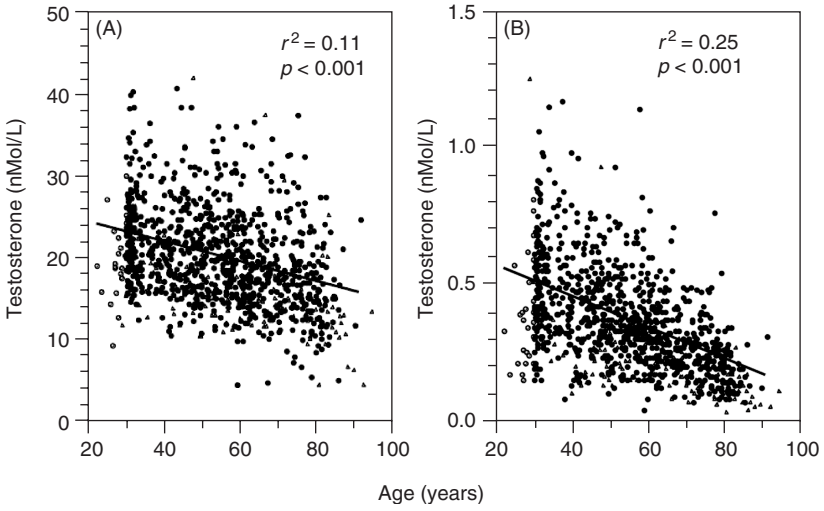

Figure 1 Effects of age on serum T (A), free T index (B) in men in the Baltimore Study on Aging (BLSA). Individual data points from the earliest available (usually first) visits during 1963–94 are shown as filled circles and the additional set of 120 serum samples from later visits (1995–98) are plotted as filled triangles. Total T concentrations and free T index values decreased linearly with increasing age. Reproduced from Harman SM, Metter EJ, Tobin JD, *et al.* (2001) Longitudinal effects of aging on serum total and free testosterone levels in healthy men. Baltimore Longitudinal Study of Aging. *Journal of Clinical Endocrinology and Metabolism* 86(2): 724–731.

osteoporosis is a problem for men as well as women. Although osteoporotic fractures are about one-third as frequent at any age in men as in women, hip fractures are more likely to be fatal in men. In addition, total and central abdominal fat increases with age. Changes in fat volume and distribution impair insulin sensitivity so that aging leads to higher fasting and postprandial blood sugar and increases the risk of type 2 diabetes. Deleterious alterations in LDL and HDL cholesterol and triglycerides also occur, producing greater risk of cardiovascular disease. Finally, normal aging is associated with reductions in total body protein synthesis, subtle impairments in cognition with deficits in memory and concentration, loss of libido, diminished sexual activity, and greater prevalence of erectile dysfunction.

Male hypogonadism resembles normal aging in certain particulars. In non-elderly hypogonadal (T < 250–300 ng/dl, depending on the laboratory) men, there are also reductions in lean body mass and muscle strength, increases in total and abdominal fat and impaired glucose tolerance, lower levels of sex drive and activity, and, in some studies, affective and cognitive dysfunction, including depression.

The associations suggest that the aging phenotype may be, in part, related to decreases in sex steroid hormones. If this hypothesis is correct, then the extent of the decreases in bioavailable T levels in elderly men should parallel and predict losses of lean body mass, bone density, muscle strength, cognitive function, and sexual capacity, as well as the increases in body fat and insulin resistance. Some studies in older men have demonstrated significant relationships between total or free T levels and lean body mass or muscle strength. Positive correlations have also been observed between bone mineral density and T levels, but these are weaker than those for estradiol. T concentrations have also been reported to be negatively correlated with body mass index (BMI) and percent body fat as well as with increased intra-abdominal fat and insulin resistance. Consistent with the preceding, there appears to be an overall greater risk of the metabolic syndrome (a combination of central obesity, hypertension, and insulin resistance) in older men with low T levels. Sexual activity and libido have been reported to be better in old men with higher T levels. Some studies have suggested a correlation between T and erectile function, but these data are weak. Finally, higher T levels have been correlated with improved performance on particular cognitive axes in some studies but not in others. Recently, it has been suggested that elderly men with low T levels may be at greater risk for Alzheimer's disease.

Are There Benefits of T Treatment in Older Men?

In studies of non-elderly hypogonadal men, T replacement has increased lean mass, muscle size, and strength while diminishing central obesity and insulin resistance. T may increase perfusion of brain regions involved in cognition and improve cognitive function in hypogonadal men. Results of investigations to determine whether T in physiological doses would have similar beneficial effects in elderly men

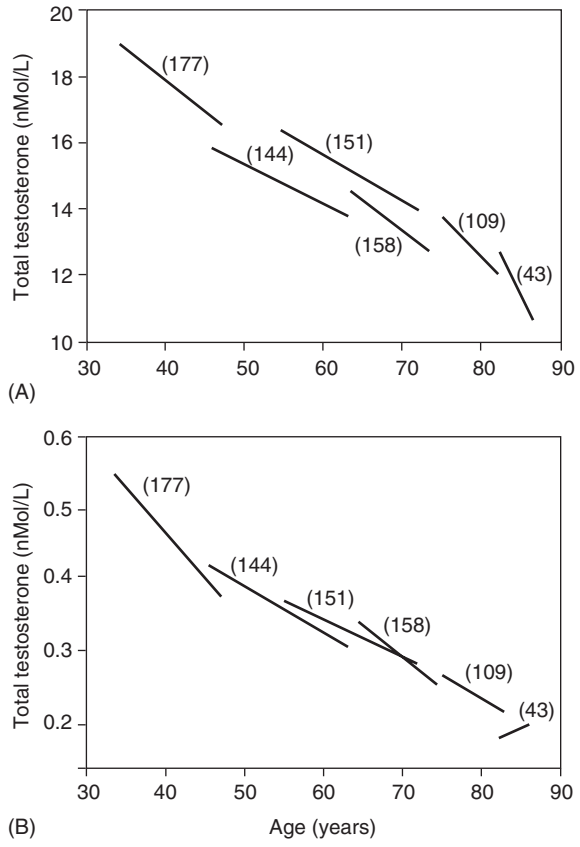

Figure 2 Longitudinal effects of aging on date-adjusted T (A) and free T index (B). Linear segment plots for total T and free T index vs. age are shown for men with T and SHBG values on at least two visits. Each linear segment has a slope equal to the mean of the individual longitudinal slopes in each decade, and is centered on the median age, for each cohort of men from the second to the ninth decade. Numbers in parentheses represent the number of men in each cohort. With the exception of free T index in the ninth decade, segments show significant downward progression at every age, with no significant change in slopes for T or free T index over the entire age range. Reproduced from Harman SM, Metter EJ, Tobin JD, *et al.* (2001) Longitudinal effects of aging on serum total and free testosterone levels in healthy men. Baltimore Longitudinal Study of Aging. *Journal of Clinical Endocrinology and Metabolism* 86(2): 724–731.

with PADAM have been inconsistent, perhaps due in part to the employment of varying androgen doses and routes of administration, varying durations of treatment, and differences in populations studied.

In 60- to 75-year-old men, graded doses of T during suppression of pituitary LH secretion with a GnRH analogue produced dose-related responses of lean mass, muscle strength, and fat mass resembling those observed in young men, suggesting that elderly men may respond to androgens similarly to the way younger men do. **Table 1** presents results of several studies of T treatment in older men. As shown, gains in lean body mass have tended to exceed those in muscle strength or VO_{2max}. Although treatment with T has been reported to decrease body fat in men over 65 and abdominal fat mass in middle-aged men with low to low-normal T levels, in one study 6 months of relatively low-dose T injections given to old men did not cause significant decreases in, or redistribution of, body fat.

Loss of bone mineral density (BMD) was not significantly improved in men over age 60 given T by scrotal patch with baseline low to low-normal T levels. However, loss of BMD was significantly ameliorated in this same study in men whose T levels at baseline were <200 ng/dl. Other studies of T effects on bone in older men have found that T treatment for 36 months prevented loss of BMD at the lumbar spine ($P<0.001$) and at the hip ($P\leqslant 0.02$), and that diminished bone loss occurred in the femur, but not in the lumbar spine.

Positive effects of T treatment on libido and of dihydrotestosterone treatment on erectile function have been reported in older men. In a study of cognition, scores on the Digit Symbol and Trailmaking B tests were slightly but not significantly better in T-treated than in placebo-treated men. Androgen treatment may improve cognitive and visual-spatial skills in elderly men with mild to moderate Alzheimer's disease. Finally, some evidence suggests that T may moderate depression in older men with low T levels.

The question of T interaction with other hormones was addressed in a study in which T was given to healthy men over 65 with low T and insulin-like growth factor-1 (IGF-1) levels for 6 months, alone or with human recombinant growth hormone (rhGH). The T plus GH combination produced greater increases in lean body mass and muscle strength and decreases in body fat than were seen with T alone. It may be the case that administration of T in older men with low GH levels, another endocrine concomitant of aging, may result in suboptimal responses.

What Are the Risks of T Treatment?

Potential benefits of T treatment in older men must be weighed against risks of adverse effects. In young hypogonadal men, physiological T replacement is low risk. In older men, risk–benefit ratios may be less advantageous. Minor adverse effects of T treatment include fluid retention, erythrocytosis, and sleep apnea, problems that may be more common in old men. Of greater concern are possible increases in atherosclerosis and greater risk of prostate cancer.

T treatment may lower HDL cholesterol and raise LDL cholesterol. Evidence indicates that excessive doses of anabolic steroids taken to build muscle mass may lead to premature coronary vascular disease (CVD). However, low T levels may also be associated

with greater CVD risk. For example, in a study by Muller *et al.*, free T levels in elderly men were directly related to rate of progression of common carotid artery intimal medial thickness, independent of cardiovascular risk factors. As noted previously, low T levels have also been associated with increased abdominal fat and insulin resistance and the metabolic syndrome. Finally, transdermal or injected T in men with low T levels may improve lipid pattern, reduce abdominal fat, decrease insulin resistance, lower triglycerides, and lead to more beneficial cardiac risk profile overall. Nonetheless, the net influence of exogenous T on atherosclerosis progression or incidence of CVD remains unknown.

The most worrisome issues with regard to T in older men are potential adverse effects on prostate cancer risk and benign prostatic hyperplasia (BPH). In a study in which elderly men were treated with T for 3 years, one treated group took T alone and the other T plus finasteride (F), a 5α-reductase inhibitor, given to block DHT production. PSA increased significantly in the T group, and prostate volume changes were smaller in the T plus F group. Effects of T on bone and muscle were similar in men treated with T or T plus F.

Novel pharmaceuticals called selective androgen receptor modulators (SARMs), which function as partial androgenic agonist/antagonists in prostate and seminal vesicle but full anabolic agonists in muscle and bone, may improve male anabolism but avoid potential effects on prostate disease. With regard to this putative risk, it is of note that most observational studies have failed to detect a significant association of endogenous T levels and prostate cancer incidence. Enlargement of the prostate and small increases in serum PSA have been observed in older men given exogenous T, without notable worsening of urinary tract symptoms or increased frequency of prostate

cancer. However, in the absence of a large randomized trial of prostate effects of T, this question will remain a serious consideration.

Summary and Conclusions

T, and to a greater extent bioavailable and free T, decrease with age in otherwise healthy men, reaching hypogonadal levels in a substantial fraction (PADAM). T replacement at physiological doses in men with PADAM may have potential for reducing loss of muscle and improving strength as well as diminishing body fat and benefiting glucose tolerance. T may even help protect against cardiovascular disease and preserve cognitive function. However, the population most likely to benefit from such treatment is undefined. Moreover, there is insufficient reliable information as to potential adverse effects of T replacement in older men. Despite the absence of definitive information on risk–benefit ratios, large numbers of middle-aged and older men are using exogenous T to treat or prevent effects of normal aging. The number of prescriptions for T has increased in the last decade from hundreds of thousands into the millions annually, in part fueled by the availability of non-injectible products such as skin patches, dermal gels, and buccal and sublingual systems. Only new trials of sufficient size and duration to determine with confidence the magnitude of benefits and incidences of adverse outcomes can provide the data needed for physicians to confidently advise men with regard to the use of male hormone replacement.

Anxiety Disorders

K M Connor and D G Blazer, Duke University Medical Center, Durham, NC, USA

Glossary

Agoraphobia – Disorder characterized by an irrational fear of leaving the familiar setting of home or venturing out into the open.

Anxiety – Excessive or irrational fear associated with a real or anticipated stimulus.

Generalized Anxiety Disorder (GAD) – Disorder characterized by worry that is excessive and difficult to control and that lasts for 6 months or more.

Panic Disorder – Disorder characterized by recurrent, unexpected panic attacks and consequent fear of having another attack.

Introduction

Anxiety is characterized by excessive or irrational fear associated with a real or anticipated stimulus. Anxiety is often accompanied by phobic avoidance and a constellation of somatic symptoms. Phobic avoidance may be seen as an adaptive mechanism that enables the individual to minimize exposure to situations that may be anxiety provoking. But such avoidance can become maladaptive when it leads to significant behavioral changes, including social isolation and agoraphobia. Common somatic manifestations of anxiety include cardiovascular (palpitations, non-cardiac chest pain), respiratory (dyspnea), neurological (dizziness, headache, tremulousness), laryngeal (lump in the throat), and gastrointestinal (diarrhea, abdominal cramps) symptoms. The somatic complaints are often the impetus for the individual to seek treatment, usually with a primary care provider, and can result in extensive medical workups that fail to find an underlying medical etiology for the symptom.

Clinically significant symptoms of anxiety are common in the elderly. Such symptoms may represent the physiological consequences of a treatable medical illness, the result of psychiatric illness, and/or an exaggerated or normal response to life events. Anxiety disorders are often chronic conditions, persisting in various forms across the life span, and in the elderly they exist in a number of clinical presentations. For example, anxiety may be chronic and relapsing, as with a manifestation of a lifelong disturbance or condition. Alternatively, anxiety may present in the short term, in response to an acute stressor. Anxiety is also frequently associated with other chronic problems in the elderly, such as cognitive decline and impairment, medical problems in self and/or spouse, and depression.

This article briefly reviews the epidemiology, etiology, and differential diagnosis of anxiety in the elderly and discusses treatment and management issues in this population.

Epidemiology of Anxiety in Later Life

At least one in five people over age 65 suffers from a mental disorder, and it is anticipated that by 2030, the number of elderly with psychiatric disorders will equal or exceed the number of those in younger age groups with these disorders. Of psychiatric illnesses in older adults, anxiety disorders are among the most common, with clinically significant symptoms affecting approximately 10–20% of individuals over 55 years of age. Much of what we know about the epidemiology of anxiety disorders in older populations is extrapolated from findings in younger adult populations. However, the prevalence of these disorders does not appear to be consistent across the life span, as noted later. A listing of the various anxiety disorders as recognized in the 4th edition of the *Diagnostic and Statistical Manual for Mental Disorders* (DSM-IV) is presented in **Table 1**. It is important to note that the majority of older adults with anxiety, however, will fail to meet criteria for a specific disorder, due in part to insufficient symptom intensity and frequency, but also due to limitations in current diagnostic classification systems in capturing the quality of anxiety in the elderly, often characterized by anxious mood, tension, and diffuse somatic complaints. Nevertheless, the anxiety can be moderately disabling and deserving of clinical attention.

As with depression, anxiety can cause significant impairment in functioning and quality of life in the elderly. It has been shown that older adults (over 75) taking medication for anxiety, depression, or insomnia report significantly worse physical functioning and mental health and greater pain and role limitations due to physical impairment when compared to peers who were not taking psychotropic medications.

Generalized Anxiety Disorder (GAD)

Generalized anxiety disorder (GAD) is considered by many clinicians to be the most common anxiety disorder in the elderly, in whom it is more prevalent

Table 1 Anxiety disorders and their core symptom profiles

Disorder	*Core anxiety symptoms*
Generalized anxiety disorder (GAD)	Worry, anxiety, tension
Panic disorder	Recurrent, unexpected panic attacks; may be accompanied by agoraphobia
Agoraphobia without panic disorder	Avoidance of situations due to fear of inability to escape
Obsessive-compulsive disorder (OCD)	Obsessive thoughts; compulsive behaviors; marked anxiety may develop if behaviors are interrupted
Post-traumatic stress disorder (PTSD)	Following a traumatic event that is associated with intense fear, horror, or helplessness; intrusive recollections and re-experiencing symptoms; avoidance and numbing; hyperarousal
Social phobia[a]	Fear and avoidance of a variety of social encounters; often accompanied by autonomic arousal
Specific phobia	Fear and avoidance of specific objects/situations

[a] Also known as social anxiety disorder.

than in younger adult populations. GAD is characterized by worry that is excessive and difficult to control and that lasts for 6 months or more. The worry does not focus on any specific topic and is accompanied by a variety of somatic complaints, such as fatigue and muscle tension. GAD is frequently comorbid with major depression, a presentation that portends a more chronic course, takes longer to respond to antidepressant medication, and is less likely to remit.

Agoraphobia

Another disorder that is more common in the elderly than in younger adults is agoraphobia, a condition characterized by an irrational fear of leaving the familiar setting of home or venturing out into the open. While commonly associated with panic attacks in younger age groups, this is not necessarily the case in the elderly, in whom agoraphobia often develops following a traumatic event. Agoraphobia can be most disabling to older adults, especially if they live alone. Elders literally feel trapped in their homes and therefore do not attend to necessary daily activities, including appointments with health-care professionals.

Panic Disorder

Panic disorder is a condition characterized by recurrent, unexpected panic attacks and consequent fear of having another attack, a fear that ultimately leads to significant distress and behavioral changes. Panic disorder is a condition that typically presents in the late teens to mid-30s, but rarely begins in old age. While qualitatively similar to panic attacks in younger adults, panic attacks in the elderly tend to be less frequent, with less intense symptoms, and are associated with fewer avoidance behaviors. Panic attacks that begin in late life should prompt careful assessment for depression, an underlying medical illness, or medications that may be contributing to the symptoms.

Obsessive-Compulsive Disorder (OCD)

Obsessive-compulsive disorder (OCD) with late life onset is uncommon. The development of obsessive thoughts and/or compulsive behaviors in this population should prompt assessment for other psychiatric disorders such as delirium or psychotic depression. In addition, the clinician should review with the patient and family a lifelong pattern of such behaviors that perhaps increased in frequency and/or severity at the time of evaluation.

Social Phobia

Social phobia, or social anxiety disorder, is the most common anxiety disorder, typically with onset in adolescence. While little is known about the epidemiology of this condition in the elderly, community studies have shown a slight increase in the prevalence of social anxiety disorder in the 50–60 age group. This group may represent individuals who had lifelong underlying social anxiety that was previously manageable and that did not manifest as a disorder until later in life, at a time when exposed to social situations that were no longer avoidable, e.g., having to enter the work force for the first time following divorce or the loss of a spouse.

Post-traumatic Stress Disorder (PTSD)

The epidemiology of post-traumatic stress disorder (PTSD) in the elderly is not well characterized. Much of what we know about PTSD in this population is derived from retrospective studies of survivors 40–50 years after mass trauma, primarily interpersonal trauma (e.g., Holocaust survivors, World War II combat veterans). Relatively low rates of PTSD have been observed in these populations, and possible explanations for this finding are as follows: individuals with more severe PTSD symptoms (particularly avoidance) may not have participated in the studies;

PTSD may be associated with greater morbidity and mortality over decades and many with the disorder may have died in the intervening years; and the salutogenic effects of trauma contribute to lower prevalence rates, with psychological development favoring personal growth and wisdom. However, it is important to recognize that some symptoms, such as insomnia and nightmares, may persist for decades and that stressors of aging do not necessarily exacerbate PTSD. Further, post-traumatic psychological sequelae may complicate or worsen physical illness and health-related functioning. To this end, it has been suggested that PTSD symptoms may tax the body's protective and self-regulatory systems, thereby exacerbating illness while also reducing the individual's capacity to recover and function fully in life.

Anxiety Secondary to Changes in Physical Health

Anxiety can also present in the setting of failing physical health later in life. For example, fecal or urinary incontinence can be associated with shame and embarrassment, which may present as anxiety and social isolation. In an individual who develops a terminal illness, his or her concerns need to be considered in the context of possible retirement, loss of (or leaving) spouse, other medical disabilities, and other losses. Auditory sensory loss may lead to communication breakdown, which can be compounded by personal, situational, and environmental triggers. Older adults who are unstable on their feet may be especially anxious when required to walk in a crowded area, such as a mall or a busy medical clinic.

Etiologic Factors in Anxiety in the Elderly

The etiology of anxiety disorders is considered to be multifactorial, with significant contributions from both genetic and environmental influences. In the elderly, however, heritable factors have a lower impact, and greater emphasis is placed on the role of the biochemical alterations that occur with aging and illness and with neurodegenerative changes. The role of medications should also be considered, as medication side effects or as drug interactions in the setting of polypharmacy. For example, an older adult may be treated with a synthetic thyroid preparation and experience heightened anxiety secondary to a pharmacologically induced hyperthyroidism.

Psychological and social factors also play a prominent role in development of anxiety in this population. For example, aging adults may become anxious in stressful situations that they may have handled without difficulty when younger, such as driving in heavy traffic, or in social situations when subjected to criticism or embarrassment. Older adults may develop anxiety when in unfamiliar situations (an experience that may be made worse by mild memory impairment), such as when awakening in a strange environment when traveling. They may have realistic safety concerns that become exaggerated, causing subsequent changes in behavior, including limitations in social interactions. It is also important to consider issues associated with life transitions, such as loss (of family, spouse, peers/supports, health), financial stressors, and moving or downsizing.

From a psychoanalytic perspective, helplessness secondary to the following events may serve as a precipitant for anxiety: loss of partner or other supports, medical infirmity, sensory loss, and loss of mastery or control.

Issues in Proper Diagnosis

Despite the high prevalence of anxiety in the elderly, these disorders have not achieved the level of prominence of other disorders in geriatric psychiatry, such as Alzheimer's disease and major depression, and thereby remain underrecognized and undertreated. In addition, elderly individuals with anxiety often present to medical attention with comorbid depression as the primary focus for referral and treatment. Most anxiety disorders begin earlier in life, recurring over decades, and if an individual has not sought treatment for the condition previously, it is less likely that he or she will enter the mental health system at this stage. In addition, due to life circumstances, it may be easier for the elderly to conceal their anxiety by avoiding anxiety-provoking situations, such as those that could arise in work, school, or other social settings. Anxiety is underrecognized not only by geriatric health-care providers, but also by elderly patients, who tend to have greater difficulty identifying symptoms of anxiety. Thus, proper recognition of anxiety disorders is further complicated by the unique presentation of anxiety in the elderly, as well as by inadequate instruments for assessment and diagnosis and confounding effects of psychiatric and medical comorbidity in this population.

The differential diagnosis for anxiety in the elderly is broad, as presented in **Table 2**. Anxiety may present as a primary anxiety disorder or as a symptom secondary to another mental disorder, a physical illness, or a medication side effect or drug interaction.

Anxiety Secondary to Another Mental Disorder

Anxiety is a symptom commonly seen with dementia, major depression, and hypomania. For example, 60%

Table 2 Differential diagnosis of anxiety disorders in the elderly

Primary anxiety disorders	Generalized anxiety disorder Obsessive-compulsive disorder Panic disorder Agoraphobia Post-traumatic stress disorder Social anxiety disorder Specific phobia
Anxiety secondary to another mental disorder	Dementia, with agitation Major depression, with agitation Bipolar disorder, hypomania Alcohol abuse or dependence, with intoxication or withdrawal
Anxiety secondary to a medial condition	Hypoxia or ischemia Cardiac arrhythmias Congestive heart failure Pheochromocytoma Hyper/hypothyroidism Hypoglycemia B12 deficiency Alcohol withdrawal Parkinson's disease Primary sleep disorder Delirium of any cause
Anxiety secondary to medications	Amfetamines Anticholinergics Antidepressants/SSRIs (initiating; discontinuation) Antipsychotics B-agonists Benzodiazepine withdrawal Caffeine-containing products Herbal supplements: ginseng, ephedra, mahuang, guarana Sympathomimetics (including over-the-counter cold remedies containing pseudoephedrine) Thyroid medications Vasopressors

of patients with dementia at some point experience agitation that may be difficult to distinguish from anxiety or that may co-exist with anxiety, potentially important distinctions when considering treatment options. Factors to consider in distinguishing between anxiety and agitation include onset (acute vs. chronic), acuity, course, cognitive status, and underlying medical morbidity. In contrast to anxiety, agitated patients may also exhibit loss of impulse control that can result in disruptive and inappropriate behavior.

As noted earlier, anxiety with comorbid depression is the most common presentation of anxiety in the elderly. This presentation tends to be associated with a more severe depressive illness, more suicidality, and poorer treatment outcome, with delayed or diminished response and greater likelihood of treatment non-adherence and dropout. The treatment team plays an important role in optimizing treatment outcome in this situation, as the quality of clinical management has been found to have the greatest impact on the likelihood of remission in elderly with anxious depression.

Problem drinking is also important to consider in the differential diagnosis for anxiety in the elderly. As many as one-third of older adults with alcohol use problems develop the problem after age 60, and this misuse of alcohol may serve as a form of self-medication for their anxiety. It has been suggested that alcohol abuse in the elderly is substantially underdiagnosed, in part because the effects of alcohol use in this population may be less visible than in younger age groups and the elderly may be less likely to seek treatment. Underrecognition has significant clinical implications in the elderly due to the risks associated with alcohol abuse and relapse, both of which may occur in the setting of anxiety, interpersonal conflict, loss, social isolation, loneliness, and depression.

Anxiety Secondary to a Medical Condition

Anxiety is a common manifestation of a wide variety of physical illnesses, as noted in **Table 2**. With changes in multiple organ systems with aging, older adults are more likely to experience one or more of these conditions over time, placing them at increased risk for experiencing anxiety symptoms. Acute onset of anxiety in the elderly needs to be carefully assessed to determine whether an underlying treatable medical condition is present.

Anxiety Secondary to Medications

Another important consideration is concomitant medication use, including prescription drugs, over-the-counter medications, herbs and dietary supplements, and, less commonly, illicit drugs. Commonly used drugs and supplements that may be associated with symptoms of anxiety are noted in **Table 2**. It is important to remember that older adults tend to be more sensitive to both the therapeutic and toxic effects of pharmacological agents. In addition, many individuals in this age group are taking multiple medications, and the risk of drug interactions increases exponentially with polypharmacy. Treatment non-adherence should also be considered; medication misuse may be due to cognitive impairment, lack of understanding of dosing instructions, or intentional non-adherence. Last, the elderly are among the largest consumers of herbs and supplements, and they may be reluctant to disclose this use to their

doctors or not consider them of importance unless asked specifically about them. Many of these products are pharmacologically active (such as ginseng), and health-care providers need to be aware of patients' use of these agents when prescribing medications.

Treatment of Anxiety in the Elderly

Empirically validated knowledge about appropriate interventions for anxiety in the elderly is sparse. Inferences from data in younger adults typically form the basis for clinical practice in the elderly.

Management of anxiety disorders includes both non-pharmacological and pharmacological treatment. Selection of treatment should include assessment of individual risks and benefits, considering medical and psychiatric comorbidity, patient preference, cost, and availability of resources (e.g., trained therapists). A number of cognitive and behavioral therapies have been shown to be effective in treating anxiety disorders, such as cognitive-behavioral therapy (CBT), exposure therapy for specific phobias and compulsive behaviors, and even psychodynamic therapies (though the empirical evidence is sparse for these therapies). If medications must be avoided, then these approaches become the only viable therapies and should be made available to older adults. In general, when the logistics can be worked out, older adults are both willing to participate in these therapies and cooperative. In addition, anxiety symptoms can also improve with regular exercise, with gains comparable to what is observed with relaxation and meditation. Acute anxiety tends to respond better to exercise than chronic anxiety. However, any recommendations for exercise should be made in the context of the patient's physical health.

Pharmacological therapy must be prescribed with caution. The clinician must monitor for drug interactions and adverse side effects. For most medications, the side effects are more common in late life. Therefore, the clinician must begin therapy with a low dose and monitor the drugs carefully. Anxious patients often misattribute somatic symptoms of anxiety to medication side effects, which can impact on treatment adherence. If the older adult tolerates the medication yet does not respond, then the dose can gradually be increased. Clinicians can greatly augment the monitoring of these medications by maintaining phone contact with the patient or family members. Frequently a 5-min phone call can prevent an ongoing side effect from leading to more serious adverse outcomes (such as a fall) as well as prevent an office visit and enhance treatment adherence.

Antidepressants

Antidepressants are considered the first-line pharmacotherapy for anxiety disorders, with the advantage of treating symptoms of both anxiety and comorbid depression. Among the antidepressants, the serotonergic drugs (selective serotonin reuptake inhibitors [SSRIs] and serotonin norepinephrine reuptake inhibitors [SNRIs]) are widely considered the first choice. While very limited empiric data are available regarding their effect on anxiety in older adults, these drugs have demonstrated generally good tolerability in geriatric depression. Notably, some concern has been raised regarding possible cardiovascular side effects with the SNRIs in light of reports of possible impaired heart rate variability with these drugs.

Both the SSRI and SNRI drugs can be anxiogenic, particularly when initiating treatment, and it is important to discuss this possibility with the patient, along with the goal of minimizing these effects by starting at a low dose and titrating accordingly. The clinician also needs to be mindful that these medications can be associated with discontinuation symptoms when stopped abruptly. While not life threatening, these symptoms may be anxiety provoking for some individuals, especially those predisposed to anxiety, and it is important to have a dialogue with the patient about the importance of treatment adherence. Should the time come to discontinue the drug, this can be done safely by tapering the medication over several weeks under medical supervision.

While the older classes of antidepressants have demonstrated efficacy in depression and anxiety, their multiple side effects and medication and dietary interactions have relegated them to second- or third-line use in the elderly. For example, the tricyclic antidepressants, while effective, can be associated with significant toxicity, particularly anticholinergic, cardiovascular, and histaminergic effects, which may be particularly troublesome for older adults. The monoamine oxidase inhibitors are also associated with poor tolerability as well as significant medication interactions and dietary restrictions that limit their use.

Benzodiazepines

The benzodiazepines constitute the most widely used symptomatic treatment of anxiety and insomnia in adults and are disproportionately prescribed in the elderly. Among the groups most likely to use these drugs on a continuous basis are elderly with comorbid medical and psychiatric problems, elderly taking multiple medications, and elderly women, groups that may also be more likely to experience adverse effects with treatment. In the short term, these drugs

cause cognitive and psychomotor impairment, placing users at greater risk for falls and other accidents. Longer-term use can be associated with physiological dependence and withdrawal.

Given these considerations, these drugs in the elderly are recommended primarily for short-term use. However, it should be noted that some older adults may benefit from extended, continuous use of benzodiazepines in a safe and carefully monitored setting. Further research is needed to identify individuals who will benefit from intermittent vs. continuous treatment, while minimizing risk of toxicity.

Buspirone

The 5HT partial 1A agonist buspirone is an anxiolytic drug that has demonstrated efficacy in adults with GAD and may be of particular utility in the elderly. The drug is generally better tolerated than the benzodiazepines, without sedation or psychomotor impairment, dependence, or withdrawal, and it does not potentiate the effects of alcohol. The primary disadvantages of the drug are a delayed onset of action, over several weeks, and the need for dosing several times a day.

Antipsychotics

Antipsychotics are most widely used to treat agitation and psychosis in the elderly, with almost no empiric data to support their use in geriatric anxiety. Of the first-generation antipsychotics, haloperidol is the most widely prescribed, with fairly good tolerability in low doses, though at higher doses concerns are raised about possible extrapyramidal, cardiovascular, and anticholinergic effects. While initially favored for treating agitation in dementia with delusional ideation, the atypical antipsychotics have also drawn attention regarding possible increased mortality rates in the elderly. In general, experts do not recommend the use of atypical antipsychotics in older adults with GAD or panic disorder.

Other Drugs

Several other medications have demonstrated anxiolytic effects in older adults. For example, propranolol may be helpful in reducing autonomic symptoms associated with anxiety (i.e., tachycardia, palpitations, trembling) but does not help with psychic anxiety and worry and should be avoided in those with asthma and a propensity to hypotension. Antihistamines (e.g., diphenhydramine, hydroxyzine) may also be helpful for intermittent or more extended use, but patients need to be monitored for sedation and mucosal anhydrosis.

Summary

Given these considerations, we note the following needs for the future to facilitate the proper diagnosis and treatment of anxiety in the elderly:

- Conclusions drawn based on data from younger populations of adults may not hold true for the elderly. Studies of the phenomenology and treatment of geriatric anxiety are needed.
- Traditional diagnostic and treatment approaches may not be suitable for the elderly; a multidisciplinary perspective may be more appropriate. A comprehensive assessment of anxiety symptoms requires consideration of physical, intellectual, emotional, environmental, and social determinants.
- The anticipated growth of the population of older persons with mental disorders underscores the need for a strategy to facilitate systematic and effective implementation of evidence-based practices in geriatric mental health care.

Arthritis and Rheumatic Diseases

S Walji and E M Badley, The Arthritis Community Research and Evaluation Unit, University of Toronto, Toronto, ONT, Canada

Glossary

Arthritis – A general term encompassing over 100 types of diseases that involve joint pain and inflammation.

Cyclooxygenase-2 Inhibitors (Coxibs) – New class of medications with action similar to non-steroidal anti-inflammatory drugs (NSAIDs) but with fewer gastrointestinal side effects.

Musculoskeletal – System of the body comprising the bones, cartilage, ligaments, tendons, and joints.

Non-steroidal Anti-inflammatory Drugs (NSAIDs) – Non-narcotic and non-steroidal drugs used to treat pain and suppress inflammation in a variety of conditions.

Introduction

Arthritis is a major cause of morbidity and disability, particularly in older individuals. Strictly speaking, the term arthritis means inflammation of the joints. However, the terms arthritis and rheumatism are often used interchangeably to encompass disorders of the joints, ligaments, tendons, and other components of the musculoskeletal system. Arthritis and rheumatism comprise more than 100 different conditions, amounting to more than half of the conditions included in the larger classification of musculoskeletal disorders (MSDs). Other conditions in the larger family of MSDs are back disorders not associated with arthritis and metabolic bone disorders such as osteoporosis. These are not covered in this article.

Background

The symptoms and signs of arthritis and related conditions include pain, stiffness, swelling, muscle weakness, and limitation of movement of the joints. These are some of the most common health complaints among older people. Together these symptoms and signs greatly affect the population in terms of morbidity, disability, and cost. Traditionally, the burden of arthritis in the population has been underestimated. With the aging population, however, the impact of arthritis is becoming increasingly apparent. Arthritis is one of the leading causes of pain, physical disability, and health-care utilization in Canada. According to the 2000 Canadian Community Health Survey (CCHS), rheumatic conditions affect almost 4 million Canadians over the age of 15, with nearly 40% of these over the age of 65. By the year 2026, over 6 million Canadian adults are expected to suffer from arthritis and related conditions. In the United States, it have been estimated that 27% of the population have physician-diagnosed arthritis.

The frequency of arthritis increases with age. However, older people may often fail to seek care for symptoms because these conditions are considered by many to be a normal part of aging. Complaints pertaining to arthritis are often vague and ill defined, and may be associated with insidious decline in overall function. Pain is the most common symptom in rheumatic disease patients consulting a physician, and this may be misinterpreted due to the presence of other conditions, including depression.

Diagnosis and management of arthritis can be particularly challenging in the elderly. Musculoskeletal symptoms can also be caused by other conditions, and multiple conditions in the same patient may complicate both diagnosis and management. Unfortunately, there is no one simple diagnostic test to confirm a diagnosis of arthritis. Often a combination of radiological and laboratory testing is required in addition to clinical assessment. In addition, the prevalence of many autoantibodies (such as rheumatoid factor) and inflammatory markers (e.g., erythrocyte sedimentation rate [ESR]) increases in the elderly, leading to difficulty with interpretation of test results. Management of arthritis in the elderly also has unique challenges. Issues such as use of multiple medications, comorbid conditions, and altered pharmacokinetics must be considered when determining treatment. Clinical trials for new therapeutics have largely excluded older patients and those with multiple medical problems, leading to further difficulty for management of arthritis in the elderly.

It is not possible to review all of the different types of arthritis and related conditions here. In this article, we describe the clinical characteristics, epidemiology, and management of selected types of arthritis, indicating, whenever possible, any special considerations that might apply to the older population. A comparison of the major clinical findings of five common types of arthritis in the elderly is provided in **Table 1**. The article concludes with a discussion of the overall impact of arthritis in seniors and general management strategies to reduce the impact of arthritis in the elderly population.

Table 1 Clinical aspects of common rheumatologic disorders in the elderly[a]

Disorder	*Osteoarthritis*	*Rheumatoid arthritis*	*Polymyalgia rheumatica*	*Gout*	*Pseudogout*

Types of Arthritis in the Elderly

Osteoarthritis

Clinical Features In addition to being the most common type of arthritis in humans, osteoarthritis (OA) is also a major health problem in dogs, horses, and many other animals. Skeletal remains going back to prehistory show signs of osteoarthritis. Despite its high prevalence in the population and its importance as a cause of pain and disability, OA is less well understood than many of the other rheumatic disorders. Traditionally, OA has been thought of as a disease related to aging, with 'wear and tear' of the joint leading to loss of joint space and remodeling of bone. New insight into the disease suggests that it is a heterogeneous disease with multiple factors such as crystal deposits in the joints and inflammation contributing to disease progression. OA can occur without any obvious predispositions, or it can result from a previous injury or disease of a joint that may have occurred many years earlier.

The most common symptom of OA is pain, most often related to joint use. Pain can also occur at rest and at night. Stiffening or 'gelling' of joints in the morning or after prolonged periods of inactivity is common in OA, and often resolves within minutes of resuming activity. The stiffness associated with other types of arthritis such as rheumatoid arthritis is different and can often last for hours. Although OA is not primarily inflammatory, OA can result in swelling and warmth of the affected joint. In OA, range of motion of the joints is often restricted, with pain and limitation of movement at the end of range. Over time, this may result in atrophy of the muscle surrounding the joint, bony deformities, and disability. OA may affect one or many joints of the body, most typically the knees, hips, hands, big toes, and the spine. The joints most commonly involved in OA are shown in **Figure 1**. In all joint sites except the hip, OA is more common in women than in men. An important distinguishing feature of OA is that shoulders, elbows, wrists, and ankles are seldom affected, as they are in types of inflammatory arthritis such as rheumatoid arthritis. OA is slow to evolve, and often has periods of relative stability lasting many years. Rapid progression can occur, and

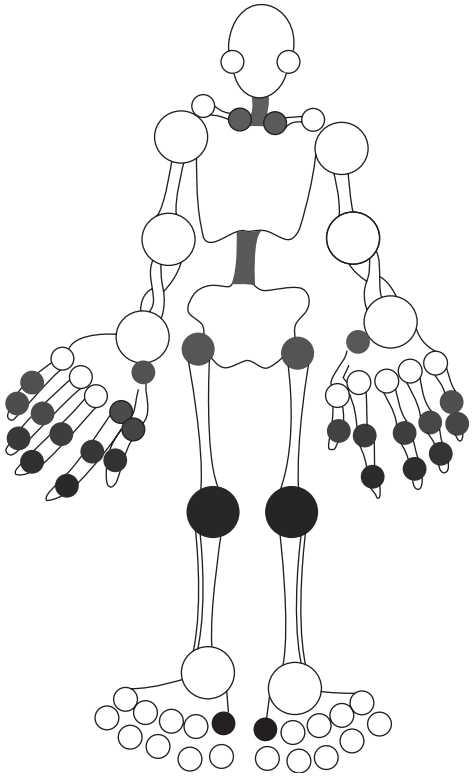

Figure 1 Black shading indicates those joints most often affected in osteoarthritis. (From Figure 1, Cooke TDV and Dwosh IL (1986) Clinical features of osteoarthritis in the elderly. *Clinics in Rheumatic Diseases* 12(1): 155–172.)

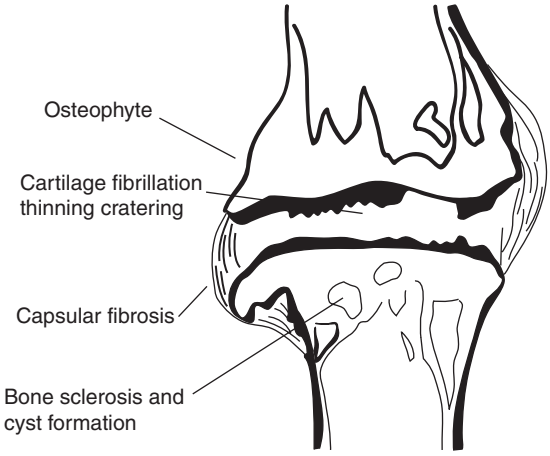

Figure 2 Pathological features of osteoarthritis. (From Figure 1, Hutton CW (1995) Practical problems: osteoarthritis—clinical features and management. In: Butler R, Jayson M, McKenna F, and Scott D (eds.) *Reports on Rheumatic Diseases*. Chesterfield: Arthritis and Rheumatism Council.)

spontaneous improvement is a rare but well-described phenomenon.

The hallmark findings of OA on plain X-ray include joint space narrowing due to loss of articular cartilage, remodeling and patchy thickening of bone (sclerosis), areas of bone loss beneath the cartilage (subchondral cysts), and formation of bony spurs (osteophytes). **Figure 2** illustrates the typical changes that can occur with OA. Diagnosis of OA can be difficult for a variety of reasons, one being that there is no clear diagnostic marker. Although many biomarkers have been investigated, their clinical use is limited by variability in test results for individual patients. While there is some agreement between the clinical and radiographic findings in OA, there is no consistent correlation between the two. Some patients will have severe radiographic findings with few clinical symptoms, while other patients display severe clinical symptoms and minor radiographic changes. Increased use of ultrasound and magnetic resonance imaging (MRI) may help to improve the correlation between radiographic and clinical tests in the future.

Epidemiology and Risk Factors OA is the most frequently occurring type of arthritis in the population. Very little data exist measuring the incidence of OA in the population, as there are problems in defining the disease onset and a lack of longitudinal data. Age seems to be one of the most important risk factors for the disease, as incidence increases with age. The prevalence of OA in the population over 65 years of age ranges from 33% with symptomatic OA to more than 80% with radiographic OA. In the United States, OA is the second highest cause of work disability in men over the age of 50. It has been found to disable 10% of people over the age of 60.

Risk factors for OA are those related to a generalized susceptibility to the disease and to mechanical factors resulting in abnormal biomechanical loading of joints. Susceptibility to OA has been found to be related to increased age, obesity, heredity, low socioeconomic status, and female gender. There are marked racial differences in prevalence and joint distribution. Trauma to the joint, joint incongruence, and occupational or leisure physical activities that involve repetitive motion have been associated with the development of OA. Osteoporosis, particularly in the hip joint, has been shown to be protective against osteoarthritis.

Management There are many challenges in the treatment of elderly patients with OA. Patients and family members often dismiss it as an inevitable part of aging for which nothing can be done. Furthermore, patients and caregivers may believe that it is best to be inactive to protect joints – a strategy that can have detrimental consequences. Finally, comorbidities and use of multiple medications can lead to difficulties with pharmacologic therapy.

The management of OA is largely symptomatic. Its objectives include relief of pain and stiffness, minimization of disability, maximization of function, and reduction of progression. Treatment can be divided into non-pharmacologic, pharmacologic, and surgical. Ideally, a hierarchical cumulative approach to management of OA should be used, encompassing both non-pharmacologic and pharmacologic treatments. All patients should receive education, counseling, and dietary advice if overweight. For those with more severe OA, teaching about joint protection may be required along with assessment of level of function and disability. Shoe alterations, braces, and walking aids can help alleviate problems of biomechanical origin, and assistive devices may improve function. Weight loss, physical therapy for muscle strengthening, and exercise are important components of a treatment program for individuals with hip and knee disease. There has recently been increased interest in acupuncture as a treatment modality for OA. Studies have found acupuncture effective for reducing pain and improving function for patients with knee OA.

Pharmacologic treatment includes analgesics, nonsteroidal anti-inflammatory drugs (NSAIDs), cyclooxygenase-2 inhibitors (Coxibs), intra-articular steroids, viscosupplementation (an injection to help lubricate the joint), and nutraceutical products.

Studies have demonstrated that for OA of the knee, simple analgesics such as acetaminophen, codeine, and low-dose salicylates can result in clinically important relief of symptoms. Analgesics may be an excellent choice for individuals with multiple medications and mild symptoms. Local applications that include NSAIDs have been developed. These and other rubs have been shown to be beneficial in some cases, without systemic toxicity. Oral NSAIDs remain the mainstay of treatment for OA. Their use in the elderly population, however, has been brought into question. Changes in the metabolism of older people, particularly kidney and liver function, may lead to potentially serious or even lethal side effects when drugs are taken in full doses. Adverse events, such as gastrointestinal bleeding, may be silent or asymptomatic and may eventually lead to a major medical emergency. As a general principle, it is recommended that elderly patients receive a reduced dose. There has been debate in the literature as to whether acetaminophen or NSAIDs should be the first choice for treatment. This decision needs to be made clinically, taking into consideration the severity of symptoms and risk factors for the medications. Alternatively, they can also be used in combination. The more recently available Coxibs have potential as safer therapy with decreased risk of serious gastrointestinal toxicity. However, these have been associated with cardiovascular and cerebrovascular risk. It is important, therefore, to carefully weigh the risks and benefits of treatment before initiation. Intra-articular steroid injections may provide relief of pain and swelling, especially if there is one predominantly symptomatic joint. These are only good for temporary symptom relief, however, and should not be given more than three times a year per joint. Viscosupplementation with intra-articular hyaluronic acid (HA) may be an option for patients who do not respond to other treatments. There is some evidence that HA may improve pain in patients with knee OA.

The nutraceuticals glucosamine and chondroitin have been found to be effective for the treatment of OA. Chondroitin is a protein that helps give the joint elasticity, while glucosamine sulfate is a type of sugar that helps cartilage formation and repair. Studies have shown that both of these substances may be effective in symptom control at doses of 1500 mg daily of glucosamine and 800 mg daily of chondroitin. In general, patients should be encouraged to try these substances at recommended doses for 3 months. At this point, if there is no improvement in symptoms, then they will likely not be effective in the future and should be discontinued. Patients should also be encouraged to carefully read labels when buying over-the-counter preparations, as there is wide variety in the content of glucosamine and chondroitin in different products.

In advanced cases, surgery may be indicated. Indications for surgery include uncontrolled pain, particularly pain at rest and pain at night, and limitations in performing activities of daily living. Surgical techniques include realignment of joints by osteotomy (the cutting and repositioning of parts of the bone), chondrocyte grafting to resurface damaged cartilage, and joint replacement surgery. Total hip and total knee replacements are well-established procedures and frequently result in dramatic relief of pain and improvement of function. Joint replacement prostheses have a limited life (around 20 years), but this is not a contraindication in the older individual.

Gout

Gout is the most common kind of crystal-induced arthritis. The types of crystal arthritis have in common the finding of microscopic crystals in the tissues or synovial fluid of the joint. The crystals are believed to play a role in the inflammatory process of the disease.

Clinical Features Gout occurs when uric acid crystallizes in the joints, causing intense inflammation. The joint is typically hot, red, swollen, and extremely painful. Attacks of gout are usually acute, self-limited episodes of monoarthritis (arthritis in one location) but may be polyarticular (affecting many joints) and chronic. The initial attack usually occurs after years of asymptomatic hyperuricemia (high blood urate levels) and it only affects one joint in 85–90% of patients. Attacks frequently affect the lower extremities and last from a few days to 3 weeks. The big toe is the most common site, but almost any joint in the body can be affected. Patients are usually asymptomatic between attacks. Over years, attacks occur more frequently, last longer, may become polyarticular, and may be associated with systemic symptoms including fever. Chalky deposits called tophi may occur under the skin, and chronic polyarthritis may develop. In the elderly, gouty arthritis is more difficult to diagnose as it has a number of features that are different than gout found in younger patients. For example, in older patients, polyarticular gout involving the small joints of the fingers is more common, especially in women. Additionally, in the elderly, tophi often occur earlier and in atypical areas. Attacks of gout are commonly associated with diuretic use and renal insufficiency. Gouty arthritis can be misdiagnosed as OA and even RA, and this

can be further complicated as occasionally gout and OA coexist, even in the same joints.

Epidemiology and Risk Factors Gout is the most common cause of inflammatory arthritis in men over the age of 40, with a peak incidence in the fifth decade. The peak incidence for females occurs over the age of 60. It is difficult to determine incidence and prevalence rates of the disease, as the course of the disease is characterized by exacerbations and remissions, and there is also a tendency for misdiagnosis by both patients and clinicians. Estimated prevalence for self-reported gout in the general population is 0.7–1.4% in men and 0.5–0.6% in women. This is higher in adults over 65, with prevalence of 4.4–5.2% in men and 1.8–2.0% in women. Studies of gout over the past two decades suggest increasing incidence, especially in the elderly population.

It has been estimated that gout is the second most common form of inflammatory arthritis in the United States. It occurs worldwide, and regional differences may reflect racial predisposition, although this has not been proven. Gout frequently results in occupational limitations, increased use of medical services, and significant short-term disability, making the disease a significant public health problem.

The epidemiology of gout appears to be changing. Studies of temporal trends have indicated increases in prevalence over the last few decades in several countries with high standards of living. The sex ratio has also changed. The ratio of males to females with gout was previously 20:1 but has recently been estimated at 2–7:1. It has been suggested that these changes are related to the use of medications (particularly thiazide diuretics), increased longevity, and changes in lifestyle.

Risk factors for gout are varied. Plasma urate concentration is directly related to the risk of developing gout. Hyperuricemia can be due to decreased renal excretion or overproduction of uric acid. In the majority of individuals, it is related to underexcretion. The risk of developing gout is similar in males and females for particular urate concentrations, and the lower prevalence of gout in females is likely indicative of lower urate concentrations. Urate concentrations are highly age dependent, with levels increasing with age. There appears to be a genetic predisposition to the disease, as gout is associated with inherent enzyme abnormalities and inherited urate underexcretion. Environmental factors are also important. The risk of gout is increased with diets rich in meats, seafood, and alcohol. Medication use, including thiazide diuretics, low-dose aspirin, and cyclosporine, and toxin exposure (e.g., lead) has been associated with hyperuricemia and the development of gout.

Management Management of gout includes treatment of acute attacks and prevention of recurrent attacks. For acute episodes, treatment options include local cortisone injection, a short course of systemic steroids, NSAIDs (particularly indometacin), Coxibs, and colchicine. Colchicine is rarely used alone for the treatment of acute attacks due to gastrointestinal side effects. Patients with more than three gouty attacks in 1 year, tophi, polyarticular disease, and gouty nephropathy may benefit from long-term therapy (hypouricemic therapy) to lower the level of uric acid in the blood and prevent future attacks. The most commonly used medication for hypouricemic therapy is allopurinol, a xanthine oxidase inhibitor. However, allopurinol should never be used during an acute attack because there is a risk of triggering an attack with the onset of treatment. For this reason it is often initiated with low-dose colchicine in the first few months for prophylaxis. Uricosuric drugs such as allipurinol are seldom used in elderly patients, as they are often poorly tolerated and may have decreased efficacy.

Calcium Pyrophosphate Deposition Arthropathy (Pseudogout)

Clinical Features Calcium pyrophosphate deposition arthropathy is a further kind of crystal-induced arthritis. There is a broad spectrum of diseases associated with calcium pyrophosphate dehydrate deposition disease (CPPD or pseudogout). Included in this category are asymptomatic chondrocalcinosis, acute monoarthritis (pseudogout), and clinical presentations mimicking OA (pseudo-osteoarthritis), rheumatoid arthritis (pseudorheumatoid arthritis), and neuropathic joint disease. In CPPD, inflammation is induced by the presence of crystals of calcium pyrophosphate in the joints. The most common clinical presentations include acute mono- or polyarthritis, chronic arthropathy, and asymptomatic radiographic findings. In pseudogout, at least 50% of attacks are in the knees, but the shoulders, wrists, and ankles may also be affected. Although not as painful or intense as gout, acute monoarthritis due to CPPD is just as common. It is often seen in individuals with preexisting OA and is commonly precipitated by trauma or acute medical illness.

Epidemiology and Risk Factors CPPD arthropathy occurs most often in aging females. The mean age of onset is between 65 and 75 years. It is estimated to affect 10–15% of individuals between 65 and 75 years of age and more than 40% of individuals over age 80. CPPD has been reported throughout the world. There appears to be familial aggregation that

has shown an autosomal dominant transmission pattern, involving single gene mutations. There is also an association with endocrine and metabolic diseases including hyperparathyroidism, hypophosphatasia, hypomagnesemia, and hemochromatosis. CPPD arthropathy appears to be linked with aging of the articular cartilage, although the nature of this relationship has not been clarified. Most cases of CPPD have no known cause.

Management The goals of treatment are to reduce symptoms, identify and treat any triggering illness, and rapidly mobilize the patients as inflammation settles. Rapid mobilization is important, as older patients are prone to complications from prolonged immobility. In many cases, joint aspiration to remove synovial fluid from the joint may be the only treatment required. An intra-articular steroid injection may be appropriate for a joint that does not settle after the first aspiration. Analgesic and anti-inflammatory drugs may provide additional benefit when used with caution in elderly patients. NSAIDs, colchicine, physiotherapy, and education can all help to reduce pain associated with CPPD. For patients with rheumatoid-like disease, there may be some benefit from the use of hydroxychloroquine, an antimalarial medication with anti-inflammatory properties. Surgery such as total joint replacement may be necessary in the presence of advanced joint degeneration.

Rheumatoid Arthritis

Clinical Features Rheumatoid arthritis (RA) is one of the most common autoimmune diseases. It typically begins as symmetrical pain and swelling of the small joints of the hands and feet, along with stiffness in the morning that can last for several hours. The disease is typically accompanied by fatigue, anorexia, and weight loss. **Table 2** compares the characteristics of RA and OA.

Older RA patients fall into two categories: patients who have suffered from chronic RA for many years or even decades and patients with recent or new onset of disease. Patients with established disease may still have active disease, or may be burnt out but still have symptoms because of damage and deformities in joints previously affected by RA. Disease onset is often acute, with disabling morning stiffness, limited range of motion, severe soft tissue swelling, and marked elevations in inflammatory markers. Involvement of the large joints, especially the shoulders, is common along with involvement of wrists, and metacarpophalangeal (MCP) joints and proximal interphalangeal (PIP) joints in the hand. Extra-articular manifestations of the disease (such as vasculitis) occur less often in the late-onset patient. Laboratory tests for the diagnosis of RA may be different in the elderly. For example, rheumatoid factor, an antibody that recognizes the Fc portion of the IgG molecule, increases with age, and so may be less useful for diagnosis. Furthermore, elevations in inflammatory markers (including ESR and C-reactive protein) may be misleading in the elderly, in whom they may be elevated due to comorbid conditions or due to aging itself. This combination of factors can make the diagnosis of RA in the elderly extremely challenging.

The course of RA is unpredictable. In some cases, late-onset RA has been found to have a more favorable outcome than younger-onset RA, while in other cases, the prognosis is worse. The majority of patients will experience intermittent periods of active disease alternating with periods of relative or complete remission. A minority may have complete remission, but a small group of patients will have severe, unrelenting, progressive disease. Irreversible joint deformities may also characterize the physical findings of people with long duration and greater severity of disease. These deformities may lead to difficulties in walking and with activities of daily living (ADLs) and result in significant functional disablement. RA is an important cause of disability.

Epidemiology and Risk Factors The peak onset of RA is midlife, although the prevalence of RA increases with age up to approximately age 85. The

Table 2 Clinical features of osteoarthritis versus inflammatory arthritides[a]

Clinical features	*Osteoarthritis*	*Inflammatory arthritides*
Duration of stiffness	Minutes	Hours
Pain	Usually with activity	Occurs even at rest and at night
Fatigue	Unusual	Common
Swelling	Common, but little synovial reaction	Very common with synovial proliferation and thickening
Erythema and warmth	Unusual	Common

[a] Osteoarthritis may also be inflammatory.
From Table 8-6 in Kane RL, Ouslander JG, and Abrass IT (1983) *Essentials of Clinical Geriatrics*. McGraw-Hill Book Company.

prevalence of RA in the population over 60 years of age is reported to be 2%, double the prevalence in the general population (1%). The sex ratio of RA varies with age. The disease affects mainly females under the age of 60, but over age 60 the sex ratio is much more equal.

Although the cause of RA is unknown, many risk factors, genetic, hormonal, and environmental, are associated with its development. The risk of developing RA is 1.5 times higher if a first-degree relative also has RA, and in twin studies, the concordance for monozygotic twins was 12–15% while that in dizygotic twins was 3.5%. The development of RA has been associated with certain alleles of major histocompatibility complex class II including HLA-DR4, HLA-DR-1, and DR-14. Other genes have also been found to play a role. Aside from genetics, hormones and environmental factors have been implicated. Increased risk of RA has been associated with nulliparity in women and low testosterone levels in men. Pregnancy is associated with remission, while menopause is a common time of symptomatic onset of RA. Decreased risk is associated with breast-feeding and oral contraceptive use. Infections, including bacterial and viruses, may contribute to risk of RA. Thus, it appears that a range of genetic, hormonal, and environmental factors can influence the development of RA.

Management Treatment of RA focuses on decreasing pain, swelling, and stiffness, improving function, and preventing damage and disability. The mainstay of treatment for RA in the elderly is medication, which is similar to that in the younger patient, with the caveat that adverse drug reactions may be more likely. Classically, physicians have followed the pyramid approach when selecting drugs for the treatment of RA. This involves starting with NSAIDs and using more potent drugs as required. The pyramid approach to treatment is no longer accepted, however. Studies have shown that joint damage occurs early in the disease. Furthermore, early and aggressive treatment has been found to prevent disability many years later. There is thought to be a 'window of opportunity' early in the disease, when RA is more responsive to immunosuppressive treatment. In addition, combination therapy with two or more agents has consistently been found to be superior to monotherapy. Therefore, current recommendations include early and aggressive treatment with combination therapy. Disease-modifying antirheumatic drugs (DMARDs) are used to prevent progression of disease for patients with RA. These drugs take several months for clinical response and carry a risk of serious adverse effects. Therefore, their use needs to be carefully monitored under the supervision of a physician experienced in the treatment of RA. Corticosteroids may also have a place in treatment, either systemically in low doses or injected into inflamed joints to reduce inflammation. Over the past few years, biologic therapeutic agents have been introduced and used for the treatment of RA. These are an alternative for patients not responding to traditional DMARDs. NSAIDs and Coxibs can also be used, with caution, for symptom control. Physiotherapy to treat pain and swelling and maintain range of motion and function is often an excellent adjunct to medical therapy.

Surgical treatment may be recommended for RA patients to relieve unresolved pain, loss of function, and deformity. Joint replacements of hips and knees, tendon repairs, and carpal tunnel releases are some of the more frequently employed measures in the elderly. Age itself is not a contraindication for surgery, nor is it a predictor of poor results.

Polymyalgia Rheumatica

Clinical Features Polymyalgia rheumatica (PMR) is a clinical syndrome of middle-aged and elderly people characterized by pain and stiffness in the neck, shoulder, and pelvic girdles, often accompanied by constitutional symptoms such as fever, fatigue, anorexia, and weight loss. Stiffness is the predominant feature and is particularly severe after rest. In extreme cases, the stiffness may prevent the patient from getting out of bed in the morning. Muscular pain is often diffuse and is accentuated by movement. Pain at night is common.

Epidemiology and Risk Factors PMR is a condition of the older patient. It is seldom diagnosed under the age of 50. The mean onset of PMR is approximately 70 years, with a range of about 50–90 years. Women are affected two to three times more often than men. It is difficult to determine prevalence and incidence of the disease, as there is a lack of specific signs and symptoms. In older persons, its estimated prevalence approaches 1% and the annual incidence rate has been estimated at 13 to 113 per 100 000 individuals over age 50. Incidence varies by geography.

There appears to be a genetic predisposition to the disease, as evidence exists for familial aggregation. Environmental factors may also be important, as there is clustering of cases in time and place. The greatest majority of patients are Caucasian, and the disease appears to be more common in the northern United States, Canada, and Europe, compared to southern regions.

PMR has been associated with giant cell arteritis (GCA). Symptoms typical of GCA include headache, scalp tenderness, jaw pain on chewing, and visual changes. Approximately 15% of patients with PMR will go on to develop GCA, while almost 50% of patients with GCA will have concurrent PMR. It is important to rule out GCA in PMR patients, as if left untreated, it can lead to irreversible blindness. For definitive diagnosis of GCA, temporal artery biopsy should be performed.

Management Of the forms of arthritis affecting the elderly, PMR is one of the most difficult and important to diagnose. The main treatment is systemic corticosteroids. Patients have a dramatic response to even small doses of prednisone, a corticosteroid. In fact, administration of low-dose prednisone is often used as a diagnostic test in patients with vague complaints. There is no universally accepted approach to initial corticosteroid therapy, maintenance, or dose reduction. Once symptoms have resolved and inflammatory markers have normalized, the dose of steroid may be slowly tapered. During tapering, inflammatory markers should be assessed regularly. If there is recurrence of symptoms or increase in markers, the steroid dose should be increased accordingly. Patients will generally require treatment for up to 2 years. Patients should be counseled regarding the side effects of prolonged steroid use. Regular assessment of blood pressure, blood sugar, and bone density should be done while on therapy. Bone protection with calcium, vitamin D, and bisphosphonate should be considered. Patients with concurrent GCA will require higher doses of prednisone along with appropriate monitoring.

Impact of Arthritis in the Elderly Population

The greatest impact of arthritis is morbidity and disability, with the major burden being on the elderly population. Arthritis is the most frequently cited cause of activity limitations for men and women over age 45, compared to other chronic conditions, with the prevalence of arthritis disability being generally higher in females. According to data from the US National Longitudinal Study on Aging of 1984, community-dwelling elderly (ages 70+) who report arthritis represent the greatest proportion of individuals with physical limitations (68%), limitations in activities of daily living (ADLs) (75%), and limitations in instrumental ADLs (70%) such as shopping, managing money, and housework. Epidemiologic studies at long-term care facilities in the United States have shown that 45–80% of residents have substantial pain from musculoskeletal origin that affects their functional status and quality of life.

RA and other inflammatory arthropathies are commonly viewed as the most likely types of arthritis to lead to disability. Data from population surveys suggest, however, that the most frequent cause of arthritis-related disability is OA. Although a smaller proportion of people with OA than with RA experience disability, because of its much higher overall prevalence, OA is the most frequent cause of disabling arthritis. Population data suggest that for every person with severe disability from RA, there are over seven individuals with severe disability due to OA.

Disabling arthritis is likely to have an impact on all aspects of life. **Table 3** presents a picture of the scope of impact on individuals age 65 or older with arthritis-related disability. The data are from the 1986 Canadian Health and Activity Limitation Survey (HALS). Results from the most recent version of this survey indicate similar findings, but at the time of writing, detailed data were unavailable. Although the data cannot be broken down into types of arthritis, it is important to remember that the majority of people with disabling arthritis in this age group will have OA, which is predominant in the aging population.

For people with arthritis-associated disability, there may be an impact on many aspects of life. Mobility, including walking, standing, and climbing stairs, may be impaired, leading to loss of physical independence, with the need to rely on walking aids and the help of other people. There is also an effect on occupation, including work, leisure, and obligations in the home. This may lead to loss of economic self-sufficiency, not only through reduced earning power, but also as a result of extra expenses incurred because of the disease. Furthermore, social integration may be affected along with relationships with other people. The combination of these factors may eventually contribute to depression and poor psychosocial function.

Management of Arthritis Impact

The principles for management of the painful and disabling consequences of arthritis are similar for all types of arthritis. Ideally, arthritis is treated early to halt its progression and prevent impairment and disability. The medical management of specific types of arthritis was previously discussed. More generally, a family physician or general practitioner (or in some cases a nurse practitioner or rehabilitation specialist) may manage the arthritis problem if it is

Table 3 Indicators of the effect of arthritis on the lives of those with arthritis-associated disability over the age of 65 in Canada

Indicator of effect on daily life	*Persons with disability affected over the age of 65 (%)*
Mobility	
At least some trouble with mobility[a]	92.5
Trouble or unable to climb stairs	69.2
Trouble or unable to walk 400 yards	70.5
Trouble or unable to stand >20 min	68.0
Cannot leave residence or only with attendant	33.8
Physical independence	
Some dependence because of disability[b]	74.1
Dependent on help weekly or more often[b]	51.5
Trouble or unable to bend to pick up object	52.3
Trouble or unable to cut toe nails or fingernails	48.6
Trouble or unable to get in or out of bed	20.1
Trouble or unable to dress	17.2
Social integration	
Lives alone	32.8
Never visits relatives or friends	19.8
Occupation	
Never attends sporting events, concerts, plays, or movies	83.3
Never participates in hobbies, arts, crafts	46.0
Never participates in social activities	20.1
Socioeconomic self-sufficiency	
Income <$20 000	63.4
Out-of-pocket expenses because of disability[c]	35.6
Base population >age 65 (thousands)	266 195

[a]Has trouble with or is unable to do one or more of the following: walk 400 yards without resting, walk up or down a flight of stairs, carry an object of 10 lbs for 30 ft, move from one room to another, stand for more than 20 min.

[b]Dependence, help because of health problem. Occasional: heavy household chores; looking after personal finances (e.g., banking, paying bills). Weekly or more frequent: shopping for groceries or other necessities; everyday housework. Daily: personal care (e.g., washing, grooming, dressing, feeding); moving about within own residence; preparing meals.

[c]Out-of-pocket expenses for medication, special aids or supplies, health and medical services not covered by insurance, modifications to residence, transportation personal services (e.g., attendant, housekeeping services).

Data from the 1986 Canadian Health and Activity Limitation Survey.

straightforward or can act as a gatekeeper for referral to other services. Unfortunately, research shows that due to inadequate training regarding musculoskeletal conditions, primary care management may be suboptimal. The medical specialists specifically trained in the diagnosis and treatment of individuals with arthritis are rheumatologists, orthopedic surgeons, and rehabilitation medicine specialists. Medical care usually includes a complete diagnostic work-up, advice regarding the appropriate drug regime, and appropriate monitoring of the patient for medication side effects. Tertiary care services may also be provided in some centers by rheumatologists who specialize in some of the rarer arthritis disorders. Appropriate and timely referral to orthopedic surgery is also important, particularly in view of the potential for total joint replacements and other types of surgery to control pain and restore function.

Physical therapy and occupational therapy are also important in the management of arthritis. Physical therapy strategies aim to maintain or increase range of motion, correct or prevent muscle weakness or wasting (which may also lead to instability of joints), and help correct malalignment of joints, abnormal use of joints, or both. Hydrotherapy (exercise in water) can have advantages, particularly for people with severe arthritis, as the buoyancy of water helps reduce the stress on the joints. Exercise can reduce pain, suppress the need for medication, and help maintain function. There is also some suggestion that cartilage repair occurs with a regular program of exercise.

It is important to encourage moderate levels of general physical activity within the limits of severe fatigue. Brief periods of several days of enforced rest may be followed by loss of muscle strength, with the risk of permanent decline in functional ability, including ability to walk. Even in the presence of active RA with constitutional manifestations, it is important that elderly persons maintain a certain level of physical activity to maintain function.

Occupational therapists are involved in the care of people with arthritis, by constructing splints to stabilize joints and reduce pain, and by providing input regarding environmental modifications to facilitate the performance of ADLs. Occupational therapists also conduct functional evaluations that are essential for treatment planning for older patients. Being able to transfer from a chair to a standing position, walk short distances, and get on and off a toilet independently may make the difference between living independently and requiring physical assistance or even institutionalization. Occupational therapists also offer education regarding joint protection and energy conservation techniques, which may help to reduce and improve joint alignment and prevent muscle fatigue.

Both occupational therapists and physical therapists may provide input regarding assistive devices and environmental modifications. The availability and use of assistive devices can make an important contribution to maintaining independence in people with arthritis disability. Assistive devices may be useful, for example, to help put on shoes and stockings or to open jars. Other devices include raised

chair or toilet seats to facilitate rising from a sitting position, and bath seats to assist with bathing. Adapted shoes are also particularly important in lower limb arthritis. Extra-depth shoes and orthotics may accommodate the anatomical changes of aging and help cushion the heel to absorb impact loading. Simple walking aids such as a cane can also reduce joint loading and decrease pain. Finally, adaptations to the physical environment in the home, such as handrails in the bathroom and on stairs, may be important in preserving independence.

Education is another important management strategy that may be offered at many different levels. Physicians, therapists, and trained laypeople may all be involved in educating people about their arthritis. Education is important to promote the patient's and family's understanding of the condition, so they know what they can do to adapt and cope with pain and the disabilities that may result from arthritis. Educational and community support interventions have been found to have a positive impact on many aspects of health status, including knowledge, pain, compliance with medication, emotional and social well-being, and disability. Programs that include and emphasize problem solving, coping, self-efficacy, and endurance exercise have proven more effective than traditional programs that focus exclusively on changes in the joints, range of movement, and joint protection.

All of these management strategies focus on the individual and on what can be done within the immediate environment to manage arthritis. The broad social environment can also make an important contribution to reducing the impact of arthritis on individuals. The social environment encompasses the attitudes of others, both within the family and in the community in general, cultural background, values, and expectations. Increased public awareness of arthritis could result in changes that would greatly enhance an individual's quality of life, by providing a more accepting and adaptable environment that would ultimately facilitate function of older people with arthritis.

Glossary

Clinical Neuropsychology – A subfield of clinical psychology involving systematic evaluation, rehabilitation, and treatment of cognitive and other neurobehavioral deficits, generally using standardized psychometrically validated neuropsychological tests, among people with known or possible neurologic or neuropsychiatric conditions.

Neuropsychology – The study of relationships between the central nervous system and the mind.

Introduction

Literally defined, the term neuropsychology refers to the study of relationships between the central

nervous system (CNS) and the mind (or *psyche*). In that sense of the word (although not necessarily under that name), neuropsychology has had an extraordinarily long history in psychology, medicine (including psychiatry and neurology), and philosophy. Moreover, neuropsychological inquiry remains a central part of a range of interrelated scientific disciplines, such as cognitive neuroscience, behavioral neurology, neuropsychiatry, experimental neuropsychology, and the like. In contemporary times, the term clinical neuropsychology has a more specific connotation, referring to a subfield of clinical psychology involving systematic evaluation, rehabilitation, and treatment of cognitive and other neurobehavioral deficits, generally using standardized psychometrically validated neuropsychological tests, among people with known or possible neurologic or neuropsychiatric conditions.

The focus of this article is the contemporary meaning of neuropsychology, with particular emphasis on the role and relevance of neurocognitive assessment in the clinical care of older patients. The intent is to provide a broad introductory overview for geriatric health-care professionals regarding the nature and role of clinical neuropsychological assessment. The specific goals are twofold: (1) to raise awareness among non-neuropsychologist clinicians regarding the potential value of referring geriatric patients for neuropsychological assessment, and (2) to provide a resource so that non-neuropsychologist clinicians can be educated consumers of neuropsychological referral resources and results.

Definitions and Process of Neuropsychological Assessment

Who or What Is a Neuropsychologist?

As noted previously, under the broader rubric of neuropsychology as the study of the relationship between the CNS and neurobehavioral functioning, the term neuropsychologist is not discipline specific. Professionals from a range of related disciplines, including cognitive neuroscience, behavioral neurology, biological psychiatry, biological and cognitive psychology, and experimental neuropsychology, conduct neuropsychology as a field of scientific inquiry. However, contemporary use of the label clinical neuropsychologist is generally taken to refer more specifically to a doctoral-level clinical psychologist, with specific training relevant to the application of neuropsychology in clinical work with patients, as well as in clinical research.

In addition to meeting all the training requirements for a doctorate, licensure, and credentialing as a clinical psychologist, those practicing clinical neuropsychology also need to obtain the relevant knowledge and experience specific to understanding and evaluating brain–behavioral relationships and working with brain-injured or other neurologic patients. All neuropsychologists should have particular expertise in neuropsychological assessment and interpretation, a detailed understanding of the various cognitive and behavioral profiles of patient populations, and specific supervised experience in the practice of clinical neuropsychology. Neuropsychologists also have working knowledge, and often particular expertise, in such subdisciplines as functional neuroanatomy, neurodevelopment, and neurologic disorders/neuropathology. These skills are generally obtained via both formal course work and supervised clinical work conducted during both doctoral training, and 1 or 2 years of supervised postdoctoral training. In the context of working with older patients, neuropsychologists are expected to also have a solid knowledge base and relevant experience in geriatric psychiatry and gerontology. In addition to licensure (required by every state for independent practice of clinical psychology), many clinical neuropsychologists also go on to seek and obtain board certification from the American Board of Clinical Neuropsychology, which is a part of the American Board of Professional Psychology, and/or from the American Board of Clinical Neuropsychology.

Neuropsychological Testing and Neuropsychological Assessment

A central component of a comprehensive neuropsychological evaluation generally includes administration and scoring of standardized tests to measure a range of relatively specific neurocognitive abilities, such as attention/working memory, verbal knowledge and receptive/expressive language functions, visuospatial and constructional skills, mental processing/psychomotor speed, executive functioning, and visual or auditory learning/memory.

Standardized testing implies that the test administration procedures, instructions to the examinee, stimuli, and scoring procedures have all been clearly specified and validated as part of the test development process. These standardized procedures allow neuropsychologists to establish reliability, such as internal consistency, interrater reliability, and test–retest reliability, where appropriate. Standardized testing also typically involves the use of normative data. Normative data are gathered from healthy controls, or sometimes from various clinical populations, using the standardized procedures. The use of normative data allows for evaluation of an examinee's performance

relative to that expected in the overall general or patient population, as well as among demographically similar healthy controls. For instance, in evaluating older patients, it is helpful to consider performance relative to age-matched peers, particularly on tests of abilities that are strongly affected by normal aging, such as psychomotor speed. This aids in distinguishing genuine but non-pathological difficulties, e.g., normal age-related forgetfulness, from those that are likely to reflect a pathological cause, e.g., a neurodegenerative condition.

There are at least two specific advantages of testing a range of cognitive abilities rather than simply examining overall cognitive functioning: (1) some disorders or localized brain lesions will impair certain abilities while leaving others relatively intact, so examination of the pattern of cognitive strengths and deficits can provide some clues regarding the nature of any present neuropathology, and (2) information about spared or residual abilities is at least as important as that regarding impaired abilities when developing plans for treatment or compensatory strategies.

Use of standardized neuropsychological tests is generally central to a neuropsychological evaluation, but the process of neuropsychological assessment is much broader and more complex than administering and scoring standardized tests. (Some neuropsychologists in fact delegate at least a portion of the actual test administration and scoring to a well-trained and supervised bachelor-level psychometrist/technician.) Rather, a neuropsychologist's training and expertise are most salient in the process of integrating and interpreting standardized test scores in the context of other available information, such as the presenting concerns, detailed behavioral observations, clinical interview of the patient and any available family members or caregivers, review of current and past psychosocial functioning, medical history, and personality functioning. The ability to form a coherent synthesis of this breadth of information, together with a consideration of the pattern of performance across a range of specific neuropsychological tests, is where both the science and art of a clinical neuropsychologist's knowledge, skill, and expertise become most apparent.

Origins and Current Roles of Neuropsychological Assessment

Detection and Localization of Neuropathology

Although neuropsychology has long historical roots, it only emerged as a subdiscipline within clinical psychology in the early- to mid-twentieth century. During the initial development period, the primary emphasis of clinical neuropsychology was detecting and/or localizing brain injury or other forms of CNS dysfunction, as well as characterizing the nature of brain injury. Indeed, many of the neuropsychological tests and techniques that are still in use today were originally designed or adapted for such purposes. For instance, in the 1930s, Ward Halstead, one of the pioneers of clinical neuropsychology, carefully observed people with brain injuries in an effort to understand the effects of such injuries on cognitive processes and behaviors. When he observed a potentially relevant behavior, he designed methods to measure or quantify that behavior. For example, having noted that many brain-injured patients had partial unilateral paralysis, Halstead developed the finger oscillation test, more commonly known as the finger tapping test, among other tests, to quantify motor difficulties. With this approach Halstead developed a battery of tests that was subsequently refined, expanded, and further validated by Ralph Reitan into what is now known as the Halstead–Reitan Battery. Portions of this battery remain among the most widely used neuropsychological tests.

Other commonly used measures of cognitive function include subtests from other batteries such as the Wechsler Adult Intelligence Scale (WAIS) and the Wechsler Memory Scale (WMS) in their various incarnations. Although earlier versions of WAIS and WMS were primarily used to measured intelligence and memory, respectively, the latest editions allow for the computation of index scores for specific neurocognitive ability areas, i.e., verbal comprehension, processing speed, perceptual organization, working memory, verbal memory, and visual memory, therefore rendering them appropriate neuropsychological instruments.

Over the last few decades, the use of neuropsychological assessment in lesion detection and localization has decreased with the development and increased availability of neuroimaging techniques such as computerized tomography (CT) and magnetic resonance imaging (MRI). But neuroimaging has not fully eliminated the usefulness of neuropsychological assessment in this regard. Neuropsychological tests are often sensitive to subtle forms of neuropathology that are not readily discernible through contemporary imaging methods. For instance, because some cell and brain volume loss, as well as plaques and tangles, are common in normal aging, the neuropathologic changes in the early stages of Alzheimer's disease (AD) can be quite difficult to distinguish from those associated with normal aging via imaging alone; however, the subtle deficits in episodic verbal memory (beyond those

attributable to normal aging) may be detected through neuropsychological evaluation. Similarly, functionally relevant non-focal lesions from traumatic head injury or other forms of neuropathology may affect neuropsychological performance and everyday functioning without clearly discernible abnormalities seen via CT or MRI.

Differential Diagnosis

Neuropsychological assessment is also frequently useful in the process of differential diagnosis of suspected neurocognitive disorders. A key component of differential diagnosis is the ability to measure relatively discrete cognitive functions, disentangle these cognitive abilities, and compare the level of observed performance to normative data from similarly aged individuals in the general population. A practical and common example is when a neuropsychologist is asked to evaluate an older adult's complaint of increasing forgetfulness. Many times what is perceived by a layperson as a memory deficit may, through neuropsychological evaluation, be revealed to be attributable to some other type of deficit, such as sensory-perceptual problems, attentional difficulties, and organizational or other executive dysfunctions, and/or may reflect depression or anxiety, or both. Skilled neuropsychologists are able to distinguish between these various potential etiologies of increasing forgetfulness and make recommendations and develop treatment plans that are targeted to the specific cause of these complaints.

Determining and Quantifying the Cognitive/Functional Impact of Known Neuropathology

Another key role of neuropsychological assessment is evaluating the cognitive and functional effects of known neurologic injuries or lesions. For instance, it may already be known that a particular patient has early AD, or has experienced a stroke or head injury affecting a specific brain region, but the effects of the known neuropathology on specific cognitive abilities and everyday functioning may remain unclear without thorough neuropsychological evaluation. In fact, over the last decade or so, there has been a growing emphasis in clinical neuropsychology in not simply documenting the presence of cognitive deficits, but also discerning the implications for such deficits in terms of everyday functioning. For example, neuroimaging may be able to identify that a patient has a lesion to the hippocampus, a structure known to be important in the formation of new memories; however, such images often tell clinicians little about the extent of the memory impairment and what this impairment means for the patient's everyday functioning. Therefore, neuropsychology can also be extremely important in the rehabilitative process and may complement such disciplines as occupational and physical therapy. For instance, even if a patient's cognitive deficits are not expected to substantially recover, clarification of his or her specific strengths and weaknesses can be key in developing compensatory strategies (whether these involve teaching the individual to rely more heavily on spared abilities or making environmental modifications to decrease the potential influence of salient deficits).

Evaluating Current and Future Decline or Recovery

Yet another common role of neuropsychological assessment in geriatric mental health and other clinical settings is determining the speed and trajectory of cognitive changes, either in terms of the rate of decline, e.g., from a neurodegenerative condition such as AD, or in terms of the rate and level of recovery, e.g., from stroke or traumatic head injury. In this vein, repeated neuropsychological assessment can be an invaluable component in long-term treatment and care planning. Some common difficulties associated with interpreting changes over repeated assessments are that examinees' performance may improve due to their becomig more familiar with the content and/or test methods, and there are generally some mild fluctuations in test scores over successive evaluations simply due to random effects. Thus, a particularly interesting and useful development in clinical neuropsychology over the past decade has been the increased interest and preliminary work among neuropsychologists to develop norms for change by which observed changes can be evaluated relative to the degree of expected practice effects and random fluctuations.

Role of Neuropsychology in the Diagnosis and Treatment of Patients with Non-Neurologic Disorders

In many clinical settings, there may be a tendency to think of neuropsychological assessment primarily in terms of working with patients with acquired neurologic conditions, such as head injury, stroke, brain tumor, and/or progressive neurodegenerative conditions. Indeed, neuropsychologists are important and valuable in the evaluation and treatment of such patients. However, other disorders frequently seen in geriatric and other mental health settings, such as mood disorders and psychosis, also commonly have clear and functionally relevant neurocognitive aspects. Even many non-neuropsychiatric medical conditions, such as cancer, cardiovascular disorders, liver disease, endocrine disorders, and some forms of

infectious disease, particularly HIV infection, and/or their treatment may adversely affect cognitive abilities to a functionally relevant degree. In terms of primary psychiatric disorders, there is a large literature on the predictors of everyday functioning and outcome among older as well as younger patients, which clearly demonstrates that neuropsychological skills, but neither primary psychiatric symptoms nor demographic characteristics, such as age or education, are the strongest predictors of level of independent functioning and long-term outcome. In short, neurocognitive assessment, whether brief screening or comprehensive assessment, has clear relevance and utility in the evaluation, treatment, and care planning for geriatric patients with neurologic, psychiatric, and other medical conditions.

Assessment of Specific Neuropsychological Domains

As described previously, a central foundation of neuropsychological assessment is the view that cognitive functioning can be, to some degree, described in terms of a number of more specific abilities that reflect the functioning of relatively discrete brain regions or systems. A thorough description of these constructs and the variety of tests available to measure each of the constructs and subconstructs is beyond the scope of the present article. Nevertheless, the following brief examples are provided to give those unfamiliar with the details of neuropsychological assessment a tangible understanding of the manner in which these constructs tend to be operationalized.

Attention and Working Memory

The term attention is a rather broad construct that refers to a range of more specific abilities, such as simple or basic attention (such as the ability to repeat back strings of digits), selective or focused attention (distinguishing relevant from irrelevant stimuli or information), maintenance over time (ability to stay mentally on track), and vigilance (such as waiting for a particular stimulus or event over time). The concept of working memory is closely related to attention, but also to that of executive functioning, described later. Working memory is generally conceptualized as the short-term 'mental work bench,' where information is actively held for short periods of time for further processing. A key aspect of working memory is that it has limited capacity and requires active rehearsal or allocation of attentional resources for retention. For instance, if an individual needs to hold a telephone number in his or her working memory for a period sufficient to dial the telephone, that retention is generally facilitated by active rehearsal over the delay period. Given the diffuse nature of attention as a neuropsychological construct, there is not one neuroanatomical region responsible for these abilities; however, it is widely accepted that relatively intact frontal lobes are needed for most attentional skills.

Some common examples of attention and/or working memory tasks include the serial 7s subtraction subtask from the Mini-Mental State Examination (MMSE) and the Digit Span subtest from third editions of the WAIS (WAIS-III) and WMS (WMS-III). In the latter, the examinee is first asked to repeat strings of digits of increasing length and then in the second half is asked to repeat strings of digits in reverse order. Others include any of the various cancellation tasks; examples include the Digit Vigilance from the expanded Halstead–Reitan Battery, in which the examinee is asked to rapidly identify and cross out every instance of a target number within a much larger array of numbers, and any of the various versions of the Continuous Performance Test (CPT), such as the identical pairs version, in which the examinee watches a series of numbers rapidly flashed on a computer screen and is required to make a response after any number is shown twice in a row. There are also spatial working memory tasks, e.g., in which examinees are asked to remember the location of a particular stimulus over a brief delay and/or to tap out a sequence of blocks in the same or reverse order as presented by the examiner, e.g., the Spatial Span subtest of the WMS-III.

Verbal Abilities

Verbal abilities may include both crystallized knowledge and language functions. Crystallized knowledge is declarative knowledge of the type that is generally acquired in school or other social or learning environments and experiences. Examples of tests used to measure this construct include vocabulary knowledge as measured by the WAIS-III Vocabulary subtest, in which the examinee is asked to define a series of presented words, and general information as evaluated by the WAIS-III Information subtest, in which the examinee is asked to answer common knowledge questions.

Common receptive language measures may include both written presentation, as in reading comprehension tasks, and tasks such as the Token Test, in which the examinee is required to follow a succession of increasingly complex aurally presented instructions, and the Complex Ideational subtest from the Boston Diagnostic Aphasia Examination, which

requires the examinee to answer several two-part aurally presented questions. Two examples of commonly used expressive language tests include the Boston Naming Test, in which the examinee is shown drawings of objects one at a time and asked to identify each one in succession, and letter fluency tasks, such as the FAS task, in which the examinee is given three 1-min trials to name as many words as he or she can think of that begin with the letters F, A, and S, respectively. Lesions to brain areas known to mediate specific language skills, such as Broca's area of the frontal lobe, which is important in the motor programming of speech, and Wernicke's area of the temporal lobe, which is involved in the auditory comprehension of spoken words, would impact performance on some of these tasks.

Visual-Spatial and Constructional Skills

Visual-spatial or perceptual organizational skills refer not simply to visual acuity, but moreover to the ability to discern the pattern and relative location of visual stimuli, as well as manipulate objects in three-dimensional space. Common measures of these abilities include several subtests from the WAIS-III, e.g., Block Design, in which the examinee is required to rapidly match a two-dimensional figure by combining three-dimensional colored blocks, Picture Completion, in which the examinee must identify the important missing element in a series of pictured scenes, and Matrix Reasoning, a visual reasoning task in which the examinee must identify the missing element in a matrix by discerning the rule underlying the relationship between each of several subparts. Another widely used test in this area is the Hooper Visual Organization Test, in which the examinee is shown several pictured objects that have been cut and randomly arranged in pieces; the examinee must mentally rotate the various pieces and put them together, and then name the object. Posterior right hemisphere lesions are often responsible for impairment on many visuospatial and construction tasks; however, left hemisphere lesions can also disrupt these abilities, but typically present with a different pattern of impairment.

Mental Processing and Psychomotor Speed

Psychomotor and mental processing speed refer to the speed of thinking and/or integration of speed of thinking with rapid motor action. Common measures of this domain include the WAIS-III Digit Symbol task, in which the examinee is asked to rapidly draw a set of symbols that are matched via a key to a series of numbers, and the Trail Making Test (Part A). The latter task was originally developed in the 1930s by John Partington and published as Partington's Pathways Test; it requires the examinee to rapidly connect a series of circled numbers. At least one test of psychomotor speed is almost invariably included in neuropsychological evaluations, as these tests tend to be among the most sensitive to any form of CNS dysfunction. However, this is also the domain most clearly and consistently affected by normal aging. Declines in psychomotor speed relative to younger adults are evident among those in their 30s, and slowing progresses with further aging.

Neuropsychological batteries also commonly include more direct measures of motor functioning, e.g., the Hand Dynamometer Test of grip strength, in which the examinee's strength in each hand is evaluated, and Test of fine motor dexterity the Grooved Pegboard in which the examinee is required to rapidly place a series of keyed pegs into metal slots. These motor tasks can be particularly helpful in identifying lateralized patterns of impairment, and specifically lesion to the motor cortex, as well as having potential implications for everyday functioning.

Executive Functioning

The term executive functions is one that is particularly important in describing human cognition, yet at the same time it is one of the most difficult to precisely define. Very broadly, executive functions are those higher-order functions that allow an individual to initiate and maintain goal-directed behavior, as well as to disengage from such behaviors when appropriate to the goals and/or in response to environmental cues. Some of the underlying skills generally classified within this area include abstraction and problem solving, cognitive flexibility and set shifting, response inhibition, and planning. As noted previously, the concept of working memory also has some overlap with that of executive functioning. Historically, the term executive functions was frequently used interchangeably with the term frontal-lobe functions (with particular emphasis on the prefrontal cortical regions). However, not all activities of the frontal lobe are executive in nature, and the neurologic systems needed to carry out these executive functions are clearly not limited to the frontal lobe; over the past two decades, there has been increased recognition of the role of frontal–subcortical circuits in the various executive functions.

Some of the most widely used measures of executive functions include the Wisconsin Card Sorting Test (WCST), Booklet Category Test, Stroop task, and Trail Making Test (Part B). Consideration of the specific tasks in each of these tests is helpful in

illustrating the range of functions subsumed under the label of executive skills. For instance, successful performance of the WCST requires the examinee to discern an unspoken rule that defines correct versus incorrect matches, and also requires the examinee to change strategies when appropriate. The Booklet Category Test similarly requires the examinee to discern the pattern or rule underlying the sequence of presented stimuli, but that rule may change over various subsections. Thus, the WCST and Booklet Category Test may both measure abstraction/problem solving, as well as mental flexibility (or perseverative thinking). The Stroop task seems to require a somewhat different skill, particularly response inhibition. On the color–word interference portion of this task, the examinee must rapidly tell the examiner the color of the ink that the word is printed in rather than read the printed word (e.g., say the word red when the word blue is printed in red ink). This requires the examinee to inhibit the more automatic or quickly processed reading response in favor of a more effortful color-naming response. Trail Making Test Part B is generally administered immediately after Part A (described previously), and requires the examinee to rapidly connect a series of numbers and letters (alternating between the number and letter sequences). Letter fluency (FAS, described earlier) as well as category fluency, such as the ability to rapidly name types of animals, are also sometimes interpreted in terms of executive functions, as rapid performance is facilitated by use of an effective strategy for mental search of the lexicon.

Learning and Memory

Neuropsychological batteries, particularly those used with older patients, almost invariably include one or more measures of auditory and visual episodic declarative memory. Tests of auditory and visual episodic learning and memory have similar methods; they often include several trials, followed by a delay trial. Distraction tasks or other neuropsychological tests are often administered during the delay period to prevent rehearsal of the test stimuli. Measures of delayed recall often include a free recall trial and recognition, and sometimes include cued recall. Examples of reliable and often-used measures of auditory learning and memory tests include the Hopkins Verbal Learning Test, Rey Auditory Verbal Learning Test, and California Verbal Learning Test, all of which are list-learning tasks, and Logical Memory (from the WMS-III), in which the stimuli are stories or short passages. Visual learning is often measured with the Brief Visuospatial Memory Test (BVMT) and the WMS-III Visual Reproductions (VR) and Family Pictures subtests. One thing to note about the BVMT and VR is that both not only require the examinee to learn and remember geometric figures, but the free recall portions also require the examinee to draw those figures. Thus, each of these latter tests also has a visual-constructional element in addition to a visual memory component. This provides yet another example of why neuropsychologists are reluctant to interpret isolated test scores: performance on one test may color the appropriate interpretation of a second test. Encoding and retrieval of new information are thought to be dependent on the intact functioning of the hippocampus and associated parahippocampal gyri, although recent literature has shown that the frontal lobes are also involved in these abilities. And, as was pointed out previously, many of these tests require additional cognitive skills (such as visual-constructional skills) that are not controlled by these neuroanatomical areas.

Other Assessments

In addition to tests of the preceding or similar constructs, comprehensive neuropsychological assessment frequently includes measures to estimate premorbid functioning, as well as standardized measures of motivation or effort. In terms of premorbid functioning, word reading (another example of crystallized knowledge) tends to be relatively resilient to the effect of many (although not all) forms of acquired neurologic dysfunction. Thus, word reading measures such as the American National Adult Reading Test or the Word Reading subtest from the Wide Range Achievement Test, third edition, are often included as part of an overall neuropsychological evaluation as a way of estimating premorbid verbal functioning.

Tests of motivation and effort (or symptom validity testing) are most frequently employed in forensic contexts, in which there may be some monetary or other tangible benefits to the examinee to appear cognitively impaired. These tests can also be useful in other contexts to detect suboptimal effort. (These symptom validity tests are sometimes loosely referred to as malingering tests, although, strictly speaking, this term is generally inappropriate in that it implies consciously motivated deficient performance. It is generally difficult to prove that suboptimal performance is consciously motivated.)

Effects of Normal Aging on Neuropsychological Functioning

Normal aging can affect the various cognitive abilities to different degrees. Perhaps the single most

consistent finding is that of slowed psychomotor speed with age; in fact, some researchers have suggested that other normal aging-related cognitive changes are in fact due to the effects of this psychomotor slowing. Psychomotor slowing is not limited to the elderly, but rather progresses throughout most of the adult life span. People in their 30s, on average, have slower performance on psychomotor tasks than those in their 20s; the average performance of people in their late 80s on the WAIS-III Digit Symbol subtest is two standard deviations below the mean of that of people in their 20s.

In addition to slower processing speed, one of the most frequent and salient changes with normal aging, particularly among the elderly, is a modest decline in efficiency of information acquisition and free recall retrieval (as evidenced on auditory or visual measures of episodic declarative memory). In contrast, however, actual retention of information, as evaluated through cued recall and/or recognition test formats, tends to be less affected by normal aging than initial acquisition and free recall. This contrast can be important in distinguishing normal forgetfulness from a pathological process. For instance, the hallmark of AD is a progressive decline in both efficiency of acquisition and retention of acquired information. In fact, some evidence suggests that greater than age-normal declines in episodic declarative memory may serve as an early marker of the preclinical stages of AD.

Normal aging can also be associated with some declines in perceptual-organizational/constructional skills, as well as executive functions, and some aspects of working memory, particularly those requiring more active manipulation of information, rather than simple momentary rehearsal and storage. In contrast, performance on verbal tasks (other than verbal memory) tends to be relatively unaffected, particularly those emphasizing crystallized verbal knowledge. For example, comparison of the various age group norms for the WAIS-III Vocabulary test suggests that vocabulary knowledge remains stable or even increases through the late 70s, and even among those in their 80s, declines are relatively modest. Thus, an apparent change in an older person's crystallized knowledge, particularly if that knowledge cannot be elicited even through recognition, warrants further inquiry for possible pathological processes.

In addition to savings (retention), recognition, and verbal knowledge, basic attention also tends to be relatively unaffected by normal aging. For instance, age accounts for only about 2% of variance in the performance of Digit Span scores within the general population, although the backward component can be more difficult, as it draws more heavily on the executive functioning aspects of working memory. Aging also appears to have minimal influence on vigilance, such as measured by errors of omission on CPT tasks, although there is some evidence that commission errors may increase, perhaps reflecting more difficulty with response inhibition. Among attentional tasks, age appears to have a stronger effect on cancellation tasks such as the Digit Vigilance task. This may in part be secondary to changes in processing speed, as most cancellation tasks require rapid performance. (This possibility also illustrates the dangers of interpreting scores from an individual test in isolation, e.g., impaired versus intact performance on measures of psychomotor/processing speed would appropriately affect interpretation of impaired scores on a cancellation task purely in terms of attentional difficulties.)

Screening versus Comprehensive Assessment

One common concern that arises in applied settings is that a comprehensive neuropsychological evaluation may require several hours to complete. Indeed, due to changes in managed care and health-care reimbursement patterns, many clinical neuropsychologists are under increasing pressure to streamline cognitive assessments. There are many contexts in which full and comprehensive neuropsychological evaluation is clearly warranted, and the time is easily justified. For other situations, such as general or routine screening, however, there also exist shorter screening methods.

The Folstein Mini Mental State Examination (MMSE) is probably the most widely used cognitive measure in medical and psychiatric settings. The MMSE is a 30-item measure that includes items related to orientation, attention/working memory, recall, language and constructional skill. Advantages of the MMSE include ease and time of administration (it can be administered by trained staff, and it generally requires 10 minutes or less), and because it is so widely used, most clinicians have a general sense of what to expect from patients with MMSE scores in various ranges. It also can be frequently repeated to document the course of cognitive decline. Due to these aspects, the MMSE is a useful (if imperfect) tool to include in general clinical evaluation, particularly with older adults. It must be noted, however, that the MMSE items are quite easy for cognitively intact or even mildly impaired individuals, and it is strongly influenced by education. Thus, a key disadvantage is that it is often insensitive (having a high

false-negative rate) as a general cognitive screening tool. Even people with AD sometimes score in the normal range of the MMSE, particularly those with high levels of education in the earlier stages of the disorder. Moreover, the MMSE tends to be even less sensitive to some other forms of neurocognitive deficits, such as subcortical dementias, e.g., dementia due to Parkinson's disease, or Huntington's disease. Finally, the MMSE fails to assess the domain of executive functioning, which may be among the most important in terms of ability to function independently, and is commonly affected by a number of neurocognitive disorders.

An intermediate choice between a very brief screening tool such as MMSE and a full comprehensive neuropsychological evaluation is a somewhat more comprehensive and sensitive screening battery. For instance, the Repeatable Battery for Assessment of Neuropsychological Status (RBANS) requires about 30 minutes to administer and screens for deficits in a number of cognitive functions of frequent interest. Another widely used option is to administer a subset of standard neuropsychological tests, either several tests from a cognitive domain of particular relevance to the presenting concern or one brief test from every major cognitive domain. More recently, computerized cognitive screening tests such as the MicroCog have been developed; they reduce time and administration burden. In any of these cases, there is clearly a tradeoff between savings in administration time versus depth and breadth of assessment. Nonetheless, these options are important to keep in mind, as wider or more routine incorporation of neuropsychological screening into standard clinical practice can be very useful when working with older patients, yet may often be avoided by some clinicians due to concerns about lengthy testing. By integrating a clinical neuropsychologist into the treatment team, and/or with clear communication between the referring clinician and the neuropsychologist, an effective and appropriate balance can generally be found to meet the needs and limitations of any particular clinical context.

Expanding Role of Neuropsychology in Treatment

Information garnered from such neuropsychological assessment can be an extremely valuable component of treatment in and out of geriatric health-care settings, including in those with neurologic, psychiatric, and general medical conditions that may affect cognition directly or through the effects of the primary treatment. Sometimes simply documenting the nature of specific cognitive deficits can be a substantial relief to patients and/or their family members. For example, some of the disinhibition that may be associated with executive dysfunctions can be particularly distressing to a patient's family members. Identification and explanation of the nature of executive dysfunction can be therapeutic for the family, as the behaviors are then recognized as unintentional. Identification of cognitive deficits and strengths (or at least relative sparing) is key to designing effective rehabilitation strategies, including teaching patients to rely on their strengths, as well as to planning environmental changes to diminish the potential influence of cognitive deficits.

Beyond compensatory strategies, direct treatment of cognitive deficits is itself an area of growing interest. For instance, cholinesterase inhibitors are now considered standard care for people with AD. Whereas presently available compounds convey at best modest and temporary benefits, there are research efforts underway to develop more efficacious treatments. As such treatments emerge for AD and other disorders, repeated cognitive evaluation will be key to documenting reversal (or at least delay of the progression) of cognitive decline. Likewise, there are emerging government, academic, and industry collaborative efforts, such as the MATRICS (Measurement and Treatment Research to Improve Cognition in Schizophrenia) and the TURNS (Treatment Units for Neurocognition in Schizophrenia) projects to foster development and evaluation of cognitive enhancing medications for the neurocognitive deficits associated with schizophrenia. As was noted previously, cognitive deficits have the most direct influence on level of everyday functioning and outcome; thus, as pharmacologic and other interventions for targeting cognitive deficits in a range of conditions begin to emerge, the importance of neuropsychological assessment will continue to expand as a means of gauging treatment needs and treatment effectiveness.

Summary and Conclusions

This article only briefly discusses the current and potential relevance of a neuropsychological perspective in the care of geriatric patients. Nonetheless, several key points are: (1) clinical neuropsychology is a unique discipline combining expertise from an array of disciplines relevant to systematic evaluation of brain–behavior relationships and patterns of specific neurocognitive strengths and weaknesses, and involves more than administration of standardized cognitive tests; (2) such evaluation can provide valuable information in detecting functionally relevant

cognitive deficits, differential diagnosis, determining the impact of known neurologic insults, and determining the speed and trajectory of cognitive decline or recovery, as well as in differentiating pathological changes from those associated with normal aging; (3) neuropsychological assessment has clear utility in the care and treatment of not only neurologic patients, but also those with psychiatric disorders and many other medical conditions; (4) there are numerous neuropsychological domains, and specific tests have been developed to assess these domains; (5) some age-related neuropsychological changes, such as declines in processing speed, are expected, whereas other cognitive abilities, such as crystallized verbal skills, should remain relatively intact over the life span; (6) comprehensive neuropsychological evaluations assess a wide variety of specific cognitive abilities, but a balance must be struck between comprehensive assessment and the need for time-efficient screening methods; and (7) neuropsychological evaluations are likely to continue to be important as newer treatments are developed for cognitive difficulties of various conditions. In short, clinical neuropsychological consultation can provide unique and valuable information to clinicians working with older patients.

Atherosclerosis

G Spinetti, M Wang, R E Monticone and E G Lakatta, National Institute on Aging, Baltimore, MD, USA

Published 2007 by Elsevier Inc.

Glossary

Advanced Glycation End Products (AGEs) – Modified proteins or lipids, late products of nonenzymatic glycation and oxidation reactions.

Atherosclerosis – An inflammatory fibroproliferative disease of large arteries, of humans and most other species, that underlies almost all human coronary heart diseases, as well as many other cardiovascular diseases.

Chemokines – A subfamily of small cytokines (8–10 kDa), mostly known for their chemotactic properties, but recently shown to be involved in the control of cell proliferation, survival, and differentiation.

Cytokines – A family of secreted molecules with a role in many biological processes, such as cell activation, growth and differentiation, inflammation, and immunity.

Fibrous Cap Atheroma – An advanced stage of progressive atherosclerotic lesions characterized by a well-formed necrotic core with an overlying fibrous cap.

Hyperlipidemia – Elevated triglyceride or low-density lipoprotein (LDL) cholesterol levels and multiple lipoprotein metabolic abnormalities.

Inflammation – A series of responses of vascularized tissues to injury, i.e., stimuli or insults. It includes alteration of hemodynamic and vascular permeability and consequent infiltration of leukocytes. Inflammatory factors have recently been shown to

be produced by vascular cells and regulate their functions predisposing the vessel wall to an enhanced response to injury.

Intimal Xanthoma (Fatty Streak) – Accumulation of macrophages and lymphocytes within the thickened intima, without a necrotic core or fibrous cap.

Tunica Intima – A layer of endothelial cells lining the vessel lumen, in direct contact with the blood flow, separated from the tunica media by the internal elastic lamina.

Tunica Media – Middle layer of the vessel wall containing mostly smooth muscle cells interspessed with elastic lamallae.

Introduction

The average age of the population of Western countries is increasing. Demographic data show that in the United States, for example, 35 million people are now 65 years of age and older, and this number will double in 2030 (**Figure 1**). Although data from epidemiological studies have discovered that lipid levels, diabetes, sedentary lifestyle, and genetics are risk factors for cardiovascular diseases (CVDs) such as atherosclerosis, hypertension, congestive heart failure, and stroke, advancing age confers the major risk.

This article first describes the development of the atherosclerotic lesion in the context of the emerging role of inflammation, then reviews some of the epidemiological data that support the notion that aging is the major risk factor for atherosclerosis. Finally, it summarizes the age-associated changes within the vessel wall in humans and experimental animal models and discusses how specific pathophysiological mechanisms become superimposed on vascular substrates that have been modified by aging, therefore conferring upon age, per se, the role of the major risk factor for CVDs.

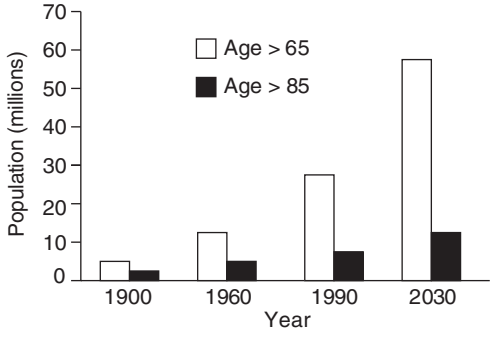

Figure 1 The demographic imperative of aging. Population of United States from 1900 to 2030. The white bars represent people 65 years of age and older; the black bars represent individuals 85 years and older. Data replotted from the US Census Bureau data, with projections for 2030. Reproduced with permission from Spinetti G. et al. 2004 Rat aortic MCP-1 and its receptor CCR2 increase with age and alter vascular smooth muscle cell function. Arteriosclerosis, Thrombosis, and Vascular Biology 24: 1397–1402, Lippincott Williams & Wilkins.

Pathogenesis of Atherosclerosis

Development of Atherosclerosis and Progression to Thrombosis and Clinical Events

Cardiovascular diseases are the leading cause of mortality in Western societies. Among these, atherosclerosis, a progressive disease in which lipids and extracellular matrix components accumulate in the large arteries, represents one of the most important contributors. The traditional view of the atherosclerotic lesion as a pool of lipid debris embedded in vascular smooth muscle cells (VSMCs) has dramatically changed in the past decade with the recognition of a prominent role for inflammation. This article reviews the characteristics of atherosclerotic plaque development and describes some new concepts associated with inflammatory cells and molecules.

Recently, experts in the field have revised the classification scheme of the American Heart Association (AHA) for atherosclerotic lesions. This new classification scheme is consistent with the AHA categories but does not imply an orderly, linear pattern in the progression of the lesion, as was the case of the former categories, and thus reflects the wide array of morphological modifications that are evident from recent autopsy studies. This article uses this morphological classification scheme.

The wall of large arteries is composed of three layers: the tunica intima, tunica media, and adventitia (**Figure 2**). The circulating blood is in direct contact with a monolayer of endothelial cells (ECs) that constitute the first barrier of the intima. In humans in addition to ECs, the intima contains few VSMCs, which are normally absent in most other species, and extracellular matrix components. In contrast, the medial layer is composed of VSMCs and matrix, which is represented by elastin and collagen. Two types of nonatherosclerotic arterial remodeling that can lead to atherosclerotic lesions are diffuse intimal thickening and intimal xanthoma (traditionally referred to as the fatty streak), although both conditions can exist without progression. Intimal thickening is characterized by VSMC accumulation in a proteoglycan-rich matrix, in the absence of leukocyte transmigration and lipids. In humans there are very few reports on the progression of localized intimal thickening to atherosclerotic

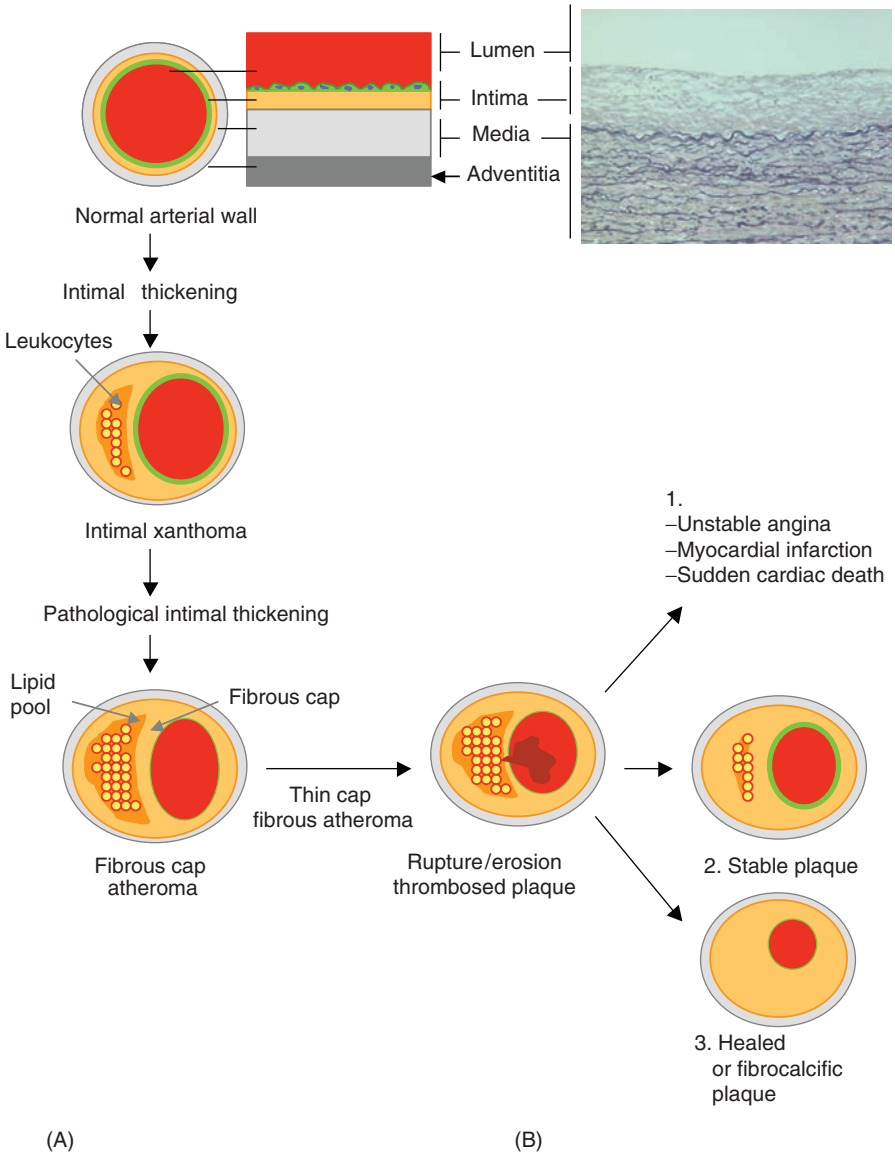

Figure 2 Schematic view of the development of an atherosclerotic lesion. (A) From the top to the bottom of the figure: the typical structure of the arterial wall to the atherosclerotic plaque and its healing or complications. Details are described in the text. The yellow circles represent leukocytes. (B) Photomicrographs of grossly normal human aorta. Original magnification: 100×. Note that the adventitia layer depicted in blue in the schematic view is not shown in the photomicrograph reported in panel B.

lesions. It is of note that, as reported by Velican, the distribution of this normal, developmental localized intimal thickening in children can be correlated with the distribution of characteristic lesions seen in adult humans. Moreover, a study from Kim et al. in swine shows that atherosclerotic lesions produced in the coronary by 90 days of feeding a hyperlipidemic (HL) diet arise almost exclusively in the normally occurring localized intimal thickening.

Intimal xanthomas are pre-atherosclerotic lesions in which macrophages and lymphocytes accumulate within the thickened intima without a necrotic core or fibrous cap. The human xanthomas, in most cases, can regress. In this respect, as shown by the aforementioned study by Velican et al. and by the results of the Pathobiological Determinants of Atherosclerosis in Youth (PDAY) study, the distribution of atherosclerotic lesions in the third decade of life and beyond is very different from the intimal xanthomas seen in children. Intimal thickening and xanthomas are present in all human populations, but xanthomas have been preferentially observed in association with exposure to the Western diet. Several observations show that this arterial remodeling is mediated by EC activation in response to risk factors such as hyperlipidemia. The activated ECs mediate the

recruitment of leukocytes by expressing adhesion molecules, i.e., vascular cell adhesion molecule (VCAM-1), P-selectins, E-selectins, and chemotactic molecules, mostly belonging to the chemokine subfamily of cytokines, that facilitate the rolling, adhesion, and consequent transmigration of leukocytes. Modified lipoproteins, i.e., oxidized phospholipids and aldehydes, or cytokines, i.e., interleukin (IL)-1β and tumor necrosis factor-α (TNF-α), can induce the nuclear factor-κB (NF-κB)-mediated increase in VCAM-1.

Shear stress can modulate atherosclerosis formation. Laminar shear stress (>15 dynes/cm^2 s^{-1}) is known to have a protective role, while turbulent, low shear stress (<5 dynes/cm^2 s) in regions of arterial bifurcation can be pro-atherosclerotic. Several studies report that genes associated with atheroprotection have shear stress responsive domains on their promoters and ultimately can decrease EC apoptosis and leukocyte transendothelial migration. Among these laminar shear stress-induced genes are superoxide dismutase (SOD) and endothelial nitric oxide (NO) synthase, both leading to increased nitric oxide bioavailability. In addition, laminar shear stress inhibits the expression of adhesion molecules, e.g., VCAM-1, and possibly the activation of pro-apoptotic factors, e.g., caspases. Moreover, laminar shear stress downregulates the chemokine monocyte chemotactic protein-1 (MCP-1/CCL2) gene expression by ECs, potentially maintaining atherosclerotic lesion-free areas under steady flow. In fact, this chemotactic cytokine, MCP-1, through the activation of its receptor CCR2, can induce migration of monocytes, lymphocytes, ECs, and VSMCs. Of note, all these cells express MCP-1 during atherogenesis or following balloon injury and can recruit other arterial cells to migrate into the intima as well as recruit leukocytes from the blood. Both transgenic and knockout mice for MCP-1 and CCR2 have demonstrated a role for these molecules in the pathogenesis of atherosclerosis and intimal hyperplasia. Other chemokines have functions similar to MCP-1 but recruit and activate different classes of leukocytes to the arterial intima. For example, T lymphocytes migrate to the intima toward a concentration gradient of three other chemokines, inducible protein-10 (IP-10), monokine induced by IFN-γ (Mig), and IFN-inducible T cell α-chemoattractant (I-TAC), all of which are induced by interferon-γ (IFN-γ), and bind the chemokine receptor CXCR3. Chemoattraction of mast cells, also found in the intima, is mediated by another chemokine, eotaxin, which binds to the CCR3 receptor. Once these leukocytes are resident in the arterial intima they undergo modifications that contribute to the potential development of the atherosclerotic lesions. Monocytes acquire the characteristics of tissue macrophages and express scavenger receptors, CD36, on their surface, which permit internalization of modified lipoproteins, causing a transition of macrophages to foam cells. Macrophages also secrete cytokines and growth factors, e.g., tissue factor (TF) and matrix metalloproteinases, that mediate the development of the atherosclerotic process. Transmigrated T cells within the arterial intima may encounter antigens, such as oxidized low-density lipoproteins (ox-LDL), and after activation these can produce cytokines that also modify the function of other resident cells. In addition, mast cells within the intima degranulate and release, among other factors, TNF-α and chymase. In summary, growth factors, proteases, and cytokines, which include several chemokines, play a crucial role in the transition to the atherosclerotic lesion.

Pathological intimal thickening is the first evidence of progressive atherosclerotic lesions. This stage is often referred to as an intermediate lesion and is poorly defined. Virmani et al. histologically described the pathological intimal thickening as a lesion with some lipid accumulation but no evidence of necrosis. A fibrous cap overlies the lipid area and is rich in VSMCs and proteoglycans. Macrophages and lymphocytes are sparse. At this stage, VSMCs may change their phenotype and function and switch from a so-called contractile to a synthetic phenotype, losing their differentiated function as their contractile filaments are replaced by endoplasmic reticulum and Golgi. Synthetic VSMCs proliferate and migrate in response to growth factors and cytokines, and also secrete extracellular matrix components and more growth factors, cytokines, and proteases in a vicious cycle. As the lipid core grows, activated leukocytes secrete proteinases that degrade the extracellular matrix and cytokines, such as interferon-γ (IFN-γ), that inhibit the deposition of collagen. This process results in a more definitive lesion, the fibrous cap atheroma, in which a necrotic core is present, with cholesterol, phospholipids, and triglycerides. At this stage the fibrous cap is a distinct layer of connective tissue that covers the lipid core. It is composed of VSMCs embedded in extracellular matrix, and is infiltrated with macrophages and lymphocytes. Lesions that are most likely to evolve toward rupture are those defined as thin fibrous cap atheroma (<65 μm thick). In this case the necrotic core is very large, with observed presence of vasa vasorum, hemorrhage, and/or calcification, and the fibrous cap has lost VSMCs, matrix, and the inflammatory infiltrate.

The most advanced stage of atherosclerosis, the lesion with thrombi, can be the result of three

different processes: rupture, erosion, and, less frequently, calcified nodulation. When an atherosclerotic plaque ruptures, a defined area of the fibrous cap is disrupted, and coagulation molecules that are present in the blood may come into contact with TF produced by the leukocytes in the lipid core, which causes thrombosis. If the local conditions are prothrombotic and profibrotic, the formation of an occlusive thrombus can cause an acute coronary event. Alternatively, factors associated with the thrombus, such as thrombin, platelet-derived growth factor (PDGF), and transforming growth factor-β (TGF-β) may mediate the healing and induce collagen deposition and VSMC proliferation, leading to an advanced fibrous and often calcified plaque. Plaque ruptures are the most common cause of death in young men (<50 years of age) and in older women (>50 years), and are found in the 60% of people dying of sudden luminal thrombi. The type of rupture caused by erosion is defined as the area in which the endothelium is absent, with consequent exposure of VSMCs and extracellular matrix. In some cases the fibrous cap rupture results in a lesion with a calcified nodule. The origin of this kind of lesion is not well known, and it occurs more frequently in areas of the arteries of maximal torsion stress. Finally, examples of lesions not necessarily associated with thrombi are fibrocalcific plaques, characterized by a thick fibrous cap and extensive accumulation of calcium in the intima. The necrotic core, if present, is very small, pointing to these lesions as a potential result of healing after plaque rupture. More commonly, healed plaques show a disrupted fibrous cap filled with VSMCs, proteoglycans, and collagen.

Inflammation: A Target of Novel Therapeutic Interventions for Atherosclerosis

The most commonly accepted hypothesis for the initiation of atherosclerosis assigns the most prominent role to lipids. LDL cholesterol is undoubtedly an important contributor and may be the permissive factor for atherogenesis. In this regard, it is important to note that the average levels of cholesterol in Western countries most probably exceed the true normal levels for our species, as suggested by evidence in animal models and humans in agrarian societies. With this consideration in mind, cases of individuals with proven coronary artery disease and with normal levels of cholesterol exist, and therapies that target LDL cholesterol are effective in decreasing coronary events by one-third over 5 years of treatment.

Novel risk factors currently under consideration are lipoprotein (a), oxidant stress by angiotensin II (AngII), and infectious agents. Studies that have addressed the role of infectious agents in atherosclerosis, of which *Chlamydia pneumoniae* has been the primary focus, thus far have given inconclusive results. New classes of atherosclerotic drugs include inhibitors of hydroxymethylglutaryl coenzyme A (inhibitors of HMG CoA reductase, or statins), angiotensin-converting enzyme inhibitors (ACE), and angiotensin receptor blockers (ARBs).

Statins inhibit HMG CoA reductase, the enzyme that catalyzes the rate-limiting step in the synthesis of cholesterol. In addition, statins also have a pleiotropic effect and can alter many cellular processes, at least at high concentrations *in vitro*. This is due, in part, to the inhibition by statins of polyisoprenoids, other bioproducts of the cholesterol synthesis pathway. When these polyisoprenoids are linked to proteins, they generate prenylation and alter the protein function. One target of prenylation is the Rho family of small G-proteins, important downstream molecules in receptor-mediated signals that control cell migration and proliferation. Therefore, the inhibition of prenylation by statins has a direct effect on cellular functions, independent of lipid lowering. This inhibition of cellular migration and proliferation is especially important with respect to VSMCs and their role in the atherosclerotic plaque stability. It is important to note that the inhibition of VSMC proliferation by statins is still controversial: as plaque progression occurs, this inhibition could be beneficial by interfering with development of the lesion, while in the established atherosclerotic lesion the lack of VSMCs may adversely alter plaque stability. Other interesting effects of statins observed in animal models are to decrease TF expression by macrophages and to increase NO synthase expression.

Recent clinical trials suggest that blocking AngII by inhibiting its activator ACE or its receptor-mediated signals using ARBs can be beneficial beyond the effect on blood pressure. Data from the Heart Outcomes Prevention Evaluation (HOPE) trial show that ACE inhibition therapy, at doses that had little effect on blood pressure, significantly reduced cardiovascular events. Blocking the angiotensin type I receptor (AT_1) by using ARBs can be very selective and resulted in a better side effect profile compared to ACE inhibitors as shown by recent clinical trials, e.g., the Valsartan in Acute Myocardial Infarction Trial (VALIANT), among others. One of the targets of ACE inhibition or ARBs could be the ability of AngII to produce pro-inflammatory molecules such as IL-6 and MCP-1. Furthermore, ACE inhibition in

rabbits with experimental atherosclerosis reduces the activation of the transcription factor NF-κB, an upstream factor in the production of IL-6 and MCP-1.

Chronological development of pre-atherosclerotic lesions occurs with advancing age. Intimal xanthomas have been observed in individuals in the first and second decades of life, preatheromas in the second, and fibroatheromas in the third decade and later.

The remainder of this article reviews the current knowledge regarding the effect of aging on the arterial wall and its emerging role as an independent risk factor for atherosclerosis as well other CVDs.

Advancing Age Is the Major Risk Factor for Vascular Disease

The incidence and prevalence of CVD increases exponentially with advancing age, both clinically and subclinically, i.e., silent coronary atherosclerosis, and have an important impact on morbidity and mortality in Western society (**Figure 3**). Epidemiologists, gerontologists, and vascular biologists have teamed up to define the risk of the aging process–exposure time interaction with respect to the development of CVD in apparently healthy humans and animal models.

Several explanations for the role of arterial aging in atherosclerosis have been postulated. One is that aging, per se, is a disease, but the fact that some persons age without evidence of arterial diseases does not support this hypothesis. Another is that the dose of other risk factors for the development of age-associated arterial diseases progressively increases with advancing age, and moreover that aging is associated with increased exposure time to such risk factors. A distinct but somewhat related view is that the structure and function of the cardiovascular system undergo age-associated changes that alter the substrate on which pathophysiological disease mechanisms take place. Thus, in older persons mechanisms that underlie age-associated changes in arterial structure and function become partners with mechanisms linked to arterial diseases. This interaction is further complicated by the genetic background, lifestyle, and environment of each individual.

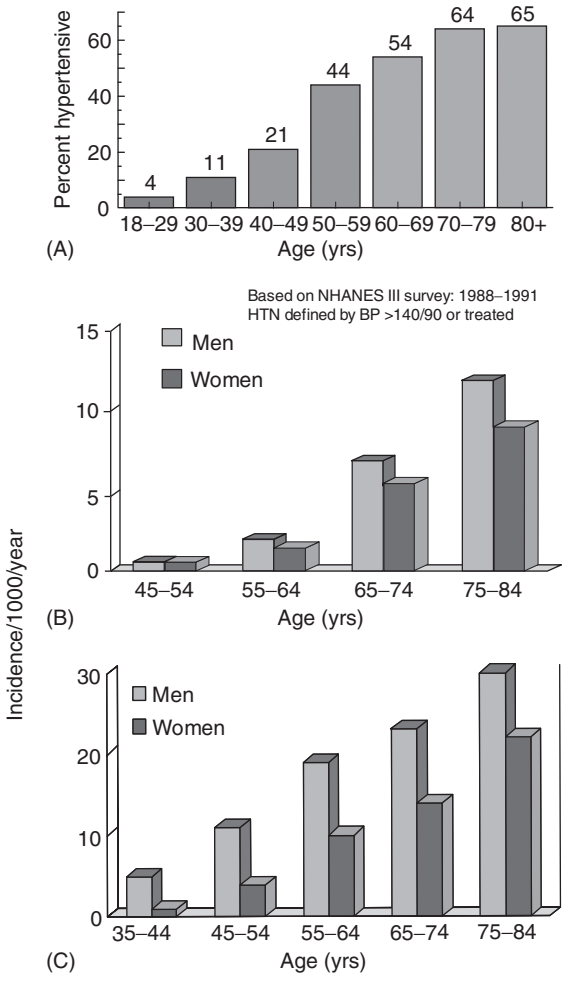

Figure 3 The incidence and prevalence of cardiovascular disease increase with aging. (A) Prevalence of hypertension defined as systolic blood pressure (BP) $\geqslant$140 mmHg, diastolic BP $\geqslant$90 mmHg, or current use of medications fro treatment of high BP. Data are based on National Health and Nutrition Examination Survey III (1988–1991), Burt VL, Whelton P, Roccella EJ, et al. (1987) *Framingham Study: An Epidemiological Investigation of Cardiovascular Disease*, Section 34. NIH Publication No. 87-2703. Bethesda, MD: National Heart, Lung and Blood Institute.

Human Arterial Structure and Function: Age-Associated Changes

Increased Intimal Thickening as a Risk Factor for Atherosclerosis Longitudinal studies are a powerful tool for understanding the aging process. These studies follow apparently normal participants that are selected for the absence of disease over many years and keep track of their health status and lifestyle habits, which could influence the onset of age-associated diseases. Among these studies, the Baltimore Longitudinal Study on Aging (BLSA), has contributed to characterizing multiple aspects of the effect of aging on cardiovascular structure and function in a single study population.

In humans, large elastic arteries, i.e., aorta and carotid arteries, thicken and show increased dilatation with advancing age, and this remodeling is observed in postmortem analysis to be present mainly in the intima. The carotid wall intimal media (IM) thickness increases two- to threefold from 20 to 90 years of age, but heterogeneity among older individuals is very prominent. Data show that this remodeling occurs in the context of EC dysfunction, but no detailed information is available yet.

IM thickening at a given age predicts the presence of silent coronary artery disease (CAD) (**Figure 4B**), which often progresses to clinical CAD. Interestingly, the difference in IM thickening between young and old individuals in the absence of CAD exceeds the difference among older persons free of disease and those with evidence of CAD. These data from the BLSA suggest that IM thickening is a risk factor for atherosclerosis and is strongly influenced by aging. Several other studies on individuals not previously screened for the absence of occult CVD have also shown that increased IM thickening is a predictor of cardiovascular events. Consequently, the degree of risk varies with the degree of thickening (**Figure 4C**), and the IM thickening is as potent a predictor of the development of disease as other traditional risk factors, such as LDL levels, diabetes, smoking, blood pressure, and atrial fibrillation (**Figure 4D**).

It is important to note that age-associated IM thickening also occurs in nonhuman primates and rodents in the absence of lipid infiltration or other evidences of atherosclerosis (**Table 1**). Therefore, the excessive IM thickening in humans with advancing age, in the absence of evidence for plaque, is not necessarily a manifestation of early atherosclerosis, but rather is attributable to arterial aging. This, combined with age-associated endothelial dysfunction, vessel stiffening, and changes in arterial pulse pressure, may lead to age-associated diseases. Thus, in Western societies the atherosclerotic plaque is activated by additional risk factors such as hypertension, smoking, dyslipidemia, diabetes, diet, and genetic factors that interact with aging of arteries. Evidence in rabbits and nonhuman primates supports this hypothesis: in these models an atherogenic diet that leads to equivalent increases in plasma lipids for a fixed period of time causes more severe arterial lesions in older than in younger animals.

Arterial Stiffening and Pressure During aging the IM thickening in both men and women is accompanied by increased stiffness of central arteries (measured as pulse wave velocity [PWV]), a decrease in compliance, and luminal dilatation. Arterial stiffening, reflected as an increase in PWV, is often

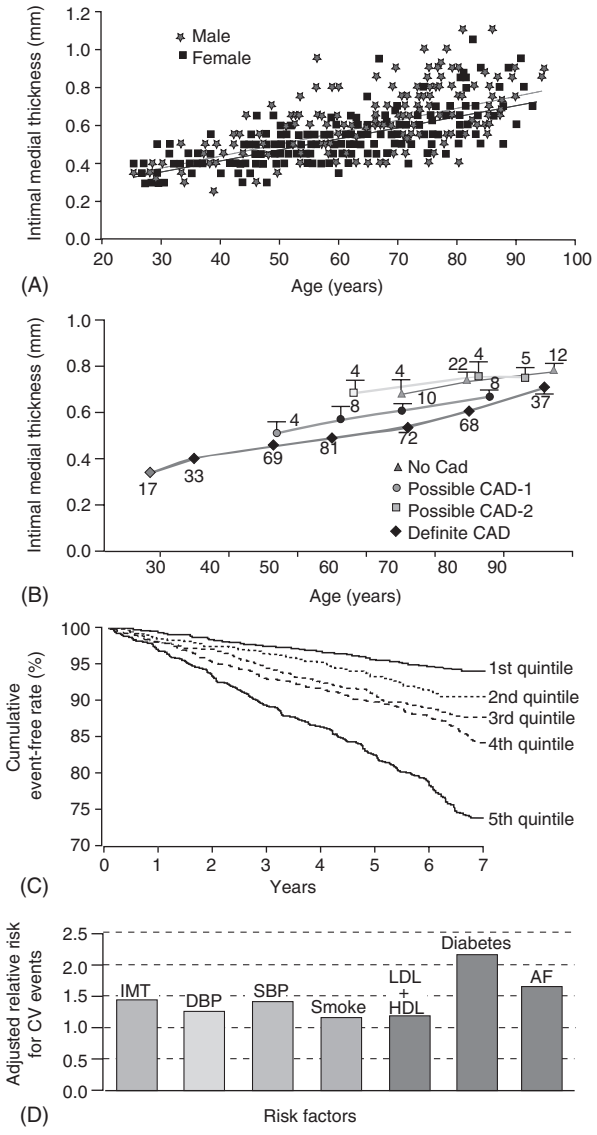

Figure 4 (A) The common carotid intimal medical thickness in healthy BLSA volunteers as a function of age. Data from Nagai Y, Metter J, Earley CJ, et al. (1998) Increased carotid artery intimal-medial thickness in asymptomatic older subjects with exercise-induced myocardial ischemia. *Circulation* 98: 1504–1509. attributed to changes in the vascular media, such as increased collagen, reduced and fragmented elastin, and calcification. Increased PWV with aging has been observed in humans in the absence of atherosclerosis, but more recent data show that atherosclerosis and diabetes contribute to increased large vessel stiffness. Therefore, arterial stiffening may be mediated not only by matrix changes but also by EC dysfunction, observed in the aforementioned pathologies, and consequent compromised regulation of VSMC tone. It has been shown that endothelial function is altered from the sixth decade of life, concomitant with observed elevations in pulse pressure. Both elevated pulse pressure and PWV are now known to be independent risk factors for cardiovascular events. It has been hypothesized that nonenzymatic glycation of extracellular matrix components could lead to cross-linking of such molecules and participates in increasing arterial stiffness in aging and diseases. For example, nonenzymatic cross-linking of collagen due to advanced glycation end products (AGEs) results in stiffer fibers and consequently less distensible old arteries, in which the resident cells, ECs and VSMCs, have modified migratory and proliferative capacities. Of note, a new thiazolium derivative, ALT-711, that is able to break AGE-derived cross-linking, has an effect in reducing age-associated arterial stiffness and compliance in rats, nonhuman primates, and humans.

Age-Associated Molecular and Cellular Changes within the Arterial Wall

Increasing data support the notion of age-associated arterial remodeling as an inflammatory response that creates a metabolically active environment where diseases can flourish. Age-associated arterial remodeling shows similar characteristics at the cellular and molecular levels in all species, from rodents and nonhuman primates to humans (see **Table 1**). As noted, the mechanisms involved in this remodeling likely confer upon arterial aging the status as the major risk factor for arterial diseases. Specific facets of age-associated remodeling include luminal dilation, thickening of the intimal and medial layers with cellular and extracellular matrix reorganization, increased stiffness, and endothelial dysfunction (**Table 1** and **Figure 5A**). Studies have shown that diffuse intimal thickening with aging is characterized by accumulation of fibronectin, collagen, and VSMCs, with an increase in matrix metalloproteinase-2 (MMP-2) expression. In addition, aortic intracellular adhesion molecule (ICAM) and TGF-β1 expression markedly increase with age and localize to MMP-2-positive staining areas. Arterial aging is also characterized by an increase in NAD(P)H oxidase activity, reactive oxygen species (ROS) production, and a reduction in NO bioavailability (**Figure 6** and **Table 1**). Moreover, increased arterial levels of pro-inflammatory cytokines, such as MCP-1, TNF-α and IL-6, accompany aging.

Several of the molecules listed above that are changed with advancing age within the arterial wall are under the control of the AngII signaling system (**Figure 6**). Aortic ACE activity is increased in rodents and non-human primates with advancing age. Moreover arterial AngII itself increases in these animal models and colocalizes with ACE and MMP-2. Recent data show that other components of the AngII system are also changed with age,

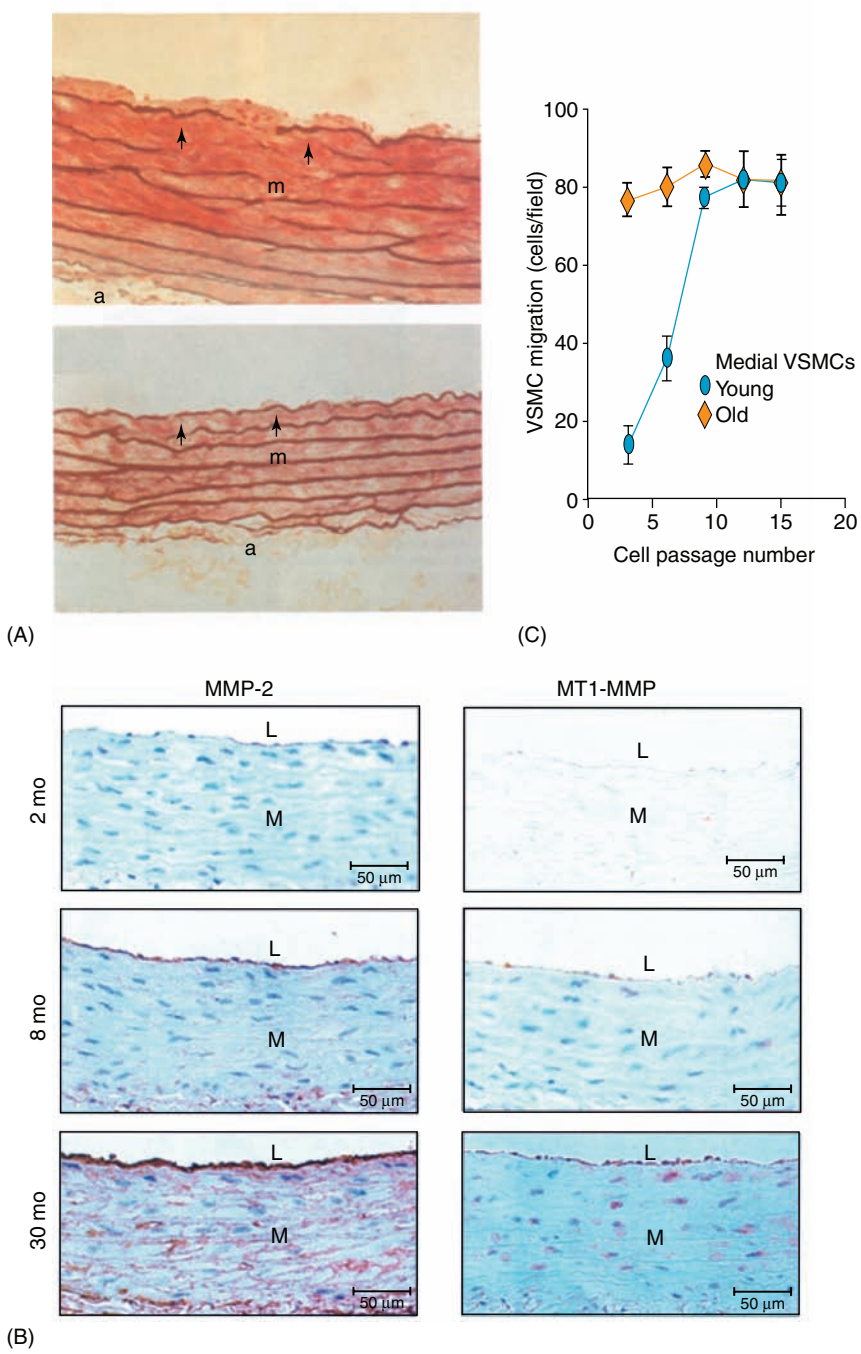

Figure 5 (A) Morphometric changes in the aortic wall of rats showing significant aortic intimal thickening in old rats (upper), as compared with young rats (lower). m, media; a, adventitia. Arrows show the internal elastic lamina. (B) Representative aortic sections from 2-, 8-, and 30-month-old rats stained with an antibody against MMP-2 and MT1-MMP, a tissue activator for MMP-2. The antibody stains brown. L, lumen; M, media. (C) Chemotaxis in response to a PDGF gradient is increased in early passage VSMCs from the aortic media of old rats compared with those from younger rats. VSMCs within the older aorta are primed to respond to the growth factor. Reprinted, and replotted in the case of panel C, from Lakatta EG (2003) Arterial and cardiac aging: major shareholders in cardiovascular disease enterprises: part III: cellular and molecular clues to heart and arterial aging. *Circulation* 107: 490–497.

and, in particular angiotensinogen and AngII receptor type 1 (AT1R), are increased. Of note, chronic administration of ACE inhibitors ameliorates or delays some aspects of age-associated arterial changes, such as intimal thickening and matrix remodeling. Thus, the local AngII system may play an important role in the arterial remodeling that accompanies aging.

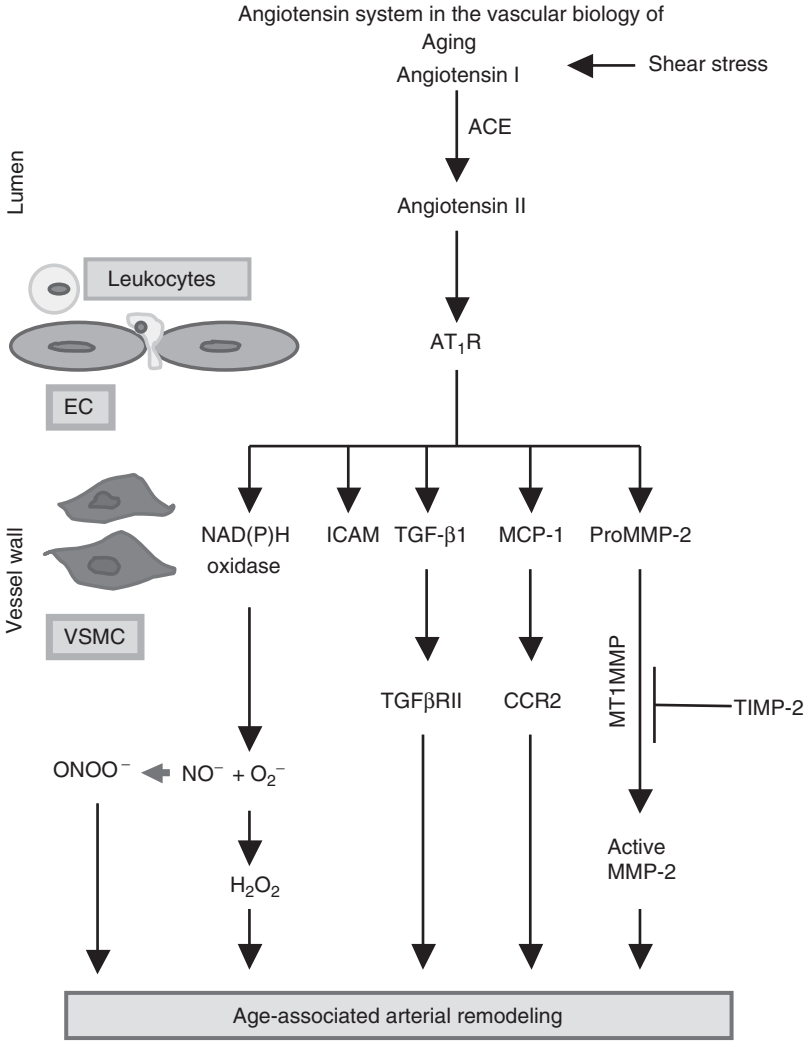

Figure 6 The potential role of the local angiotensin system in the vascular biology of aging. Schematic diagram of the angiotensin pathway-associated molecules that have potential role in the aging vascular remodeling.

Vascular Smooth Muscle Cells

Studies in rodents show that the structural and biochemical changes that occur within large arteries with aging are accompanied by a shift of the VSMC phenotype from the contractile to the synthetic state. This less differentiated state of VSMCs is characterized by an increased proliferative and migratory responsiveness to growth factors, as described in the case of the VSMCs that participate in the atherosclerotic plaque development. Early passage VSMCs isolated form older rats, for example, show exaggerated migratory capability in response to factors such as PDGF-BB, while cells from the aorta of young animals require many more passages in culture to give a similar response (**Figure 5C**). Synthetic VSMCs are thought to migrate from the media, invade the internal elastic lamina, and populate the intima, contributing to the process of the thickening. The involvement of cells from the circulation or resident ECs or VSMCs that undergo transdifferentiation to a VSMC phenotype, expressing characteristic markers, e.g., α-SMA, have not been demonstrated yet but represent a potential mechanism for the age-associated increase in VSMCs. Of note, while inflammatory cells are not detected in the arterial wall of rat, rabbit, or monkey (**Table 1**), VSMCs and ECs in the aged intima secrete inflammatory molecules. Among those factors, chemokines can affect migration and proliferation of VSMCs, ECs, or macrophages. One chemokine known for its crucial role in atherosclerosis, MCP-1, is also elevated in the plasma of older persons in the apparent absence of cardiovascular disease. Interestingly, recent studies have shown that MCP-1 is also upregulated in the aged rat aortic wall and regulates VSMC functions,

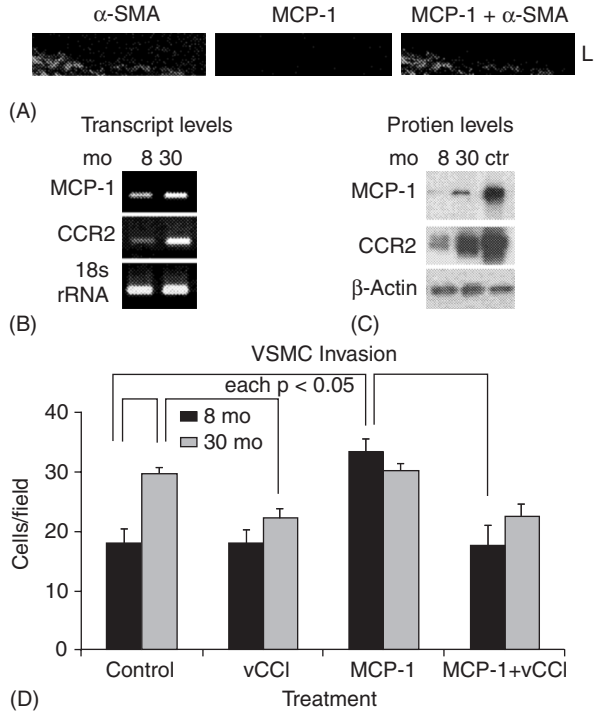

Figure 7 (A) Aortic cellular components associated with MCP-1. Immunofluorescence: double staining. MCP-1 (red, middle panels) increases in the rat aorta with age and localizes mainly in the intima. The left panels show the staining with a VSMC marker, α-SMA (green, upper panels), and an EC marker, CD31 (green, lower panels). The merged images show that MCP-1 staining colocalizes with CD31- and α-SMA-positive areas, as indicated by the white arrows (upper and lower right panels, yellow). L, lumen; M, media. (B and C) CCR2 and MCP-1 transcript and protein expression increase during aging *in vivo*. (B) A representative agarose gel showing the amplified cDNA fragments by real time PCR analysis, normalized to the expression of rRNA 18 s. (C) Representative Western blot analysis on protein extracts from rat aortae. CTR represents 50 ng of recombinant MCP-1 (upper panel) or protein extract from THP-1 monocytes cell line (lower panel), normalized to the level of expression of β-actin. m, months old. (D) MCP-1 pretreatment affects VSMC invasion. VSMCs isolated from old rat aortae show increased basal invasiveness in the absence of a chemoattractant, compared to cells from younger animals. Treatment with MCP-1 (50 ng/ml for 24 h) increases the basal invasion potential of young (8 months) VSMCs to the level of untreated VSMCs from old rats (30 months). The CCR2 antagonist vCCI (150 ng/ml) blocked this effect. Reprinted and remodeled from Spinetti G, Wang M, Monticone R, Zhang J, Zhao D, and Lakatta EG (2004) Rat aortic MCP-1 and its receptor CCR2 increase with age and alter vascular smooth muscle cell function. *Arteriosclerosis, Thrombosis, and Vascular Biology* 24(8): 1397–1402.

suggesting a role for this chemokine in age-associated vascular remodeling. Both the MCP-1 transcript and protein are increased within the rat arterial wall and are associated with ECs and VSMCs (**Figure 7A**). Treatment of young rat VSMCs with MCP-1 can increase their invasion ability in a receptor (CCR2)-dependent manner.

The migration of VSMCs is dependent at least in part on the activation of MMP-2 and degradation of the extracellular matrix in which these cells are embedded (**Figure 5B**). MMP-2 is secreted from ECs and VSMCs as an inactive enzyme. Its activation is dependent on the balance between membrane-bound activator (MT1MMP) and tissue inhibitor (TIMP-2), among other factors. Altered levels of these factors have been observed in the arterial wall of older rats, monkeys, and humans, leading to a marked increase in MMP-2 with aging.

Interestingly, MMP-2 is one of the enzymes responsible for the activation of TGF-β1, another growth factor increased within the aged arterial wall and a downstream product of AngII signaling (**Figure 6** and **Table 1**). Both circulating and arterial TGF-β1 increase with aging, and within the arterial wall TGF-β1 localizes mainly in the thickened intima in the same areas of MMP-2.

Endothelial Cells

Several reports have described EC dysfunction within the intima of older human and animal models. These cells are enlarged and show evidence of polyploidy and altered cytoskeletal arrangement and integrity that is reflected in their impaired ability to migrate and proliferate. The age-associated characteristics of ECs have been linked to both apoptosis and telomere shortening. In addition, adhesion molecule expression increases with aging in the rat aorta, and increased monocyte adhesion has been observed in the old rabbit vascular wall. Moreover, glycosaminoglycans are found in the subendothelial intimal layer. Glycosaminoglycans are important players in the regulation of vascular permeability and can affect the retention of macromolecules, e.g., ox-LDL. These altered features of ECs in older arteries can be partially responsible for the increased vulnerability to the development of atherosclerotic lesions of old arteries. In this regard it is interesting to note that ECs from older donors secrete increased levels of plasminogen activator-1 (PAI-1), an important prothrombotic factor. Furthermore, ECs from old vessels can secrete increased levels of AngII and endothelin, two known vasoconstrictor factors, supporting the role of AngII in the age-associated arterial remodeling. Parallel reduction in the expression of molecules with vasodilator properties, such as NO and prostacyclin 2 (PGI2), occurs with advancing age. The decreased NO bioavailability in the old rat, monkey, and human arteries results in reduced endothelial vasodilatation. Factors that can regulate the production of NO, directly or indirectly, e.g., endothelial NO synthase (eNOS) and NAD(P)H oxidase, are

also changed with advancing age. The latter is a major regulator of ROS generation in the vessel wall. The expression of its p22phox subunit is increased in the aged rat arteries, and the consequent increased ROS can then sequester NO and thus contribute to the diminished NO bioavailability (**Figure 6**). The activation of NAD(P)H oxidase is also induced by the triggering of the receptors of the family of the RAGEs by their ligands, AGEs. AGEs are proteins or lipids that have been irreversibly modified by non-enzymatic glycation and oxidation. These products increase with aging and have a potential role in age-associated arterial remodeling. AGEs can signal through the activation of the RAGEs. This activation mediates not only the aforementioned NAD(P)H oxidase activation, but also the production of TF and cytokines, i.e., IL-6 and MCP-1, the recruitment and activation of inflammatory cells, platelet aggregation, EC apoptosis, and VSMC proliferation and invasion. In addition to this function, AGEs have a well-known role in cross-linking collagen and several growth factors; this process is observed during aging even in euglycemia.

Arterial Stiffening

The increased arterial stiffening observed with aging is due, at least in part, to changes in an important component of the extracellular matrix: elastin. Elastin represents about 30% of the dry weight of the arteries, and the integrity of its fibers allows the correct stretch and recoil of the artery. Recently, several reports have demonstrated that elastin not only has a mechanical role in the arterial wall, but also can affect VSMC proliferation, migration, and vascular inflammation, since it acts as a growth factor and cytokine reservoir. When the elastin fibers are damaged, i.e., during aging, those molecules are released in the microenvironment and directly affect the VSMCs in the media. With aging, not only are the elastin precursor, tropoelastin, mRNA levels decreased, but also its degradation by MMP-2 is increased in parallel, leading to a net reduction of this important vascular tone modulator. As a result, old arteries show fragmented elastin (**Figure 6A**). Another mechanism potentially responsible for the increased stiffness is vascular calcification. Bone formation-associated genes, i.e., bone morphogenic protein-2 (BMP-2), osteopontin (OPN), and osteonectin, are all expressed with advancing age within the vessel wall, in addition to the bones. These factors bind calcium and can influence transdifferentiation of ECs and VSMCs to osteogenic and chondrogenic phenotypes.

Summary and Conclusions

In summary, molecular, cellular, and structural age-associated changes of large arteries resemble in many ways those observed in the development of an early atherosclerotic plaque (**Table 1**). But aging and atherosclerosis are two clearly separate conditions, as shown by the evidences in rodents and nonhuman primates, in which the same remodeling is present with aging in the absence of atherosclerosis. The pro-inflammatory condition observed in the arteries of such animal models, in the absence of leukocyte infiltration or lipid involvement, points to a new definition for inflammation in the context of the arterial wall as a physiological process to maintain homeostasis that involves inflammatory molecules affecting vascular cell functions. In humans the arterial changes during aging become part of the risk associated with advancing age of developing CVD and the increased susceptibility to traditional risk factors, e.g., lipid-rich diet, smoking, and diabetes. In conclusion, the age-associated pro-inflammatory phenotype of the arteries represents a highly responsive environment for the development of age-associated CVD.

Attention

P A Allen, University of Akron, Akron, OH, USA
E Ruthruff, University of New Mexico, Albuquerque, NM, USA
M-C Lien, Oregon State University, Corvallis, OR, USA

Glossary

Attentional Capacity – The ability to process information quickly and/or the ability to process multiple stimuli or multiple tasks simultaneously.

Event-Related Potential (ERP) – A measure of electrical activity on the scalp triggered by a particular event.

Stroop Effect – When subjects take longer to name the ink color of a presented word when it is incongruent with the meaning of the word than when it is congruent.

Introduction

At any moment in time, our senses are flooded with a diverse array of sights, sounds, smells, tastes, and textures. We cannot deeply process all of these stimuli, nor would we want to (most are irrelevant to current goals). Therefore, it is imperative that we be selective in which stimuli we process and which we ultimately respond to. It is also imperative that we be selective in which tasks we perform on these stimuli. When hurriedly leaving the house, one needs to find the keys without being distracted by other potential tasks (e.g., reading the paper, cleaning the floor).

Control over cognitive processing, which is often loosely called 'attention,' becomes even more critical as we age. Sensory and motor processes can slow dramatically, further increasing the need for selectivity in which stimuli we perceive and respond to. Fortunately, many forms of attention are preserved with age. Other forms of attention, however, decline with age, resulting in severe performance problems. The purpose of this article is to review this important area of research, highlighting reliable generalities as well as unresolved issues.

Varieties of Attention

The study of attention is complicated by the fact that it is not a unitary construct. There are many different varieties of attention that are used in different situations and that are sensitive to different variables. In the present article, we concentrate on three important and widely studied varieties: attentional capacity, attentional selectivity, and executive task control.

The scientific study of attention is based on many years of theoretical and methodological development. Progress has been driven in part by the development of more precise quantitative methods and more sophisticated brain-imaging techniques. Despite this progress, not all theoretical controversies have been resolved. For example, there is still no consensus on whether there exist single or multiple pools of attentional resources, or how bottom-up (stimulus-driven) and top-down (goal-driven) processes combine to drive spatial attention. Controversies also abound in the study of aging and attention. One commonly held theory is that the declines in cognitive performance are due primarily to declines in processing speed. We will revisit this widely held but controversial hypothesis at several points. We conclude that although there are situations in which this proposal seems to hold, there are also replicated studies in which it does not.

Much of the research discussed here is based on the assumption that human cognition involves a series of distinct mental operations. Stimuli impinging on the sense organs (e.g., light on our retinas) are converted into neural signals, which then undergo a series of transformations, sometimes culminating in an observable response. Often these mental processes are modeled as discrete (strictly serial) stages, such as stimulus encoding, categorization, response selection, and response execution. This simplified stage framework allows one to ask whether and how specific stages are influenced by attention. One can also examine whether the effects of age are general (influencing all stages equally) or specific to certain stages.

Adult Age Differences in Capacity

The term 'attentional capacity' has been used in many different ways by many different researchers. Typically, it refers to the ability to process information quickly and/or the ability to process multiple stimuli or multiple tasks simultaneously. A multitude of approaches have been used to assess capacity and how it changes with age. In the following sections we review several prominent lines of research on capacity and the conclusions they afford.

Simultaneous Presentation Dual-Task Methodology

One way to assess an individual's mental capacity is to see how performance degrades as the number of tasks is increased. The classic method is to compare performance when two tasks are presented simultaneously to performance when only one task is presented. The net difference is often called the dual-task cost. Typically, the primary task (e.g., word recall or visual search) and the secondary task (e.g., tone discrimination: high- versus low-pitched tones) involve different sensory modalities. A common finding is that dual-task costs are substantial and increase as the difficulty of either task increases. These findings have been interpreted as evidence that the task demands exceeded the available attentional resources.

In aging research, simultaneous presentation dual-task studies have consistently shown larger dual-task costs for older than for younger adults. Furthermore, this difference increases as the secondary task difficulty increases. These results have been interpreted as evidence that older adults have decrements in attentional capacity. Craik and McDowd, for example, examined age differences in divided attention when participants performed a four-choice response time (secondary task) while simultaneously attempting to recall a list of words. Because dual-task costs were larger for older adults than for younger adults, Craik and McDowd concluded that older adults had fewer processing resources to allocate to word recall.

Although these conclusions seem reasonable, the interpretation of simultaneous presentation dual-task data is subject to certain conceptual problems. In this paradigm, people can trade performance between the two tasks (doing one better at the expense of the other). Such tradeoffs complicate interpretations of the data, especially when performance is reported for only one task (as is often the case). A further limitation of this paradigm is that the single-task and dual-task conditions are run in different blocks of trials. Consequently, these conditions differ not only in their capacity demands (dual-task vs. single-task), but also in the number of tasks that must be prepared and held in memory. The blocking of conditions also invites unwanted strategic differences between conditions (e.g., more effort or more cautiousness in dual-task blocks than in single-task blocks).

Sequential Presentation Dual-Task Methodology

Another dual-task methodology for assessing capacity is the sequential presentation method. The best-known and most widely used variant is the psychological refractory period (PRP) paradigm. In the PRP paradigm, two tasks (T1 and T2) are presented in close succession with a variable stimulus onset asynchrony (SOA). Participants are instructed to make speeded responses to T1 and T2 (denoted R1 and R2, respectively), and the response time (RT) for these two tasks is referred to as RT1 and RT2. Typically, RT1 is unaffected by SOA. A ubiquitous finding,

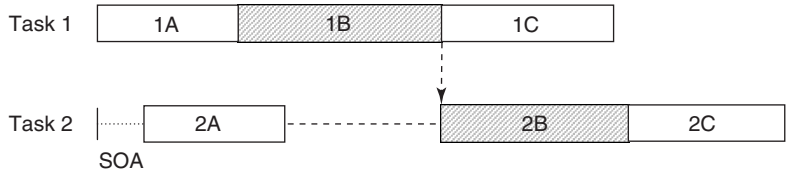

Figure 1 A central bottleneck model. This model assumes that the task 2 central processing stage cannot start until the task 1 central processing stage is completed. 1A, 1B, and 1C are, respectively, the prebottleneck, bottleneck, and postbottleneck stages of task 1. 2A, 2B, and 2C are the corresponding processes for task 2. SOA, stimulus onset asynchrony.

however, is that RT2 increases as SOA decreases (i.e., as temporal overlap between tasks is increased). This increase in RT2 has been termed the PRP effect.

PRP findings generally support the central bottleneck model, shown in **Figure 1**. This model hypothesizes that peripheral processes (encoding and response execution) can proceed in parallel for T1 and T2, but central processes (e.g., response selection) cannot. Thus, at short SOAs, T2 central processes must wait for T1 central processes to finish. This waiting produces the PRP effect on T2.

Sequential presentation dual-task methods (such as the PRP paradigm) address the two conceptual complications mentioned in the previous section on simultaneous presentation dual-task methods. First, sequential presentation (typically with same task order on every trial) tends to encourage a consistent dual-task strategy. Often, interference is restricted to T2, so that there is no performance tradeoff between tasks. Second, this approach uses several different SOAs between the presentations of task 1 (primary task) and task 2 (secondary task), mixed within a single block of trials. Mixing minimizes unwanted strategic differences between conditions. Because participants must always prepare for both tasks and hold both tasks in memory, this paradigm makes it possible to isolate true dual-task costs from the costs of preparing and maintaining two task sets in working memory.

Most studies of aging and PRP effects have shown evidence of larger PRP effects for older adults than for younger adults. However, the theoretical interpretations for this interaction differ widely across studies. Allen *et al.* proposed an executive control deficit that decreases the efficiency of switching between T1 and T2. Hartley and Little argued that older adults do not have an executive control deficit, but rather are less efficient in managing input interference and output interference. Finally, Glass *et al.* proposed that older adults exhibit poorer task coordination strategies. Although the Allen *et al.* and the Glass *et al.* viewpoints both emphasize executive control deficits, they are based upon opposing interpretations of PRP effects (the former is based upon Pashler's central bottleneck architecture and the latter is based upon Meyer and Kieras's executive process interactive control [EPIC] model). Consequently, although there is some agreement that older adults have difficulty in task coordination or time-sharing, there is no consensus as to the specific mechanisms involved.

Another major advantage of the sequential presentation method is that it provides an independent set of analytical tools to assess capacity – locus-of-slack logic. This logic allows one to determine which mental operations are capacity-limited (i.e., are subject to the processing bottleneck) and which are not. For instance, to determine whether a particular T2 process is subject to the bottleneck, one can manipulate the duration of that stage and measure the interaction with SOA. If the manipulated T2 stage occurs at or after the bottleneck, the effects should be constant across SOAs (an 'additive' interaction; see **Figure 2A**). If the manipulated T2 stage occurs before the bottleneck, the effects should decrease as SOA decreases (an 'underadditive' interaction, also known as 'absorption' of a factor effect into 'cognitive slack'; see **Figure 2B**). Thus, by examining whether a manipulation has additive or underadditive effects with SOA, one can determine whether the corresponding stage of T2 is subject to the bottleneck (capacity-limited).

Research using locus-of-slack logic with younger adults has revealed that perceptual processing (up to identification, in the case of letters) is generally not subject to the bottleneck. However, many subsequent processes are subject to the bottleneck, including response selection, memory retrieval, memory encoding, mental rotation, and lexical access.

With these findings in mind, it is interesting to ask whether the bottleneck has the same locus for younger and older adults. Given the hypothesis of reduced capacity for older adults, one might assume that they would have a longer list of bottleneck processes. In fact, the opposite appears to be true. Allen *et al.* reported a study in which T1 was tone discrimination and T2 was a lexical decision task (word vs. non-word). The difficulty of T2 lexical access was manipulated by choosing words with either high or low frequencies of use in the English

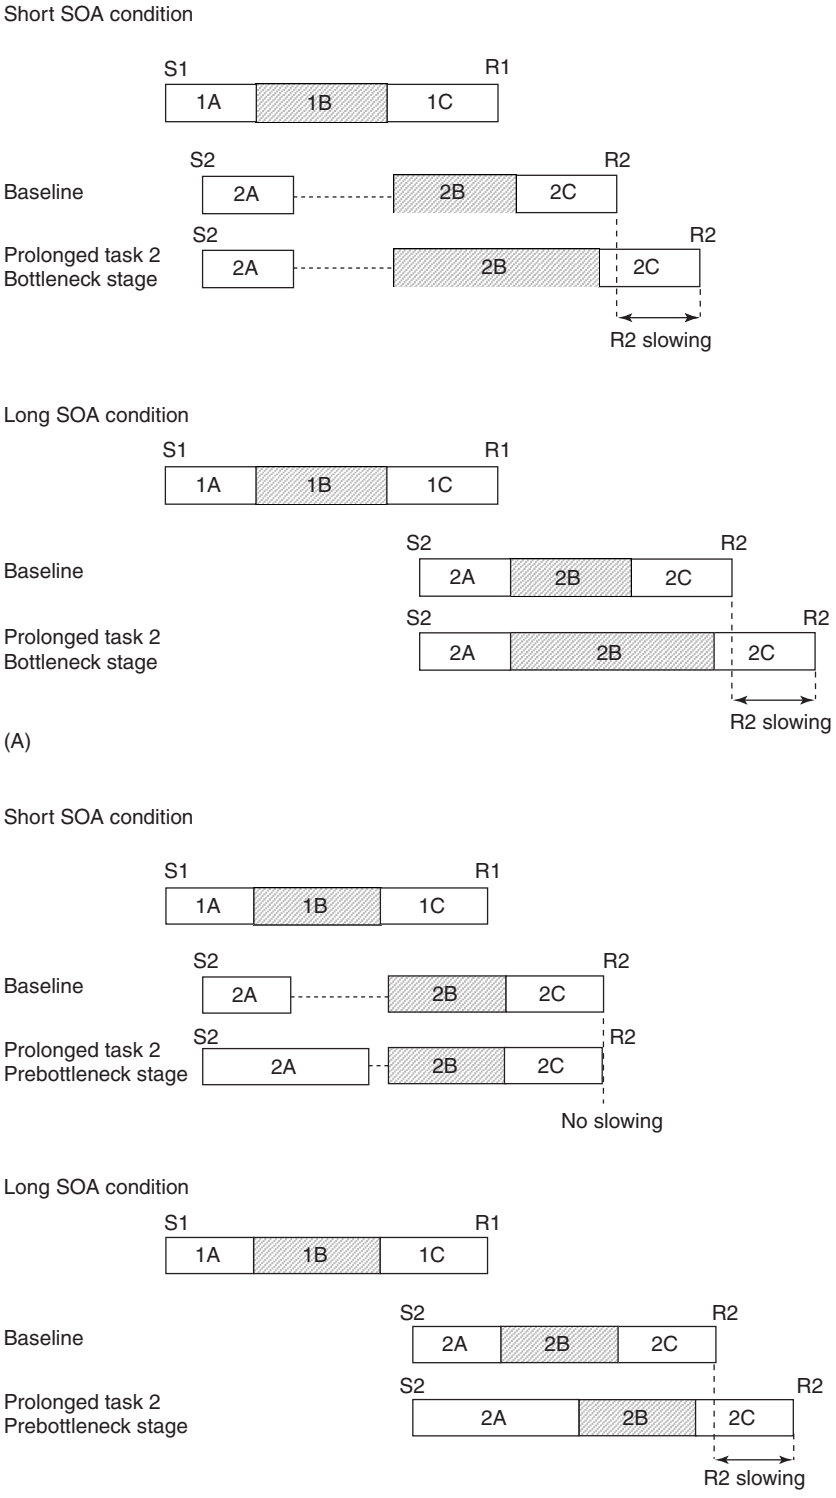

Figure 2 Predictions of a central bottleneck model. (A) Prolonging the central bottleneck stage in task 2 delays R2 at both short and long SOAs. (B) Prolonging the prebottleneck stage in task 2 delays R2 at long SOAs but not at short SOAs. 1A, 1B, and 1C are, respectively, the prebottleneck, bottleneck, and postbottleneck stages of task 1. 2A, 2B, and 2C are the corresponding processes for task 2. S1, stimulus for task 1; S2, stimulus for task 2; R1, response for task 1; R2, response for task 2; SOA, stimulus onset asynchrony.

language. Although word frequency effects on RT2 were roughly additive with SOA for younger adults, they were underadditive for older adults. These results suggest that lexical access was subject to the bottleneck for younger adults, but not for older adults. Furthermore, older adults actually showed shorter dual-task RTs than younger adults, after appropriately controlling for generalized slowing. Thus older adults actually demonstrated greater capacity than younger adults, at least with respect to the lexical access stage. One explanation for this surprising finding is that older adults have automatized lexical access due to their far greater cumulative experience with words.

An important question to address is why older adults appear to exhibit capacity decrements in simultaneous presentation dual-task paradigms yet can exhibit capacity advantages in sequential presentation dual-task paradigms. One possible explanation is that simultaneous presentation methods confound executive control effects (preparing for two tasks, deciding which to do first) and capacity effects (resource conflicts), whereas the sequential presentation methods allow one to isolate capacity effects. Perhaps much of the age deficit found in simultaneous presentation divided attention tasks is due to executive control effects rather than capacity effects. Consistent with this hypothesis, task-switching studies (see later section on executive task control) have often revealed evidence of executive control deficits in older adults.

Coactivation

In the dual-task studies described previously, each stimulus required a separate response. What would happen if multiple, redundant stimuli were presented, each pointing to the same response (as when using multiple clues to solve an entry in a crossword puzzle)? In a laboratory study, for example, participants might be asked to press a button if any stimulus in the display is the letter 'T'; will they respond more quickly when there are two Ts in the display, rather than just one? Typically, they do. This benefit of multiple targets is commonly known as a 'redundant signals effect' or just 'redundancy gain.'

One possible explanation for redundancy gain is that the redundant target stimuli are processed in parallel, and the first one to reach the central executive triggers the corresponding response. In other words, there is a sort of race between the stimuli. The more runners in the race (the more target stimuli), the faster the race will be completed (triggering a response). As an analogy, if a businessman sends two copies of a package, one by FedEx and one by UPS, he has two chances to get a quick delivery. This source of redundancy gain is typically referred to as 'statistical facilitation.'

According to the race model just described, each target stimulus is processed separately. In theory, even more efficient parallel processing would be possible if evidence from the different input channels could be combined together (as when a police detective combines multiple lines of evidence to conclude that a suspect is guilty). This summation of evidence is referred to as 'coactivation.' To provide evidence of coactivation, it is important to first show that the redundancy gain exceeds the amount of statistical facilitation that could be produced by a race between separate processes. Miller's 'race model inequality' provides just such a test:

$$P(RT < t|S_1 \text{ and } S_2) \leq P(RT < t|S_1) + P(RT < t|S_2) \quad [1]$$

The race model inequality provides a very conservative test of the race model. It gives the maximum amount of facilitation that a race could produce under the most extreme assumptions (i.e., perfect negative correlation between target detection times). Despite the conservative nature of the test, violations of this inequality have been frequently observed (at least for simple tasks). In these cases, race models can be discarded in favor of coactivation models.

Coactivation effects are thought to arise from combined activations in decision stages. These are the very stages that Cerella, in an influential meta-analysis of age-related slowing, hypothesized to be at the core of age deficits. Accordingly, one might expect older adults to show less redundancy gain and less evidence for coactivation. In actuality, older adults tend to show larger redundancy gains than younger adults. In 2005, Bucur *et al.* specifically looked for evidence of coactivation in older and younger adults. This study used the original paradigm of Miller with a visual target (an asterisk) and an auditory target (a tone). Interestingly, older adults and younger adults both showed large violations of the race model inequality, suggesting that both groups benefited from coactivation. These results have now been replicated and extended to conditions in which targets were defined along two dimensions of a visual target (e.g., shape and color).

The preserved redundancy gain and coactivation in older adults suggest that they have not lost any capacity to process multiple targets in parallel. Note that this is the same conclusion reached by PRP studies using locus-of-slack logic. These findings contradict the widely held belief that age-related slowing is due primarily to reductions in capacity. We return to this issue in the conclusions section.

Capacity as Speed

According to one school of thought, the slowing of cognitive processing with advanced age is a direct consequence of a decline in processing capacity. One could argue that this statement is circular, though, because there typically is no independent measure of capacity other than processing speed. A way to sidestep this circularity problem is to simply assume that processing speed is synonymous with attentional capacity. Evidence in favor of this view comes from studies assessing statistical mediation using hierarchical regression, path analysis, or structural equation modeling (SEM). The critical finding is that processing speed (e.g., as measured by a digit-symbol substitution task) mediates dual-task performance.

Not all attention studies find that processing speed mediates age effects, however. Many studies continue to find age × task complexity interactions even after a measure of processing speed has been co-varied out. Furthermore, Allen *et al.* re-analyzed earlier data reported by Salthouse and colleagues using SEM techniques and showed that direct age effects persisted independent of effects mediated by a common factor (such as processing speed). Although the situation is complicated, there is now conclusive evidence that common factors in SEM aging research are not consistent across studies and that processing speed is not a parsimonious synonym for attentional capacity.

Neurophysiology

Neurophysiological measures provide a direct window into central nervous system (CNS) function (more so than RT and accuracy measures) and have been profitably used to assess capacity and other aspects of human attention. Three functional measures are widely used: (1) event-related brain potentials (ERPs), (2) positron emission tomography (PET) scanning, and (3) functional magnetic resonance imaging (fMRI). Whereas ERPs have good temporal resolution but poor spatial resolution, both PET and fMRI methods have poor temporal resolution but good spatial resolution. In some cases, researchers employ both ERP and fMRI techniques to simultaneously obtain good spatial and good temporal resolution (this is referred to as multimodal imaging).

The ERP is a measure of electrical activity on the scalp triggered by a particular event (e.g., the activity following a stimulus or the activity leading up to a response). Because the signal-to-noise ratio is low, many trials must be averaged together to produce reliable data. The resulting average waveform consists of a series of positive and negative deflections. Often this waveform is summarized in terms of the amplitude and location of the individual peaks (also known as components). The most investigated ERP component is the P300 (a peak in positive amplitude approximately 300 ms after stimulus onset), thought to primarily reflect encoding and categorization processes but not response processes.

ERPs have been used to study the effects of age on cognitive performance. Bashore *et al.* conducted a meta-analysis of studies that used P300 measures and RT measures for a group of simple cognitive tasks. They summarized the results using a Brinley plot of older adults' performance versus younger adults' performance. For RT, the Brinley plot showed a slope greater than one (1.27), but for P300 amplitude values, the Brinley plot showed a slope close to equality (0.95). This dissociation suggests that age-related slowing with more-complex tasks is due to response processes that take place after the central operations that produce the P300. Note that the P300 data did show an elevated intercept for older adults, suggesting an encoding decrement that was insensitive to task complexity.

Although ERPs have excellent temporal resolution, they have poor spatial resolution. When researchers are interested in the spatial locus of brain activity, they often utilize PET and fMRI. PET methods measure regional cerebral blood flow, whereas the blood oxygenation level-dependent (BOLD) response in fMRI measures oxygen uptake from small blood vessels that nourish neurons. PET methods are relatively invasive – they require either injection or inhalation of radionuclides and relatively long scanning times. fMRI methods are non-invasive and therefore have become increasingly popular compared with invasive methods.

In a study of age differences in attention, Madden *et al.* found that older adults in a dual-task condition showed greater regional cerebral blood flow in prefrontal cortex areas than did younger adults. These findings, which have been replicated in several other studies of executive control, have been interpreted as a compensatory mechanism on the part of older adults – recruiting prefrontal areas to make up for deficiencies in other brain areas. Similarly, Cabeza found that older adults show bilateral prefrontal symmetry in cortical activation, whereas younger adults show prefrontal lateral asymmetry. He concluded that older adults recruit neurons from both prefrontal hemispheres to compensate for less efficient encoding. In 2005, Springer *et al.* provided additional fMRI support for this hypothesis. For younger adults, higher levels of education were associated with greater medial temporal cortical activation; for older adults, higher levels of education were associated with greater prefrontal activation. These findings, along with those of Cabeza and

DiGirolamo *et al.*, suggest that older adults recruit prefrontal regions so that executive control can compensate for less-efficient peripheral processing.

In contrast to the many studies showing increased prefrontal activity in older adults, West reported evidence of prefrontal deficits in older adults. Part of this discrepancy might stem from changes in activity in subcortical areas connected to the prefrontal areas. Rubin, for example, suggested that neural pathways between the prefrontal areas and the basal ganglia resulted in basal ganglia-based deficits being mistakenly labeled as prefrontal deficits. Also, caudate nucleus and related subcortical areas appear to be involved in controlling psychomotor processing speed. The effects of age on these cortical–subcortical relations should be examined with imaging techniques before the seeming paradox between prefrontal deficits and more active prefrontal recruitment on the part of older adults can be fully understood.

Adult Age Differences in Selectivity

Thus far, we have focused on capacity, which is often operationalized as the ability to process multiple stimuli at the same time. In this section, we now turn to the issue of attentional selectivity, which is operationalized as the ability to process relevant stimuli while ignoring irrelevant stimuli. Most of the research discussed here concerns selection of visual stimuli, as when searching for a specific visual target among distractors (*see* Perception). Researchers often attribute the enhanced processing of targets to the application of 'spatial attention' (often described as a 'spotlight') to the location of the target object. There is still disagreement, however, regarding whether selective attention is directed to spatial locations or to entire objects.

A distinction is often made between two qualitatively different modes of selection: top-down (directed by the observer) and bottom-up (drawn by stimuli in the environment). Bottom-up selection is often referred to as 'attention capture.' It has been shown that certain salient visual cues, such as a flash of light, can automatically pull spatial attention toward their location. It is considered automatic (not initiated by top-down mechanisms) because it occurs (1) very quickly (perhaps in less than 100 ms) and (2) even when the observer knows with 100% certainty that the location could never contain a target. A central issue concerns how endogenous (top-down) and exogenous (bottom-up) control interact. A fairly general consensus is that even though bottom-up control of spatial attention is involuntary, it occurs primarily for stimuli that match top-down control settings. When looking for a red object (say, a red car in a parking lot), other red objects can capture spatial attention. When looking for a new object to appear (e.g., a person to come around a corner), any other abrupt visual onset can capture spatial attention.

Next we describe how selective attention changes as adults age. A common finding is that older adults show performances similar to those of younger adults when top-down guidance is used and general slowing is taken into account. However, in conditions where there is less top-down guidance, older adults may show poorer performance than younger adults even after controlling for generalized slowing.

Top-Down Guidance of Visual Selection

When searching for an object, it often helps to have advance information about the target (e.g., when looking for one's keys, it helps to know where they might be and what they look like). Research suggests that older adults are just as able (if not more able) to utilize this top-down guidance of visual search as younger adults. For instance, older adults are just as able to use spatial cues that narrow down the possible target locations. Older adults also can benefit just as much as younger adults from knowledge of the likely identity of a target.

An important question is why older adults benefit so much from top-down attentional control relative to purely bottom-up attentional control. One possibility is that top-down control allows older adults to take advantage of their greater expertise in attentional search from a lifetime of experience. An alternative explanation is that cuing and singletons simply make tasks easier and that age differences are lessened because task difficulty is lessened.

Visual Search

There is some evidence for age effects in visual search for a target among distractors. Rabbitt, for example, reported a card-sorting study (a type of visual search task) with younger and older adults in which he varied display size. As display size increased, older adults performed progressively more poorly relative to younger adults.

However, age differences in visual search are not always found. When tasks require searching multielement displays in both static (non-moving) and dynamic (movement) conditions (distributed attention), there are many cases in which older adults continue to show preserved selective attention. Kramer *et al.*, for instance, found efficient search for both younger and older adults in both static and dynamic conditions. Also, Atchley and Kramer found that older adults could search efficiently when

a depth dimension was added. Hahn and Kramer found that older adults were able to divide their attention between two target locations while ignoring distractor stimuli. Madden found that older adults took longer to process spatial cues and shift their attention across display locations, although this slowing does not necessarily reflect selective attention deficits, per se.

Inhibitory Control and Selection

Rabbitt's hypothesis that older adults exhibit a search deficit because they are more distracted by irrelevant stimuli than younger adults (a filtering deficit) was elaborated upon by Hasher and Zacks. These researchers proposed that the filtering deficit reflects a very general inhibitory control deficit. According to their theory, one consequence of this deficit is an increase in the amount of task-irrelevant stimuli stored in working memory.

This issue has been extensively investigated using the well-known Stroop effect. The Stroop effect is when subjects take longer to name the ink color of a presented word when it is incongruent with the meaning of the word (e.g., when the word 'green' is presented in red ink) than when it is congruent (e.g., when the word 'green' is presented in green ink). Older adults consistently show filtering decrements in Stroop tasks, which has been interpreted as evidence for inhibitory deficits.

It is possible, however, that some filtering problems in older adults are due not to inhibitory deficits, but rather to enhanced automaticity. For example, older adults' greater word-reading expertise (from a lifetime of practice) is likely to result in greater word activation and greater interference on a Stroop task, compared to younger adults. Interestingly, age differences in Stroop interference are strongly attenuated in a modified Stroop task in which the color and the word belong to separate perceptual objects (a color patch at one spatial location and a word at another). Thus, older adults do not have a problem inhibiting words when they are not the focus of attention. Kramer and colleagues found in a number of other filtering paradigms (e.g., negative priming and inhibition of return effects) that older adults do not show larger inhibitory control effects than younger adults. Finally, Allen *et al.* examined visual search in a two-position redundant signals paradigm using 'go'/'no-go' and two-choice tasks. A key prediction of an inhibitory control account of age differences in attention is that older adults should make significantly more false alarms on 'no-go' trials than younger adults. Contrary to this prediction, Allen *et al.* found no age differences in 'no-go' false alarms. They did, however, find age differences in 'go' misses. Although the inhibitory control model of age differences in attention is an intriguing hypothesis, it does not appear that age differences in selective attention are due to a general inhibitory deficit.

Adult Age Differences in Executive Task Control

At each moment, we face a wide array of stimuli, each of which may afford a wide array of tasks. Thus, executive control is needed not only for selecting relevant stimuli, but also for selecting relevant tasks – those that help us to achieve our current goals. People have a remarkable ability to flexibly reconfigure their mental task set in accord with changing task demands. Although impressive, this executive control is not without limits. Studies have repeatedly shown that performance declines when people switch between two tasks compared to when they simply repeat the task. This switch cost persists regardless of how much time people have to prepare.

The classical method of studying task switching is to compare the performance of pure task blocks and alternating task blocks. As a concrete example, a pure task block might include several repetitions of an addition task, whereas an alternating task block might contain an alternating sequence of an addition task and a subtraction task. Rogers and Monsell proposed an alternating runs paradigm. In that paradigm, two tasks ('A' and 'B') are performed in a mixed task block with a task sequence such as AABBAABB, etc. One advantage of this design is that task switches and task repetitions can be compared within a single block of trials. Studies using this paradigm with younger adults have consistently found relatively small switch costs with univalent stimuli (associated with only one task), but large switch costs with bivalent stimuli (associated with both tasks). Bivalent stimuli provide no reliable task cue and therefore place a heavy burden on internal task control (e.g., inhibiting irrelevant task sets and/or activating relevant task sets).

In this section we discuss the effects of age on executive task control. One important distinction in these studies is that between the costs of task switching (repeat vs. switch) and the costs of task mixing. Mixing costs refer to slower task repetition performance in mixed task blocks than in pure task blocks (task A only or task B only); presumably, they primarily reflect the cost of maintaining two task sets in working memory rather than just one.

Mixing Costs

Although younger adults tend to produce little or no mixing cost, older adults often produce relatively large mixing cost. This difference in mixing costs is generally much larger than would be expected based on generalized slowing alone. Kray and Lindenberger proposed that the increased mixing costs reflect general impairments in working memory. Mayr, however, provided evidence that mixing costs are maximized when the tasks share the same stimuli and the same responses. Accordingly, he proposed that older adults have a specific difficulty in updating their internal control settings (differentiating between tasks).

These findings have important implications for dual-task methodology. As noted previously, the simultaneous presentation method involves comparing dual-task blocks to single-task blocks. Thus, the costs of mixing are confounded with the costs of temporal overlap in processing (reflecting capacity). Given that mixing costs increase with age, they alone might explain why overall dual-task costs often increase with age. This consideration suggests that dual-task and single-task conditions should be mixed within a block, as in the sequential presentation method.

Switching Costs

Studies that isolated switch costs from mixing costs have yielded inconsistent results regarding the effects of age. Whereas a few studies have revealed age effects on task switching after taking generalized slowing into account, many others have not. Although the source of the discrepancy is unclear, there is some evidence that age effects are elevated for tasks that impose a high memory load.

Why do mixing costs generally increase with age even though switching costs do not? It is tempting to conclude that older adults have difficulty maintaining two task sets (due to reduced working memory capacity) but have no difficulty switching between them. Another (admittedly subtle) explanation, however, is that older adults do have difficulty task switching and that this difficulty spills over to task repetition trials as well. Consistent with this explanation, note that older adults' task switch performance is generally very poor. It is only when one compares this poor task switch performance to the also poor task repetition performance (in the same block) that there appears to be little net switch cost. In this view, supposedly sophisticated attempts to isolate switch costs from mixing costs can produce misleading results. Arguably the best way to assess overall executive task control deficits in older adults is to study the sum of switch costs and mixing costs (i.e., compare task switch performance with task repetition performance from pure task blocks).

Conclusions

In the introduction to this article we noted that attention is not a unitary construct – rather, it consists of several distinct abilities, such as capacity, attentional selection, and executive task control. It is perhaps not surprising, therefore, that unitary theories of attention and aging have not held up to further scrutiny.

Perhaps the most widely held view is that age differences in performance are mediated by processing speed (an operational definition of attentional capacity). Although processing speed clearly plays an important role, there are documented cases of age differences that are not mediated by processing speed. Further evidence against this view comes from findings of preserved capacity in older adults, demonstrated by locus-of-slack and coactivation studies. Thus, rather than simply alluding to a general common factor (speed), component cognitive processes (such as selective attention) must be taken into consideration.

Another widely held theory of age differences in selective attention is that older adults exhibit poorer inhibitory control (a filtering decrement). Although this approach does have some empirical support, there are many cases in which older adults did not demonstrate inhibitory control deficits. It appears that age effects are due not only to deficits in inhibition (filtering) but also to deficits in activation (focusing).

A third theory of age differences in attention is the frontal lobe decrement model, based upon the observation that older adults show loss of cerebral volume of the frontal lobes. The theory is supported by the finding of executive control deficits in certain task switching conditions. However, there is mounting evidence that older adults do not show frontal deficits. Both PET and fMRI imaging have revealed greater bilateral prefrontal lobe recruitment on the part of older adults, suggesting that older adults use greater frontal activation to compensate for decrements in other neural processing (e.g., temporal cortex processing). Perhaps, for older adults, part of what we refer to as expertise involves developing compensatory recruitment.

Since Rabbitt's pioneering work on age differences in attention, much has been learned. The bad news is that age-related performance declines in capacity, executive task control, and selective attention do occur under many task conditions. The good news, however, is that there are also many cases of

preserved attentional functioning. In fact, there are even documented cases of age-related improvement in expertise, automaticity, and top-down attentional guidance. Recognition of these positive influences of aging might lead to explanations for some of the lingering controversies in the study of aging and attention.

Autonomic Nervous System

S E Borst, S Goswami, D T Lowenthal and D Newell, Geriatric Research, Education and Clinical Center, Veterans Administration Medical Center, and University of Florida, Gainesville, FL, USA

Glossary

Adrenergic – Having the properties of epinephrine or norepinephrine (NE). Drugs that produce effects similar to those of epinephrine are said to be adrenergic, as are nerve endings that release norepinephrine and the cell surface receptors that bind NE and epinephrine.

Baroreceptor Reflex – A mechanism for minute-to-minute regulation of blood pressure (BP). Baroreceptors located in arteries of the upper body respond to a reduction in BP by signaling the brain to activate the sympathetic nervous system, thereby raising the arterial pressure.

Catecholamines – Any of various amines that function as hormones and neurotransmitters in the autonomic nervous system, most notably epinephrine, norepinephrine (NE), and dopamine (DA). The former British names for epinephrine and NE are adrenaline and noradrenaline.

Cholinergic – Having the properties of acetylcholine; refers to drugs that mimic acetylcholine (ACh), nerve endings that release ACh, and the cell surface receptors in tissues that respond to ACh.

Neurotransmitter – A chemical substance that is released from nerve endings when the nerve fires. The neurotransmitter diffuses across the small space of the synapse and binds to a receptor located on an adjacent cell, where it produces its physiological effect.

Postural Hypotension – Reduced arterial pressure in the upper body after rapidly standing upright.

Renin-Angiotensin System – A mechanism for longer-term regulation of blood pressure and plasma volume. A fall in arterial pressure or sympathetic nerve stimulation causes release of renin from the juxtaglomerular apparatus of the kidney. The enzymatic action of renin causes the formation of angiotensin II, a peripheral vasoconstrictor that stimulates the release of aldosterone, facilitating sodium and water retention by the kidney.

Introduction

The autonomic nervous system (ANS) controls involuntary, vegetative, and visceral functions, including heart rate, blood pressure (BP), the motility and secretion of the digestive system, the urinary bladder, and aspects of sexual function. Some of the major responses elicited by the ANS are listed in **Table 1**. The responses of the ANS are involuntary. In contrast, the somatic nervous system controls voluntary

Table 1 Autonomic responses in aging[a]

	Sympathetic response	*Parasympathetic response*	*Aging effect*

[a] Bold capitals indicate SNS- or PNS-predominant tone.

responses of skeletal muscle. Somatic impulses arise in the motor region of the cerebral cortex. Autonomic impulses arise in the spinal cord, brain stem, and hypothalamus. Autonomic impulses also receive higher control from the limbic region of the cerebral cortex.

There are three separate arms of the ANS: the sympathetic nervous system (SNS), the parasympathetic nervous system (PNS), and the enteric nervous system (ENS). The SNS and PNS are under central control and are distinct in details of their anatomy and biochemistry. They are also partially opposing in the nature of the physiological responses that they provoke. Activation of the SNS produces a state of arousal and readiness. The PNS generally governs digestive and secretory functions, and the ENS is a local nervous system within the gastrointestinal tract.

General Description of the ANS

Anatomy of the ANS

The motor neurons of the somatic nervous system arise in the spinal column, and their axons pass directly to skeletal muscle without synapsing. The outgoing fibers of the ANS also have their cell bodies in the spinal column, but before reaching the target organ, they synapse in one of the peripheral autonomic ganglia. Thus, the autonomic pathway from the spinal cord to target tissue consists of two neurons: one preganglionic and one postganglionic.

Sympathetic fibers emerge from the thoracic and lumbar regions of the cord and pass into one of the sympathetic chain ganglia, which are located close to the spine. Some fibers synapse in the chain ganglia. This results in the spreading of the impulse to other fibers both higher and lower in the chain. Other fibers pass through the chain ganglia uninterrupted and synapse in one of the two major peripheral sympathetic ganglia, the celiac ganglion and the hypogastric plexus. In general, the spreading of sympathetic impulses leads to a diffuse activation. Often, many sympathetic responses are elicited together. This is ideal for a system that produces the fight-or-flight state of arousal and readies the body for action. Blood pressure and heart rate are elevated; glucose is released into the blood; the pupils dilate and digestion is inhibited. One more feature of the SNS aids in its diffuse activation. Sympathetic fibers innervating

the adrenal medulla stimulate release of epinephrine and norepinephrine (NE) into the systemic circulation. These two hormones stimulate a variety of tissues expressing adrenergic receptors, including tissues that are not innervated. Sympathetic activation remains somewhat of a challenge to measure accurately. In older adults, several techniques are used to measure NE, including microelectrode implantation and sampling of 'arterialized' venous blood.

The organization of the PNS is simpler than that of the SNS. Parasympathetic neurons emerge with the cranial nerves or from the sacral region of the spinal cord. They pass most of the way to their targets before synapsing in ganglia that are located close to or are imbedded within the target organs. The postganglionic neurons are very short. The anatomy of the PNS is designed for discrete activation. Parasympathetic responses are often evoked singly. The ENS is composed of the myenteric plexus of Aurbach, which coordinates contractions of the gut, and the submucosal plexus of Meissner, which controls secretions. The ENS is under higher control from the ANS. Sympathetic stimulation decreases intestinal motility, reduces intestinal blood flow, and suppresses mucosal transport. Parasympathetic innervation promotes secretion of gastric acid and pepsin secretion, increases gastrointestinal motility, and stimulates water and electrolyte transport.

Neurotransmitters and Receptors of the ANS

There are three major types of synapse in the SNS and PNS: the adrenergic synapse, located in the target organs innervated by the SNS; the muscarinic cholinergic synapse, in the target organs innervated by the PNS; and the nicotinic cholinergic synapse, located in the ganglia for both the SNS and PNS. Consideration of the effects of age on the postsynaptic receptors located in these synapses is important for two reasons. First, changes in the receptors or postreceptor biochemical events play an important role in the impairment of some autonomic responses with age. Second, these receptors are the major targets for drugs affecting the ANS. Thus, the response to many drugs may also be altered with age.

Acetylcholine (ACh) is the neurotransmitter at both the autonomic ganglia and parasympathetic target organs. However, the postsynaptic receptors are different at these two sites. The ganglionic synapse is called nicotinic, and the PNS effector synapse is called muscarinic, based on the ability of the postsynaptic receptors to preferentially bind either nicotine or muscarine. NE is the neurotransmitter at sympathetic effector sites (*see* Neurotransmitter and Neurotrophic Factors). The postsynaptic receptor for NE may be either α- or β-adrenergic, based on the preferential binding of certain agonists and antagonists. Many clinically useful drugs have been synthesized to specifically stimulate or block α-adrenergic, β-adrenergic, and muscarinic cholinergic receptors. In some cases, the response to these drugs is altered in senescence; this is discussed later. Drugs that interact with the nicotinic cholinergic receptors in the autonomic ganglia do not see widespread clinical use. These drugs produce many undesired effects, as they affect both the SNS and the PNS.

Autonomic Responses and the Principle of Predominant Tone

As mentioned previously, the SNS and PNS often innervate the same tissues. The responses of these two arms of the ANS are opposing in some cases, but not in all. When both the SNS and PNS innervate the same tissue, one system may be more active at rest than the other. In such a case, either the SNS or PNS is said to exert a predominant tone. The most important examples of predominant tone are listed in **Table 1**. The terms 'resting tone' and 'intrinsic tone' are synonymous with 'predominant tone.'

An example of predominant tone is seen in the control of heart rate. Activation of the SNS increases heart rate, and activation of the PNS decreases heart rate. At rest, the PNS is active and the SNS is inactive. ACh is released in the heart and NE is not. As a result, the heart beats slower at rest than it might if there were no autonomic innervation. When the subject is exercising, the situation is reversed. The sympathetic drive is higher and the heart rate increases dramatically. Thus, the predominant tone to the heart is parasympathetic at rest and sympathetic during exercise.

Predominant tone is important in considering the actions of agonists (receptor stimulators) and antagonists (receptor blockers). Agonists mimic the effects of the neurotransmitter, directly stimulating the receptor, and thus will always produce a response. In contrast, antagonists are effective only when an agonist or neurotransmitter whose action can be blocked is present. As a result, antagonists may have little effect on tissues in which there is no predominant tone. Atropine (a muscarinic blocker) blocks the action of ACh in lowering heart rate. Propranolol (a β-adrenergic blocker) blocks the action of NE in elevating heart rate. Atropine markedly elevates heart rate in a resting subject, while propranolol has little effect on resting heart rate in the same individual (*see* Cardiovascular System).

Anatomic Changes in the ANS with Age

A number of global changes occur in the human nervous system with age. These changes affect the ANS as well as other parts of the nervous system. The weight and volume of the nervous system reaches a maximum at puberty and later begins a progressive decline beginning in middle age. Some areas are relatively spared, such as the parietal lobes and brain stem. In the peripheral nerves, there is a loss in fiber number and a loss of myelination. The number of neurons is reduced with age, although the extent of loss has been difficult to assess in humans. The remaining neurons have a reduced cell volume and fewer dendrites. The most reliable marker that has been identified for aging of the nervous system is the accumulation of the fatty brown pigment lipofuscin within the neuron. Lipofuscin is absent in the neurons of newborns. Its accumulation increases progressively until senescence, when 60–70% of neurons contain inclusions.

In human autonomic ganglia, there is an age-related increase in lipofuscin accumulation and neurofibrillary tangles and a decrease in catecholamine content, as assessed by norepinephrine fluorescence. The number of cells is preserved in ganglia, but there is a distinctive neuroaxonal dystrophy characterized by large (5–30 μm) swellings. The density of autonomic innervation has been difficult to study in humans, so we have to rely mainly on animal data. One human study found that sympathetic innervation of the posterior tibial artery is reduced with age. Animal studies are not in complete agreement, but suggest that the sympathetic innervation decreases in some tissues with age. For example, arteries are more affected than veins.

Functional Changes in the ANS with Age

Sympathetic Nervous System

Circulating Catecholamines Circulating NE is increased in humans with age and epinephrine is unchanged. Most of the NE that circulates in the blood derives from adrenergic nerve terminals. In contrast, all of the epinephrine derives from the adrenal medulla. NE released into the synapse either may be degraded, reabsorbed by the same nerve terminal that released it, or may spill out of the synapse and eventually enter the systemic circulation. The possible explanations for increased NE levels in the elderly include reduced clearance across the capillary bed and increased release from sympathetic nerve terminals. Most evidence points to the latter.

Circulating epinephrine and NE increase in response to a variety of stimuli, including exercise, standing upright, and a mental stress test. The increase in NE is exaggerated in the elderly, but the increase in epinephrine is not. Because the epinephrine derives from the adrenal medulla and the NE mainly from adrenergic nerve terminals, one can conclude that under a variety of conditions, NE release resulting from sympathetic nerve activity is increased in the elderly, especially elderly men. This can be confirmed by measuring sympathetic nerve activity more directly using the microelectrode technique; it is found to be increased in the elderly.

There are two reasons for the increase in the release of NE in sympathetic nerve terminals. First, sympathetic responses are impaired as a result of age in a number of important target tissues. It is thought that greater release of NE occurs in an attempt to get an adequate response from these failing target tissues. The second reason concerns the loss of sensitivity in the baroreceptors. When pressure increases in the carotid artery and some other vessels, those vessels expand, activating the baroreceptors, which in turn act to reduce sympathetic outflow. Reduced sympathetic outflow reduces heart rate and peripheral resistance, thereby correcting the original increase in pressure. In older individuals, the vessels are more rigid and do not stretch as much in response to pressure. Thus, decreased baroreceptor sensitivity contributes to elevated NE and may also contribute to hypertension in the elderly. The vasoconstrictor component of the baroreflex is as strong in the elderly as in the young, despite the likelihood that α-receptor response of the vessel decreases slightly with age.

β-Adrenergic and α-Adrenergic Responses In the heart, NE released from sympathetic nerves stimulates β-adrenergic receptors. These receptors mediate increases in heart rate and in the force of contraction. The impairment of these responses with age results in a reduced ability to increase cardiac output during exercise. Because cardiac output is a limiting factor in exercise, exercise capacity is also impaired. β-adrenergic stimulation of the heart is also required for the postural hemodynamic response, which is called into play when BP drops in the upper body, such as after standing up rapidly. Thus, decreased β-adrenergic responsiveness in the elderly contributes to postural hypotension, or an inability to maintain BP after standing up. The primary deficits with aging are a 90% loss of sinus node cells between the ages of 20 and 75 and an uncoupling of β-receptors in the myocardium from the intracellular signaling required to cause an increase in the force of contraction.

β-Adrenergic dilation of blood vessels is also impaired with age. Dorsal veins in the hands of elderly

subjects display reduced relaxation in response to the β-agonist isoproterenol after first being constricted with the α-agonist phenylephrine. The response to isoproterenol is reduced with age in terms of both maximum response and sensitivity. The inherent ability of the vessel to relax is not impaired with age, as shown by the fact that dilation in response to papaverine and nitroprusside is unchanged with age.

β-Agonists are useful in treating asthma because of their ability to open the airways by causing a relaxation of bronchial smooth muscle. Adrenergic fibers are associated directly with submucosal glands of the lung and bronchial arteries, but not bronchial smooth muscle. β-Agonists act indirectly by opposing the parasympathetic constriction of bronchial smooth muscle. Adrenergic fibers innervate parasympathetic ganglia and cause bronchodilation by inhibiting cholinergic output. Animal studies show that β-adrenergic bronchodilation is impaired in aging.

α-Adrenergic responses are impaired with aging in some but not all cases. In human arteries, α_1-stimulated constriction is unchanged with age. In human veins, the α-constriction is reduced with age. Both the β-adrenergic stimulation of the heart and the α-adrenergic constriction of veins contribute to the postural hemodynamic response. Because both responses are impaired with age, the elderly experience postural hypotension.

There is evidence in both animal and human studies that the SNS has a protective role against autoimmune disease. In mice, the chemical destruction of sympathetic nerve endings exacerbates various experimental models of autoimmune disease. The β-adrenergic agonist isoproterenol has a protective effect against these same models of autoimmunity. Thus, it is possible, although not proven, that reduced adrenergic responsiveness is involved in the increased incidence of autoimmune disease in the elderly.

Aging is accompanied by impaired temperature regulation, resulting in increased susceptibility to hypothermia and hyperthermia. Hyperthermia can result from reduced density of eccrine sweat glands although there is no deficit in sudomotor activity (sympathetic nerve activity leading to sweat glands). Hypothermia may result from a decrease in nonshivering thermogenesis. This impairment is due to a decrease in the quantity of brown adipose tissue, specialized adipose tissue that generates heat in response to β-adrenergic stimulation.

Parasympathetic and Enteric Nervous Systems

The predominant parasympathetic tone, or vagal tone, to the heart is reduced with age due to a decrease in the intrinsic sinus rate in the elderly and the resulting reduced need to 'brake' the heart. The reduced vagal tone can be seen in the response to atropine, a blocker of the muscarinic receptor present in parasympathetic nerve endings. Atropine produces a smaller increase in heart rate in the elderly than in young subjects. There is also direct evidence in animal studies that parasympathetic responsiveness of the heart is reduced with age. Bradycardia, or slowing of the heart, in response to cholinergic agonists is reduced with age.

Bronchoconstriction occurs due to contraction of bronchial smooth muscle in response to parasympathetic stimulation. Animal studies have shown that this response is exaggerated in senescence. The mechanism is a decrease in the content of acetyl cholinesterase, the enzyme that terminates the action of the neurotransmitter ACh. As a result, ACh released into the synapse has a more prolonged action.

Gastrointestinal (GI) function is impaired in the elderly, and certain aspects of this impairment suggest autonomic dysfunction. However, it is important to distinguish GI dysfunction due to aging from the side effects of medication. With aging, there is difficulty in swallowing, increased gastric emptying time, increased intestinal transit time, constipation, and reduced absorption of calcium and fat. The rat model has also shown reduced transport of water, sugars, and amino acids. The density of innervation of the enteric nerve plexus is reduced in senescence. Impairments in the ENS play a key role in the changes in GI function that accompany aging. There is a specific loss of intrinsic sensory neurons, with preservation of nitrergic neurons. Irritable bowel syndrome and other related conditions are thought to occur due to changes in the function of enteric neurons, based on animal models. Reduced parasympathetic responses in the GI tract result in reduced secretions and motility. These changes contribute to a number of problems that are more common in the elderly, including achalasia and pseudo-obstruction. Achalasia is a disorder of swallowing involving a failure of the lower esophageal sphincter to relax. This relaxation is mediated by a parasympathetic discharge of the vagus nerve, which is impaired with aging. Pseudo-obstruction is dilation of the large bowel in the absence of an obstruction and occurs almost entirely in the elderly (*see* Gastrointestinal System: Function and Dysfunction). The PNS controls salivary excretion of fluid and electrolytes. Xerostomia, or dry mouth, is common in the elderly. However, parasympathetic responses in the salivary glands are unchanged with age and do not play a role in xerostomia.

Changing Role of the ANS in Cardiovascular Responses

Control of Blood Pressure

Falls and the attendant risk of hip fracture are an important problem in the elderly. Postural hypotension increases the risk of falls by causing a transient cerebral hypoperfusion and is caused in part by autonomic dysregulation. Postural hypotension may be defined as a drop in systolic pressure of ≥ 20 mmHg or diastolic pressure of ≥ 10 mmHg, or symptoms of cerebral hypoperfusion within 2–5 min of standing. Postural hypotension occurs in approximately 30% of those 65 or older. The causes of postural hypotension in the elderly include an impaired postural hemodynamic response due to impaired β-stimulation of the heart, volume depletion, and the presence of certain drugs. Chronic hypovolemia is a frequent condition in the elderly, and patients with severe volume depletion may experience orthostatic hypotension despite normal autonomic reflexes. Studies have shown that volume expansion resulting from 6 months of endurance training is helpful in correcting orthostasis.

Postprandial hypotension is also a common problem in the elderly, with the greatest drop in BP occurring about 1 hour after eating. Carbohydrate meals produce the greatest drop. Postprandial hypotension results from the inability to compensate for vasodilation in the GI tract. After a meal, the plasma NE concentration should increase two- to threefold as a result of increased SNS activity; this response is blunted in the elderly. The clinical significance of postprandial hypotension is unclear. It may precipitate strokes and myocardial infarction. Postprandial hypotension is also a factor in producing postural hypotension. Additional susceptibility to postural hypotension and syncope come from the increased preload to the heart in aging. The latter causes an elevation of circulating atrial natiuretic peptide, which in turn causes increased excretion of water and sodium, resulting in decreased blood volume.

Exercise Performance

The increase in cardiac output that occurs during exercise is, in part, mediated by the SNS. During exercise there is an increase in heart rate, an increase in the force of contraction, and an increase in stroke volume. Shunting of blood to the skeletal muscle is accomplished by vasodilation in the muscle and vasoconstriction in other tissues. In the elderly, two key sympathetic responses are impaired: β-adrenergic stimulation of the heart and β-adrenergic dilation of arteries supplying skeletal muscle. The increase in cardiac output that occurs during exercise is rate limiting for the amount of exercise that can be performed before the anaerobic threshold is reached and lactic acid accumulation begins. Thus, autonomic dysfunction may limit exercise capacity in the elderly. This decline is also due to other factors, such as reduced cardiac reserve, peripheral circulatory factors, and reduced muscle mass (*see* Motor Control). A lifelong active lifestyle may play an important role in preserving cardiac ANS responses and baroreflex sensitivity in older people.

Autonomic Dysfunction in Diseases Common in the Elderly

Primary autonomic failure is a degenerative disorder of the postganglionic neurons of the SNS. The symptoms, which include postural hypotension, impaired thermoregulation due to inability to sweat, low circulating catecholamines, impotence, and GI and urinary dysfunction, are most severe in the elderly. Any condition requiring extended bed rest in an older person can contribute to postganglionic sympathetic dysfunction in the lower extremities. This situation can lead to the inability to walk, thus further promoting deconditioning and risk of falls. It is suggested that the length of time one remains bedfast should be closely monitored with ambulation promoted early in the course of a condition, as appropriate.

Multiple system atrophy (or Shy-Drager syndrome) is a disease of preganglionic neurons of the SNS. There is degeneration in the sympathetic centers of the brain and in the lateral horn of the thoracic segments of the spinal column. Most of the same autonomic symptoms are seen in Shy-Drager syndrome as in primary autonomic failure, but there are often motor deficits as well, including marche à petits pas (the short-stepped gait). Circulating catecholamines are normal at rest, but fail to increase properly in response to a stimulus, such as rapid standing.

In Parkinson's disease, there is often autonomic dysfunction, with PNS dysfunction selectively occurring early in the course of the disease. Postural hypotension is a side effect of medication with l-dopa; the addition of a peripheral decarboxylase inhibitor, such as carbidopa, can eliminate this problem by confining the actions of l-dopa to the CNS and thus preventing the action of l-dopa on the autonomic ganglia. Other signs of autonomic dysfunction in Parkinson's disease, such as increased salivation, decreased frequency of bowel movement, and dysphagia, result from the disease process itself. Parkinson's disease is often accompanied by lesions of the spinal column similar to those that cause motor difficulties

in Shy-Drager syndrome. The impotence associated with Parkinsonism may have a basis in autonomic dysfunction. Abnormalities in thermoregulation are due to lack of sweating. Accidental hypothermia is a risk due to the absence of shivering.

In older patients with stable angina, research shows that the SNS plays a role in acute episodes of regional myocardial ischemia. Chronically elevated sympathetic nerve activity both increases metabolic demand and impairs myocardial perfusion.

Altered Autonomic Responses to Drugs Commonly Prescribed in the Elderly

Treatment of hypertension in the elderly is a double-edged sword. Effective lowering of BP often brings increased incidence of postural hypotension, a contributor to falls. α-Blockers often induce postural hypotension in the elderly, which may limit their use for treating hypertension and prostatic outflow obstruction. β-Receptor stimulation of the heart, which occurs during the postural response, is already diminished in normal aging. Thus, with the introduction of an α-blocker, both the α- and β-adrenergic arms of the postural response are now impaired. β-Blockers and diuretics also increase the likelihood of postural hypotension. Calcium channel blockers and angiotensin-converting enzyme inhibitors carry less risk.

The elderly have an increased susceptibility to adverse effects of tricyclic antidepressants. Pretreatment electrocardiogram (ECG) is necessary to determine whether or not QRS and QT prolongation coexist, an indication that the potentially lethal arrhythmia 'torsade de pointes' may develop when a tricyclic is given. Tricyclics such as amitryptyline exert their antidepressive effects by inhibiting neuronal reuptake of NE. These compounds also have α-blocking and anticholinergic effects. As a result of underlying autonomic dysfunction, the elderly are more susceptible to these side effects. Because tricyclics block α-receptors, they may on rare occasion cause sinus tachycardia in the elderly due to vasodilation and postural hypotension for the reasons described previously. The anticholinergic side effects of tricyclics include xerostomia (dry mouth), blurred vision, constipation, and urinary retention. The xerostomia is caused by an inhibition of parasympathetic stimulation of salivary fluid and electrolyte secretion. The blurred vision is caused by impaired contraction of the ciliary muscle of the eye, which is involved in accommodation for near vision. Newer SSRI antidepressants such as fluoxitine (Prozac), dertraline (Zoloft), and paroxitine (Paxil) work by inhibiting the neuronal reuptake of serotonin rather than NE. Whether the side effects of these drugs present a special problem in the elderly remains to be seen.

Balance, Posture and Gait

M Woollacott, University of Oregon, Eugene, OR, USA

Glossary

Adaptive Postural Control – Modifying sensory or motor response strategies in response to changing task and environmental demands.

Anticipatory Posture Control – Pretuning sensory and motor processes in expectation of postural demands based on previous experience.

Cognitive Processes – Higher level neural processes such as attention, motivation, and planning. It is difficult to make a clear distinction between higher-level perceptual/motor processing and cognitive processing, since there is a gradual transition and overlap between processing levels.

Postural and Balance Control – Regulating the body's position in space for the dual purposes of stability and orientation. Stability is the ability to maintain the position of the center of body mass (COM) within specific boundaries, or stability limits. Orientation is the ability to maintain an appropriate relationship between the body and the environment or task.

Sensory Strategies – Organizing sensory information from visual, somatosensory, and vestibular systems for postural control.

Introduction

Research on balance, posture, and gait in older adults has become a priority in the health-care field because data indicate that falls are a major threat to independence in older adults and an important contributor to fatalities. For example, it has been shown that nearly one-third of adults over the age of 75 experience at least one fall per year, and 6% of these adults sustain fractures as a result. Research on balance and gait in the older adult has focused on (a) determining whether there are specific neural and musculoskeletal subsystems that show a decline with aging and (b) creating effective measures for the prevention and the rehabilitation of decline in balance function with aging. Several approaches have been used in the past to study and assess balance and locomotor skills in the elderly from both a research and a clinical perspective. Traditionally, balance control was studied from a reflex perspective, and global methods of measuring balance were used. Since the 1990s, researchers have begun a systems approach to the study of balance in the older adult. This approach has the advantage of allowing clinicians and researchers to assess whether there is a decline in identified subsystems contributing to balance and gait.

Balance Control in Older Adults

Early Studies

Before reviewing studies on the changes in balance control in the older adult, we first define balance control and discuss the ways one can measure balance function. Balance control may be defined as the maintenance of a person's center of mass (COM) within his or her stability limits, which are defined as the person's base of support. Balance control thus indicates the ability to regulate one's static upright posture or to recover from unexpected threats to balance, such as the balance threat that occurs when standing on a bus that starts to move.

In addition to static balance control, an adult must also be able to maintain balance during many other daily activities, such as standing and walking. Maintaining balance during walking requires the integration of postural adjustments into the step cycle in order to allow safe forward movement. In this dynamic task the COM is not maintained within the base support, but moves along the medial border of the support foot. This integration of balance control into voluntary activities is essential to the accomplishment of most goal-oriented tasks and requires the ability to respond to constantly changing environmental and task demands.

Classically, the assessment and treatment of balance function in the older adult has been centered around global measures of balance abilities, such as the measurement of total body sway. For example, in 1963 Sheldon performed a study examining the degree to which sway during quiet stance changes across the lifespan. He found that subjects at both ends of the age spectrum (6–14 years and 50–80 years) showed significantly more sway during quiet stance than did young adults. **Figure 2** shows the sway path of representative subjects in each of the age groups tested.

Other research by Fernie and colleagues, which used a measure of both the amplitude and velocity of global body sway to assess the balance skill of institutionalized older adults, indicated that sway velocity is correlated with frequency of balance loss. Older adults who fell more than once per year showed higher velocities of sway when standing quietly when compared to those who did not fall.

Some of the earlier studies regarding balance function in the older adult often assumed that one could find a single cause of instability in an individual, such as peripheral neuropathy or postural hypotension. In addition, clinicians typically assessed balance function using a reflex model of balance control, limiting tests to evaluation of tendon reflexes, righting reflexes, and vestibulo-ocular reflexes, and predicting that with aging more 'primitive' reflexes would be released from inhibition. However, more recently research has indicated that a reflex framework of motor control is limited, since many other motor processes contribute to motor function.

It has become clear that for any given individual there are complex interactions between intrinsic factors related to the level of function of different nervous or musculoskeletal subsystems and also extrinsic environmental factors. It is important to study these interactions in order to clearly understand the factors that contribute to falls in the older adult. In one study, Campbell and colleagues observed a group of community-dwelling older adults for 1 year and documented all falls. The study concluded that reductions in physical activity, reduced proximal muscle strength, and reduced stability during quiet stance were all strongly linked with an increased risk of falling. They also showed a significant association between falls and arthritis of the knees, stroke, impairment of gait, hypotension, and the use of psychotropic drugs. The study concluded that multiple risk factors, many of which are remediable, are associated with most falls in older adults.

Though this approach has significantly improved our understanding of factors contributing to balance deterioration in the older adult, it is limited by the use of relatively broad categories to classify intrinsic factors related to falls, such as 'loss of stability while standing.' Such categories do not allow the identification of problems in specific subsystems that may be constraining balance abilities.

Systems Approach to Age-Related Changes in Balance

More recently, researchers have begun to use a new approach for testing balance control in older adults. This method, often called a systems approach, attempts to identify the relative contribution of deterioration in specific neural and musculoskeletal subsystems to a decline in balance function. The systems model of balance control has the advantage of being able to aid the clinician in evaluating the degree to which a decrease in the function of individual subsystems contributes to deterioration in balance and gait in the older adult. According to the systems model, balance stems from complex interactions among several factors, including a variety of neural subsystems, the musculoskeletal systems of the individual, and the task and environmental situations in which the individual is balancing and moving. The postural control system is usually identified as the neural and musculoskeletal subsystems that contribute to balance function.

In assessing balance function in the older adult from a systems model, one would evaluate both the neural components (motor systems, sensory/perceptual systems, adaptive systems, and cognitive systems) and the musculoskeletal components (muscle strength, range of motion of ankle, knee, and hip joints, and the vertical alignment of the body) that contribute to balance. The following section reviews research on changes in balance control in the older adult from the systems perspective.

Musculoskeletal Changes Many research studies have examined the extent to which postural components of the musculoskeletal system characteristics change with age. For example, it has been shown that strength of the leg muscle can show a reduction of 40% in young (30 years) vs. older adults (80 years). Whipple and colleagues showed that older adults with a history of falls (nursing home residents) show an even greater reduction in muscle strength, with ankle dorsiflexor strength being 14% of that of nonfallers. In addition, the muscle fatigues more rapidly and the rate of tension development is slower in older adults. Buchner and deLateur showed that there is an association between strength and physical function, with over 20% of the variance in functional status explained by relative muscle strength. Finally, spinal

flexibility is reduced in the older adult, causing a rounded or forward flexion of the posture alignment, and arthritis may cause a decrease in the range of joint motion in the ankle, hip, and knee joints.

Neuromuscular System Changes Most falls occur during dynamic balance situations, and older adults, especially those with balance impairments, may have difficulty regaining stability after a slip or trip. In order to understand the extent to which constraints on neuromuscular responses contribute to poor balance in these situations, researchers have been asking the following question: When healthy older adults are faced with an unexpected threat to standing balance, such as the sudden start or stop of a bus or a subway car on which they are standing, are they capable of responding to that threat in a manner as efficient as a young adult? In order to answer this question research has been performed to simulate these situations and to examine the characteristics of postural muscle response patterns that are activated in response to the unexpected forward or backward movement of a platform on which the subject is standing or walking (see **Figure 1**).

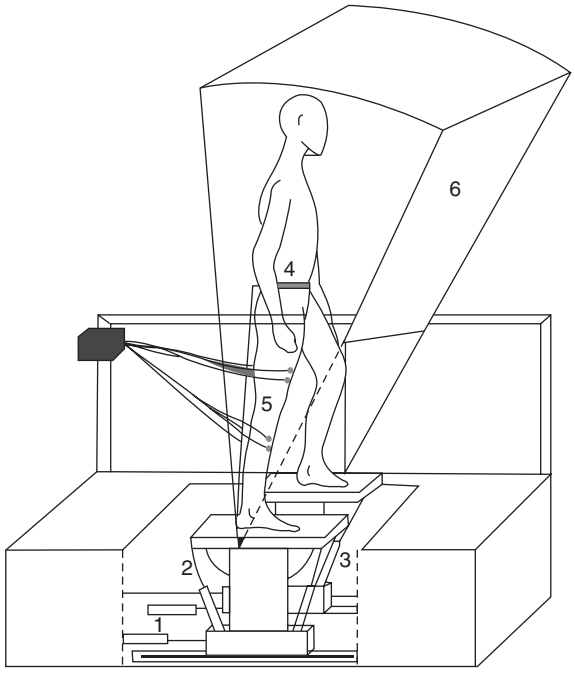

Figure 1 Experimental paradigm. Subject stands on hydraulically activated platform that moves unexpectedly forward or backward (1–3, hydraulic cylinders). A belt attached to the hips measures sway (4). Surface electrodes (5) measure muscle responses. A visual surround (6) can be rotated with the subject's sway to minimize sway-related visual inputs. (From Woollacott MH, Shumway-Cook A, and Nashner LM (1986) Aging and posture control: changes in sensory organization and muscular coordination. *International Journal of Aging and Human Development* 23: 100.)

When the balance of a young adult is disturbed by an unexpected movement of the surface on which they are standing, there is typically sway focused at the ankle joint; then muscle responses that return balance to normal are activated first in the stretched ankle muscle and radiate upward to the muscles of the thigh and hip.

Research by Woollacott and colleagues comparing the response characteristics of younger adults (mean age 25 years), healthy older adults (mean age 74 years), and balance-impaired older adults (mean age 76 years), showed that the postural muscle response organization was generally similar between the three groups, with responses being activated first in the stretched ankle muscle and radiating upward to the muscles of the thigh.

However, the groups also showed specific differences in response characteristics:

1. Onset of contraction for the postural muscles (ankle dorsiflexors) was significantly slower for both the healthy and the balance-impaired older adults compared to the younger adults when platform movements caused backward sway (**Figure 2A**); slowing of contraction onset was correlated with age (**Figure 2B**).
2. For almost half of the older adults, there was an occasional disorganization of the muscle response pattern, with proximal (thigh) muscles being activated before distal (ankle) muscles. It is interesting that this type of response organization is typical of certain patients with central nervous system lesions.
3. The older adults co-activated the antagonist and agonist muscles of a joint together significantly more frequently than the younger adults, possibly to stiffen the joints as an alternate way to increase joint stability.
4. Older and balance-impaired older adults used a higher percentage of maximum voluntary contraction amplitudes when responding to faster balance threats (**Figure 3**).
5. Older adults also tended to use a strategy of balancing that involved hip movements rather than simple ankle movements to control sway. It has been suggested that some falls in the older adult may be caused by a drop in the use of the classical ankle balance strategy and a shift toward the use of a hip balance strategy, as a result of pathological conditions such as ankle muscle weakness or peripheral sensory neuropathy.

Sensory Contributions In order to balance effectively, in a variety of environments it is necessary to utilize information from three sensory systems: the visual, somatosensory (proprioceptive, cutaneous, and joint receptors), and vestibular systems. This

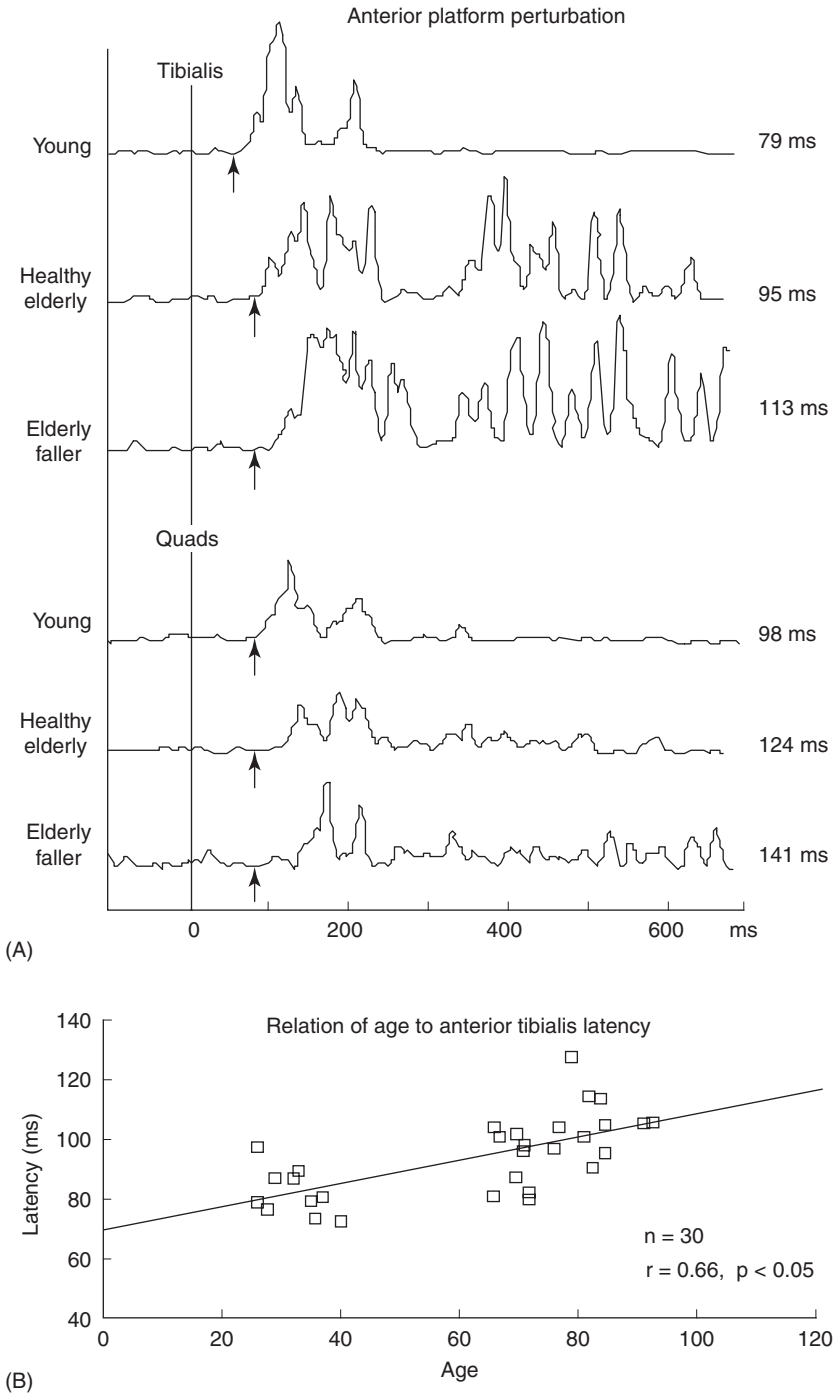

Figure 2 Changes in temporal characteristics of muscle response synergies in the healthy and balance-impaired elderly. (A) Examples of muscle responses to an anterior platform movement causing backward sway in a young adult, an older adult who was non-impaired, and an older adult with balance impairments. The onset of contraction is progressively later for the non-impaired and balance-impaired older adults. (B) The relationship between onset of contraction for the tibialis anterior muscle and age, with older adults showing slower contraction onsets. (Panel A from Shumway-Cook A and Woollacott M (2000) *Motor Control: Theory and Practical Applications*, p. 231. Lippincott Williams and Wilkins.)

information must be combined appropriately to accurately represent the body's position in space. Each sensory system contributes a different frame of reference for balance orientation. There are different sensory strategies that can be used in balance control, each involving a different weighting by the higher nervous system centers of the visual, somatosensory, and vestibular inputs. In order to remain balanced in

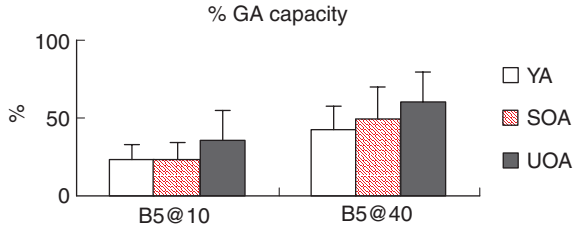

Figure 3 Graph showing the percent of maximum voluntary contraction amplitude for the gastrocnemius muscle used by young adults (YA), stable healthy older adults (SOA), and unstable balance-impaired older adults (UOA) in response to two different velocities of balance threat (5 cm at 10 cm/s and 5 cm at 40 cm/s). Balance-impaired older adults used higher levels of maximum voluntary contraction than young or healthy older adults at slow velocities (10 cm/s), while both healthy and balance-impaired older adults used a larger percentage of voluntary contraction at fast velocities (40 cm/s). (Adapted from Lin S and Woollacott M (2002) Postural muscle responses following changing balance threats in young, stable older and unstable older adults. *Journal of Motor Behavior* 34: 42.)

changing task conditions one must also be able to appropriately select the most effective sensory input for the specific task. Older adults have been shown to have deficits in specific sensory systems that could contribute to a difficulty in organizing sensory inputs appropriately for changing task conditions.

For example, studies by Whanger and Wang indicated that cutaneous vibratory sensation thresholds at the knee are increased in the frail elderly (70–90 years) compared to young adults. They noted that many of the older adults had difficulty perceiving stimulation at the ankle joint, and thus they did not include information about ankle thresholds in the study. These problems could be due to problems with peripheral neuropathy in their population.

Research on age-related changes in the visual system indicates that less light is transmitted through the retina with increasing age. Also, age-related reductions in visual contrast sensitivity cause problems in contour and depth perception, which are critical for postural control. These types of visual deterioration could result from cataracts, macular degeneration, and ischemic retinal or brain disease.

Studies by Rosenhall and Rubin on vestibular system changes in the older adult indicated that there is a 40% reduction in hair cells in the semicircular canals and the utricule and saccule, along with a similar reduction in myelinated fibers of the vestibular nerve. However, it has also been pointed out that a 75-year-old showed an almost normal number of nerve fibers in the vestibular nerve. This again points out that age-related degeneration of specific systems is not inevitable, but may be related to pathology. A partial deterioration in vestibular function can result in dizziness, which may also lead to loss of balance in the older adult. Deterioration of otolith function can lead to positional vertigo.

Older adults may not have a balance problem with deterioration in any one of these sensory systems, since the other systems contribute redundant information on balance and are usually available to compensate for this loss. However, balance problems could become apparent when walking in dimly lit areas or on unusual support surfaces such as ramps, thick carpets, or grass, because these situations have reduced sensory input redundancy. Multisensory deficits may also occur in older adults. In this case, the ability to compensate for loss of sensory information with alternative senses is difficult or impossible.

Adaptation As mentioned previously, older adults may show problems with adapting their use of sensory inputs to varying task and environmental situations. If an older adult has peripheral neuropathy and thus does not rely on somatosensory inputs, he or she may overly rely on visual inputs, even when they are inappropriate. For example, older adults may have difficulty balancing when crossing a busy intersection because visual cues from moving cars and pedestrians may create the illusion of self-sway, and the resulting postural response could cause balance loss.

How can the ability of older adults to balance under changing environmental conditions be tested? A technique called moving platform posturography allows the researcher to measure the balance of a subject under a combination of sensory conditions, including one in which the support surface rotates with the person's sway, distorting ankle joint somatosensory inputs, and another in which the visual enclosure around the subject also rotates in the anteroposterior direction with sway, again distorting visual inputs related to sway.

The labs of Woollacott, Horak, and others have examined the ability of elderly people to adapt their senses to changing conditions using posturography testing. It is of interest that there were no significant differences in amount of body sway for healthy active older adults vs. young adults except in conditions in which both ankle joint inputs and visual inputs were distorted or absent (conditions 5 and 6 as defined in the study). In these conditions, half of the older adults lost stability and needed an assistant's aid to balance. However, most of the older adults maintained stability on the second trial of these conditions, indicating the ability to adapt to changing sensory conditions with some practice.

In order to determine if the preceding types of changes in postural control with aging were indicative of normal aging or were instead due to borderline

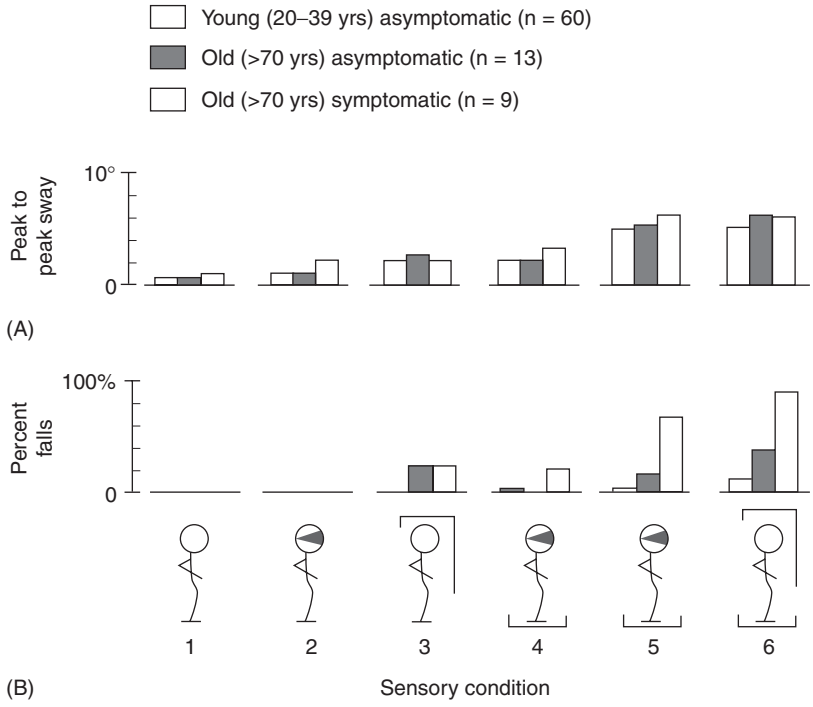

Figure 4 A comparison of the number of falls under the six sensory conditions in young non-fallers, elderly non-fallers, and elderly fallers. (From Horak F, Shupert C, and Mirka A (1989) Components of postural dyscontrol in the elderly: a review. *Neurobiology of Aging* 10: 732.)

pathology, the older adults in one of the studies (who considered themselves healthy and active) were given a neurological exam. The results of the exam were correlated with their performance on the balance tasks. Interestingly, the neurologist noted borderline neural impairment such as diminished deep tendon reflexes, mild peripheral nerve deficits, distal weakness in tibialis anterior, and gastrocnemius and abnormal nystagmus in many of the older adults. These results suggest that borderline pathology may contribute significantly to balance dysfunction in the older adult.

In a second study by Horak and colleagues, the performance of older adults with balance problems (symptomatic) was compared to that of healthy older adults (asymptomatic) and young adults (young). As shown in **Figure 4**, the older adults with balance problems showed significantly more falls with conditions 5 and 6 (both visual and ankle joint inputs were distorted or absent) than did the young and healthy older adults.

Anticipatory Postural Adjustments

Postural adjustments may be used in a reactive manner, as described previously, or in an anticipatory manner, in order to stabilize the body in advance for instability caused by a voluntary movement. One cause of falls in the older adult could be an inability to activate these anticipatory responses before voluntary movements, such as lifting a heavy object, resulting in loss of balance during the subsequent movement. Studies have shown that it is in dynamic situations such as walking, lifting, and carrying objects that a majority of falls in the older adult occur.

In the young adult, the same postural muscle response patterns that are activated during stance balance control are activated in an anticipatory manner before making a voluntary movement while standing. For example, when the adult is asked to pull on a handle, first the gastrocnemius muscle of the calf is activated, followed by the hamstrings muscle of the thigh, and then the prime mover muscle, which is the biceps muscle of the upper arm. Thus the responses are activated starting with the muscles closest to the base of support, and the response then moves upward to the proximal muscles. A research study by Inglin and Woollacott examined age-related changes in the ability of older adults to activate these postural muscle response synergies in an anticipatory manner. The study showed that older (mean age 71 years) adults showed significantly longer muscle onset latencies for postural muscles as compared to young adults (mean age 26 years) when the participants were asked to push or pull on a handle in a reaction time task. **Figure 5** shows the postural vs. voluntary muscle reaction times for each subject in the young vs. older adult group. Note that there was an increase in both

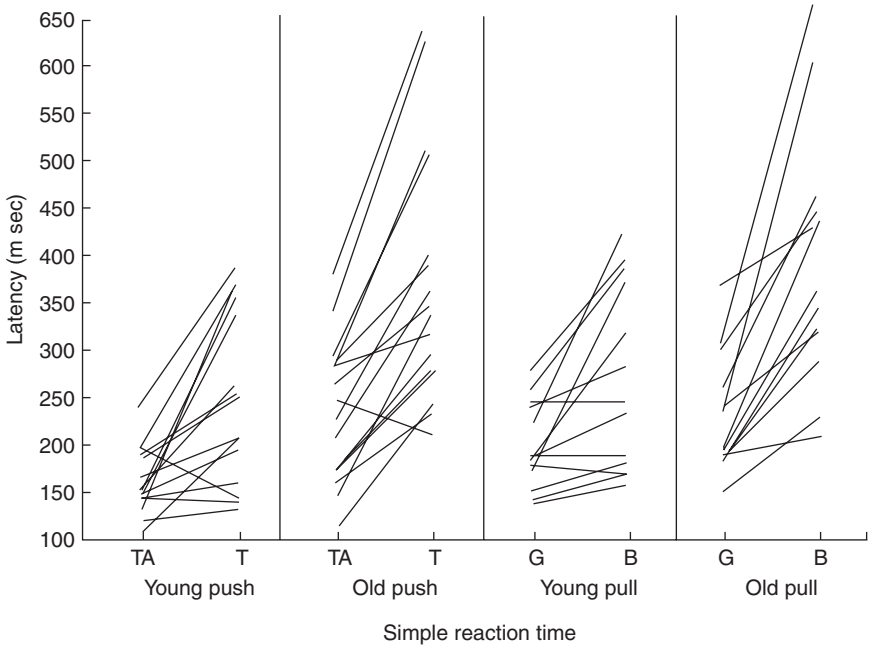

Figure 5 Individual values of postural and prime mover (voluntary) muscle onset latencies in young vs. older adults for a simple reaction-time task in which the standing subject pushed or pulled on a handle at chest height. (From Inglin B and Woollacott MH (1988) Age-related changes in anticipatory postural adjustments associated with arm movements. *Journal of Gerontology* 43: M109.)

postural muscle reaction time and the prime mover voluntary muscle reaction time. It was also noted that muscle response latencies were much more variable in the older compared to the young adults, and the organization of postural muscle responses was also significantly different. It is not clear whether these differences in postural response organization are due to nervous system deficits or to the use of an alternate strategy to compensate for other constraints within the nervous and musculoskeletal system.

A systems model of balance control would predict that this slowing in voluntary reaction time in the older adult could be caused by the need for advance stabilization by the already delayed and possibly weaker postural muscles and/or slowing in the voluntary control system itself. Since the absolute differences in onset times between the young and the older adults were larger for the voluntary muscles than for the postural muscles, there may be a slowing in both systems in the older adult.

Cognitive Systems

It is possible that, with aging, people's abilities to balance may be reduced compared to their abilities at a young age, but they may balance normally as long as they can focus attention on the task. When they have to focus on many tasks at the same time, however, they may find that their capacity to perform both the postural task and the other tasks well is reduced. For example, if an older adult is walking quickly along a busy street while carrying many packages and talking to a friend, if his or her balance is threatened, it may be more difficult to recover than if the person were walking alone in a quiet environment.

A significant amount of research from many labs (Teasdale, Redfern, Maki, and Duysens, for example) has been performed to determine the extent to which both healthy and balance-impaired older adults may have problems with balance when their attention is distracted. Shumway-Cook *et al*. showed that older adults with a history of falls swayed significantly more than young adults and healthy older adults when they were asked to perform a secondary task (a sentence completion task) compared to a control (no task condition) while standing quietly. This effect of the secondary task was increased further when older adults were asked to stand on a compliant surface, which increased postural demands. The authors suggested that healthy young and older adults could allocate attentional resources to postural control in a flexible and dynamic way, while older adults who had experienced falls had more difficulty allocating attention to postural demands.

Other studies by Brauer *et al*. showed that when balance-impaired older adults must respond to a balance threat while performing a second cognitive task, they take significantly longer to stabilize balance, as seen in **Figure 6**. This figure graphs the velocity of

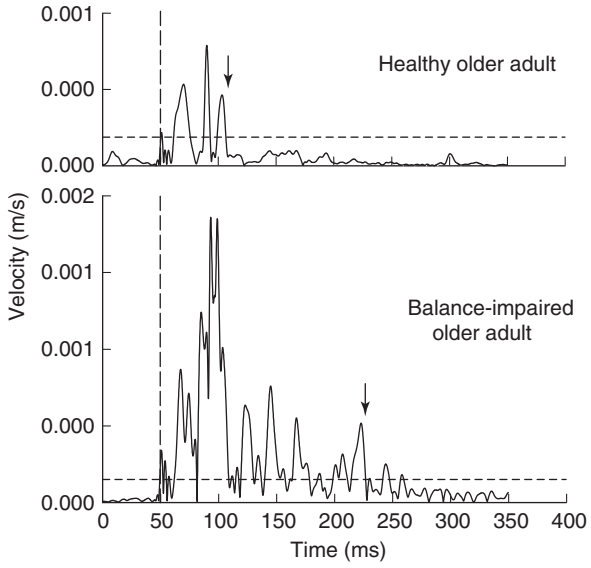

Figure 6 Graph showing the velocity of sway during recovery from a balance threat for a healthy older adult and a balance-impaired older adult when performing a second cognitive task simultaneously. Onset of platform displacement is indicated by the vertical dotted line. The time at which balance was stabilized for each person is indicated by the arrow. Note that the balance-impaired older adult required twice the time of the healthy older adult to recover balance when performing the cognitive task. (From Brauer S, Woollacott M, and Shumway-Cook A (2001) The interacting effects of cognitive demands and recovery of postural stability in balance-impaired elderly. *Journal of Gerontology* 56: M489.)

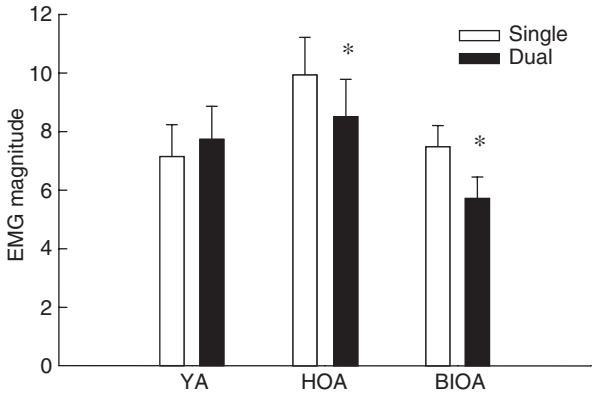

Figure 7 Graph showing the muscle response amplitudes of the gastrocnemius muscle in young adults (YA), healthy older adults (HOA), and balance-impaired older adults (BIOA) when taking a step to recover from a balance threat in a single task (balance alone) vs. a dual task (balance plus cognitive task) situation. Both healthy and balance-impaired older adults showed significantly reduced muscle response amplitudes in the dual task compared to the single task condition (noted by the asterisk). (From Brauer S, Woollacott M, and Shumway-Cook A (2002) The influence of a concurrent cognitive task on the compensatory stepping response to a perturbation in balance-impaired and healthy elders. *Gait and Posture* 15: 91.)

sway during recovery from a balance threat for a healthy and a balance-impaired older adult. The balance-impaired older adult requires almost twice the time to stabilize balance as the healthy older adult during the performance of a secondary task. In addition, when taking a step in order to recover from a balance threat, the muscle responses of both healthy and balance-impaired older adults were significantly reduced in size in the dual task compared to the single task (posture alone) condition, while those of young adults were not, as seen in **Figure 7**. This reduction in muscle response amplitude could lead to reduced step efficiency and a fall when older adults are performing a second task while recovering balance.

A second cognitive factor, fear of falling, may also affect balance performance. Maki *et al*. found that fear of falling affected balance during a spontaneous sway test and one leg stance test. The authors commented that it was not clear whether subjects with a fear of falling had a true deterioration in postural control mechanisms, or whether the fear of falling affected the balance performance in an artifactual manner.

Balance Retraining Research

The preceding research suggests that there is a significant deterioration in balance abilities in many older adults and that decreases in level of function of specific neural and/or musculoskeletal systems contribute to this deterioration. A number of laboratories are now focusing on exploring whether this deterioration in balance function can be reversed with training. Research concerning balance training has included a variety of training paradigms related to such areas as muscle strength increases, sensory balance training, and Tai Chi.

Fiatarone and colleagues studied the efficiency of muscle strength training to improve balance in frail nursing home residents. This study used high-resistance weight training of the quadriceps, hamstrings, and adductor muscle groups and found highly significant gains in muscle strength in all subjects. Changes in balance control were not measured directly, but it was noted that subjects increased walking velocity and two subjects no longer used canes to walk by the end of the training period.

A study by Hu and Woollacott used a balance training protocol that focused on improving the use of different sensory inputs and the integration of these inputs for balance control in older adults from 65 to 87 years old. Subjects were asked to balance under eight different sensory conditions in which visual and somatosensory inputs were gradually reduced or distorted. **Figure 8** shows the changes in sway of one subject under the eight conditions for the 10 days of training. Significant reductions were found in the amount of sway in the training group between the first and the last day of training in the

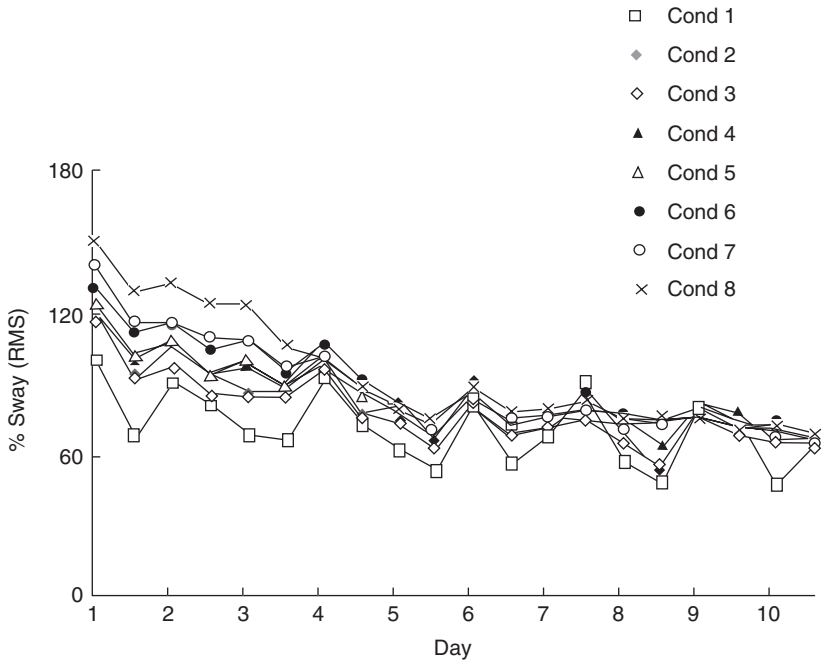

Figure 8 Percent reduction in body sway (root mean square [RMS]) under eight sensory conditions during the training period for one subject. (From Woollacott M, Moore S, and Hu M (1993) Improvements in balance in the elderly through training in sensory organization abilities. In: Stelmach GE and Homberg V (eds.) *Sensorimotor Impairments in the Elderly,* p. 384. Dordrecht: Kluwer.)

five most difficult training conditions. In addition, performance remained above control levels for at least 4 weeks after the training ended, and it transferred to a second balance task, that of standing on one leg with eyes open and closed.

In addition, increased balance abilities were accompanied by specific changes in muscle response characteristics to platform perturbations. These included significantly less co-activation of antagonist muscles after training, indicating that subjects were using more-refined balance strategies.

In a randomized controlled trial, Wolf and colleagues examined the effects of Tai Chi training vs. static balance training on balance in community-dwelling older adults. The training consisted of 1–2 sessions per week for 15 weeks. Results showed that the risk ratio for falls was reduced in the Tai Chi group but not the static balance group. In another study, Gatts and Woollacott examined the neuromuscular mechanisms contributing to improved balance as a result of intensive Tai Chi training (1.5 hours per day for 3 weeks) in balance-impaired older adults. They found that Tai Chi-trained older adults showed significantly faster postural muscle responses when recovering from a slip during walking, along with reduced co-contraction of antagonist muscle responses (compared to a control group), suggesting that their postural muscle response characteristics were more efficient after Tai Chi training.

Finally, Shumway-Cook and colleagues determined the effects of a multidimensional exercise program on balance and falls risk in 105 balance-impaired older adults (65+ years). The program consisted of muscle strength training, mobility exercises, static and dynamic balance training, and aerobic activity (walking) for 8–12 weeks (physical therapy sessions twice per week and 5–7 days of exercise at home). Results showed that participants who were fully compliant in exercise participation showed a 33% reduction in falls risk compared to the control group, which showed an 8% increase in risk across the training period.

Walking Characteristics in Older Adults

Many of the same issues that were addressed previously in relation to questions concerning the inevitability of balance deterioration in aging also apply to the research on age-related changes in gait. Earlier clinical studies on gait disorders often included patients with such problems as gait apraxia, hypokinetic-hypertonic syndrome, and marche a petit pas, and thus considered the characteristics associated with these types of pathology to be associated with the normal aging process. These disorders were often called 'senile gait.' In 1992 a careful survey by Sudarsky and Ronthal on 50 patients with previously undiagnosed gait disorders showed that a causal

diagnosis could be made in 84% of the older adults. They found that myelopathy, Parkinsonism, frontal gait disorder (normal-pressure hydrocephalus, multiple strokes), cerebellar degeneration, and sensory imbalance were typical disorders that had been previously undiagnosed. Thus, as with balance disorders, gait disorders may not be a pure age-related phenomenon.

Changes in Velocity/Stride Length

The characteristics of gait patterns can be reported in many ways. One common way to measure gait patterns is to use a stopwatch to measure walking speed. Using simple techniques such as this, it has been consistently reported that there is a decrease in walking speed with age. One of the first investigations on age-related changes in gait patterns was performed by Speilberg. He described the earliest stage of gait pattern change (between 60 and 72 years of age) as consisting of a slower walking velocity, smaller displacement amplitudes of the joints, and a shorter stride length.

Another early approach involved observations of pedestrians walking in New York City.

Walking cadence and velocity were measured using a marked distance on the sidewalk. As age increased, there was a decrease in walking velocity, step length, and step rate. These changes were similar to the first stage of change in gait in Spielberg's report. While this approach has the advantage of being performed in a setting where gait characteristics will be more natural, the disadvantages include being unable to control for difference in walking goals, such as taking a stroll vs. hurring to work, and relative health of the subjects. To overcome these limitations, laboratory studies have been performed.

Kinematic Analysis

Though information on age-related changes in walking speed and stride length is useful, it does not allow the determination of age-related changes in the movement of body segments that may cause the reductions in speed and stride length. Kinematic (video, film, or optoelectronic) analysis of gait has been used by investigators to investigate age-related changes in body motion during gait.

Murray *et al*. photographed subjects from 20 to 87 years of age while they were walking at preferred and fast speeds. Twenty kinematic measures were made from the resulting photographs. They found that, in men, gait cycle duration and stance duration increased after 65 years of age, while stride width increased after 74 years of age. They also noted that out-toeing and gait variability (rhythmicity of repeated strides) increased while peak heel elevation decreased after 80 years of age. There were also age-related changes in floor clearance patterns for the foot, decreases in knee flexion amplitude, and decreases in ankle extension amplitude at push-off. For women, similar changes were seen, except that a decreased stride length was noted after 50 years, along with a slower walking speed and faster cadence. It is interesting to note that for women, habitual use of high heels significantly influenced the gait characteristics.

Kinetic Analysis

Kinematic analysis of gait allows the description of locomotion movement patterns, but it does not give information regarding force generation by the subject. In order to determine whether there were changes in characteristics of force generation in older (62–78 years) vs. young (21–28 years) adults, Winter *et al*. compared the kinetic data of walking trials for the two groups, using an inverse dynamics model. They noted that older adults generated significantly less power by the plantar flexors at push-off and absorbed significantly less energy by the quadriceps femoris muscle during the late stance and early swing phase of gait. They suggested that a reduction in plantar flexor power during push-off could cause a shorter step length, a more flat-footed heel strike, and increased double-support stance duration, all of which have been observed consistently in other studies on gait characteristics in older adults. One cause of a weaker push-off could be a reduction in ankle plantar flexor muscle strength, which has, in fact, been noted in many other studies. In addition, high push-off power is known to act upward and forward, and is thus destabilizing. Thus it is also possible that this change is adaptive to give a more stable gait pattern.

Winter *et al*. also noted that older adults showed a trend toward reduced knee–hip covariance. Winter calculated the covariance of knee and hip from the moment-of-force characteristics between the two joints, and suggested that it can be used as an 'index of dynamic balance.' It is interesting that 10 of the older adults in Winter's study showed covariances that were similar to those of the young adults, while five of them had low covariances. Winter *et al*. suggested that the five subjects with low hip–knee covariances may have had neural or musculoskeletal dysfunction not detected on their clinical exams.

Neuromuscular Analysis

How do the previously described changes in kinetics and kinematics relate to changes in muscle response

patterns underlying gait? Finley *et al*. compared patterns of muscle activity in younger (19–38 years) and older (64–86 years) women during normal gait. They found that average electromyograph (EMG) activity levels in gastrocnemius, tibialis anterior, biceps femoris, rectus femoris, and peroneus longus muscles were higher in the older age group than in the younger group. They also noted that there were changes in muscle response characteristics at specific points in the step cycle. Thus, at heel strike, the activity of peroneus longus and gastrocnemius was elevated in the older women, compared to the younger women. The authors suggested that this elevated activity could be a result of a strategy to increase co-activation of agonist and antagonist muscles, thus increasing the stiffness of the joint and improving stability during the stance phase of gait. This strategy is often used by subjects who are not skilled in a task, or who require increased control of the task.

Studies have also examined the effects of changes in sensory systems on gait patterns in the older adult. Simoneau *et al*. examined the effect of changing the visual environment on gait characteristics during stair descent in older women (55–70 years). Stair descent was tested under the following conditions: stairs painted black, stairs painted black with the subject wearing a headband with a light-scattering plastic shield (called the blurred condition), and stairs painted black with a white stripe added at the edge of every tread. Motion analysis of the subjects' stair-climbing performance showed significantly slower cadence, larger foot clearance, and more posterior foot placement when the older adults were asked to walk under the blurred condition as compared to the other two conditions. It was also noted that foot clearance was larger than that observed previously in studies with young adults.

Changes in Adaptive Control

An important aspect of locomotor control is the ability to use visual information to change gait characteristics in order to avoid upcoming obstacles. Patla performed experiments that asked whether one contributing factor to poor walking performance in older adults might be a reduced ability to sample the visual environment during walking. In this experiment he asked both older and young adults to wear opaque liquid crystal eyeglasses with a switch that could be pressed by the subject to make the glasses transparent whenever the subject wished to sample the environment. Participants walked across a floor that either was unmarked or had regularly marked footprints on which the participants were supposed to walk. When asked to walk on the footprints, the young subjects sampled frequently and for short intervals, while the older subjects sampled less often, but for longer periods. This resulted in the older adults monitoring the terrain much more than the young adults.

Patla also performed a study in which young and older adults were asked to walk along a walkway, and when cued by a light at specific points along the walkway, to either lengthen or shorten their stride to match the position of the light. They thus tested the ability of older adults to modulate the step cycle to avoid an object. They found that the older adults had more difficulty than the younger adults in modulating their step length when the visual cue was given only one step duration ahead. They noted that young adults succeeded 80% of the time, while older adults succeeded 60% of the time when they were required to lengthen the step and only 38% of the time when required to shorten the step. However, both young and older adults performed equally well when the visual cue was given two steps in advance. Patla suggested that balance difficulties contributed to the problems that older adults had in shortening their step. This requirement of older adults to make modifications to gait patterns more than one step before meeting an obstacle may contribute to their need for increased visual monitoring of the environment during walking.

Because older adults show a decreased floor clearance for the swing leg, this could cause problems in stepping over objects, and thus result in trips. Therefore Chef *et al*. analyzed the kinematics of gait of healthy young and older adults while they stepped over obstacles of varying heights (0 inches vs. approximately 1, 2, and 6 inches). The smaller heights corresponded to typical floor and door thresholds and the larger ones to a curbstone, or a toy or pet that might be found at home. They found no age-related change in foot clearance over an obstacle. However, they noted that four of 24 older adults compared to no younger adults stepped on an obstacle during the experiment. Since the trials with obstacle contact were found equally throughout the test period, the authors predicted that inattention, rather than fatigue, was probably the cause of these incidents. They also found that older adults used a more conservative strategy while crossing the obstacles. This consisted of a slower crossing speed, shorter step length, and placement of the last heel strike before the obstacle closer to the obstacle.

The authors noted that the age-related differences in gait characteristics while crossing obstacles may be in part caused by decreased joint range of motion in the legs of the older adults. Thus age-related changes

in cognition and range of joint motion might be two factors causing changes in older adults' gait characteristics during obstacle crossing.

A second aspect of adaptive control of locomotion involves the ability to recover from a trip or slip during gait. Tang and colleagues tested the ability of young (mean age 25 years) vs. healthy older (mean age 74 years) adults to recover from an unexpected slip during gait. In this study, participants were asked to walk across a platform that unexpectedly moved forward at heel strike, simulating a slip on ice. The results showed that older adults were less stable in recovering from slips, often tripping with the swing leg, which caught on the support surface, during their recovery phase, showing trunk hyperextension in response to the slip and using a shortened stride length during recovery, as shown in the stick figure of a young vs. an older adult when recovering from a slip in **Figure 9A**. Neuromuscular response changes that contributed to this impaired recovery included a slowing of muscle contraction onset and a reduced muscle response amplitude. These delayed and weaker muscle responses thus contributed to the trips seen in the older adults during recovery. Longer-duration muscle responses were used to compensate for the slower and smaller response amplitudes, as shown in **Figure 9B**.

Factors Influencing Changes in Gait Characteristics

Though there are small but significant differences in the gait characteristics of healthy older adults compared to younger adults, studies by Heitemann *et al*. and Gehlsen and Whaley showed that older adults with a history of falls have significantly different gait characteristics than those without falls. Heitmann and colleagues noted that older women fallers were able to stand for significantly shorter times with feet in tandem position than non-fallers, and also showed increased step width during gait. These changes could be caused by undiagnosed pathology in these subjects. However it is also possible that, as a result of many falls, older adults develop a fear of falling, which also contributes to changes in gait patterns.

The results of many studies indicate that one reason older adults walk less quickly than young adults is that they consciously choose a more conservative or safe walking style. This suggests that fear of falling may contribute to changes in gait in the older adult. For example, Tinetti and colleagues found that preferred walking speed, anxiety level, and depression are significant predictors of fear of falling in older adults.

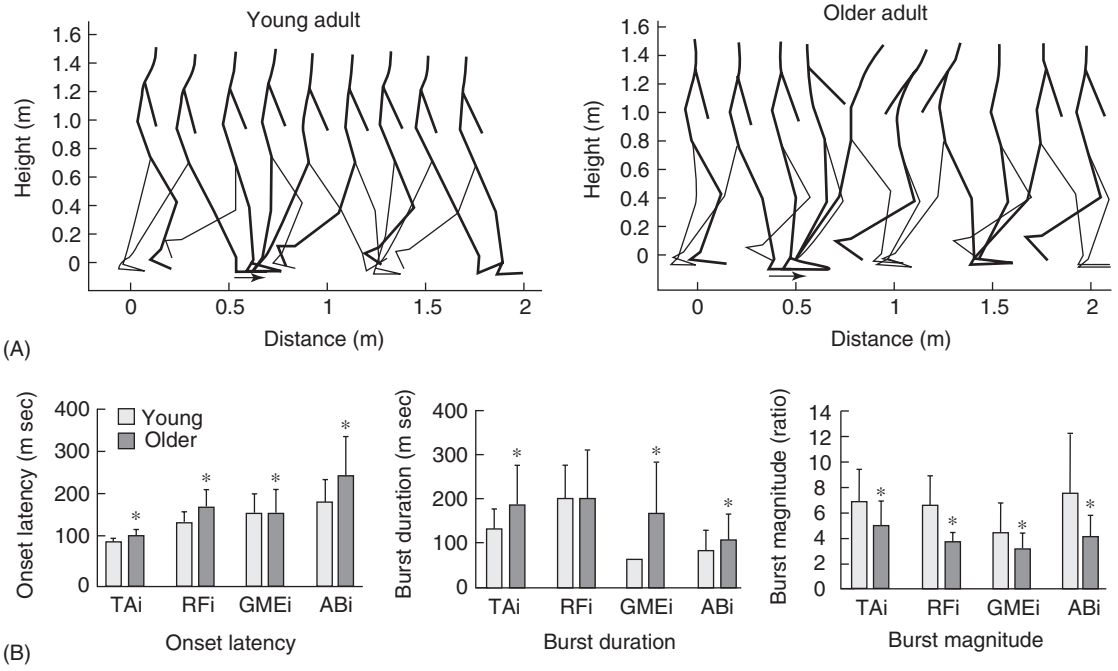

Figure 9 (A) Stick figures taken from the motion analysis of the movements of a young adult and a healthy older adult when recovering from a forward slip. The older adult shows backward extension of the trunk and the raising of the arm during balance recovery. (B) Means and standard deviations of muscle contraction onset latency, muscle burst duration, and muscle burst magnitude for the anterior muscles of the stance leg, involved in the slip. TAi, ipsilateral tibialis anterior; RFi, ipsilateral rectus femoris; GMEi, ipsilateral gluteus medius; ABi, ipsilateral abdominal muscles. (From Tang P-F and Woollacott M (1998) Inefficient postural responses to unexpected slips during walking in older adults. *Journal of Gerontology* 53: M476, M477.)

Summary

The research discussed here examined age-related changes in various neural and musculoskeletal systems contributing to balance and gait. Studies on age-related changes in balance control have shown changes in the neuromuscular response characteristics, including decreased muscle strength, a slowing of response latencies, occasional disruption in response organization, and an increased co-activation of agonist and antagonist muscles when responding to threats to balance. In addition, older adults showed more problems than young adults when balancing under conditions in which sensory inputs were reduced or absent, or when balancing when performing a second cognitive task.

Similarly, in research on gait, studies have reported a reduction in walking speed and in stride length, with an increased double support phase. This was accompanied by increases in co-activation of muscles around the ankle joint. Older adults also show less power generated by the plantarflexor muscles at push-off, which could cause the reduced stride length. The reason for the weaker push-off could be reduced muscle strength. Studies examining the effects of a variety of training programs on balance and gait characteristics have shown that muscle strength training, sensory organization training, and dynamic balance training programs, such as Tai Chi, significantly improve balance function in the elderly.

Behavioral Genetics

C S Bergeman and A D Ong, University of Notre Dame, Notre Dame, IN, USA

Glossary

Additive Genetic Variance – The extent to which genotypic values add up linearly in their effect on the phenotype.

Behavioral Genetics – The study of genetic and environmental factors that create behavioral differences among individuals.

Concordance – The presence of a given trait in both members of a pair.

Genotype–Environment Correlation – The extent to which an individual's environmental experience is systematically related to their genetic predispositions.

Genotype–Environment Interaction – The extent to which the effect of a particular environment depends on someone's genetic propensity.

Heritability – A statistic that describes the proportion of phenotypic variance that is due to genetic variance, which can be partitioned into two types – additive and non-additive.

Non-additive Genetic Variance – Genetic influences due to dominance (interactions between alleles at a single locus), as well as the variance due to the higher order interactions called epistasis (interactions between alleles at different loci).

Non-shared Environment – Any environmental influence that makes family members different from

one another (including error variance; also called specific or within-family effects).

Shared Environment – Influences that contribute to phenotypic similarity among family members (also referred to as common or between-family effects).

Introduction

The age-related diseases and physiological changes that we have come to think of as part of 'normal aging' do not affect all people in the same way, nor do all individuals experience the same changes as they age. In fact, older adults are thought to be more diverse than younger adults in health, psychological functioning, and dimensions of social interaction. In other words, the observed heterogeneity among age peers increases over the life course, and the members of a cohort are said to 'fan out' as they age, becoming more dissimilar for any given characteristic. The need to explain this functional heterogeneity is a major objective of research in gerontological behavioral genetics. This article provides a brief overview of prior research on behavioral genetics, giving emphasis to the conceptualizations, empirical findings, and age focus that characterize previous studies. The next section describes research assessing genetic and environmental influences on longevity, health, cognitive functioning, personality, and psychopathology in later life. A final section reviews future research directions in the rapidly developing field of gerontological behavioral genetics.

Behavioral Genetic Studies of Aging

As of 1980, only one study specifically designed to address issues of genetic and environmental influence on biobehavioral aging had been reported: the New York State Psychiatric Study of Aging Twins, which was started in 1946 to study hereditary aspects of aging and longevity. Since that time, there has been an explosion in the number of behavioral genetic studies of aging.

American Samples

Several twin samples that focus on issues relative to gerontological research were derived from military records. The National Academy of Science-National Research Council Twin Study (NRC-NAS), started in 1955, originally consisted of almost 16 000 white male twin pairs born in the years 1917 to 1927, who were in the armed forces during World War II. Detailed assessments of lifestyle and health behaviors, medical conditions, occupation/retirement, social support, and cognitive functioning were obtained on these twins in 1965, 1983–86, and 1998–99. The current sample includes approximately 2055 pairs of twins. The National Heart, Lung, and Blood Institute Twin Study (NHLBI) represents a subsample of the original NAS-NRC twin study. The study includes 514 pairs of male twins who have participated in five in-person exams (1969–71, 1981–83, 1985–87, 1995–97, and 1999–01), with a focus on the psychological, demographic, metabolic, cardiorespiratory, anthropometric, and social aspects of proneness to coronary heart disease (CHD) and related disorders.

Other samples have been developed in specific states. The Minnesota Twin Study of Adult Development and Aging (MTSADA) is a population-based registry that includes information from 901 pairs of twins born in the state of Minnesota between 1897 and 1955 (with a majority born from 1904 to 1934). Participants were identified by birth records from the Minnesota State Health Department and were recruited using state marriage and motor vehicle records. Twins were assessed on a variety of cognitive, personality, and lifestyle measures.

The family portion of the Seattle Longitudinal Study was initiated in 1990 by selecting the adult offspring and siblings of the original sample. The sample includes 531 target parents (age range = 39–91; mean = 64), their siblings (age range = 22–89; mean = 58), and their adult children (age range = 22–74; mean = 40). All participants were community-dwelling individuals at the time of testing. Multiple measures of psychometric cognitive attributes, family environment, and personality were administered.

The Carolina African American Twin Study of Aging (CAATSA) was designed to assess genetic and environmental influences on the etiology of memory, personality, health behaviors, stress, chronic illness (e.g., cardiovascular disease, high blood pressure, arthritis), and social forces in a sample of African American twins ranging in age from 25 to 85. The registry was developed using birth records from 19 counties in North Carolina, and the current sample contains 202 monozygotic (MZ) twin pairs, 364 dizygotic (DZ) pairs, 62 siblings, and 78 singletons.

The Health of Older Twins Study (HOOTS) and the Black Elderly Twin Study (BETS) were created using national, population-based samples and were designed to estimate genetic and environmental contributions of physical frailty in older Caucasian and African American twin pairs. The sampling strategy capitalized on the use of date of birth, race, and characteristics of the Medicare health insurance claim number to identify potential pairs for study. The AARP Twin Study, on the other hand, includes volunteer sampling from the American Association of Retired Persons database.

European Registries

Much of what we know about genetic and environmental influences on the aging process comes from European registries. The Swedish Twin Registry contains information on nearly 25 000 pairs of twins born in Sweden between 1886 and 1958, with a primary focus on cancer, cardiovascular disease, depression, health and health-related behaviors, substance use and abuse, cognitive functioning, and personality. The Swedish Adoption/Twin Study of Aging (SATSA) is a subsample of the Swedish Twin Registry that includes information from 351 pairs of twins reared apart as well as a matched control group (based on age, gender, and county of birth) of 407 pairs of twins reared together. A variety of measures assessing different phenotypic traits (e.g., health, cognitive functioning, personality, social support, environmental contexts) has been obtained longitudinally at 3-year intervals from 1984 to 1993, which also include extensive in-person testing on a subsample of 150 pairs (at 3-year intervals from 1985 to 2002).

A second subset of the Swedish Twin Registry is the Octogenarian Twin Study (OCTO Twin), which is based on twins ranging in age from 80 to 89 (born prior to 1914). The twins have been assessed at 2-year intervals over an 8-year period for a total of five occasions of measurement. The sample at the first time point included 702 individuals (351 pairs; 93 MZ and 141 DZ pairs of female twins and 56 MZ and 61 DZ male twin pairs). Measures include health, personality, psychological well-being, cognitive ability, and interpersonal factors. A third subset is the Study of Dementia in Swedish Twins (HARMONY), which includes Swedish twins (65 and older) in which at least one member of the pair screened positive for dementia. Identified pairs were given an extensive evaluation that included physical and neuropsychological exams, a family history, and assessments of possible environmental factors. Association studies with candidate genes for Alzheimer's disease are also being done.

The Danish Twin Registry includes twin pairs born in Denmark between 1870 and 1910 and same-sexed twins born between 1911 and 1930 (old cohort) and 1931 to 1952 (new cohort), resulting in data from more than 32 000 twin pairs. The Longitudinal Study of Aging Danish Twins (LSADT) originated in 1995 and incorporates all registered Danish twins born prior to 1920, regardless of whether the co-twin was still living at the time the sample was created (included 3099 individuals and 733 intact pairs). The surviving members of the original cohort have been assessed at 2-year intervals since 1997. The LSADT is a cohort-sequential design, with additional cohorts added at each assessment, including twin pairs who were born in 1920–23 (in 1997), 1923–28 (in 1999), and 1929–30 (in 2001). A total of 4731 individual twins have completed an LSADT intake assessment, either through in-person interview or by proxy, including 1112 same-sex twin pairs with known zygosity. Data collection centers on aging and age-related health, metabolic and cardiovascular disease, longevity, and mortality.

The Danish Adoption Register is a study of families (e.g., adoptees, adoptive parents, biological parents, siblings) from non-familial adoptions in Denmark between 1924 and 1947. The primary focus has been on genetic and family environmental influences on psychiatric disorders (especially schizophrenia), but more recent work has also included indices of physical health (e.g., obesity, somatic disorders), health-related risk factors (e.g., smoking), and mortality and morbidity.

The old Cohort of the Finnish Twin Registry (Old Finnish Twin Cohort) includes information on 13 888 twins with a research focus on physical activity and health outcomes, including premature mortality, CHD, diabetes, hip fractures, sleep disorders, and cancers. Twins have been followed up for mortality with the National Medical Registries. In 2000, the Finnish Twin Study on Aging (FITSA) was developed to assess frailty and disability in older women. The subsample of the registry includes 217 pairs of female twins (102 MZ and 115 DZ) ranging in age from 65 to 75. The primary focus of this research is on physical capacity and functional abilities.

The Norwegian Twin Register is a population-based registry based in Oslo, Norway, that contains between 800 and 900 pairs of twins for each cohort born between 1895 and 1944. The primary focus of research using this registry is mental illness, especially manic depression, Alzheimer's disease, and schizophrenia.

The St. Thomas UK Adult Twin Registry, started in 1993, contains 10 000 pairs of twins ranging in age from 18 to 80 (average age is 45), 3000 of whom are at least 50 years of age. It is a volunteer sample, primarily female, recruited with successive media campaigns. The focus of the registry is common diseases of aging, primarily cardiovascular, metabolic (immune function), musculoskeletal (osteoporosis, arthritis, back pain), and related physical attributes (e.g., obesity). The majority of the twin pairs have participated in clinical screenings that have assessed multiple aspects of health and functioning and provided DNA samples for future work in this area (1500 of the pairs have information from a full genome scan).

The Munich GOLD Project (Genetic-Oriented Longitudinal Study of Differential Development)

includes about 250 identical and fraternal pairs of twins born between 1912 and 1932. The twins were ascertained via newspaper advertisements in Munich, Germany. The variables of primary interest are personality, intelligence, motivation, emotion, and aspects of social behavior.

The Italian Twin Registry includes a sample of 120 000 twins, with a substantive focus on aging, dementia, cardiovascular disease, diabetes, and asthma. The Twin Epidemiological Register of Rome (TERRY) includes information from 13 228 twins with data collected to assess lifestyle, development, and aging. Of these twins, 3000 pairs were born prior to 1950, and in 1997, researchers created a subregistry referred to as 'Lifestyle and Aging' (LISA), which focuses on the role of physical activity on successful aging.

Asian Registries

The Osaka University Aged Twin Registry (OUATR), formerly referred to as the Kinki University Panel, includes 12 000 pairs of oriental (primarily Japanese) twins born between 1900 and 1935, 250 pairs of which were separated early in life and reared apart. The registry reflects a volunteer sample ascertained through media advertising. The focus of the registry is on aspects of aging, including dementia, disease, changes in cognitive functioning, life satisfaction, and quality of life. A subsample has been assessed by multiple in-person cognitive tests, received comprehensive medical exams, and participated in interview assessments of lifestyle factors, family history, medical history, and diet.

The Korean Twin Registry (KTR) includes 990 pairs of twins born before 1930 and 6243 born prior to 1950. This sample is still in the developmental phases; the initial focus of the research will be health morbidity and mortality. This is a population-based registry, and to date it has only been linked with available health data from the Korean National Health Insurance. Detailed data on medical history, subjective health status, family history of disease, exercise, diet, and cancer screens are available. Cause of death, for those twins who are deceased, is also available.

Other Registries

The Australian Twin Registry was established in the late 1970s and contains more than 30 000 pairs of Australian twins. The ATR does not undertake research itself but acts as a facilitator, providing an important national and international resource for medical and scientific researchers. The old cohort of the Australian Twin Registry is composed of approximately 1200 pairs of twins ranging in age from 50 to 90 (mean = 61.4), who have been assessed multiple times since 1993 on a variety of health and lifestyle attributes.

Studies of Mid-Life

Additional studies focus on mid-life participants, with plans to follow them into old age. Adult Russian Twin Study includes data from 130 pairs of twins – 79 MZ and 51 DZ – from the metropolitan Moscow area. The mean age of the sample is 42 years (standard deviation [SD] = 8.9). Measures focus on personality, health, smoking behavior, and contextual factors that might inform on cultural and environmental influences on individual differences in health outcomes.

The German Observational Study of Adult Twins (GOSAT) is a subsample of twins from the Bielefeld Longitudinal Study of Adult Twins, which is a population-based registry in Germany. The full sample of twins consists of more than 2500 pairs ranging in age from 18 to 70 (mean = 34) recruited from all over Germany. These twins have been assessed longitudinally on measures of personality and cognitive decline. The GOSAT consists of 300 pairs of twins (162 MZ and 132 DZ), primarily females (78%), who have been assessed using peer report and observational/videotaped methods in addition to the more typically used self-reports. More specifically, data include videotapes of behavioral observations in quasi-natural settings, objective temperament assessments, unobtrusive behavior registrations, psychometric intelligence data, and measures of mental speed using elementary cognitive tasks. The primary objective is to use multiple methods to better understand genetic and environmental influences on the attributes of interest.

The Minnesota Study of Twins Reared Apart began in 1979 and has since studied more than 100 sets of reared-apart twins or triplets. Subjects participate in approximately 50 hours of medical and psychological assessments at the University of Minnesota. The majority of the twins are from the United States and Great Britain, but some reside in other countries. The sample generally includes data from 49 pairs of MZ twins (47 pairs and two sets of triplets) and 25 DZ pairs, and is predominantly females (64%) with a mean age of 40 (SD = 11.5). The members of the sample were separated very early in life (1.5 years on average) and were not reunited until adulthood (mean age of reunion = 32.6). The assessments included a large battery of cognitive tests, as well as multiple measures of personality, a medical exam, social attitudes, occupational

interests, a life history interview, assessments of the rearing environment, and a psychiatric interview.

The Mid-Atlantic Twin Registry (MATR) is a combination of the Virginia and North Carolina Twin Registries with the addition of a population-based twin sample from South Carolina. The sample includes 46 000 twin pairs, with 2250 over the age of 55. The mean age is 35, with birth years ranging from 1913 to 2000. The attributes relevant to aging include cardiovascular disease and mental health problems such as depression and anxiety.

The MIDUS (National Survey of Midlife Development in the United States) twin sample was recruited using a nationally based telephone screening survey that contacted 50 000 households for the presence of a twin. The sample includes 998 twin pairs, ranging in age from 25 to 74 (mean = 47.2; SD = 12.6), assessed on a broad battery of questionnaires in the areas of physical health, psychological well-being, and social connectedness. In addition, 216 same-sex pairs (116 MZ and 110 DZ) participated in a study of daily experiences via telephone on each of eight consecutive evenings.

The Vietnam Era Twin Registry (VET) includes information from 7375 male twin pairs, both of whom served during the Vietnam conflict (1965–75). The twins were born between 1939 and 1957, with current ages ranging from 47 to 66. The focus of the registry is on genetic epidemiological studies of physical and mental health, primarily cognitive functioning, health and disease, personality, and aspects of psychopathology. Detailed lab and clinical assessments are available on a subsample of the registry. The long-term goal is to study attributes of the aging process from middle into old age.

Genetic and Environmental Influences in Later Life

Longevity and Health

More than a century ago, Oliver Wendell Holmes suggested that "several years before birth, advertise for a couple of parents belonging to long-lived families." Because familial resemblance includes both genetic and environmental influences, however, family studies alone do not provide conclusive evidence for a genetic component to longevity. Results from twin and adoption studies are also necessary to support the conclusion that genetic factors play a role in how long people live. The most extensive work of this type comes from the Danish Twin Registry. Results from this research indicate a moderate heritability across the life span ranging from 20 to 25%, with no differences by gender. The majority of the variance is environmental in origin and is of the 'nonshared' variety, contributing to differences rather than similarities among family members.

One reason why the relationship among family members for longevity is modest is that what children inherit from their parents is not longevity per se, but rather 'frailty.' That is, children inherit susceptibility to disease, or other risk factors that contribute to their chances of death at different ages. For example, results from a Danish adoption study indicated that the early death of a biological parent corresponded to a twofold increase in mortality of the adoptee. Additionally, despite different structures in the survival data from Swedish and Danish twins, the results in both studies suggest a heritability of individual frailty of about 50%. Similar results were found in the NAS-NRC Twin Registry. In this sample, genetic differences for liability to death from disease accounted for 54% of the individual differences for this trait, indicating that significant familial resemblance for disease mortality is due to hereditary influences. Thus, estimates of the heritability of frailty have consistently been around 50%, suggesting that hereditary predispositions may influence the risk of death at different ages, rather than directly determining age at death.

Cardiovascular Disease Cardiovascular disease is a complex disorder that is determined by multiple genes, environmental factors, and their confluence. For example, the risk of death from myocardial infarction (heart attack) is one and a half to two times greater in a man whose male sibling died at an early age (less than 50 years of age). This type of premature CHD is a single gene defect, affecting lipoprotein metabolism, which accounts for about 5% of coronary disease in the population.

Because of the multidimensional nature of cardiovascular disease, attributes such as blood pressure, cholesterol levels, and glucose intolerance have been studied separately. For example, 44% of individual differences in systolic and 34% in diastolic blood pressure were genetic in origin using data from SATSA, with shared family environment accounting for up to 27% of the variance. Model-fitting analyses indicated significant age differences in heritability for serum lipid (e.g., cholesterol) and apolipoproteins. In the young cohort (age <65) the heritability estimate for total cholesterol was 63%, whereas in the older group (age >65) the heritability was 26%. Although hereditary factors are clearly important, genetic influences appear to be more pronounced at younger ages. Shared rearing environment also contributed to individual differences in total cholesterol levels (especially in the older cohort), accounting for 16 and

36% of the variance in the young and old cohort, respectively.

A report from the NHLBI focused on risk factors for cardiovascular disease in middle-aged men. The patterns of similarity for male twins suggest that the familial aggregation of cardiovascular disease results from a heritability of 60% for blood pressure (both systolic and diastolic), 25% for hematocrit, 53% for uric acid, and 56% for triglyceride levels. In addition to shared environment, genetic influences accounted for 14 to 31% (corrected for a variance difference in DZ versus MZ twins) of individual differences in cholesterol levels in these twins. In a 16-year follow-up of this sample, an inverse relationship between plasma high-density lipoprotein cholesterol (HDL-C) and the risk for the complication of arteriosclerosis was found, with a bivariate heritability of 56%. In a Japanese sample (OUATR), heritability for both types of cholesterol (low-density lipoprotein [LDL] and HDL) was 0.50.

Reports from the NAS-NRC Twin Registry demonstrated that 'healthy aging' (primarily defined as the absence of cardiovascular disease up to age 70) is under a significant degree of genetic influence, with estimates hovering around 50%. Work in this area in the early twenty-first century has begun to focus on identifying chromosomal areas that may be linked to the healthy aging phenotype.

Stroke Although multiple studies have assessed vascular disease (primarily cardiovascular), few studies have looked at the etiology of cerebrovascular accidents (CVA), more commonly referred to as strokes. Researchers, using male twins from the NAS-NRC Twin Registry, reported concordance rates of 17.7% for MZ and 3.6% for DZ twins. Although there were too few pairs of twins with strokes to reliably estimate the magnitude of heritability, these results indicate a nearly fivefold increase in the co-occurrence of stroke in MZ twins when compared to DZ twins. A long-term follow-up of twins from the Danish Twin Registry indicated that genetic factors increase the risk of stroke but that the effect is more moderate, showing a twofold increase for concordance in MZ versus DZ pairs in this sample.

Diabetes Mellitus Close relatives of patients with diabetes mellitus (DM) have increased risk of developing the disease, but the risk is almost exclusively for the same form of the disorder (insulin or non-insulin DM) as is present in the proband. Heritability appears stronger for non-insulin (type II) diabetes; concordance rates for MZ twins are 70 to 100%, whereas for insulin-dependent (type I) diabetes, the MZ concordance rates are 10 to 50%. Perhaps the strongest evidence for genetic influence on type II diabetes comes from a study on glucose intolerance; data from the NHLBI study indicated that the heritability for glucose intolerance was 88%. Others have suggested a genotype–environment interaction, speculating that environmental agents (e.g., diet) may be important in determining the severity of glucose intolerance in genetically predisposed people.

Self-Reported Health Self-reported health is of particular relevance because as a global indicator, it reliably predicts functional ability, survival, and objective measures of health status. It is also related to life satisfaction and overall cognitive functioning, and as such reflects the complex relations between physical and psychological aspects of health and illness. Research in this area has indicated that heredity is of moderate importance for perceptions of health status. For example, the heritability is 0.43 in the MTSADA, with the remaining variance due to non-shared environment. In the data from the Swedish Twin Registry, twins were divided cross-sectionally into four age groups (17–44, 45–64, 65–74, and 75–91), and results suggested that variability in self-rated health increased linearly across age groups. These age differences were also characterized by significant differences in genetic and environmental influences on the change in variability across cohorts, with the increase in variance early and late in adulthood primarily due to environmental factors and the variance in mid-life – 45 to 75 years of age – influenced by hereditary factors as well. Additionally, women generally report worse overall health, but studies do not show that this difference is genetically influenced. Similar results have emerged from Denmark and Norway. It should be noted, however, that longitudinal data are necessary to distinguish cohort differences from aging effects and to assess continuity or change in environmental influences.

Functional Status Studies have also assessed the extent to which individual differences in functional abilities (e.g., mobility, participation in leisure activities, ability to engage in light or heavy household chores, work, and travel) are affected by heredity in later life. For example, data from the NAS-NRC Twin Registry indicated that additive genetic effects accounted for 19 to 33% of the variance in functional ability in 8 of the 10 indicators assessed, but the 95% confidence intervals included 0.0 in all but three cases. Non-shared environmental effects accounted for almost all of the remaining variance. In considering the extent to which health limitations impair functional activity, the results

indicated that 21% of the variance was due to additive genetic influences and 78% to non-shared environmental effects (in this case the 95% confidence interval did not include 0.0). In female Danish twins 75 and older, heritability estimates of functional ability ranged from 34 to 47% in women 80 and older, but only 15 to 34% in women 75–79. These results suggest that interventions directed toward unique aspects of the environment (e.g., diet, nutrition, health-care utilization, stress maintenance) may be especially important in lengthening the period of active life and contributing to positive outcomes in later life.

For many aspects of health and longevity, results of behavioral genetic research indicate that similarities between parents and offspring are typically lower than resemblance between siblings within a family, suggesting that cohort or age is important to consider. It is also likely that apparent differences in heritability across the life span are due to selection effects on longevity or functional capacity. For example, genetic influences may appear to be more important for health in middle adulthood, because characteristics that are highly heritable may result in the death of one or both of the twins. The impact of the loss of these subjects from the sample (or potential sample) is an artificially lower heritability estimate for the later age groups. Gender may also be a factor; unfortunately, studies do not always converge as to whether genetic and environmental effects differ for males and females. Given that many studies, especially on adults, control for possible gender effects by statistically removing differences by gender or by including only males or females in their sample, important information may be missing regarding the role that gender plays in genetic and environmental etiologies of disease and its physiological markers.

Cognitive Functioning

Cognitive abilities are among the most heritable dimensions of behavior, with genetic factors consistently accounting for about 50% of the variability in studies of childhood, adolescence, and young adulthood. Studies of later life have indicated higher levels of heritability for general cognitive abilities (see **Table 1**) than are typically observed in younger populations. For example, assessments from the SATSA indicated that 80% of the variability for twins 60 years of age (average age) was due to genetic differences. It was originally speculated that the higher heritability estimates could be related to specific characteristics of the Swedish sample, but these results have been replicated in studies using middle-age and older subjects in United States and Norwegian samples.

Research on specific cognitive abilities (e.g., verbal, perceptual speed, spatial orientation, memory) also implicates substantial genetic involvement, albeit less than what is reported for general abilities. Across multiple studies, the heritabilities range from 0.0 to 0.86, with the lowest estimates for measures of memory and the highest estimates for verbal ability and perceptual speed. A perusal of **Table 1**, however, indicates that there is much variability in these results. It has been hypothesized that the genetic influences on the cognitive domain are more general than specific. An interesting analysis from the SATSA looked at the relationship between the factor loading of the specific scale on the principal component and estimates of heritability, and found that the factor loadings were correlated with the heritability of the tests. The authors speculated that the more a trait taps into general cognitive ability, the more heritable it is.

Interestingly, much of the remaining variance in cognitive functioning is due to non-shared environment, although there are notable exceptions here as well. For example, findings from verbal ability tests consistently illustrate the importance of environmental factors in contributing to familial similarity, with estimates for shared environment ranging from 0.14 to 0.30. The Seattle Longitudinal Study explicitly assessed the extent to which aspects of the early and current family environment (measured with the Family Environment Scale) contributed to familial similarity (between siblings and between parents and offspring) for cognitive abilities. Results indicated that early family environment, both shared and uniquely experienced, impacted familial similarity in adult cognitive functioning, especially in siblings.

Another area of later life that has received much attention is cognitive decline, and multiple studies have measured different aspects of cognitive status (e.g., the Mini-Mental Status Exam [MMSE]). One sample in which cognitive decline has been extensively studied is the NHLBI, which showed heritability estimates of 0.22 for the Iowa Screening Battery, 0.38 for the MMSE, and 0.76 for Digit Symbol. A subsample of 44 of the male twin pairs was followed over a 5-year period to assess changes in cognitive function, based on the digit symbol measure. Although the sample was small, the results indicated that digit symbol substitution was heritable (0.80 and 0.88 at times 1 and 2, respectively). The prevalence of decline (defined as one or more SD changes) was similar in both MZ (35%) and DZ (39%) twins, but the concordance rates for decline were not. For identical twins, the concordance rate

was 45%, whereas in fraternal twins the rate was 8%; thus, at least a portion of the rate of change in cognition (indexed by a measure of perceptual speed) is influenced by hereditary factors.

The MTSADA researchers looked at the relationship between memory and cognitive functioning, lifestyle, and personality factors. They were interested in the general observation that there are large individual differences in memory ability among older individuals. In addition, older individuals who are high in verbal ability maintain a high level of intellectual activity, have larger working memory capacity, maintain a high level of general or physical activity, and manifest little test anxiety. The researchers specifically focused on the etiology of the relationship between measures of memory capacity and measures of social class (occupation, education, and vocabulary), processing speed (reaction time, digit symbol), intellectual activity, and physical activity. The results indicated that genetic influences on memory are largely mediated by processing speed and social class, whereas environmental influences on memory are mediated to some extent by physical activity. Thus, the authors suggested that interventions for a decline in memory functioning might best be targeted at lifestyle variables such as physical activity.

Personality

Results of research in childhood, adolescence, and young adulthood indicate that genetic influence for self-reported personality is significant, but moderate, ranging from 30 to 50%. Although environmental influence is important, almost all the environmental variance is non-shared. Nonetheless, most of the variance is environmental, even for the most heritable personality traits. As is indicated in **Table 2**, heritability for personality in later adulthood is only slightly lower than results reported earlier in the life span.

Researchers have also looked at the extent to which genes and environment contribute to longitudinal stability in aspects of personality across

adulthood. In the MTSADA, genetic correlations for various aspects of the Multidimensional Personality Questionnaire across a 5-year period ranged from 0.93 to 1.0; non-shared environmental correlations ranged from 0.53 to 0.73. Similar results were found in the Finnish Twin Cohort and the SATSA. The investigators concluded that, relatively speaking, environmental influences are more important at each time point, but are less stable from time to time, whereas genetic effects are stable, but are of slightly less importance. Thus, although measures of personality are moderately heritable, the genetic effects over time appear to be consistent, contributing to continuity and not change.

One advantage of the GOSAT sample is that multiple methods of data collection are used – self-report, peer-report, and observational assessments. Their self-report data were consistent with heritability estimates from other studies of older samples (ranging from 0.42 to 0.56), whereas estimates from the peer-report (ranging from 0.57 to 0.81) and the combined self- and peer-report (ranging from 0.66 to 0.79) data were substantially higher, probably because these data allowed for measurement error to be removed from the non-shared environment category. The observational data that were collected focused on 'talkativeness,' an aspect of extraversion. Results of the questionnaire data indicated that self-reported extraversion showed a heritability of 0.56, peer-reported was 0.60, and the observational measure was 0.30. Thus, although the heritability across all types of measures was significant, the observational measure showed less heritability than the survey methods. Additional research on the impact of methodological variance is needed to fully interpret these results.

Behavioral genetic research has also assessed characteristics of personality that may be particularly relevant in later life. One example is locus of control, which has been associated with both physical health and psychological well-being. Analyses in the SATSA indicated that genetic influences are most important for self-attributions concerning responsibility and life direction, accounting for 30% of the variance. The familial similarity for the perceived role of luck in determining life's outcomes, however, is largely due to shared rearing environmental influences. Similar results were found in the OCTO Twin sample, which was used to test genetic and environmental influences on health control beliefs (i.e., due to internal control, chance, or powerful others) and the relationship with depression, life satisfaction, and indices of health in the oldest old.

A second dimension especially relevant to later life is 'type A' personality, which has been associated with cardiovascular disease. Attributes such as 'ambition,' 'hostility,' 'pressure,' and 'hard-driving,' using a structured interview, the Framingham measure, and multiple other self-report measures, indicated heritabilities accounting for 14 to 63% of the variance, with a typical heritability of 0.35. These results come from the SATSA, NHLBI, Finnish Twin Registry, Norwegian Twin Panel, and Australian Twin

Registry; in fact, quite similar results were reported across a variety of samples from different cultures, utilizing different measures and analytical techniques.

Psychopathology

Dementia Dementia is a global term for any neurological disorder whose primary symptomology is the deterioration of mental functioning. Alzheimer's disease (AD) is arguably the most severe and devastating of all of the different types of dementia, accounting for about 50% of all cases of severe dementia. Many epidemiological studies have been carried out in order to identify risk factors for AD. Apart from increased age, the other variable that has been consistently identified is a family history of the disorder. For example, first-degree relatives of individuals with AD have more than double the risk of also developing AD. Twin studies, across multiple large registries, report heritabilities that range from 55 to 70%. One important use of twin studies is to try to identify environmental factors that contribute directly to the development of AD or interact with genetic effects. In a study using discordant MZ pairs from the Swedish Study of Dementia in Twins, three factors were identified that may contribute to the difference: early health, education, and experiencing a stroke. Although potential targets for intervention, these factors may be markers for more-global indices of health and environmental influence.

From a genetic perspective, AD is a complex disorder. Four different loci have been identified that relate to different forms of the disease; mutations in three of these, presenilin I (chromosome 14) and II (chromosome 1) and the amyloid precursor protein (chromosome 21), cause early-onset AD. The apolipoprotein E (APOE) gene (chromosome 19), involved in cholesterol transport in the blood, is associated with late-onset AD. The different alleles also appear to act in a dose-related fashion to increase risk and decrease age of onset, with the E4 allele being the most deleterious. A fifth site on chromosome 12 has been identified in a study of 54 families with late-onset AD. This influence on the development of AD appears independent of the APOE-4 allele and is more highly associated with the dementia with the Lewy bodies form of AD. A sixth site on chromosome 10 has also received much attention and has been replicated in several large studies. The genes at all sites related to late-onset AD contribute in some way to the formation of plaques and tangles, and involve the development or inhibition of amyloid.

Depression Depression in older adults is extremely common: perhaps as many as one-third of older adults are clinically depressed. Research is not yet sufficient to draw clear conclusions about the extent of genetic influence on depression throughout the life span; however, a meta-analysis of major depression using data from family, adoption, and twin studies estimated heritability at 37%, with the remaining variance due to unique environmental factors.

In terms of non-clinical levels of depressive affect in an older population, SATSA results suggest only modest genetic influence on self-reported depressive symptoms. There is some evidence, however, that genetic factors might increase in importance after 60 years of age, perhaps due to genetic influences on frailty or vitality. Unlike most personality measures, shared rearing environment accounted for more variance than genetic factors. Using twins from the Danish Twin Register, researchers focused on occasion-specific depression, and found that the heritability estimates ranged from 22 to 37% and were similar in males and females. If the level of depressive affect was assessed, the heritability was 69% in females and 64% in males; the researchers interpreted these findings as genetic influence on overall vulnerability to depression. The residual indicated no heritability, and the authors argued that it captured the occasion-specific circumstances that could either modify or intensify the inherited vulnerability.

Several large family studies have indicated a familial resemblance for depression. The morbidity risk for depression was about 25% for first-degree relatives of depressed probands as compared to about 10% in the population. A particularly interesting aspect of these studies concerned life events. The frequency of stressful life events was greater among the relatives of depressives than in the general population, even when negative events associated with the probands were discounted. These results suggest that both the liability for depression and the propensity to experience stressful life events are familial. Such data suggest that the relationship between life stress and depression may be more complex than was previously thought. The surprising finding that experiencing (or reporting) life events is familial is explored further in the following section.

Life Events, Social Support, and Family Environment

A new area of interest in behavioral genetics is the possibility of genetic influence on measures that are presumably measures of the environment. This line of research is based on the supposition that measures of the environment are often indirect measures of the behavior of individuals. Rather than thinking in terms of genetic influences on the environment per se, genetic influences on experiences are most

likely due to genetically influenced characteristics of individuals.

Life events is a category of environmental measures used in more than 1000 studies, with reports suggesting that life events happen (or are perceived to happen) to some people more than others. Model-fitting analyses in the SATSA demonstrated significant genetic influence on individual differences in reports of the occurrence of life events. This implies that negative life events may be genetically influenced by attributes of individuals and that events of the type traditionally reported do not just happen capriciously. To test this hypothesis, it was predicted that controllable life events, which may be related to aspects of an individual's personality or mood state, should be more heritable than uncontrollable ones. As predicted, controllable events showed greater genetic influence ($h^2 = 0.43$) than uncontrollable events ($h^2 = 0.18$) in the sample of Swedish twins. These results were confirmed in a sample of young and middle-aged adults from the Virginia Twin Registry, now part of the MATR.

Research from the SATSA and the Virginia Twin Registry has also indicated that measures of social support are heritable. This may not be surprising given that genetically influenced characteristics such as personality may affect how individuals construct their social environments and how they feel about and behave toward others. In addition, others may respond to individuals on the basis of genetically influenced characteristics. It is also possible that genetic influences are detected because most of these measures rely on self-reported perceptions of the environment, and genetic effects could accrue because these perceptions filter through a person's memories, feelings, and personality.

Multivariate genetic analyses have explored the etiology of the association between measures of social support and psychological well-being in later life. Results consistently indicate that both genetic and environmental influences are important in the etiology of this relationship. That is, the genetic influences that contribute to the perceived adequacy of the support network also contribute to depressive symptoms and life satisfaction. Non-shared environmental influences also mediate this phenotypic relationship. The process by which this occurs awaits longitudinal analyses. However, some research has suggested that genetic and environmental effects that contribute to perceptions of social support may act as a resource for psychological well-being.

Similar types of analyses have also focused on the etiology of measures of family environments. Results indicate that measures of family environment, whether retrospective to the rearing environment or involving the current family environment, show at least some genetic influence. Even more surprising, across a variety of studies, measures of warmth consistently show greater genetic influence than measures of control. Studies of this type establish a need to reformulate thinking about the environment as being something 'out there' that impinges on the organism in a unidirectional manner. One direction for future research in this area is to begin to identify those genetically influenced characteristics of individuals that are responsible for the genetic variance found in these 'environmental' measures. Likely candidates include cognitive functioning and personality traits.

Future Research Directions

Results of behavioral genetic research of the second half of the life span indicate the need to consider both genetic and environmental sources of individual differences in the aging process. Behavioral genetics provides a theory that can go beyond the simple nature–nurture comparisons to consider different types of genetic (additive and non-additive) and environmental (shared and non-shared) influences, the developmental interface between nature and nurture, and the etiology of age-to-age continuity and change.

Although most of the gerontological behavioral genetic studies described are ongoing, additional longitudinal research is needed. Results of cross-sectional studies of genetic and environmental influences on behavior have indicated that there may be some important etiological differences at various points in the life span. Additionally, the etiology of continuity and change for one trait of interest is not necessarily related to another; thus, the assessment of whether genetic influences are stable needs to be tested empirically for each phenotype of interest. It has also been suggested that gerontological research should concentrate on understanding transition periods in later life, especially those that have functional significance. In other words, research of the future may focus on the etiology of functional changes in older adults as they move from optimal functioning to normal functioning, or from normal functioning to disease states or pathological functioning. Through the use of longitudinal behavioral genetic designs (e.g., longitudinal analyses of phenotypic relationships in genetically related individuals), it is possible to disentangle the dynamic pattern of genetic and environmental influences on development in later life.

Most of what is known about the genetics of individual differences in aging comes from quantitative genetic research on twins and adoptees. Stunning advances in molecular genetics, however, will

make it increasingly possible to identify specific genes responsible for the nearly ubiquitous genetic influence seen for behavior. Many of the studies described have banked subjects' DNA for future studies, are conducting candidate gene searches, or have done entire genome scans. The allure of molecular genetics, however, should not detract from the need for more quantitative genetics research that can guide the search for genes. Such quantitative genetic research is likely to be most helpful in understanding nurture rather than nature, and especially the interface between them.

Genetic influences are likely to be significant and substantial for many dimensions of variability in later life. Understanding the etiology of differences among individuals may be critically important for improving the quality of later life. Understanding the causal factors underlying individual differences in functioning and adjustment late in the life span represents a compelling route to advancing primary prevention and intervention programs in later life. Because the health problems discussed in this article are complex, it is unlikely that a single intervention will be appropriate. Given the results of behavioral genetic research to date, it may prove fruitful to examine the ways in which combinations of genotypes and environments work. For example, research on CHD has indicated that even individuals who eat essentially the same diet show large individual differences in CHD, probably due to differences in genetic predisposition – this is referred to as a genotype–environment interaction. In fact, research has indicated that a high blood cholesterol level appears to be a prerequisite for the deleterious effect of other secondary factors, such as hypertension, diabetes, autoimmune disorders, and coagulation factor levels. Thus, if an individual is not genetically predisposed to high levels of LDL cholesterol, then the other risk factors such as smoking or high blood pressure may not be as important to the development of cardiovascular disease. Because people are so different, it is unlikely that any single intervention or prevention strategy will work for all elderly individuals. Behavioral genetic research on individual differences in aging takes an important first step in the direction of understanding the etiology of these individual differences.

Bereavement and Loss

D A Lund, Center on Aging, University of Utah, Salt Lake City, UT, USA

Glossary

Bereavement – Both the situation and the long-term process of adjusting to the death of someone to whom a person feels close.

Grief – The affective or emotional responses that people often experience during the early phases of the bereavement process.

Mourning – The commonly accepted or culturally patterned ways people behave and express themselves during the bereavement adjustment process.

Resiliency – The ability to bounce back or recover from stressful and difficult losses and bereavement experiences.

Introduction

Bereavement refers to both the situation and the long-term process of adjusting to the death of someone to whom a person feels close. The term also has been used in reference to losses other than death, such as the loss of a home or personal belongings due to fire or a natural disaster. It is more common, however, to use the term bereavement in situations following the death of a friend or relative, or even an animal companion. Other terms associated with the bereavement process include grief and mourning. These terms are distinguishable from bereavement in that they refer to specific aspects of the broader process. Grief is characterized by the affective or emotional responses that people often experience during the early phases of the bereavement process. These feelings frequently include disbelief, confusion, shock, numbness, sadness, and sometimes anger and guilt. Feeling abandoned, lonely, or depressed and being preoccupied with thoughts of the deceased person and the events surrounding the death are often components of grief.

Not all persons experience these feelings, and the degree of intensity varies in those who do, but it is common for bereaved persons to feel a wide range of emotions that come and go quickly and that can reappear over many months or even years. Culture plays a role in shaping how people experience and express bereavement. Most professionals use the term mourning to refer to the commonly accepted or culturally patterned ways people behave and express themselves during the adjustment process. Mourning refers to such behaviors as crying, missing work, altering daily routines, attending funerals, cremations, and burials, following standards for dress and appearance, and participating in other rituals that are influenced by the surrounding culture.

Variety of Bereavement Experiences

Throughout our lives we experience many kinds of losses that require us to make adjustments. As infants, we become temporarily separated from parents and siblings. We leave the familiar surroundings of the home to attend school. As children, we lose toys, clothes, pets, and valued belongings. We, or our friends, move away to new neighborhoods. Children lose relationships with teachers, clubs, organizations, and peers as they advance from elementary grades through high school and college. Over the life course we lose more friendships and relationships due to job relocations, deaths, and retirement. With divorce rates near 50% in the United States, millions are experiencing the loss of marital relationships, parents, and family life. Some people also will lose hair, hearing, sight, muscle tone, independence, and mobility. In short, if we are fortunate to live long lives we will experience many significant losses. Each loss has the potential of disrupting patterns of behavior, requiring adjustments, but also adding to the course of our development. Bereavement can accompany these losses, if what was lost was highly valued by the individual.

It is important to acknowledge the numerous and diverse losses that people experience, because each can contribute to a better understanding of how people manage and cope with other bereavement situations. For example, we might better understand and help older bereaved spouses if we know more about how they experienced relocation, physical, and relationship losses earlier in their lives. Similarly, we need to appreciate the uniqueness of each loss or bereavement experience. Although sadness might be a grief response common to both relocation and the death of a spouse, it is unlikely that anger or guilt would be equally present in both situations.

As stated previously, bereavement is most commonly used in reference to losses due to death. In the field of gerontology, some of the most common death-related losses are the deaths of parents, spouses, siblings, and friends. Much of the information in this article is based on spousal bereavement in later life because more gerontological research has focused on this loss. At younger ages we are most likely to experience the death of a parent, older relative, or school classmate. Some experts have described the death of a parent as the loss of our past, the death of a spouse or sibling as the loss of the present, and the death of a child as a loss of part of our future. Again, we have learned that our early and consistent experiences with death-related losses can shape our attitudes and ways of coping well into later life. For example, the young boy who is told to be strong and not to cry after his father's death might easily grow up to be the unexpressive and isolated widower in late life.

Although statistics cannot capture the full essence of the bereavement process, they are very helpful in documenting the commonality and expectedness of the experience. Government reports have indicated that over 2 million people die each year in the United States. Over 400 000 of the deaths are children and youth under the age of 25. Also, each year there are at least 800 000 new widows and widowers.

The death of a spouse is an increasingly common experience among aging adults, particularly women. The 2000 census revealed that only 1% of the population between ages 18 and 54 were widowed, but 32% of those 65 and over and 66% of those 85 and over were widowed. A gender difference becomes increasingly apparent in the later years of life. After

age 65, nearly 45% of the women but only 14% of men were widowed. In the 85+ category, 79% of women and 38% of men were widowed. These high percentages actually underestimate the number of persons who experience the death of a spouse because they do not include those who remarried.

Multidimensional Nature of Bereavement

Bereavement is an important topic because the adjustment process can impact virtually every aspect of a person's life. This multidimensional nature of bereavement means that the coping process can affect emotions, spirituality, identity, social interactions and relationships, sexuality and intimacy, work productivity, financial stability, health, and even death. Patterns of interaction in family life are radically altered when someone dies. Family meals and other daily rituals related to getting ready for work, school, or church are affected by the absence of the deceased family member. In the case of spousal bereavement the survivor often changes her or his self-concept to an 'uncoupled identity' because she or he now carries out daily life alone rather than as part of a couple. Bereaved persons may lose their appetite and motivation to remain physically active, so nutrition, exercise, and physical well-being can be essential parts of the coping process.

The multidimensional nature of bereavement is evident in the topics that professionals from different disciplines choose for special attention. Sociologists often examine bereavement's impact on family life, interactions, life satisfaction, and the role of culture and socioeconomic characteristics in shaping these bereavement outcomes. Finding differences among men and women, rich and poor, and diverse ethnic groups are common concerns for sociologists. Psychologists frequently examine the emotions of grief, attachments to the deceased, depression, morale, and identity and how previous relationships and personality of the bereaved influence their coping strategies. Social workers are likely to assess family functioning and the need for and effectiveness of specific community services. Nurses and other health professionals are often concerned about the mental and physical well-being of bereaved persons. Economists are usually interested in the financial stability of bereaved persons and families. Because many women in the United States do not have the same level of retirement and other financial benefits as men, they are much more likely to suffer economically during widowhood. Each discipline and professional group adds a unique focus to examining bereavement experiences, and, collectively, help us to better understand the many ways that bereavement can affect our lives.

Another way to appreciate the multidimensional nature of bereavement is to recognize that bereavement takes place in a context. Although there are many common reactions and feelings that most people experience during the course of bereavement, there also are many experiences that may not be widely shared. For example, some bereaved persons feel intense guilt and anger, whereas others feel relief or a sense of celebration for the life of the deceased person. Some are overwhelmed with sadness and immobilized by depression, whereas others confront the loss as a challenge and opportunity for growth. In order to understand why one person manages very well and another never seems to adjust to the loss, it is necessary to examine the multidimensional nature of the context in which bereavement occurs. Previous life experiences, personality traits, social support received from others, circumstances surrounding the death, and a person's competency in managing the many tasks of daily living are some of the many factors that comprise the context of bereavement. Health professionals and clinicians who work with bereaved persons are better able to provide assistance when they know more about the specific aspects of each individual's bereavement context. What helps one person may not be of much value to another.

Sources of Knowledge about Bereavement

Although the subject of death has received considerable thought and discussion for thousands of years, much less attention has been devoted to the subject of how death affects those who are left to grieve. Since the mid-twentieth century, however, there has been a steady increase in interest and writing about bereavement, especially since 1990. Academic disciplines, especially psychology, sociology, social work, nursing, and other behavioral and health professions, have contributed attention and knowledge to the subject through the development of theory and research. Clinicians who work directly with the bereaved have added their knowledge about ways to help those having the greatest difficulty. Religious leaders and members of various clergy have shared their experiences regarding spiritual aspects of the bereavement process. Local bookstores are now replete with numerous autobiographical reports written by bereaved persons who have had experiences that they want to share. Four sources of knowledge – theory and research, clinical reports, religious accounts, and autobiographical accounts – each make unique contributions to our understanding of bereavement. These different sources of knowledge, however, have unique advantages and limitations that need to be

recognized because they can lead to different and competing conclusions (*see* Death and Dying).

Bereaved persons frequently turn to their clergy or their religious beliefs for comfort and guidance. Most religions have a set of beliefs regarding the questions of ultimate meaning. What is the purpose of life? Does God or a supernatural being have a plan for each specific person? Is there special meaning in the death of the loved one? Because most religions offer answers to these and other questions, religiously oriented people can find predictability, structure, and meaning to help them during the upheaval of bereavement. We have learned from research, however, that religion and spirituality are only part of the bereavement context and that the long-term adjustment process involves much more than a religious code to follow. Research has not confirmed that religious beliefs and practices are universally helpful to bereaved persons, but we do know that many people turn to their spiritual views as a source of knowledge (*see* Religion and Spirituality).

Autobiographical books on grief and bereavement are abundant because bereaved persons want to know how others have managed, whether their experiences are unique or common, and how they can cope better with their loss. These personal accounts can be useful because they offer detailed descriptions of feelings, problems, and solutions that worked for the authors. Some bereaved persons, for example, might find comfort in knowing that their feelings of anger and guilt were shared by the author and might benefit by following some of the suggestions in the book. Much caution should be exercised, however, because the author's credentials are most likely in the field of journalism rather than bereavement.

Books, articles, and reports written by therapists, counselors, and other clinicians also provide valuable knowledge about bereavement. Like autobiographical accounts, clinical reports offer detailed personal descriptions of the bereavement process and usually give suggestions for helping to alleviate problems. These in-depth reports about individuals' bereavement experiences not only are interesting, but also help to organize the experiences of people, identify serious adjustment difficulties, and inform other professionals and bereaved persons of specific intervention strategies and their consequences. Knowledge that comes from clinical practice, however, must be interpreted in a way that recognizes the uniqueness of the clients or patients. Those who receive counseling or professional clinical services are likely to differ in some important ways from those who never seek help. Bereaved persons who receive these services are more likely to be experiencing the greatest difficulty in adjusting, have less social support available to them, have financial resources adequate to pay for the services, and have a tendency to rely on others for help. If we based our knowledge about bereavement solely on information from clinical clients we would not know about the experience of the majority of bereaved persons. It is equally important to know how people manage their grief on their own and to what extent they want and need help even though they do not seek professional assistance.

Research and theory have been much slower in adding to our knowledge about bereavement, but their contributions have been essential. Sigmund Freud was one of the earliest to theorize about bereavement. In the early 1900s Freud practiced and wrote extensively about psychoanalytic theory and applied it to understanding the feelings and thoughts that follow separation or loss of attachment. His work was followed by other theorists, and eventually systematic research studies were completed. Erich Lindemann also used a psychoanalytic framework to guide perhaps the first bereavement study in 1944. His study interviewed more than 100 relatives of 13 people killed in a fire at the Boston Coconut Grove night club. Research and theory related to bereavement have steadily increased since these early beginnings. We now have numerous theories and research findings that both support and challenge what we initially believed to be true about bereavement.

Knowledge that is based on theory and research has given us information on a broader range of bereaved persons. By collecting data from people who have not sought professional help, and who represent varied cultures and social classes, we have learned much more about what is common and what is unique during bereavement. Systematic research studies, using well-developed and standardized scales, longitudinal designs, representative samples of bereaved persons and non-bereaved control groups have revealed findings that are inconsistent with and challenge some of the previous views based upon the other sources of knowledge. One of the most prominent research findings is that although bereavement is a highly stressful experience and some people report 'never getting over it,' the majority of bereaved persons are very resilient. They find personal and social resources to meet their needs and manage their adjustment process. Research also has not been able to confirm that people go through specific stages, as suggested by many clinicians and some theorists. The process is much more varied and complex than the uniform course depicted in the stage theories. Also, research has documented that not all people need to equally express their emotions outwardly to others in order to avoid a buildup of problems that will come out even worse later. Many

people who appear to be in control and able to manage their early grief very well tend to be doing very well years later. In short, all four of the sources of knowledge have added to a fuller and more useful understanding of bereavement.

Course of Adjustment

Perspectives, Theories, and Models

Because the bereavement process is multidimensional, and professionals from different disciplines are educated to emphasize specific aspects of human behavior, we have numerous perspectives, theories, and models that provide divergent views about bereavement. Perspectives, theories, and models differ in their degree of specificity and complexity, but they essentially provide a framework or set of guidelines to help describe, interpret, explain, and understand behavior, in this case, grief and bereavement. They help to focus attention on specific parts of the bereavement context and provide clarity and orderliness. If the perspectives, theories, and models are adequate and relatively accurate, they can be applied to predict bereavement adjustments and guide the development of interventions to help those in greatest need. The following section briefly summarizes some of the most prominent theories about grief and bereavement.

Psychoanalytic Theories Most of the variations in psychoanalytic theory applied to bereavement emphasize the importance of recognizing the conscious and subconscious ties or attachments that the bereaved person formed with the deceased. According to this view, the bereaved person must express rather than repress all of the feelings associated with the detachment or loss. Anger, guilt, fear, and love, when expressed by the bereaved, help lead to normal instead of abnormal grief. These theories also stress the importance of early childhood relationships and separations, because these first experiences remain throughout life. When children have traumatic losses in early life they often form ambivalent relationships later, repress their anxieties, and have greater difficulty with grief and bereavement. Separation anxiety is seen as an instinctive reaction to loss, but it is essential that the bereaved person withdraws from the deceased and forms new attachments.

Sigmund Freud, Erich Lindemann, John Bowlby, Colin Murray Parkes, and Peter Marris are the most prominent contributors to psychoanalytic theory and bereavement. Although each theorist has his own unique interpretations, they have generally agreed that grief is largely an intrapsychic process that each bereaved person must cognitively resolve in order to avoid delayed, distorted, or abnormal grief. Some of the abnormal reactions include social withdrawal, hypochondriacal symptoms, psychosomatic illnesses, and hyperactivity. Normal grief is thought to be marked by distress and impaired functioning, but recovery is expected. The bereaved person usually has a period of upset, protest, and anxiety because of the separation. He or she is likely to search for the deceased in familiar settings. Despair and depression can follow because the deceased does not return. A reorganization phase occurs when the griever accepts the reality of the loss, resolves the feelings of guilt and anger, restructures his or her life, and returns to normal functioning. These theories suggest that bereavement follows a relatively ordered progression of phases and that unresolved grief occurs when the sequence is disrupted or distorted.

Stress, Appraisal, and Coping Theories Theories of stress, appraisal, and coping have been applied to bereavement because the death of a spouse, parent, child, or sibling is generally considered to be among the most stressful events that can happen. Stress exists when the demands on the individual exceed the resources readily available to meet the demands. The death of a loved one, particularly when the deceased was an important part of the daily life of the bereaved, creates stress in many ways for the survivor. Daily life is radically changed because the bereaved can no longer rely on the deceased for ongoing companionship, conversation, security, guidance, comfort, love, sharing, listening, and instrumental assistance, such as financial support, transportation, and caregiving. Bereavement requires the survivor to change and adjust to an environment in which the deceased is absent.

When bereavement occurs, each person must appraise cognitively his or her situation; this is usually done consistently with their previously established patterns of dealing with stress. Cognitive appraisal means that people consciously assess their loss, try to make sense out of it, and determine the consequences. The degree of stress and subsequent adjustment difficulties are largely dependent on the bereaved person's appraisal of the situation and the coping strategies that she or he uses.

The most common types of appraisal are pain, threat, challenge, and relief. Those who primarily see the pain of their loss often focus their attention on the damage already done and expend much of their energy in anger, sadness, and depression, and their coping strategy often involves withdrawal, self-blame, and feeling overwhelmed. Those who see their loss as a threat are aware of the stress but are

uncertain about their ability to deal with it. The death of their loved one means that they see other losses that are likely to follow. Their coping strategies usually include fear and worry about future threats to their lives. Rather than focusing their energy in broader ways to make their adjustment easier, they often engage in wishful thinking. The bereaved who see the loss as a challenge recognize the stress and the need to adapt. They assess their strengths, limitations, and needs and pursue a course of action that will allow them to learn and possibly grow from the experience. Having pride, self-confidence, motivation, and some skills in doing the many tasks of daily living helps the bereaved to define the situation as a challenge and follow a more problem-focused approach to adjustment. Richard Lazarus, Susan Folkman, Leonard Pearlin, and many others have advanced the theory and research on stress, appraisal, and coping in which their perspective continues to make very important contributions to understanding bereavement.

Stage and Task Models Ever since Elizabeth Kubler-Ross proposed the well-known stage model of the dying process, it has been applied to many discussions of how people deal with problems and life crises. According to this model, the dying person passed through a naturally occurring sequence of experiences, beginning with denial and progressing through anger, bargaining, depression, and eventually culminating in acceptance. Because bereaved persons and many professionals became familiar with the stage model developed by Kubler-Ross and they could see many similar emotions, thoughts, and issues expressed during the course of bereavement, it seemed only natural to apply the sequential and progressive stages to bereavement.

Although research has identified and confirmed that bereaved persons experience many of the same kinds of emotions, thoughts, and behaviors presented in the stage models, the overall bereavement process appears to be much less orderly, sequential, and uniform than these models suggest. For example, some bereaved persons report many years after the loss that they sometimes feel the sadness, pain, and regret that they experienced in the first several weeks. The stage models have contributed to our knowledge about bereavement, however, because they have helped to identify parts of the complex process and have provided a foundation for further study.

Similar to the stage models, and building on some of the concepts from other theories, is the idea that adaptation requires the bereaved person to accomplish or complete specific tasks. William Worden's 'tasks of mourning' approach is an example. His work is based on the assumption that grief is work, requiring both emotional and physical energy to complete. He suggests that it is important for the bereaved to eventually accept the reality of the loss, to experience the pain of grief, to adapt emotionally and socially to an environment in which the deceased is missing, and to psychologically relocate the deceased person in their life and move forward. Although many other specific tasks can be added to his model, it does provide another useful approach to be used in helping bereaved persons. The task-oriented approach highlights the importance of being active and learning new skills rather than simply being passive and allowing time to pass and heal the wounds of grief. Worden's tasks of mourning approach is further extended by another theory described next.

Dual Process Model The most recent and important theoretical development in the field is the emergence of the dual process model (DPM) of bereavement, described by Margaret Stroebe and Henk Schut. This model suggests that positive adjustments require the person to deal effectively with two types of stressors and processes and oscillate (go back and forth) between them. First, 'loss orientation' is largely focused on expressions of emotions and finding a balance between letting go and maintaining the bonds to the deceased. Restoration is the second component; it refers to the need to attend to daily life challenges, learn to do new things, create new relationships and roles, and spend time away from the emotional features of grief. In 2005, research was under way to test the DPM among those experiencing traumatic grief and to study recently widowed older adults.

Other Theories Many other theories from social, behavioral, and health sciences have been used to understand some aspects of grief and bereavement, but most of them have not been systematically tested in research. Some of the theories have received only limited attention even though they have considerable promise in explaining and predicting bereavement behaviors and helping bereaved persons through the process. For example, family and systems theories, symbolic interactionism, and the health belief model have much to add but have not been extensively used.

Family and systems theories are relevant to bereavement because bereaved people are members of nuclear and extended families and their lives take place within functioning systems. People do not live in total isolation from families, groups, and organizations, and their experiences within these units are

important parts of the broader bereavement context. An 80-year-old widow is impacted by how other family members grieve the death of her husband, who also may have been a father, grandfather, uncle, or brother. Just like individuals, families grieve. During bereavement, some family members provide strength and support to one another, and other families create more conflict and tension. Systems theory recognizes that people are parts of larger systems and that individual lives consist of various functioning parts as well. Anger and depression following bereavement can easily carry over from the home to the workplace and many other social settings, thereby impacting and further complicating other relationships. Symbolic interaction theory, which comes from the discipline of sociology, has much to offer on the topic of bereavement. The theory emphasizes the importance of social interactions with others and how they shape a person's self-concept or identity, which in turn influence behavior. Bereavement losses have the potential of altering a person's interactions and self-concepts, and ultimately bereavement adjustments. From the field of health education, the health belief model examines the way bereaved persons make decisions and what they take into account when deciding on a course of action. Bereavement can very easily lead to neglect of one's own health. This approach suggests that a broad range of factors, including messages in the media, can influence bereavement behaviors by identifying healthy behaviors to pursue and stressing the likelihood of positive outcomes that will follow. Grief requires energy, for example, so good nutrition and some regular exercise might assist with making other bereavement adjustments.

Finally, the most prominent theories in the field of gerontology are relevant to understanding bereavement, but they have not received much attention. Disengagement, activity, continuity, and age-stratification theories have contributions to make, and it is hoped that in the future they will be examined and tested in research. Disengagement theory would suggest that those who were already gradually withdrawing from society would have less difficulty during bereavement than those who have not yet begun the process of withdrawal, as the bereavement experience would not seem as abrupt to them. Activity theory would argue in favor of maintaining relatively high levels of physical activity during bereavement because that would help create greater life satisfaction and well-being. Continuity theory would suggest that the best course of action during bereavement would be for the bereaved to continue doing most of the things that she or he had always enjoyed. Age-stratification theory could be used to better understand why age might influence bereavement adjustments and that people in different age cohorts have different needs and values, differences that will create somewhat unique grief experiences. In short, theory helps to inform and guide research, and considerably more of both theory and research is needed to improve the knowledge about grief and bereavement.

Research on the Bereavement Process

Research on bereavement has increased considerably since the mid-1980s. In some studies, researchers waited many weeks and months to interview bereaved persons, and in others they obtained information only days after the death occurred. Some followed bereaved persons for several years to examine long-term outcomes, but many studies obtained information at just one point in time, providing a limited picture of the process. Only a few projects included non-bereaved control groups, even though it is valuable to be able to compare the thoughts, feelings, and behaviors of bereaved persons with those who are not experiencing death-related bereavement. Research has included more women than men, more adults than children, and more Caucasians than racial and ethnic minorities. Even with these and other limitations, research has improved the understanding of grief and bereavement. It is not possible to review all or even most of these findings, but five of the most important general conclusions are presented here.

First, bereavement is very stressful, but many people manage their losses with considerable resiliency. In the case of spousal bereavement, the majority of research participants report that their loss situation is the worst and most stressful thing that has ever happened to them. The death of a child also creates stress and is particularly difficult because children are expected to live longer than their parents. To adults, it is disturbing when both of their parents are deceased because it means that their own generation in the family is now the oldest. The death of a spouse, parent, or child almost always brings out thoughts of mortality and death among the survivors. In our culture, thoughts about the inevitability of death are usually troubling because we have not openly discussed death. Some researchers have attempted to identify how many people continue to have major difficulties that interfere with their daily lives for several years. It has been estimated that between 15 and 25% will need some kind of professional help with their bereavement adjustments.

Even though bereavement is extremely stressful, it is somewhat surprising that so many people are resilient and able to restructure their lives in ways that

allow them to find enjoyment again. Knowing this helps direct attention to those 15–25% who are most distressed and unable to manage their bereavement losses alone. This issue is discussed in greater detail in the next section, which presents information on the predictors of bereavement adjustments.

Second, there is considerable diversity among and within bereaved persons. Not all people experience the same feelings, thoughts, and actions as they move through the process. For example, a 65-year-old widow described herself in the following way 4 weeks after her husband's death: "I am a very lonely person. Lousy, all washed out, despondent, feel deserted, angry, hurt, hopeless, alone, mixed-up, cannot concentrate, very emotional, very tired, cry a lot, hateful, very bitter, misfit, nobody, very miserable, very much of a loner." This same woman described herself in much the same troubled way 2 years into the bereavement process. She added that she was concerned about herself and really hurt inside. She noted that she was sick of living alone and did not care about life. In contrast, another 69-year-old widow described herself at 6 months after her husband's death as being "independent, excited about keeping busy, enjoying the company of others, and working in my yard and doing handiwork." This diversity in bereavement reactions also is found within each individual. It is not unusual to find a person simultaneously experiencing a full range of feelings and behaviors. For example, a bereaved person can feel angry, guilty, and lonely, yet at the same time feel personal strength and pride in how he or she is coping. A 70-year-old woman described herself at length as being busy, enjoying many different activities, and doing things with other people, but her final self-descriptive comment was that she still felt lonely. It is common for bereaved persons to experience both positive and negative feelings simultaneously.

Third, a theme emerging from studies from the early twenty-first century is the recommendation to be cautious of using the terms normal and recovery to describe grief or bereavement. The same individual may experience and express herself or himself in a variety of ways during bereavement. What was once considered outside the realm of 'normal' grief may now be considered a normal part of the process. For example, talking to a deceased spouse would once have been defined as abnormal or even pathological, but more recent research findings show that this is actually a very common practice among bereaved spouses – and it is now often encouraged as a therapeutic technique.

Rather than applying rigid labels such as normal or abnormal, it is more appropriate to use terms such as common or uncommon to describe bereavement feelings and behaviors. A bereaved person is far less stigmatized from being told that she or he is experiencing some uncommon feelings than from being told "You are abnormal." Also, researchers are reporting that many bereaved persons say that they never 'get over' or recover from their grief, but they have learned 'to live with it.'

Fourth, studies have revealed that the bereavement process is more like a roller-coaster ride than an orderly progression of stages with clear time frames associated with each stage. The bereavement roller coaster is characterized by the rapidly changing emotions of grief; meeting the challenges of learning new skills; recognizing personal weaknesses and limitations; developing new patterns of behavior; experiencing fatigue, loneliness, and helplessness; and forming new friendships and relationships. Researchers have been unable to identify clear time markers associated with these many ups and downs. In fact, the highs and lows can occur within minutes, days, months, or years. Fortunately, most bereaved persons experience a roller-coaster ride that becomes more manageable over time, with fewer abrupt highs and lows. This gradual improvement may never lead to an end or resolution, however, because many bereaved spouses report: "You never get over it – you learn to live with it."

Fifth, loneliness and problems associated with managing the tasks of daily living are two of the most common and difficult adjustments for older adults. These problems are even more difficult for the spousally bereaved because their daily lives are closely connected with their spouses and they frequently become dependent on each other for conversation, love, and sharing of tasks. Loneliness is problematic because it involves missing, sadness, and a void that does not go away simply by being with or among other people. Many bereaved report feeling lonely but not being alone. In the case of experiencing the death of a parent, child, or sibling who may live many miles away, the bereaved often describe how lonely they feel when they realize they can no longer call their loved one on the phone or hear their voice again (*see* Loneliness).

Unfortunately, most older adults have not learned to do many of the tasks of daily life that are important to their health, well-being, and happiness. Many men have not learned how to prepare meals, wash clothes, and clean the house. Similarly, many older women have not learned how to do home repairs, maintain an automobile, and manage finances. Research has shown that these deficiencies further complicate the bereavement process. It is hoped that future cohorts of men and women will be better

prepared and skilled in a much broader range of tasks of daily living. Research is now under way to test the effectiveness of learning new skills as a bereavement adjustment strategy as explained in the restoration feature of the dual process model.

Predictors of Bereavement Adjustments

People often say that the passage of time will heal the wound. This statement is problematic and inaccurate because it implies that little or no effort is required to cope with the situation – simply allowing time to pass is supposed to bring about successful adjustment. Although most bereaved persons do experience less difficulty and more positive adjustments over time, it is important to recognize that it is what people do with their time that determines the outcome. Successful adjustments require active rather than passive coping strategies.

Many bereaved persons have told others that it is most helpful to take one day at a time and to remain active, busy, and socially connected with other people. Being physically and socially active during the process can help to reduce the feelings of despair, helplessness, loneliness, and being overwhelmed that often contribute to a long-term strategy of waiting – often in vain – for time to bring about healing. In addition to these active coping strategies, studies have documented the importance of having social support from others and opportunities for self-expression available, especially in the early months of bereavement. Some of the most difficult and stressful bereavement experiences occur in the first few months, when grief issues are especially intense (*see* Social Networks, Support, and Integration).

Researchers have also learned that how a person copes with loss early in the process appears to be one of the best predictors of long-term coping. Those who report having effective coping experiences in the first couple of months usually cope better than others a few years later. Bereaved persons therefore are likely to benefit most from social support that they receive early in the process and from opportunities to express how they feel at this time. Some of the most appreciated and helpful support comes from those who allow the bereaved to openly express anger, sadness, and other emotions without passing along advice and counsel. It is important for bereaved persons to know that their reactions are common and that others respect their feelings and care about their well-being. Self-help groups for the bereaved provide good opportunities for self-expression, particularly for those who do not already have someone in whom they can confide.

The importance of internal coping resources is supported by research that has focused on the role of self-esteem and self-efficacy. Both concepts represent personal coping resources that individuals develop throughout their lives. Self-esteem refers to the positive or negative judgments or evaluations that a person makes about self-worth. Self-efficacy refers to a person's ability to meet the changing demands of everyday life and feelings of confidence that he or she can do so. These two features are incorporated in the restoration component of the dual process model described earlier.

The way people feel about themselves and how skilled they are in managing the many tasks of daily living – maintaining a household, paying bills, driving a car, knowing how to access resources, and so on – will influence how effectively they adjust to the loss of a loved one. Those who develop positive self-esteem and competencies such as social, interpersonal, and instrumental skills are likely to have more favorable bereavement outcomes than those who develop negative self-images and lack self-efficacy.

Self-esteem and self-efficacy are highly interrelated because people who have confidence and pride in themselves are usually more motivated to learn new skills, and the process of becoming more competent in daily life itself creates more positive self-esteem. Bereaved persons with these positive characteristics are likely to cope quite well because they will not be content with a passive approach to coping. Conversely, bereaved who never developed these personal coping resources are likely to experience long-term difficulties because they are more inclined to believe that they deserve to remain depressed, lonely, and incapacitated. These people tend to feel overwhelmed and take few constructive actions on their own behalf (*see* Self Esteem).

The predictors of adjustment to bereavement are similar for men and women and for young and older adults; that is, age and gender are not the most influential factors in the course of bereavement. What is of greater importance is the ability of the bereaved person to develop positive feelings about her- or himself early in life, continue to enhance these views over the life course, and develop skills that help her or him to meet the changing circumstances and demands of daily living. People with these traits are more likely than others to adjust well to nearly any major life stresses or transitions. Human development is a lifelong process. In the case of late-life bereavement, the developmental process is challenged. During this transition period, the bereaved person can remain physically, psychologically, and socially disrupted or can emerge with a sense of growth from learning new skills, becoming more independent, and developing a clearer self-identity.

Interventions

Although it is tempting to conclude that most bereaved persons will need help with their adjustment process, this is not necessarily the case. Research has shown that many bereaved persons do not want or need intervention services. This point is important to recognize, because clinicians and service providers frequently assume that most older bereaved persons are depressed, socially isolated, and incapacitated by their loss. The research evidence does not support this assumption, although certainly some bereaved persons are depressed, isolated, and incapacitated. The tasks for those developing intervention services are many, and among the first should be an attempt to reach those who are at greatest risk – to seek them out rather than simply announcing the existence of the service – and encourage their participation by explaining how and why the service will be helpful. It is absolutely critical to recognize that many, perhaps most, of the potential population of bereaved persons will not want to participate. This can be discouraging to those who are committed to the value of their services, but their motivation to continue their efforts will probably be less adversely affected if they anticipate the lack of enthusiasm among many potential clients. For example, only 44% of the bereaved spouses who completed a study said that they would have liked the opportunity to attend self-help groups. In another study, only 27% of those assigned to self-help groups actually agreed to participate, and in a 2005 study, approximately 34% agreed to participate.

Interventions need to be available early in the bereavement process and continue over relatively long periods of time. There is a good deal of research evidence that the first several months (usually 1 to 4 months) are the most difficult and that early adjustments will influence outcomes much later. Also, because bereavement may last for many years and some people may not be ready for early interventions, it would be most helpful to have services available over long periods of time. This does not mean that the same people need to continue receiving services for many years, although some will have this need; rather, bereaved persons need to have an opportunity to participate when they are ready.

Because the impact of bereavement is multidimensional, it is imperative that interventions offer comprehensive and diverse services. It is unlikely that any one intervention will be capable of providing all that is needed, but each intervention should clearly identify which needs are being targeted in relation to the overall multidimensional process so that there is an awareness of what help is not being provided. For example, the death of a spouse in later life can impact emotions, psychosocial functioning, health, family life, interpersonal relationships, work, recreation, and financial situations; those designing interventions that provide primarily an opportunity for self-expression (such as self-help groups) should recognize that some dimensions are not likely to be addressed. Ideally, all communities would have available a variety of interventions or services so that each person's unique skills, resources, and circumstances could be matched to the most appropriate set of services. Although this is unlikely, we can at least strive to offer interventions with the broadest scope of impact. Therefore, whenever possible, it would be worthwhile to impact several dimensions simultaneously by providing opportunities for self-expression and the enhancement of self-esteem; by teaching new skills to complete the tasks of daily living; by enhancing and mobilizing already existing social support networks; by providing education and assistance regarding health, nutrition, and exercise; and by encouraging social participation.

Various intervention formats and professionals are needed to ensure that appropriate services are available. Not all people experience bereavement in the same way; similarly, not all people will use or benefit from the same interventions. In terms of format, some people will want to have only a one-on-one type of intervention. This might be because they are reluctant to express personal and sensitive feelings in group situations. Others have reported that they particularly enjoyed being in a self-help group because they learned from others, recognized some commonalities in their situations, and enjoyed the socializing and friendships that developed. Other new and promising formats for intervention services are those using Internet-based technology. Many organizations have created web sites offering a wide array of educational materials, and in some cases, Internet bulletin boards, chat rooms, and discussion groups. Very little research has been done to examine the effectiveness of these new formats, but they do offer opportunities to reach those who live in more remote areas, are homebound, or simply prefer to use this immediate, readily accessible technology.

Many people have skills and expertise that are well-suited for helping the bereaved. Phyllis Silverman, who developed the widow-to-widow program, has shown that widows are quite capable of assisting each other. An experienced widow can reveal to the new widow that she has been there and that she knows how it feels to grieve. Also, there are important contributions that can be made by researchers, gerontologists, psychologists, psychiatrists, physicians, social workers, nurses, occupational therapists,

art therapists, counselors, clergy, and many other professionals, including social scientists, lawyers, accountants, educators, and direct service providers. Again, because bereavement has a multidimensional impact, interventions can be developed by many different professional and trained team members. Other bereaved persons can provide a sharing of experiences while trained persons assist with legal, financial, health, spiritual, and educational issues. A multidimensional team approach is highly recommended because it will increase the likelihood of developing interventions that address the diversity of needs and lead to greater success.

It should be understood that bereavement is a common and natural experience that we all share. Unfortunately, many people are not well prepared for the pain, threats, and challenges that it presents. Because bereavement occurs in broader contexts, we do not all have the same personal and social resources available, or have the same experiences and needs. What appears to help one person may have an entirely different impact on someone else. The best way to be prepared to help bereaved persons is to be educated about the process, assess the context in which it occurs, become familiar with a wide range of helping resources, and be patient, a good listener, and non-judgmental.

Bioenergetics

J J Ramsey and K Hagopian, University of California, Davis, CA, USA

Glossary

Basal Metabolic Rate (BMR) – Metabolic rate measured in a resting, postabsorptive individual at thermoneutrality.

Calorie Restriction (CR) – Reduction of energy intake without malnutrition by restricting dietary intake through the use of a specially formulated nutrient-dense diet. Other terms that have been used to describe this process include energy restriction and dietary restriction.

Calorimetry – A technique for determining energy expenditure by measuring heat production (direct calorimetry) or measuring oxygen consumption and/or carbon dioxide production (indirect respiration calorimetry).

Doubly Labeled Water Method – A technique used to determine production of carbon dioxide in free-living individuals by measuring differences in the rate of loss of the stable isotopes oxygen-18 (^{18}O) and deuterium (^{2}H) from individuals dosed with $^{2}H_2^{18}O$. ^{18}O equilibrates with both body water and CO_2 pools and may be excreted as either water or CO_2, while ^{2}H is entirely excreted as water.

Energy Balance – The mathematical difference between total energy intake and total energy expenditure. A positive energy balance is indicative of weight gain (energy storage), and a negative

energy balance is indicative of weight loss (energy depletion).

Free Radicals – Highly reactive molecules containing unpaired electrons that may oxidize cellular lipids, proteins, and nucleic acids.

Thermic Effect of Meals (TEM) – The energy expenditure associated with the digestion, absorption, and assimilation of food into body stores.

Total Energy Expenditure – The sum total of energy expenditure from basal metabolic rate, TEM, physical activity, and theromogenesis (i.e., energy expenditure required for maintenance of body temperature).

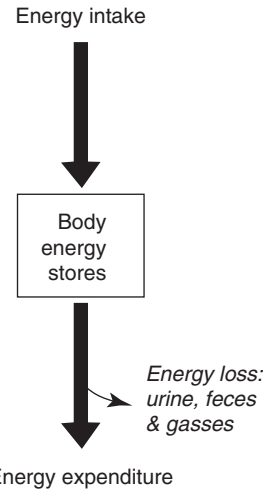

Figure 1 The energy balance equation. Aging is associated with a decrease in energy intake and energy expenditure, and at advanced age, a decrease in body energy stores.

Introduction

Bioenergetics is a broad subject covering all aspects of energy metabolism, from the biochemical and cellular level to the whole animal. The aging process is associated with changes in nearly all aspects of bioenergetics. Aging is associated with decreases in both energy intake and energy expenditure. These changes contribute to an age-related shift in body composition toward a decrease in lean body mass (LBM) and an increase in percent body fat. These age-related changes in energy metabolism place older individuals at greater risk for detrimental weight loss when faced with injury or disease. Experimental manipulations of components of energy metabolism have also been shown to have dramatic effects on life span and physiological parameters. Specifically, dietary calorie restriction is the only intervention that has consistently been shown to increase maximum life span in mammalian species, while increased energy expenditure through physical activity slows the decline in some physiological parameters with aging. Thus, bioenergetics appears to play a central role in the aging process.

Background

In animal studies, dietary calorie restriction has consistently been shown to extend life span and decrease or delay the development of physiological impairments and diseases associated with aging. This retardation of aging by calorie restriction suggests a link between energy metabolism and the fundamental mechanisms of aging. Changes in many aspects of energy metabolism are among the most consistent and noticeable characteristics of aging. These changes in energy metabolism may contribute to physical impairments and disease. Although age-related changes in the various components of bioenergetics show some differences between species, this article focuses on aging and human energetics with occasional reference to animal experiments.

Aging is often associated with shifts in energy balance, with obesity being a particular problem in midlife and wasting a problem for many who survive to advanced age. Changes in body weight (BW) and body composition are a function of total body energy balance (the difference between energy intake and energy expenditure). BW loss is accomplished by a negative energy balance. The factors in the energy balance equation, therefore, are energy intake, energy storage, and energy expenditure (**Figure 1**).

Energy intake is simply the caloric content of the food eaten by the individual. Energy consumption is a function of the total amount of diet consumed and the chemical composition of the diet. Energy intake is controlled by both psychological and physiological factors, which are discussed later in this article. Energy intake declines with advancing age.

Energy storage refers to the chemical form in which excess energy is stored in the body. Excess energy may be stored as fat, protein, or carbohydrates. The majority of the body's energy is stored either as fat (which contains the most calories per gram of tissue) in adipose tissue or as protein in muscle, with limited amounts stored as carbohydrates in the form of glycogen. Aging is associated with a decrease in LBM (muscle). During middle age, fat mass increases, while with advanced age body mass tends to decrease due to loss of both lean and fat mass.

Energy expenditure is the final component of energy balance. Energy expenditure is composed of four parts: basal metabolic rate (BMR) or resting energy expenditure, the thermic effect of meals (TEM), physical

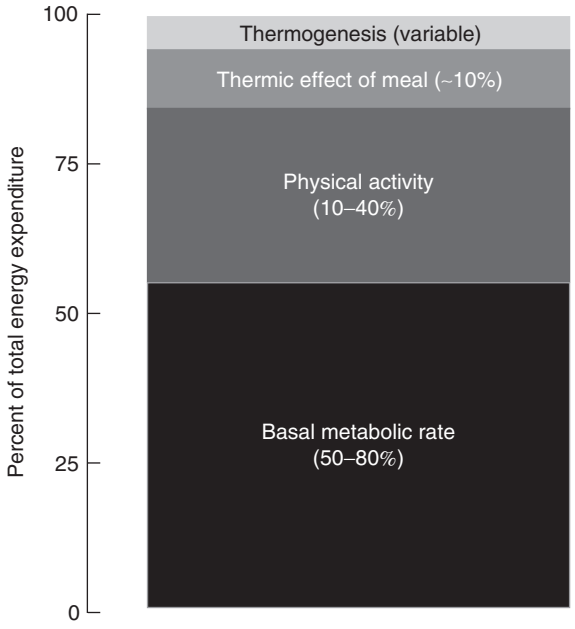

Figure 2 The components of total energy expenditure. The typical contribution of each component to total energy expenditure is indicated in parentheses. Thermogenesis represents heat production for the maintenance of normal body temperature and is typically a minor contributor to energy expenditure in the absence of significant thermal stress. All components of energy expenditure may be altered with aging.

activity, and thermogenesis (i.e., energy expenditure required for maintenance of body temperature) (**Figure 2**).

BMR is defined as the measurement of resting, postabsorptive energy expenditure in individuals at thermoneutrality; it is typically responsible for 50–80% of total energy expenditure. BMR represents the energy cost of cellular 'maintenance' processes, such as Na^+/K^+-ATPase activity, mitochondrial proton leak, protein turnover, ionic calcium movements, triacylglycerol turnover, and other substrate cycles.

TEM describes the energy expenditure associated with the digestion, absorption, and assimilation of food. TEM is responsible for approximately 10% of total energy expenditure but will vary depending on meal size and composition.

Physical activity is the most variable component of total energy expenditure and is typically responsible for 10–40% of total energy expenditure. Physical activity is the energy expenditure associated with muscular movement (beyond muscular activity that typically occurs in the resting state). Thermogenesis is the component of total energy expenditure that represents heat production for the maintenance of normal body temperature. This is typically a minor contributor to energy expenditure in individuals that are not undergoing significant thermal stress.

Aging tends to result in a decrease in all of the components of energy expenditure. Age-related decreases in BMR, physical activity, and total energy expenditure have been reported in multiple studies. The exact effect of age on TEM is not clear, with studies reporting either a decrease or no change in TEM with aging.

Energy Intake

Aging is generally associated with a decrease in energy intake, which has the potential to cause several problems. First, a decrease in energy intake is often not matched with a proportionate change in energy expenditure, which can lead to negative energy balance and loss of body mass. This can be extremely damaging to an individual already with a compromised body composition and lead to an increased risk of morbidity and mortality. Second, a decrease in energy intake is usually associated with a decreased intake of other nutrients, resulting in increased risk of malnutrition-related illnesses. Several studies have shown that a significant portion of the elderly population is deficient in at least one major nutrient. Matching energy intake to energy expenditure is clearly an important concern in the elderly.

Decreases in energy intake may be associated with several other changes that occur with the aging process. Impairment of taste and smell sensation occurs with increasing age; however, the impact of these changes on energy intake is not clear. Depression and some forms of medication are common causes of decreased appetite and food intake in the elderly. Problems with oral health, poor dentition, and gum disease also contribute to decreased food intake in some elderly people. Additionally, aging is associated with decreased saliva production and swallowing problems that can make eating difficult for some individuals.

Several studies have demonstrated that aging is associated with an impairment in the regulation of food intake that prevents appropriate compensation for periods of either under- or over-feeding. For example, young individuals typically follow a period of decreased energy intake with a compensatory increase in food intake to make up for the energy deficit, while several studies have shown that older individuals do not show this response. The mechanism for this impairment in the regulation of food intake is not entirely known. Aging has been associated with a decrease in factors that control short-term regulation of energy intake (i.e., stimuli that determine meal length). In a few studies, aging has been shown to decrease the number of opioid receptors, reduce opioid stimulation of food intake, decrease gastric fundal compliance and increase antral stretch, and slow the rate of passage through the gastrointestinal tract. Several studies have also

reported that aging is associated with increases in circulating cholecystokinin (CCK) levels and sensitivity to CCK. However, it is not clear whether these short-term signals play any role in the age-related decrease in energy intake. In experiments, total food intake is not altered by administration of short-term food intake inhibitors, presumably because the decrease in meal energy intake is compensated by increased meal frequency. Therefore, it is likely that the decreases in food intake with aging are primarily due to alterations in 'long-term' regulators of energy intake. Energy intake is controlled through a complex interaction of hormones (i.e., leptin and ghrelin) and neuropeptides located in the hypothalamus and other brain regions. While aging does not consistently increase serum leptin levels, it has been proposed that alterations in leptin sensitivity may play a role in age-related decreases in energy intake. Ghrelin levels have been reported to increase with aging, and it appears that this hormone does not play a major role in decreasing food intake with aging. In the hypothalamus, aging is associated with decreased sensitivity and/or decreased levels of neuropeptide Y (NPY). It appears that decreased NPY stimulation of feeding occurs in later life and contributes to age-related decreases in energy intake. Studies have also reported that aging is associated with a decrease in the hypothalamic levels of agouti-related peptide (AGRP) and orexin (both stimulators of food intake) and an increase in levels of cocaine-and-amfetamine-regulated transcript (CART, an inhibitor of food intake). Levels of circulating cytokines are also commonly increased in the elderly, and it is possible that they could contribute to alterations in energy intake with aging. Thus, there is evidence to indicate that neuropeptides such as NPY, AGRP, CART, and orexin may be involved in age-related decreases in food intake. Additional research to determine other 'long-term' regulators may also contribute to alterations in energy intake with aging.

It is likely that multiple factors contribute to age-related decreases in energy intake. Tremendous progress has been made in elucidating the neuroendocrine pathways responsible for controlling energy intake, and it is hoped that this work will lead to further identification of mechanisms contributing to age-related decreases in energy intake.

Body Composition and Aging

Aging is associated with very clear changes in body composition. In general, aging results in a decrease in total body mass along with a decrease in LBM and total body protein while increasing percent body fat.

Progressive loss of body protein due to a large decline in skeletal muscle mass (sarcopenia) is a well-established component of the aging process. There is evidence that muscle mass declines by up to 7% per decade between early adulthood and old age. The changes in body protein with aging are primarily a function of decreases in skeletal muscle mass, because non-muscle LBM (internal organs) often shows only slight decreases with aging. This reduction in skeletal muscle mass decreases the overall motor function of the muscles and may limit the individual's ability to respond to stresses requiring mobilization of body protein stores. Although only a slight decrease in non-muscle LBM has been reported, these changes should not be ignored and may be extremely important since the internal organs have high rates of energy expenditure. Therefore, a slight change in organ weight could have a large impact on overall energy expenditure.

The aging process results in several changes that probably contribute to the loss of muscle mass. First, aging is associated with a decrease in physical activity, reducing biomechanical forces on skeletal muscle needed for maintenance or growth of muscle mass. Exercise, especially strength training, can reverse the decline in muscle mass in the elderly. Changes in levels of anabolic hormones also contribute to the age-related decline in muscle mass. Spontaneous and stimulated growth hormone (GH) secretions are decreased with age. Similarly, circulating levels of insulin-like growth factor-1 (IGF-1) and insulin-like growth factor binding protein-3 (IGFBP-3) also decrease with age. Deficiencies in GH and IGF-1 are both associated with reduced protein synthesis and loss of LBM. Decreases in testosterone and estrogen levels probably also play a role in the depletion of LBM. Insulin-mediated suppression of body protein breakdown, unlike other actions of insulin, does not appear to decrease with age. Overall, a decrease in physical activity and decreased levels of anabolic hormones appear to be the likely causes of loss of LBM with aging.

Changes in body protein content are accompanied by an increase in percent body fat in elderly individuals. During middle age, a doubling of total body fat can occur, and development of obesity becomes a major problem. After 65–70 years of age, however, there is frequently a decrease in body weight that is the result of decreases in both lean and fat mass. However, the decrease in lean mass typically occurs at a greater rate, resulting in an increase in percent body fat and potentially the development of sarcopenia-related obesity.

Several factors contribute to increases in percent body fat in the elderly. First, a decrease in physical

activity during middle age may result in a positive energy balance and increased storage of energy in adipose tissue instead of increasing muscle mass. Second, aging is associated with a decrease in catecholamine activity and hormone-induced lipolysis in adipocytes. In women, fat accumulation also appears to be associated with hormonal changes with menopause, since estrogen and progesterone treatment tend to prevent increases in abdominal fat accumulation. Overall, aging is associated with the inability to match energy intake with energy expenditure. Decreases in energy expenditure and adipocyte lipolysis together appear to be major contributors to possible age-related increases in body fat.

Energy Expenditure

Previous attempts to determine the effect of aging on energy expenditure have been criticized for their failure to screen for 'healthy' individuals or for their reliance on cross-sectional analysis. It has been argued that many reported age-related changes in energy metabolism may reflect disease or illness rather than aging. While disease or illness can certainly alter energy expenditure, work in 'healthy' individuals has confirmed that aging is associated with a decrease in energy expenditure. Decreases in BMR, TEM, and physical activity may all be important contributors to the overall etiology of aging.

BMR is a function of the energy requirements of each of the internal organs and tissues. Research has indicated that internal organs are responsible for approximately 60% of resting energy expenditure. Skeletal muscle accounts for 35–40% of resting energy expenditure, with adipose tissue typically accounting for less than 5% of resting energy expenditure. These values show that the internal organs and skeletal muscle are responsible for approximately 95% of BMR. A change in either organ or skeletal muscle weight can, therefore, have a substantial influence on BMR. Aging is associated with a substantial decrease in skeletal muscle mass, a slight decrease in organ mass, and a decrease in BMR.

An age-related decline in BMR is a characteristic of aging that has been demonstrated in healthy and physically active individuals, although exercise can blunt the decrease in BMR. BMR decreases between approximately 13 and 20% as individuals age from their 30s to their 80s. This change in BMR appears to be non-linear, with accelerated decreases occurring at approximately 40 to 50 years of age. Gender influences both the onset of accelerated decreases in resting energy expenditure and the magnitude of these decreases. The decline in BMR begins at approximately 40 years of age in men but does not begin until after menopause, or approximately 50 years of age, in women. The magnitude of the decrease in BMR with aging also tends to be greater in men than women.

The primary reason for a decrease in BMR in both genders is the decrease in LBM. A decrease in skeletal muscle mass (sarcopenia) is the primary factor responsible for a decrease in BMR with aging. However, a few studies have shown that decreases in BMR with age parallel a reduction in organ mass, and the slight reductions in organ mass that occur with aging likely contribute to a decline in BMR. While decreases in skeletal muscle and organ mass are major contributors to age-related decreases in BMR, it appears that other processes are also involved.

Many of the cellular processes that are involved in resting oxygen consumption have the potential to contribute to age-related decreases in BMR. Protein turnover, Na^+/K^+-ATPase activity, and mitochondrial proton leak are the primary cellular processes contributing to BMR, and together account for as much as 70% of BMR. It is reported that protein turnover decreases at a rate of approximately 5% per decade, and several studies have demonstrated a decrease in protein turnover with aging. A few research groups have also shown that Na^+/K^+-ATPase activity decreases with age. Few studies have investigated the affect of age on mitochondrial proton leak, and it is not yet clear how this process is altered with aging. These results suggest that decreases in cellular energy-expending process may also contribute to age-related declines in BMR.

Mitochondria are the primary sites of cellular ATP production, and therefore many studies have attempted to determine if mitochondrial defects could contribute to age-related alterations in energy metabolism. Studies have reported that aging is associated with decreases in mitochondrial membrane potential, volume density, respiration capacity, and complex I, complex IV, adenine nucleotide translocase, and acyl carnitine transferase activities. Oxidative damage to mitochondrial DNA, proteins, and lipids also increases with aging and may provide a mechanism for the mitochondrial dysfunction. However, some have argued that aging is not associated with impaired mitochondrial function, and that some reports of age-related mitochondrial dysfunction may be the result of methodological problems. Work using a mix of *in vivo*, cell culture, and isolated mitochondria measurements is needed to determine the exact effects of aging on mitochondrial energy metabolism. However, it is likely that some level of mitochondrial dysfunction occurs with aging, and this would contribute to age-related alterations in energy expenditure.

The effect of aging on TEM is not entirely clear, with studies reporting either a decrease or no change

in TEM with aging. Diet composition, meal size, and activity all contribute to age-associated differences in TEM. Habitual exercise has been shown to increase TEM and may lessen age-related declines in this energy expenditure component. It has been suggested that decreased activity in the elderly may primarily explain their decrease in TEM. It has also been proposed that decreased intake in elderly individuals contributes to low TEM with age because TEM changes proportionately with meal size. Meal composition also appears to influence TEM, since age-related decreases in TEM have been reported to be greatest when elderly people were consuming a high-glucose meal. Problems with glucose metabolism and insulin resistance may explain the differences in TEM between the different types of diets.

Cross-sectional and longitudinal studies have shown a decrease in physical activity with aging, and this decrease in activity is not entirely explained by disease or illness. Low physical activity is a major contributor to decreased total energy expenditure with aging. Studies have shown that total hours of activity and intensity of activity decrease with aging. An age-related decrease in physical activity can contribute to reductions in total energy expenditure either directly or indirectly by altering BMR. Studies in elderly subjects have indicated that both resistance and aerobic exercise may increase BMR, and oppose age-related decreases in this energy expenditure component.

Calorie Restriction and Exercise

Calorie restriction (CR), without malnutrition, is the only intervention that has consistently been shown to increase both mean and maximum life spans in laboratory rodents. CR affects a wide range of physiological parameters (**Figure 3**) and, therefore, must alter a fundamental mechanism(s) of aging and retard the aging process. CR has been shown to delay the onset of diabetes, cancer, nephropathy, cataracts, and other age-related diseases. This broad action of CR, however, has made it difficult to pinpoint the mechanism(s) through which CR exerts its action. It is clear, however, that overall energy restriction rather than restriction of a specific macronutrient is responsible for retardation of aging with CR. Experiments using low-protein or low-fat diets without CR have failed to produce the dramatic life-prolonging results observed with CR.

It has been proposed that a reduction in body fat may be a mechanism for the actions of CR. CR results in a decrease in body fat, but the failure of experiments to show a strong correlation between body fat and length of life suggests that decreasing body fat is not the primary mechanism of CR.

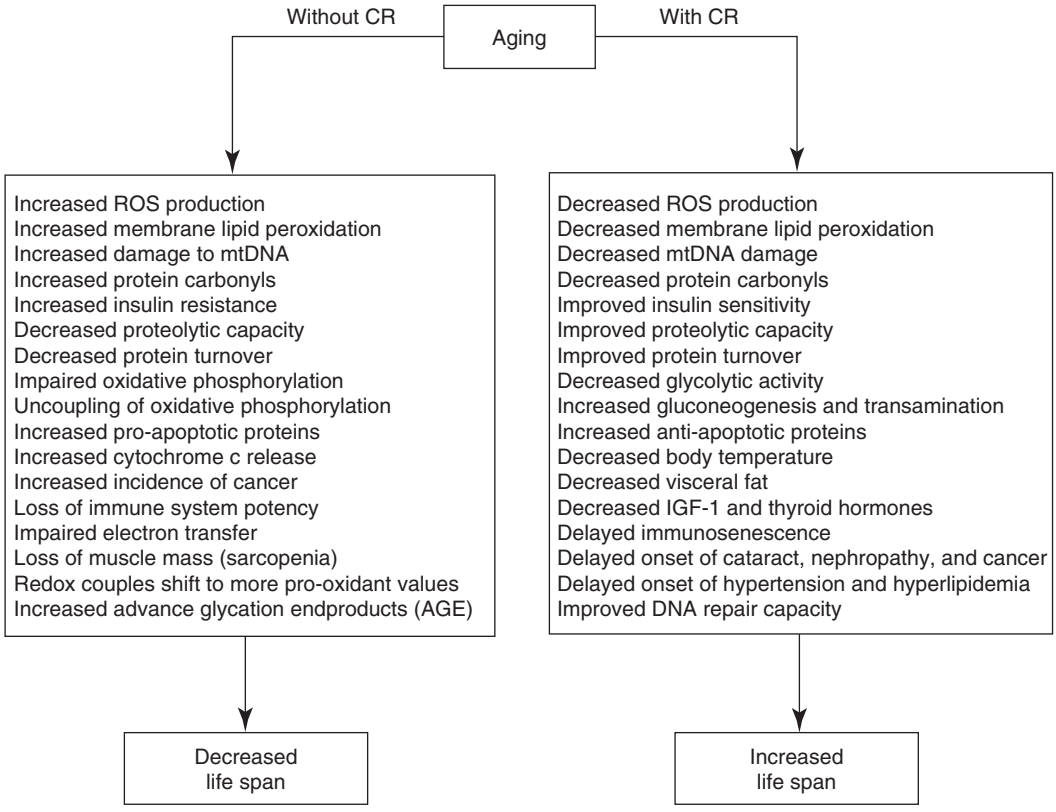

Figure 3 Physiological parameters altered by calorie restriction (CR).

CR has also been proposed to retard aging by altering the levels of hormones that regulate metabolism or mitosis. Studies in nematodes and transgenic mice have indicated that alterations in insulin and/or IGF-1 signaling are associated with increased life span. Similarly, CR has been shown to decrease circulating levels of insulin and IGF-1. Additional research is needed, however, to determine whether CR-related alterations in insulin, IGF-1, thyroid hormones, leptin, or other hormones play a central role in the retardation of aging with CR.

Another proposed theory suggests that energy expenditure and oxygen consumption are important determinates of aging. In support of this idea, long-lived animals do tend to have lower rates of energy expenditure per unit of body mass than short-lived animals. CR experiments, however, have produced mixed results, with studies reporting either a decrease or no change in mass-adjusted energy expenditure with CR. Studies investigating organ and cellular energy expenditure are needed to truly determine whether CR alters energy expenditure per unit of body mass.

The free radical theory is among the most popular theories to explain aging, and it has been proposed that CR may extend life span by decreasing cellular oxidative stress. The free radical theory proposes that aging is the result of accumulated oxidative damage produced by reactive oxygen species (ROS) generated as by-products of mitochondrial energy metabolism. Mitochondria are the principal cellular sites of ROS formation, with approximately 0.2–2% of respired oxygen converted to superoxide radicals at the mitochondria. The mitochondrial electron transport chain is the main source of ROS, with complexes I and III being the sites of ROS generation. CR has been shown to decrease oxidative damage to mitochondrial DNA, proteins, and lipids. CR also decreases mitochondrial ROS production; however, CR has not consistently been shown to alter cellular antioxidant enzymes. These results indicate that a CR-related decrease in ROS production may play an important role in the mechanism of life span extension with CR.

While CR has been shown to increase life span in a variety of animal species, it remains to be determined if it alters life span in humans. Studies in rhesus monkeys and humans do indicate that CR increases insulin sensitivity, decreases blood pressure, and reduces markers of inflammation. Long-term CR studies are under way in rhesus monkeys and humans, and the results of these studies will determine whether CR can increase life span in primate species. Physical activity is another intervention that has the potential to slow age-related changes in energy metabolism. In contrast to CR, studies in rats have shown that physical activity increases median but not maximum life span. Therefore, routine exercise may oppose age-related changes in some physiological parameters but not alter fundamental mechanisms that control longevity. Several studies have shown that routine exercise may increase total energy expenditure, BMR, and TEM. Studies in elderly individuals have shown that BMR is higher in physically active than in sedentary individuals. Physical activity, especially resistance training, may increase BMR by increasing LBM. However, aerobic exercise has also been shown, at least in some studies, to increase BMR by mechanisms independent from increases in LBM. Exercise has been shown to increase food intake and TEM, reversing typical age-related changes. Exercise programs that zincrease total physical activity would also result in increased total energy expenditure. In addition to slowing age-related decreases in energy expenditure, exercise programs have the potential to slow body composition changes with aging along with improving insulin sensitivity and reducing blood pressure. Further research, however, is needed to determine the effect of long-term exercise programs and exercise in conjunction with moderate CR, on the length of life.

Conclusions

Aging is associated with changes in nearly all aspects of bioenergetics. Energy intake is decreased with aging. Aging is also associated with a decrease in total energy expenditure, BMR, physical activity, and possibly TEM. The magnitude of these changes in energy intake and energy expenditure is generally not proportional, with weight gain and obesity occurring at middle age and weight loss becoming prevalent at advanced age. Inability to match energy intake with energy expenditure places older individuals at greater risk for detrimental weight loss associated with injury or illness.

CR and physical activity are two interventions that oppose some physiological changes with aging. CR is the only intervention that has consistently been shown to retard aging in mammalian species. Studies investigating CR have the potential to identify the mechanism(s) responsible for aging. Physical activity has the potential to slow age-related decreases in LBM and energy expenditure, and thus regular exercise programs may improve quality of life by negating these age-related changes.

Body: Composition, Weight, Height, and Build

A S Ryan and D Elahi, Baltimore Veterans Affairs Medical Center, University of Maryland School of Medicine and Johns Hopkins School of Medicine, Baltimore, MD, USA

Glossary

Body Mass Index (BMI) – A practical measure of an individual's weight in relation to height, used to define overweight and obesity.

Fat-free Mass (FFM) – Encompasses all of the body's non-fat tissues, including the skeleton, water, muscle, connective tissue, and organ tissues.

Osteoporosis – A condition characterized by low bone mass (density) and microarchitectural deterioration of bone tissue, with a consequent increase in bone fragility and susceptibility to fracture.

Sarcopenia – A condition characterized by an involuntary age-related decline in lean body mass, primarily due to the loss of skeletal muscle, that affects functional capacity and strength of older adults.

Subcutaneous Adipose Tissue – Adipose tissue between the fascia of skin and the muscles.

Visceral Fat (Intra-abdominal Fat) – A portion of the internal fat in the abdominal cavity lining the intestinal tract.

Introduction

The composition of the human body changes during the entire aging process, from development to maturation and during the advancing years. The sum of the body's components, body weight, also fluctuates during an individual's life span. When changes in the body components occur such as the increase in the amount of fat, then deleterious conditions such as diabetes and cardiovascular disease are manifested. One of the fastest growing segments of the population is individuals over 65 years of age. This age group, which currently accounts for $\sim$15% of the population, is expected to grow to a percentage between 19 and 25% by 2025. Increased body fat and loss of bone mineral density (BMD) and muscle mass are defining characteristics of the aging process. These changes in body composition occur as a result of normal aging, have a detrimental impact on health status, and have substantial economic consequences on the health-care system. Obesity is associated with an increased prevalence of comorbidities, including cardiovascular disease, type 2 diabetes mellitus, hypertension, dyslipidemia, and other metabolic diseases. The decline in skeletal muscle mass

is associated with weakness, functional disability, frailty, and morbidity, whereas the decrease in BMD increases the risk of bone fractures and ultimately results in high rates of disability, morbidity, and mortality in the elderly. This article describes the components of body weight and the various methods currently employed for the determination of body composition. A description of the age-related changes in body composition and how changes in body composition are related to disease will follow.

Body Weight and Its Constituents

Body weight is composed of the sum of the weight of a variety of tissues, the largest component being body water, which comprises approximately 60% of body weight. Body water can be further divided into intracellular (40%) and extracellular (20%) components. For instance, the body weight of a young man may be composed of 60% water, 7% skeleton, 18% protein, and 15% fat. These separate entities differ among individuals and change by gender during the aging process. Furthermore, an excessive increase or loss of various body components is associated with disease. In order to document these alterations and their health consequences, various methods have been developed to assess these changes in body composition.

Body weight is easily and accurately measurable. Recommended body weights as a function of height are based on various tables and provide some aid in assessing obesity. An individual's actual body weight is compared with that of a gender-, stature-, and age-appropriate reference or desirable body weight. The individual's actual weight is then expressed as a percentage of desirable. A desirable body weight in the normal range is usually set between 90 and 120%. Undernutrition and obesity correspond to a body weight below and above these set levels, respectively. An additional method of comparison of weight with a reference population is the calculation of body weight–stature index. This weight–stature index is independent of height and correlates with health outcomes. Since the mid-1980s body mass index tables have replaced actuarial tables to assess obesity.

Body mass index (BMI), a practical measure of an individual's weight in relation to height, is used for diagnosing protein-energy malnutrition and obesity (**Table 1**). A BMI between 18.5 and 24.9 (measured in kg/m^2) is considered normal, with varying levels below this range defined as underweight (17.0–18.5), grade II protein-energy malnutrition (16.0–16.9), and grade III protein-energy malnutrition (<16). A BMI between 25 and 29 defines overweight in adults, whereas obesity is defined as a BMI >30. These criteria for defining overweight and obesity are based on epidemiological evidence that shows a strong association between BMI >25 and an increased incidence of cardiovascular disease, type 2 diabetes mellitus, hypertension, and dyslipidemia that affect mortality and morbidity. Although BMI is a simple index of obesity to obtain, it does not differentiate between fat mass and lean muscle mass. Therefore, it can overestimate body fat in persons who are very muscular and underestimate body fat in persons who have excess fat and reduced muscle mass but normal body weight. Thus, the methods described in the following section are particularly useful in the determination of body composition.

Table 1 Classification of adults according to body mass index (BMI)

Classification	*BMI (kg/m^2)*	*Risk of comorbidities*
Underweight	<18.50	Low (risk of other clinical problems increased)
Normal range	18.50–24.99	Average
Overweight	>25.00	
Pre-obese	25.00–29.99	Increased
Obese class I	30.00–34.99	Moderate
Obese class II	35.00–39.99	Severe
Obese class III	>40.00	Very severe

Measurement of Body Composition

Direct measurement of body composition is obtained only from cadaver analysis. Results from these studies provide normative weight data on tissues and organs and are highly accurate. However, indirect methods, developed to accurately assess body composition, can be used repeatedly in clinical and research settings across the age span. The constituents of body composition and the currently available tools for their measurement are discussed in the following subsections.

Total Body Composition

Numerous methods exist for the measurement of total body fat and regional adiposity. In a compartment model for the measurement of body composition, body weight (BW) is divided into fat (F) and fat-free mass (FFM): $BW = F + FFM$. FFM is further divided into five fat-free components, namely, water, osseous and cellular mineral, protein, and glycogen. Most indirect measurements of total body fat are based on compositional differences between the estimated weight of lean and fat tissues and their respective densities. Although FFM and lean body mass (LBM)

are often used interchangeably, they are slightly different. Excluded in the estimated mass of fat is the soluble fat component (i.e., the ether-soluble fraction of the adipose tissue and fat stored in nonadipose tissue sites). Thus, FFM includes the water and protein fractions of adipose tissue. LBM equals BW minus weight of adipose tissue. LBM does not include the weight of water and protein fractions of adipose tissue. The methods that are currently used to make measurements using the two-compartment model are hydrodensitometry, isotope dilution, air displacement plethysmography (ADP), and total body potassium. Methods such as bioelectrical impedance, urinary 3-methylhistidine, and urinary creatinine are other alternatives. A three-compartment model of body composition composed of fat, FFM, and bone mineral content is assessed by dual-energy X-ray absorptiometry (DXA). Whole-body magnetic resonance imaging (MRI) is also used to quantitate adipose tissue in the entire body and lipids in muscle and cells (e.g., liver). For the determination of multi-elemental compartments, neutron activation analysis (NAA), prompt gamma neutron activation analysis (PGNA), delayed gamma neutron activation analysis (DGNA), and inelastic neutron scattering can be used. Regional adiposity and muscle mass are estimated with DXA, computed tomography (CT), MRI, or sonography. A brief description of these various techniques follows.

Hydrodensitometry Hydrodensitometry or underwater weighing, considered for many years the gold standard for measuring body fat, is based upon the Archimedes principle whereby the volume of a mass is equal to the volume of liquid displaced by that solid. Thus, BW in the air and water is measured to determine body density (D_b). Percent fat is determined with the equations described by anthropometry pioneers Siri and Brozek *et al*. as

$$\text{Siri: percent fat} = 4.95/D_b - 4.5$$

$$\text{Brozek } et\ al.\text{: percent fat} = 4.570/D_b - 4.142.$$

Fat mass and FFM are then calculated. Residual lung volume must be determined prior to or during underwater weighing using either the helium or nitrogen dilution methods. Fat and FFM values in adults are assumed to have reference values (0.9007 g/ml and 1.10 g/ml, respectively), which may not be accurate in women, athletes, or the elderly. Furthermore, this technique assumes adequate subject hydration, a fasted state, and a volume of intestinal gas.

Isotope Dilution The measurement of total body water (TBW) is made with the isotope dilution method. The method of TBW is based on the assumption that the ratio of water weight to FFM equals 0.732. Therefore, FFM is calculated as body water/0.732 and fat mass = BW – FFM. Body water may be estimated with the dilution of labeled water using heavy isotopes of hydrogen (deuterium, D_2O) and/or oxygen ($H_2^{18}O$, $D_2^{18}O$) or radioactive water using tritiated hydrogen (^3H_2O), usually administered orally. Measurement of TBW relies on the relationship that C_1V_1 equals C_2V_2, where C_1 is the concentration of the ingested isotope, V_1 is the volume of the ingested isotope, C_2 is the concentration of the isotope in the body after equilibration (as in plasma, saliva, or urine), and V_2 is the volume to be determined or TBW. The concentration of the tracer is measured both before and after its equilibration in the body compartment, and volume is mathematically determined. The assumptions of this technique are that (1) C_2 is completely at equilibrium in each body compartment at the time of measurement, (2) the isotope has not been incorporated with any body constituent other than the tracer (water), and (3) between administration of the tracer and its measurement, there has been a stable state with respect to influx and efflux of the tracee into the water compartments of the body. TBW is overestimated by about 4% for D_2O and ^2H_2O due to the exchange with hydrogen in labile non-aqueous compounds such that the tracer may be lost as the hydrogen breaks off and becomes part of another cellular compartment. With ^{18}O, the stable oxygen of water exchanges with the oxygen of bicarbonate in the blood, and thus $H_2^{18}O$ has an error rate of about 1%. Stable oxygen is very costly and the supply is rather limited. Furthermore, all methods require skilled personnel and sophisticated measuring techniques and equipment.

Air Displacement Plethysmography In ADP, body density is estimated through the measurement of body volume. Body volume is measured through the application of Boyle's law, which states that at constant (isothermal) temperature, pressure and volume are inversely related. Calculation of percent fat is derived from assessment of body volume based on the following equation:

$$\begin{aligned}\text{body volume (l)} = {} & \text{body volume}_{\text{raw}}\ \text{(l)} \\ & - \text{surface area artifact (l)} \\ & + 40\%\ \text{thoracic gas volume (l)}.\end{aligned}$$

After body volume is determined, body density is calculated by dividing mass of the subject by body volume. Thoracic gas volume is measured and

percent fat determined by the Siri equation (as given earlier). This technique, although relatively new, is a valid and reliable alternative to other body composition methods. There are small mean differences between methodologies such as hydrostatic weighing, DXA, deuterium oxide, and multicompartmental methods and ADP. The benefits of using ADP include the short assessment time, ease of use, and propensity for high subject compliance. Specific clothing instructions must be adhered to, to ensure accuracy. Body fat determinations by ADP may be especially useful for geriatric populations. Race does not appear to affect the accuracy of estimating percent fat by ADP. The method has also been validated in overweight and obese individuals.

Total Body Potassium Total body potassium (TBK) is used to estimate LBM because the ratio of potassium (K) to LBM is relatively constant. From cadaver and *in vivo* studies, the ratio is generally accepted to be 68.1 mEq K/kg LBM in men and 64.2 mEq K/kg LBM in women. In this method, ^{40}K, a naturally occurring radioisotope, is detected by a sensitive gamma ray detector placed close to the subject in a heavily shielded room. TBK is then mathematically determined from the measured ^{40}K. Although this method has an accuracy of approximately 3–4% and is non-traumatic and non-invasive, it is very expensive and technical. It should also be noted that measurement of ^{40}K may be erroneous in potassium-depleted states.

Anthropometry Anthropometry values, such as those obtained by thickness and limb circumferences, can be used in multiple regression equations to predict body density and to calculate body fatness and FFM. Skinfold thicknesses can be taken in several sites, such as bicep, tricep, suprailiac, subscapular, thigh, and abdomen. The measurement of thickness is based on two assumptions: (1) the thickness of the subcutaneous adipose tissue reflects a constant proportion of the total fat and (2) the sites selected for measurement represent the average thickness of the subcutaneous adipose tissue. The validity of using equations to predict body composition is restricted to populations from whom these equations were derived. Other contributing factors to error in this technique include the biological variation in fat in other depots such as intermuscular, intramuscular, and fat surrounding organs and the gastrointestinal tract. There is some evidence to suggest that equations need to be established that are specific for race. For additional information on anthropometry, a comprehensive manual provides details for measurement procedures and standardized techniques for more than 40 anthropometric measurements.

Bioelectrical Impedance Bioelectrical impedance (BIA) is based upon the assumption that fat acts as an insulator and FFM conducts electrical current. Body fluids and cell membranes are responsible for conductance and capacitance (low impedance), respectively, whereas bone, fat, and triglyceride are non-conductive and have high impedance. BIA is based upon the principle that the impedance of a geometrical system is related to conductor length and configuration, its cross-sectional area, and signal frequency. The impedance of the flow can be described as $Z = aL^2/V$, where Z is impedance in ohms, a is volume resistivity in ohms-centimeters, L is conductor length in centimeters, and V is volume in liters. Impedance can be partitioned into its components, resistance (R) and reactance (Xc): $Z^2 = R^2 + Xc^2$. Electrodes are placed at the wrists and ankles (hand-to-foot BIA), a small current is introduced, and the resistance to the current is measured. Appropriate regression equations are used to predict FFM and hence fat mass from BW. Prediction equations generally include other parameters such as age, gender, body circumferences, and skinfold thickness. New BIA systems utilize a foot-to-foot BIA system and resemble a bathroom scale. These systems have been validated in older adults for percent fat estimates against underwater weighing, DXA, and hand-to-foot BIA. An important assumption for BIA is a balanced hydration state; either dehydration or fluid overload reduces the accuracy of FFM.

Dual-Energy X-Ray Absorptiometry DXA allows separation of body mass into bone mineral, fat tissue, and fat-free soft tissue, a three-compartment model. DXA has an X-ray source with two photon energies including low and high energy levels. The ratio of high to low energy attenuation is specific to elements (e.g., hydrogen, which minimally attenuates photons, or calcium, which is highly attenuating). A measure of the soft tissue attenuation at the two energy levels is referred to as the Rst. The Rst correlates inversely with the proportion of soft tissue as fat. The X-ray beam scans on a pixel-by-pixel basis over the body, and the values for all pixels are summed to estimate the molecular components for the body. DXA results are highly correlated with criterion methods, but there is modest systematic variation in the estimates of body composition by DXA with the use of different hardware and software accommodations to the interpolations for soft tissues located over bone and the treatment of pixels for which a small portion is bone. There are newer and faster fan beam instruments that

may have error in the beam magnification due to the variation in heights between the source and detector of tissues. There is some evidence that certain DXA machines may overestimate FFM and underestimate FM. Radiation exposure and scanning time have been reduced with the newer DXA machines. The ease that DXA affords the subject makes it an attractive alternative for body composition assessment in the elderly or those who may fear submergence in the water with hydrodensitometry. Studies that report comparisons across different DXA machines suggest that the same system be used in longitudinal studies examining changes in percent body fat and BMD. However, comparisons of pencil beam versus fan beam DXA machines illustrate comparable and interchangeable results for appendicular lean soft tissue.

Urinary 3-Methlyhistidine and Creatinine Excretion Muscle mass analysis can be determined by techniques such as urinary 3-methlyhistidine (3-MH) excretion and urinary creatinine excretion. Creatinine and 3-MH are end products of muscle metabolism that cannot be further metabolized. They are excreted quantitatively in the urine and are directly proportional to muscle mass. High-performance liquid chromotography is conducted to determine a peak value of absorption of these products. Day-to-day variability, complete and accurate urine collections, and the need to comply to a meat-free diet prior to analysis are requirements of these methods that limit the accuracy of this technique.

Neutron Activation Analysis Neutron activation analysis (NAA) is the only technique available for the measurement of the multi-elemental composition of the body. In general, a moderated beam of fast neutrons is delivered to the subject. Unstable isotopes are created and are reverted to a stable condition by emission of one or more gamma rays of characteristic energy. The induced radioactivity is measured in a whole-body counter. The energy level identifies the element and the level of activity indicates its abundance. Neutron activation can be used for determination of Ca, K, P, N, Mg, and Na. Specifically, a method known as prompt gamma neutron activation (PGNA) analysis measures total body nitrogen. Nitrogen (^{14}N) is excited to ^{15}N and gamma rays. Delayed gamma neutron activation (DGNA) analysis allows the measurement of total body mineral through the excitation of ^{48}Ca to ^{49}Ca and gamma rays. Using appropriate equations, total body fat can be calculated with the estimation of total body protein by PGNA, bone mineral by DGNA, and body water by isotope dilution. Another system, inelastic neutron scattering, can provide an estimate of total body carbon. A miniature deuterium-tritium accelerator generates fast neutrons that result in gamma rays produced from ^{12}C. The model assumes that total body carbon is distributed to a certain percent in fat, protein, glycogen, and bone ash. Using the measurement of total body carbon, nitrogen, and calcium, total body fat can be estimated. Although NAA can provide valuable information, it is very costly and requires a high radiation dose and highly skilled investigators, and presently there are few facilities in the world where it can be performed.

A modification of this method uses simultaneous measurements of the ratio of body carbon to oxygen with large (bismuth-germanium-oxygen [BGO]) crystal detectors. The signal-to-background ratio for the carbon detection is vastly improved (sixfold) compared to the sodium iodide (Tl) detectors, and the method also allows for the measurement of regional body fat. The basis for this modification is the large differences in carbon and oxygen content between fat and lean tissue. The technical aspects of this modification have been published, and its accuracy has been validated against hydrodensitometry in humans. Additional advantages include a significant reduction in radiation exposure (much less than a chest X-ray) and cost of operation (by more than two-thirds).

Regional Assessment

Computerized Tomography Regional adiposity and skeletal muscle mass can be determined with CT. This approach relates small differences in X-ray attenuation to differences in the physical density of tissues. The scanner computer constructs a two-dimensional image of the underlying anatomy in the scan area. The cross-sectional area of adipose, bone, and muscle can be determined for each image. Because thickness is known, relative surface area or volume can be calculated. Furthermore, CT scans of the abdominal region, typically performed at the L_4–L_5 region, assess both subcutaneous and intra-abdominal (visceral) adipose tissue and are highly accurate (**Figure 1**). Subcutaneous abdominal adipose tissue can be partitioned into the plane superficial to the fascia within subcutaneous adipose tissue (termed superficial subcutaneous abdominal adipose tissue) and below this fascia (termed deep subcutaneous abdominal adipose tissue) (**Figure 1**). There are morphological differences between the two layers as well as differences in the proportion of each layer by gender, with a greater proportion ($\sim$65%) of deep subcutaneous abdominal fat in men vs. about 50% for each layer in women. These layers of

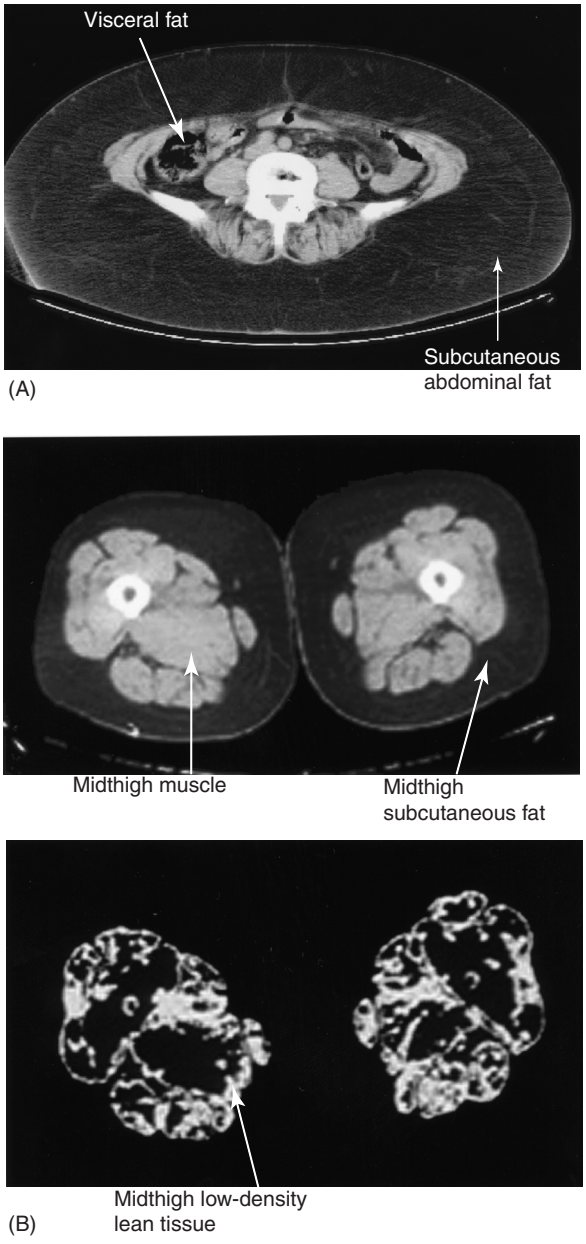

Figure 1 Cross-sectional images from the abdomen at L_4–L_5 (A) and midthigh (B) in a postmenopausal woman.

subcutaneous abdominal adipose tissue are associated with the metabolic complications of obesity. CT is also used for measurement of muscle area, subcutaneous fat, and low-density lean tissue in the thigh (**Figure 1**), calf, or other regions of interest. The CT-derived lipid within skeletal muscle, or low-density lean tissue, is determined by a reduced muscle attenuation. Because of the relatively greater exposure to ionizing radiation compared to DXA, routine whole-body scans and multiple scans in the same individual limit the use of CT. Researchers have lowered the radiation dose and have applied multiple scan slices across the total body in order to estimate total body fat.

Magnetic Resonance Imaging MRI also quantitates total fat mass and discriminates differences in regional fat and muscle tissue. MRI is based on the principle that atomic nuclei behave like magnets. An external magnetic field is applied across a part of the body. Each nucleus or magnetic moment attempts to align with the external magnetic field. A radio frequency wave is used simultaneously to rotate the nuclei to the magnetic field. The absorbed energy from the activated nuclei is released when the radio frequency is shut off. This radio signal is used to develop an image and thus a clear determination of adipose and muscle tissue. In contrast to CT, MRI does not use ionizing radiation. Its restricted availability and high cost also limit its use in body composition assessment. Whole-body MRI can be performed to assess adipose tissue and muscle areas. Acquisitions are typically taken at 40-mm intervals across the whole body with $\sim$40 axial images (10 mm thickness) obtained. MRI is also used to quantify intra-abdominal adipose tissue and subcutaneous fat of the abdomen as well as appendicular muscle mass. MRI volume estimates can be converted to mass using assumed densities for skeletal muscle and adipose tissue. The amount of intermuscular adipose tissue in the total body is about the same size as visceral fat in adults as determined by whole-body MRI. Intermuscular adipose tissue is not the same as intramyocellular lipid (lipid within muscle fibers). Intramyocellular lipid is quantifiable by single- and multivoxel magnetic resonance spectroscopy (MRS) from muscles such as the tibialis anterior.

Sonography To determine abdominal fat using ultrasound, the patient lies in a recumbent position and subcutaneous thickness and intra-abdominal fat are measured next to the umbilicus in the xypho-umbilical line. Either a 5-mHz or a 7.5-mHz transducer is used to measure subcutaneous fat thickness, whereas intra-abdominal fat is measured using a 3.3-mHz transducer. Using images on the screen, the thickness of subcutaneous fat is measured with calipers placed at the skin–fat and fat–muscle interfaces, and that of visceral fat is measured at the internal face of muscle and the anterior wall of the aorta. Both subcutaneous and visceral fat as determined by ultrasound are significantly correlated with that determined by CT in obese women across the age span. Sonography requires a skilled operator, but it is safe, is noninvasive, and does not involve radiation exposure, and the imager is widely available.

Anthropometrics The waist circumference is used to estimate central obesity. A waist circumference >102 cm in men and >88 cm in women classifies abdominal obesity by the Adult Treatment Panel III criteria. The regional distribution of fat can be estimated by the ratio of waist circumference to hip circumference (WHR). A WHR of >0.90 in men and >0.85 in women is generally considered to be upper body obese, and a WHR below these numbers is considered as lower body obese. Waist circumference and WHR correlate with CT and MRI analysis of abdominal tissue. Other simple measures of regional obesity can be made with circumferences as well as depths and breadth measurements from other parts of the body. Several researchers have developed predictive equations with the use of CT as the criterion method to estimate visceral fat. These equations utilize simple anthropometry, DXA measures, and the combination of the two to estimate visceral fat. Reports indicate that skinfold thicknesses should not be used to assess changes in body composition with age due to their failure to detect fat distribution changes with age.

Change in Body Composition with Aging

Prevalence of Overweight and Obesity

The National Center for Health Statistics has examined the prevalence and trends of overweight adults in the United States from 1960 to 2000 via the National Health Examination Survey (NHES I) and National Health and Nutrition Examination Surveys (NHANES I, II, III, continuous). The prevalence of overweight and obesity increased significantly over a 40-year period, from 43% in 1960–62 to 64.5% in 1999–2000. Most of this increase is attributable to a dramatic rise in the prevalence of obesity (BMI $>30\,kg/m^2$), which remained stable at $\sim 15\%$ for the first three survey periods (1960–80), and then rose dramatically to 30.5% in 1999–2000. The increased prevalence of overweight and obesity in adults during this time period was evident in both genders, across all races and ethnicities, and across all age groups.

Change in Body Weight and Fat Mass with Aging

In healthy people, body weight increases gradually from early adulthood until the fifth to sixth decade of life and then remains stable until age 65 to 70. During the period of weight gain, body weight increase occurs at a rate of 0.39 to 0.45 kg/year for women and 0.36 to 0.41 kg/year for men, irrespective of race. The slightly higher rate in women compared to men suggests that the transition from pre- to postmenopausal status affects the amount of weight gain. After age 60, body weight decreases slowly at a rate between 0.05 to 0.36 kg/year, depending on race and gender. The rate of decrease is usually higher in women compared to men, regardless of ethnicity. Moreover, the rate of body weight decrease is highest in African American women and lowest in African American men. The variation in body weight regulation suggests that a non-linear pattern of weight change occurs through the aging process.

The pattern of weight gain is generally consistent between cross-sectional and longitudinal studies and is characterized by a greater increase of fat than lean mass accounting for the increase in body weight. The relationship between age and body fat is curvilinear, with the greatest increase in body fat occurring in middle-aged persons and smaller increases occurring in both the young and the elderly. That is, there is a pattern of increasing fat mass with age until 50–69 years, followed by a slow decline in fat mass in older age groups (>70 years). However, irrespective of the age group, 7–31% of the variation in the increase in fat mass (absolute or relative) in the adult population is accounted for by age.

The increase in weight with age is accompanied by an age-related redistribution of fat to the abdominal region. Sedentary women in their fifth decade of life have an average 1.5- to 3-fold higher visceral and subcutaneous abdominal fat areas compared to their younger counterparts and athletes of similar age. Similarly, older women athletes in the fifth and sixth decade of life have a two- to threefold higher visceral fat area compared to younger athletes despite similar BMI and percent body fat. Therefore, there is an accumulation of fat in the abdominal region during the aging process irrespective of physical activity status. However, maintaining an active lifestyle partially negates the consequences of aging by dramatically reducing the amount of abdominal fat deposition. The ability to alter the accumulation of fat in the abdominal region is of clinical significance when one considers that intra-abdominal fat areas greater than $100–110\,cm^2$ increase the risk for developing cardiovascular disease and other metabolic diseases. The age-associated increase in visceral adiposity may contribute to the increase in triglyceride and total cholesterol concentrations and to glucose intolerance with age.

An increase in the infiltration of fat around and within skeletal muscle occurs with aging and adversely influences glucose and lipoprotein metabolism. CT scans document a twofold increase in mid-thigh subcutaneous fat between pre- and postmenopausal sedentary women. Moreover, there is also a twofold

increase in low-density lean tissue, a marker of intramuscular fat. Approximately 27–33% of the variation in the increase in mid-thigh subcutaneous fat and low-density lean tissue areas in the mid-thigh region is accounted for by age. Cross-sectional studies report increases in intramyocellular lipid and liver fat in older versus younger adults. Longitudinal studies also demonstrate increases in visceral adipose tissue and intermuscular adipose tissue with age. The contribution of intramuscular fat to the metabolic dysfunction associated with the insulin resistance syndrome may help explain racial difference in glucose metabolism.

Change in FFM and Its Constituents with Aging

As body weight and fat mass increase with aging, total FFM and its constituents (skeletal muscle mass, body cell mass, total body water, and bone mineral mass) gradually decrease. Peak FFM in males is reached in the mid-30s and then progressively declines. In females, FFM remains relatively stable until approximately age 50, then the decline in FFM occurs at a slower rate than males. The average loss of FFM is approximately 16% between the ages of 25 and 70 in both men and women at a rate of $\sim$0.16 kg/year. Since skeletal muscle accounts for more than half ($\sim$55%) of total FFM, the decrease in skeletal muscle mass between the ages of 20 and 70 is slightly lower than the loss of FFM at 10 to 15%, with the rate of decline greater in men (0.8 to 1.9 kg/decade) than women ($\sim$0.4 to 1.1 kg/decade). Although the relative decrease in FFM starts during the third decade, skeletal muscle mass is preserved until the fifth decade, with a noticeable decrease in absolute skeletal muscle mass occurring at $\sim$45 years in both men and women. Some studies suggest that the loss of skeletal muscle mass may be accelerated in individuals $\geqslant$70 years of age. In addition, the Health, Aging and Body Composition Study shows that changes in body composition with age are related to weight loss or gain and to baseline body composition. Specifically, there is a greater tendency to conserve the lean compartment than the fat compartment with weight change in generally healthy older (70–79 years) men and women, but after adjustment for selected variables, there remains the failure to conserve lean mass with weight loss in old age. In addition to changes in whole-body muscle mass, muscle cross-sectional area declines by 1.4%/year in older men (age 65 at baseline) who were followed for 12 years.

The involuntary age-related decline in FFM, primarily due to the loss of skeletal muscle, is termed sarcopenia and affects functional capacity and strength of older adults. Sarcopenia has been defined in older adults as a height-adjusted appendicular muscle mass of two or more standard deviations below the mean of young adults or as muscle mass relative to body weight. The prevalence of sarcopenia varies from 6 to 24% in persons under 70 years of age to $>$50% in persons over 80 years of age, depending on the definition and measure of muscle mass. The metabolic effects of sarcopenia include a decline in resting metabolic rate secondary to decreased FFM and decreased physical activity.

The loss of skeletal muscle mass is strongly associated with a loss of body water, because a large proportion of skeletal muscle ($\sim$75–80%) is water. Total body water accounts for approximately 80% of FFM at birth. In young adults, TBW comprises approximately 72% of FFM. Thus, a loss of body water occurs until maturity but remains relatively constant throughout adulthood and middle age. TBW on average is lower in females than in males. Losses of body water occur after age 70 in females and somewhat earlier in males, with a nadir at 70–80 years. The decline in TBW suggests a change in the hydration of the fat-free compartment (increased with normal aging). The extracellular water compartment (ECW), when expressed as a ratio to body weight, intracellular water (ICW), or FFM, is at a maximum in early life, reaches a nadir in the early adult years, and again increases in old age. The ECW:ICW is larger and ICW is smaller with increasing age after adjustment for race and body composition. Research suggests that the largest age-related differences are observed in African Americans compared to Caucasian, Asian, and Hispanic individuals. TBK, an index of FFM, begins to decline at approximately age 30 for men and women. Values are highest in African Americans, followed by Caucasians, Hispanics, and Asians. The decline in TBK is most rapid in African American women and Hispanic men, suggesting that there are significant gender and racial differences in the decline in FFM with age.

In addition to the losses of FFM, skeletal muscle mass, and TBW with age, the loss of bone mass is consistently documented. Peak bone mineral mass is reached at age 20–30 followed by a progressive decline. By age 70, spinal and femoral neck BMD is diminished by approximately 20 and 25%, respectively. Furthermore, the rate of bone loss varies with site and may be greater in areas with more trabecular bone than in areas of predominantly compact bone. Total body mineral may decline at a slower rate than that observed in specific sites. In women, a more dramatic loss of bone mass occurs during menopause. The rate of BMD loss is greater

among perimenopausal women compared to pre- and postmenopausal women and is site-specific. Longitudinal studies estimate the rate of premenopausal BMD loss at 0.7–1.3%/year at the lumbar spine and 0.2–0.3%/year at the femoral neck. In contrast, the rate of BMD loss for perimenopausal women is 2–3%/year at the lumbar spine and 0.6–1%/year at the femoral neck. The estimated loss of BMD at the lumbar spine and the femoral neck is 1.3–1.5%/year and 1–1.4%/year in postmenopausal women, with the fastest rate of bone loss occurring immediately after menopause.

The rate of osteoporotic fracture risk is higher in women compared to men, such that the rate of loss in BMD for men is two-thirds the rate of women in the spine, and one-half the rate at the femoral neck. Despite these differences, an age-related increase in fractures associated with osteoporosis is evident in men as well. The slower rate of bone loss results in a lower prevalence of osteoporosis in men ($\sim$6%) compared to women ($\sim$20%), as well as an incidence of hip and vertebral fractures in men older than 65 that is approximately half that of women of similar age. Relative risk is also site-specific, and regional adiposity specifically in the hip may be protective against fracture. Many factors influence both peak bone mass and its loss, including nutritional state, physical activity levels, disease (e.g., hyperparathyroidism), genetics, certain drugs (e.g., glucocorticoids, anticonvulsants), alcoholism, smoking, immobilization, and hormonal status.

Body Composition and Relationship to Disease

The changes in body weight and composition associated with aging have major public health implications. Obesity is a major risk factor for coronary heart disease, congestive heart failure, stroke, ventricular dysfunction, and cardiac arrhythmias. The increase in total and abdominal obesity is associated with increased risk for developing cardiovascular disease, type 2 diabetes, hypertension, dyslipidemia, and other metabolic diseases. A new important treatment for obese class III is bariatric surgery, which reverses many of these metabolic diseases. Obesity is also associated with altered pulmonary function and increased inflammatory state. Importantly, approximately 300 000 deaths a year may be attributable to obesity, with an estimated cost to the health-care system of over $100 billion/year.

The risk of cardiovascular disease is higher in the overweight and obese. In age-adjusted analyses of $\sim$18 000 middle-aged men with coronary heart disease, there is a modest elevated risk in the overweight relative to normal weight groups for all-cause mortality and coronary heart disease mortality but not stroke mortality. Similar results are obtained in obese groups, suggesting that obesity and overweight in adult life contribute to risk of total and coronary heart disease mortality. In a nationally representative survey of the US population (Medical Expenditure Panel Survey [MEPS]), the likelihood of having diabetes and diabetes-related cardiovascular comorbidities increased with BMI regardless of physical activity and increased with physical inactivity regardless of BMI. The multivariate-adjusted odds ratio for diabetes was 1.52 for normal weight inactive adults and 1.65 for overweight inactive adults. Thus, both physical inactivity and obesity are strongly and independently associated with diabetes and diabetes-related comorbidities.

In addition to the detrimental effects of total body adiposity, the location of the fat also plays a role in determining the influence of the fat on risk factors for disease. The CT-derived lipid within skeletal muscle is directly related to age and adiposity in women and is associated with insulin resistance and lower extremity dysfunction in older adults.

Low muscle mass impacts the health, independence, and welfare of older persons. Sarcopenia is associated with a three- to fourfold increase in functional impairment, disabilities, and falls in the elderly. Specific cut points have been proposed that are associated with elevated physical disability risk in older persons. Given the economic burden of physical disability on health-care systems, it is likely that sarcopenia contributes to these health-care costs.

The age-related decline in BMD results in a decrease in bone mass and strength that may lead to osteoporosis or an increase in fractures in the vertebral bodies, femur, and distal radius. As an example, the risk of hip fracture triples with each 10% decrease in femur BMD. Because men have higher bone mass than women throughout the life span, and BMD declines at a slower rate in males than females, the incidence of osteoporosis is lower in males. Osteoporotic fractures generate substantial cost due to acute hospitalization and subsequent rehabilitation at an estimated cost of $17 billon/year and, like obesity, increase morbidity and mortality (e.g., 12% mortality rate during the first year after a hip fracture).

In summary, the age-related changes in body weight and body composition are associated with a number of diseases. These changes, which can be documented by a variety of methods currently available depending upon the resources and the population being studied, are influenced by nutrition, activity, genetics, and economic and social concerns. Lifestyle behavior changes such as proper nutrition,

increased regular physical activity, and intentional weight loss reduce the risk for developing metabolic and cardiovascular diseases. For example, caloric restriction to induce weight loss with or without an exercise training program reduces the incidence of developing type 2 diabetes and improves the cardiovascular risk profiles in obese individuals. Furthermore, physical activity may help mitigate the tendency for weight gain and adverse changes in body composition and fat distribution that accompanies aging. Aerobic and resistive exercise training programs greater than 6 months in duration maintain or increase muscle and bone mass and in effect may prevent the progression to sarcopenia and osteoporosis. With epidemiological studies documenting an increase in the average life span, structured behavioral programs that include nutrition and exercise should be recommended to alter the adverse body composition changes observed with aging.

Glossary

Astroglia – A population of non-neuronal cells with numerous, branching processes that provide mechanical and functional support to central nervous system neurons.

Hippocampus – A region of the brain located in the medial part of the temporal lobe and concerned with memory.

Locus Ceruleus – A group of pigmented neurons in the roof of the pons that is the principal source of the noradrenergic innervation of cerebral cortex.

Nucleus Basalis of Meynert – A collection of neurons in the orbital frontal part of the brain that is a major provider of cholinergic innervation for the cerebral cortex.

Synapse – Point of junctional contact between neurons where electrochemical signal is transmitted.

Introduction

Although age-related changes in the human brain are readily demonstrated, it is always difficult, and in most cases impossible, to know how much of those changes are due to aging per se. Elderly humans are afflicted acutely with numerous age-related diseases and suffer the cumulative affects of numerous other chronic illnesses. They are affected by neuroactive medications used to treat their acute diseases and by the cumulative effects of other neuroactive substances, such as alcohol and caffeine. The effects of an increasingly hostile environment are often not easily differentiated from those due to the effects of aging on the structure and chemistry of the brain.

Age-related changes in brain functions are also readily demonstrated, and at least some of these appear to reflect the process of aging rather than environmental change. Age-related changes include changes in secondary memory, reaction time, visuospatial memory, complex attention, language fluency, and problem solving. Neurobiological substrata of these cognitive changes are unknown and their elucidation is the raison d'être of gerontological research.

Gross Anatomy of the Aging Brain

Structural changes due to aging in the brain have been characterized on three organizational levels. At the level of gross structure, changes in brain weight, based on measurements made after death, are significant. Although the amount is uncertain because of postmortem changes in fluid compartments, the loss is nonetheless probably in the order of 10%. Changes in brain volume are probably most reliably assessed on the basis of imaging – computed tomography (CT) or magnetic resonance imaging (MRI). Imaging shows the cerebrospinal fluid volume to be relatively constant in young adults to about age 40; then it begins to increase, especially after age 60. The brain, which occupies more than 90% of the cranial cavity between ages 20 and 50, occupies progressively less after age 50. In older adults, then, there is a significant decrease in brain-to-cranium volume and an increase in cerebrospinal fluid volume of about the same magnitude. Regional decrements in brain volume have been reported in frontal and temporal lobes, cerebral cortex, basal ganglia, corpus callosum, and hippocampus.

Microscopic Anatomy of the Aging Brain

Neuronal Death

At a microscopic level, decrements in numbers of neurons with age are well documented but not without controversy. Neuronal loss does not occur uniformly throughout the brain but occurs in selected areas, and is often difficult to evaluate because of technical limitations. These include methodological limitations of microscopic morphometry, uncertainties in differentiating neuroglia and neurons, transient neuronal atrophy as a result of which some neurons cannot be seen with a conventional light microscope. Nonetheless, in humans decreases of 15 to 57% are reported in cerebral cortex from selected gyri of the frontal, temporal, parietal, and occipital lobes, and comparable decrements are reported for locus ceruleus, substantia nigra, cerebellar Purkinje cells, and hippocampal pyramidal neurons. Neuronal loss can be regionally specific, as in the hippocampus where significant loss is reported in area CA4 and the subiculum, but not in the dentate, CA1, or CA2. Neuronal loss in the human nucleus basalis of Meynert is less certain and still less certain in other regions, although seemingly reliable decrements are reported in rodents. Decreases in the number of

synapses and perhaps in the number of dendrites are other morphometric indicators of neuronal malfunction in the aged brain. Like neuronal loss, they too may be better documented in laboratory animals than in the human brain.

Neuronal Injury

The metabolic failure of neurons and neuronal systems in old age need not require actual loss of neurons, neurites, or synapses. Neuronal atrophy and hypertrophy have both been reported as characteristics of aged neurons. Neuronal atrophy in the nucleus basalis of Meynert has been described in some rodents. In other rodent strains and in old humans these cholinergic neurons appear to hypertrophy. Neuronal atrophy in the infundibular nucleus in older men and postmenopausal women has been ascribed to the loss of steroid negative feedback. Other indications of compromised neuronal function might include the accumulation of lipofuscin and neuromelanin. Although there is no convincing evidence that the accumulation of these substances is neurotoxic, the accumulation of lipofuscin has the appearance of crowding out organelles involved in synthesis and transport, and neuromelanins can bind potential toxins such as 1-methyl-4-phenylpyridine.

Age Changes in Neurotransmitters

Morphometric changes (see above) indicate changes in the aged human brain in neurotransmitters and in interneuronal communication. There is, for example, a well-documented central cholinergic deficit in animals. In humans, deficits in choline acetyl transferase activity are reported in hippocampus, entorhinal cortex, frontal cortex, and cerebellum, and a decreased density of cholinergic fibers in amygdala has been found in older adults. Relatively little is known about cholinergic receptors, especially nicotinic receptors in the aged brain. However, muscarinic receptors appear to be decreased in the human brain, and significant decrements are reported in cerebral cortex and striatum and hippocampus in old rodents. Changes in noradrenergic and seratonergic transmission are not well defined. Norepinephrine is reportedly reduced in the aged human brain, and dopamine may be reduced in the caudate nucleus. However, in more adequately controlled studies, norepinephrine and dopamine turnover are reportedly unchanged, whereas seratonin turnover is increased in old rats. Reduced regional seratonin concentrations with no accompanying decrease in 5-hydroxy indoleacetic acid levels have been found in aged human brains. These are believed to result from decreased metabolism of the indolamine precursor, coupled with a compensatory increased metabolic activity in surviving terminals that maintains functionally normal levels of the transmitter in nerve terminals. Glutamergic function appears to be relatively stable in old age.

Age Changes in the Neuronal Microenvironment

Although they remain unexplored in the elderly human brain, changes in the extracellular neuronal microenvironment with age, which are primarily known from animal studies, can reasonably be predicted to effect neuronal aging in humans (*see* Models of Aging: Vertebrates). Their functionally important relationships with age changes in neurotransmission are outlined in **Figure 1**. The neuronal microenvironment consists, primarily, of vascular elements and extracellular space, all of which appear to change with age. A decreased extracellular space, demonstrated in the brains of old rats, may serve to limit the diffusion of metabolites and, perhaps, transmitter substances in the aged brain. Age changes in

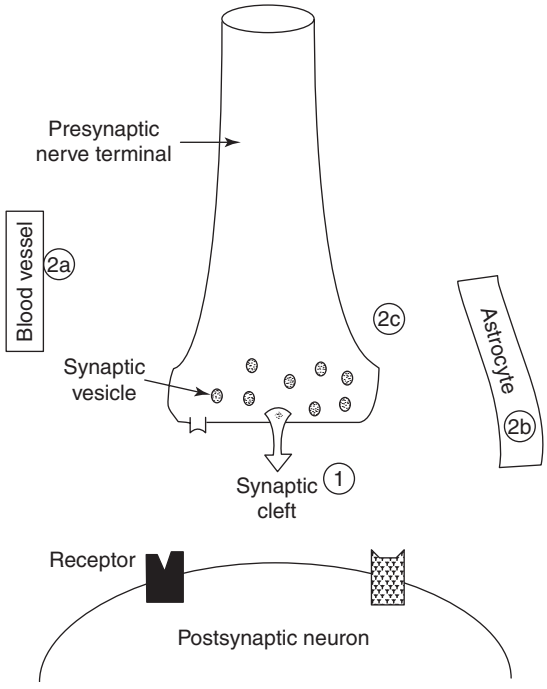

Figure 1 Age changes in the brain include (1) selective decrease in the amount of neurotransmitter substance available for neurotransmission and decrease in certain receptors, and (2) changes in the neuronal microenvironment, such as endogenous changes in the cerebrovasculature (a), astroglia (b), and extracellular space (c) that compromise neuronal nutrition and interfere with the interaction between transmitter substances and receptors.

the extracellular space have barely been investigated in the human brain. Changes in the cerebral vasculature are legion, but changes in the human brain microvasculature with age are poorly understood. Changes due to aging in cardiovascular tissues add to changes due to degenerative diseases in the same manner as age changes add to changes resulting from neurodegenerative diseases. Aging, thereby, accelerates vascular degenerative diseases with the result that systolic blood pressure and low-density lipoprotein (LDL) cholesterol increase with age and older persons are at increased risk for cerebroischemic vascular disease. Changes of vascular tissues due to aging include the decreased production of endogenous vasodilatory agents and alterations in the structure and distribution of collagen, elastin, and glycosaminoglycans. The effects of these changes on the aged brain are unknown, but likely sequelae of such changes would include interference with neurotransmission and myriad disturbances in neuronal metabolism.

It can be anticipated that age changes in the microvasculature might affect electrolytes mediating neuronal electrochemical activity. Although no changes in Na^+/Ca^{2+} exchange activity and Ca^{2+} permeability were found in a study of human frontal cortex, studies of rodent brain do reveal age changes in inositoltriphosphate receptor Ca^{2+}-release channels and calcium-mediated after-hyperpolarization. Adenylate cyclase activity, oxidative phosphorylation, mitochondrial electron transport mechanisms, and DNA metabolism all appear impaired in old rodent brains. Changes such as these, if not reflective of programmed changes in the neuronal genome, may reflect age changes in the neuronal microenvironment. It is unknown whether such changes, whatever their origin, are of sufficient severity to abolish such dynamic neuronal functions as those involved in synaptic plasticity.

The role of astroglia in the process of aging remains unclear. Astrocytic end feet contribute to the neuronal microenvironment in that they help separate neuronal and extracellular (vascular channels and extracellular space) elements. They contribute to the isolation of synaptic complexes, such as represented by cerebellar glomeruli. They can occupy space resulting from the loss of neurons and segregate pathological materials, such as degenerating extracellular neurofibrillary tangles. Astrocytes express apolipoprotein E and probably produce neurotrophic factors. They may play a role in neuronal metabolism and assist the plastic neuronal response to injury by facilitating nutrient transport. Hypertrophy of the astrocytic compartment with no accompanying increase in the number of astrocytes in old age has been demonstrated in rats, but it is not known how this might aid or inhibit processes associated with aging.

Neuronal Plasticity in the Aged Brain

Axons are regenerated more slowly in old animals, but neurons in aged brains retain the capacity for synaptic plasticity. They react to the effects of trauma or metabolic insult by replacing lost synapses with new ones, although the regenerative process may be delayed in old animals. As long as there is accurate replacement of lost connections, neuronal plasticity appears to be a continuous dynamic process underlying the capacity to form and destroy circuits continually as new material is learned or forgotten. However, aberrant axonal sprouting or erroneous replacement of synapses can also lead to faulty circuitry and environmentally non-adaptive behavior. It is unclear how much of this neuronal plasticity depends upon the presence of nerve growth factors (NGF), as NGF has been shown to improve performance on spatial memory tests when injected into the region of the nucleus basalis of Meynert in aged rats. The expression of NGF appears to be preserved in old age.

Neuropathology of Aging

A number of changes characteristic of specific neuropathological disorders are found in the aged human brain, but in smaller numbers or attenuated form. Atrophic changes in gross structure such as ventriculomegaly and sulcal widening, which are characteristic of neurodegenerative diseases often associated with dementia, are found in non-demented, apparently normal elderly persons. Although some persons showing MRI signs of cortical atrophy may be cognitively impaired, some may not be, and there is no convincing evidence that such findings herald the later development of a progressive dementing disorder. The demonstration by MRI of numerous, voluminous lesions in the periventricular white matter is, similarly, usually associated with neuropathology, although the presence of lesions of lesser number and amount is a common finding in old people who show no significant cognitive impairment, are not demented, and may never develop a dementing disease (*see* Dementia).

Microscopic neuropathological changes often found in the aged human brain include senile plaques, β-amyloid (BA) deposits, neurofibrillary tangles, and granulovacuolar degeneration complexes. These may be more numerous in the hippocampus, but they occur throughout the brain in old

age in smaller numbers. Again, their presence may be associated with impaired cognition or psychopathology, but in many cases there is no apparent pathology and no abiding evidence that such lesions represent an early stage or attenuated form of a progressive dementia such as Alzheimer's disease.

Neurofibrillary tangles and senile plaques, when they are found in non-impaired, apparently normal older adults, may be indicators of pathological aging. This refers to the presence of abnormal findings that hasten or intensify the process of what is conventionally termed normal aging. The concept of pathological aging is illustrated by a recent study of demented older adults in whose brains it was possible to demonstrate cytoplasmic structures containing ubiquitin-bound protein. These microscopic-size structures, called Lewy bodies, are characteristic findings in Parkinson's disease and a non-Alzheimer's disease dementia. They were found in the cerebral cortex unaccompanied by plaques and tangles in very few cases in which dementia was mild. They occurred more frequently in addition to abundant senile plaques and neurofibrillary tangles with more severe dementia. It can be assumed that the presence of abnormal aging will intensify the effects of a neurodegenerative disease and vice versa.

Senile plaques consist of dystrophic neurites and BA protein. The dystrophic neurites contain an abnormal form of tau protein that is aggregated so as to form paired helical filaments (PHF). These PHFs are further aggregated to form the neurofibrillary tangles occasionally found within pyramidal neurons or found extracellularly in the hippocampus in non-demented older adults. They are rarely found in the cerebral cortex in older, cognitively normal adults. Normal tau protein is not aggregated in PHFs but bound to tubulin in microtubules that are, thereby, stabilized and able to participate in intraneuronal transport. Abnormal tau protein, presumably because it is hyperphosporylated, is unable to bind with tubulin, which destabilizes microtubules and disrupts transport systems. There is evidence of slowed septalhippocampal axonal transport of glycoproteins in old rats, but the underlying mechanism is unknown. It is not known if the presence of abnormal tau protein in the hippocampus or other parts of the aged human brain plays any role in the delay of intraneuronal transport or in the dysfunctional cognition that occurs typically in older adults.

A second abnormal protein, βA, which is found in the core of senile plaques and in diffusely distributed extracellular collections, has been shown to be cytotoxic to cells *in vitro* under some conditions that are not fully defined. As it occurs in the aged brain in the extracellular space, often closely associated with blood vessels, it may interfere with the transport of ions, transmitter substances, and metabolites through synaptic clefts and the perineuronal extracellular space. It seems unlikely that the overexpression of amyloid precursor protein, from which abnormal βA protein is derived, results in the accumulation of βA in apparently normal older adults in small amounts, or in large amounts in Alzheimer's disease. It seems unlikely, also, that the formation of abnormal tau protein results from the overexpression of tau protein-related genes. The accumulation of both abnormal proteins in apparently normal old persons and in victims of Alzheimer's disease appears to be post-translational.

Cancer and Age

M L Freedman and M L R Nierodzik, School of Medicine, New York University, New York, NY, USA

Published 2007 by Elsevier Inc.

Glossary

Apoptosis – Cell death.

Growth Factors – Proteins that regulate the cell, functioning by binding to specific receptor molecules in the cell membrane and stimulating receptor-mediated activation of intracellular signal transduction pathways.

Incidence – Number of persons developing cancer in a unit of time divided by total population living at that time.

Intra-epithelial Neoplasia (also called dysplasia, atypical hyperplasia, atypical proliferation, and carcinoma in situ) – Lesions that predispose a person to develop cancer.

Oncogenes – Damaged versions of normal genes that control cell growth and differentiation.

Prevalence – Number of persons with a cancer at a given point in time divided by total population living at that time.

Introduction

Cancer is the second leading cause of mortality after heart disease and the leading cause of death among women ages 40 to 79 and men ages 60 to 79. Within the 65+ age group, the population 85 years and older is projected to double from 4.3 million in 2005 million by 2030. Life expectancy has increased. More people are treated successfully after a cancer diagnosis, resulting in a greater prevalence of the elderly living with or developing cancer. It is important for all professionals dealing with the elderly to understand what the disease is and how to deal with it. In the past, the elderly were denied treatment because they were considered 'too old.' We now know that in many instances the elderly do as well or better with cancer treatments than the young. This article reviews the causes and biology of cancer, possible ways of preventing it, clinical descriptions of some of the common cancers, how to screen for cancer, and new targeted treatment options.

Cancer may be defined by the four characteristics that describe how cancer cells behave differently from normal cells:

1. Cancer usually begins from a single cell that proliferates to form a clone of malignant cells.
2. Cancer cells grow autonomously, are not regulated by the normal controls, and do not die appropriately via programmed cell death (apoptosis).
3. Cancer cells do not differentiate in a normal coordinated manner and do not look the same as the normal cells surrounding them.
4. Cancer cells develop the capacity for discontinuous growth and spread to other parts of the body (metastasis).

Cancer is also called malignant neoplasm. This implies that the growth is a new growth (neoplasm) that if unchecked will kill the host (malignant). Normal cells can express some of the preceding properties at certain appropriate times, such as in wound healing, embryogenesis, organ repair and regeneration, and revascularization, but the proliferation is coordinated, orderly, and self-limited. In cancer, however, these characteristics are excessive, disordered, and not self-limited, resulting in an inappropriate proliferation (tumor burden) and spread that is inappropriate to the host and that has morbid implications if not successfully treated.

Cancer traditionally was classified as being either a carcinoma or a sarcoma named for the presumed cell of origin: epithelial (carcinoma) or mesenchymal (sarcoma). Recent evidence has demonstrated that most if not all neoplasms arise from immature stem cells that then differentiate along normal cell lines, but mutate and acquire the properties of autonomous growth as described previously. We now realize that carcinomas of the lung, breast, and stomach do not arise from well-differentiated 'normal' cells in these organs but

from stem cells that begin to differentiate in the direction of these tissues but then become autonomous and have impaired apoptosis. These cells lose their normal self-limiting capacity and acquire properties that allow them to enter the circulation and spread to other organs. These cancer cells are the 'seed,' and if other organ's 'soil' supports their growth, metastases grow distant to the primary site. Cancers of the lymphatic system or blood-forming cells are termed hematopoietic malignancies. Lymphoma, leukemia, and multiple myeloma are the most common of the hematopoietic malignancies. Thus, a neoplasm is usually named by what the cells resemble and where they arise. A cancer of the lung implies that the cells resemble lung cells and arise in that organ. An osteosarcoma resembles bone cells and is found in bone. Leukemia resembles white cells and is found in the bone marrow. It is still useful to classify cancer cells as a carcinoma, a sarcoma, or hematopoietic, as there are specific tumor markers (proteins on the cell surface) that are present on the tumor cells and that can be detected by the pathologist using different immunohistochemical staining techniques. The treatment depends on the cell of origin.

The traditional classification of neoplasms (new growths) divides them into benign and malignant types. These characteristics are determined by the predicted behavior of the tumor rather than by the microscopic morphology. The term malignant refers only to tumors that metastasize. Since there are some malignancies that are very slow-growing and late to metastasize, a new term is used to describe their propensity – borderline, intermediate, or undetermined.

Microscopic grading is another way of classifying tumors in an attempt to predict if the neoplasm is one that is slow growing, rarely metastasizes, and is highly curable, or if it is one that is fast growing, often metastasizes, and is rarely curable. The criteria used in microscopic grading include cellularity, pleomorphism, mitotic activity, type of margins, amount of matrix formation, and the presence of inflammation necroses and hemorrhage. Most often, the three-grade system is used: grade 1 (well-differentiated), grade 2 (moderately differentiated), and grade 3 (poorly differentiated or undifferentiated). The lower the grade, the more likely that the person with the tumor will survive. The stage of the tumor is used to determine the amount of spread; it is usually graded from I to IV. Stage I usually represents limited disease in one location, stages II and III indicates growth and spread specific to the organ system involved, and stage IV indicates spread to other organs. The prognosis usually depends upon stage and grade. Although stage and grade usually parallel each other, small high-grade tumors may be more dangerous to the host than larger lower-grade tumors.

Prediction of prognosis has been enhanced by the newer technology of gene chip arrays, which look at the molecular signature of tumors correlated with clinical data to predict prognosis. There have been several reports showing correlation of gene signatures with outcome. This may allow oncologists to design treatment based on the aggressivity of the tumor. For example, women with stage I breast cancer have a 70% chance of 5-year survival without adjuvant chemotherapy. This number increases to the 80th percentile with chemotherapy, but this also means that many women may not need adjuvant chemotherapy at all. As of mid-2005, there is no clear way to predict who does. Most women with tumors greater than 1 cm with a good performance status may be offered chemotherapy. There are multiple ongoing clinical trials to test the use of DNA chips to help determine therapies for lymph node-negative breast cancer patients and multiple other cancers. These will test whether genetic 'profiling' (a snapshot of a patient's genetic makeup with respect to relevant genes) is more effective than standard histopathological and clinical criteria in predicting which patients will develop metastatic disease.

Finally in terms of classification, there are some lesions that predispose the person to develop cancer, usually a carcinoma. Because cancer is a multistep process, what is seen microscopically are the various steps before a full-blown malignancy develops. These have been called dysplasia, atypical hyperplasia, atypical proliferation, and carcinoma *in situ*. Since these terms have been used in a confusing manner, it is probably safer to designate these lesions as intraepithelial neoplasia. Using this term plus a grading system to indicate varying degrees of severity probably is the most reasonable way to determine propensity to develop a full-blown malignancy and helps in directing therapy.

Epidemiology of Cancer

Cancer occurrence in a period of time for a given population is expressed in various ways (**Table 1**). The incidence rate is a direct measure of the probability of developing cancer and is usually expressed per year. Incidence rates may be crude (all ages) or age specific. Since cancer is very age dependent, age-specific rates are usually more informative. When comparing population groups with different age distributions (such as the United States vs. China), the incidence rate should be age adjusted by multiplying each age-specific rate by the percent of individuals in a population with the same ages and

Table 1 Measures of cancer frequency

Incidence	$\frac{\text{Number of persons developing cancer in a unit of time}}{\text{Total population living at that time}}$
Prevalence	$\frac{\text{Number of persons with a cancer at a given point in time}}{\text{Total population living at that time}}$
Mortality (death) rate	$\frac{\text{Number of persons dying of cancer in a unit of time}}{\text{Total population living at that time}}$
Case fatality rate	$\frac{\text{Number of deaths from cancer} \times 100\%}{\text{Number of persons developing cancer}}$

then summing these to produce a single value. For etiological studies, incidence rates tend to be more informative than mortality rates, as they identify all diagnosed cases.

In contrast, the prevalence rate is not usually used to study etiology, but is useful to plan health services, as it measures the burden of disease in the population. The mortality (death) rate gives us information as to which cancers are most lethal. Since this rate is derived from death certificates, it may often be inaccurate. However, it is useful to evaluate the impact of cancer prevention and treatment on the general population. The case fatality rate is a measure of the severity of the disease and is usually expressed as a percentage. This number is least useful in chronic cases, as it is expressed per unit of time. In chronic cases, it is more useful to express the survival rate per 5 or 10 years.

Patterns of Cancer Occurrence

Cancer is currently the number two killer, second only to heart disease, in the United States. It is responsible for over 22.8% of all deaths (2002 statistics). Cancer is the leading cause of death among women ages 40 to 79 and men ages 60 to 79. Cancer is mostly a geriatric illness: as the population ages, more and more people will be afflicted with and potentially die from this disease. Most epithelial cancers are rare under the age of 30, but the incidence rises with age. **Table 2** lists the major forms of cancer, the estimated number of new cases, and the case fatality rates. There are marked ethnic variations in cancer incidence as well as differences between men and women.

Table 3 shows the marked differences between men in age-adjusted incidence rates for men of selected cancer sites between Whites, Blacks, and Hispanics in the United States. In **Table 4**, similar data are shown for women. These differences suggest that there are genetic factors in the development of cancer; there are also differences in socioeconomic classes. Overall, the lower the socioeconomic class, the higher the cancer rate. This might reflect differences in the use of tobacco, nutritional status, and exposure to carcinogens. This may also explain some of the differences in Black to White to Hispanic cancer incidence.

Clusters of cancer have been found in various geographical regions and in people of similar occupations. These types of studies have been useful in identifying potential environmental risks. There are also striking international variations in incidence by geographical location that is associated

Table 2 Estimated number of new cases and case fatality rates of major cancers in the United States, 2005[a]

	Number of new cases	*Case fatality rate (%)*
All sites	1 372 910	41.5
Lung	172 570	94.8
Colon and rectum	145 290	38.7
Breast (excluding intraepithelial neoplasia)	212 930	19.2
Prostate	232 090	13.1
Urinary tract	101 880	26.1
Uterus (excluding cervical intraepithelial neoplasia)	51 250	21.5
Oral cavity and pharynx	29 370	24.9
Skin (excluding basal cell and squamous)	66 000	16.1
Pancreas	32 180	98.8
Leukemia	34 810	64.8
Ovary	22 220	73.0

with exposure to known risks in the environment, by lifestyle, or by genetic predisposition. For example, hepatocellular carcinoma is a common cancer in countries where hepatitis B is endemic, and transmission is often transplacental (mother to child) but rare in populations with low exposure. Prostate and colorectal cancer are common in developed countries and less common in developing countries. This phenomenon has been epidemiologically linked to high-fat, low-fiber diets.

Possible Causes of Cancer

The epidemiological approach has made it possible to identify lifestyles and other environmental exposures as causes of cancer.

Tobacco

Tobacco smoking is the number one risk identified to date. Smoking has long been linked to cancer of the lung, oropharynx, nasopharynx, larynx, esophagus, bladder, kidney, uterus, cervix, colon, pancreas, and leukemia. It is estimated that smoking cigarettes accounts for 40% of cancer deaths in men and 20% in women, with lung cancer being the most common type. For smokers of two or more packs per day, the risk of lung cancer is 20 times that of non-smokers. In addition, smokeless tobacco and passive exposure to smoking also increase the risk of developing cancer.

Alcohol

Consumption of alcohol potentiates the effect of smoking in cancers of the mouth, pharynx, esophagus, and larynx and is estimated to account for 3% of cancer deaths. Alcohol might also potentiate other carcinogens. In the most recent Surveillance, Epidemiology, and End Results (SEER) data there was a decrease in alcohol-related cancers in the United States. The effect of quitting alcohol and tobacco is a 70% reduction in esophageal cancer within 5–9 years.

Environmental Pollutants

The workplace also exposes people to various carcinogens, and it is estimated that 5% of all cancer deaths result from this exposure. Asbestos is the major occupational carcinogen, as it causes both lung cancer and the rarer mesotheliomas. Smoking is synergistic with asbestos, as smokers exposed to asbestos have a far greater chance of developing cancer than non-smokers. Other examples of occupational risks include benzene causing leukemia, radiation-induced cancers, aromatic amines causing bladder cancers, inorganic arsenic causing lung, skin, and liver angiosarcoma, and vinyl chloride causing angiosarcoma.

It has been difficult to ascertain how important environmental pollution is in causing cancer. It is thought that it is relatively uncommon and that only 2% of cancer deaths are caused by environmental pollution. Certainly smokers are at greater risk of developing cancer than non-smokers exposed to the same atmosphere. Some of the risks identified include asbestos, airborne arsenic, cooking oil vapors in wok cooking in China, and effluents from coal heating stoves.

Radiation

Ionizing radiation is another well-studied carcinogen. It has long been known that radiologists, survivors of the atomic bomb in Japan, and patients receiving radiation therapy are at increased risk of developing cancer. Nearly all the sites of the body are vulnerable to radiation, with the most sensitive being bone marrow, breast, and thyroid. It is not clear how much, if any, risk comes from diagnostic X-rays or background atmospheric radiation over long periods of time.

Ultraviolet radiation from the sun is the major risk factor for all skin cancers (squamous cell, basal cell, and melanoma). Skin cancers usually develop on sun-exposed areas and are more common in outdoor workers and fair-skinned individuals. Very high rates of skin cancers occur in people who have genetic illnesses exacerbated by sunlight (xeroderma pigmentosum and albinism). The offending UV radiation appears to be in the UV-B spectral range (290–320 nm). It is believed that depletion of the ozone layer has led to greater amounts of UV-B radiation reaching the earth's surface.

Medications

It is estimated that about 2% of cancers arise from exposure to pharmaceutical medications. There is evidence that conjugated estrogens taken after

menopause increase risk of developing endometrial cancer of the uterus and possibly breast cancer. Estrogens have also been implicated in causing vaginal and cervical cancer in daughters of women treated with this hormone during pregnancy. The combination of estrogens and progesterone in postmenopausal women seems to decrease the risk of cancer of the uterus when compared to unopposed estrogen therapy.

Other medications causing cancer include alkylating agents inducing non-lymphocytic leukemia and immunosuppression drugs causing non-Hodgkin's lymphoma.

Drugs are not always a negative; there is evidence suggesting that non-steroidal anti-inflammatory agents and aspirin protect against cancer of the colon.

Viruses

Viruses have been implicated in causing some cancers throughout the world. In the United States, it is estimated that 5% of all cancers are related to viruses. Epstein-Barr virus (EBV) probably causes endemic Burkitt's lymphoma in Africa and nasopharyngeal carcinoma in China. Hepatitis B virus (HBV) in Asia and China is associated with hepatocellular carcinoma; human T-lymphotropic virus type I (HTLV-1) is linked to adult T-cell leukemia in Japan and the Caribbean. Human immunodeficiency virus (HIV), which causes AIDS, is associated with lymphoma. Kaposi's sarcoma in homosexual men is probably related to both HIV and herpes simplex virus 8 (HSV8). Human papillomavirus is associated with cancer of the cervix, anus, vulva, vagina, and some cancers of the oropharynx and is sexually transmitted. Other potential virus-induced cancers include childhood leukemia and Hodgkin's disease (possibly EBV).

Diet and Nutrition

While diet and nutrition seem to be a very important factor in the high incidence of cancer in Western countries, the specific dietary components that either cause or protect against cancer remain unknown. High dietary fat intakes have been implicated as risk factors in colon and breast cancer. High-fiber diets seem to protect against cancer of the colon. Vitamins and other micronutrients may also be protective, such as carotenoids against cancer of the lung, vitamin C against gastric cancer, indole compounds in cruciferous vegetables against colon cancer, allyl sulfide in onions and garlic against gastric cancer, vitamin D and calcium against colon and breast cancer, and selenium and vitamin E against gastric cancer. In addition, certain dietary factors may cause cancer. For example, aflatoxin (a metabolite of the fungus *Aspergillus flavius*) contaminating foods such as peanuts is linked to liver cancer, salted foods are related to gastric cancer, and nitrosamine is linked to nasopharyngeal carcinoma.

Genetic Susceptibility

Genetic factors seem to play some role in the development of cancer, but it has been difficult to determine how much is due to genes as opposed to environmental and ethnic differences. For example, nasopharyngeal cancer in Chinese could result from a genetic predisposition, EBV virus exposure on a particular genetic background, or a propensity to eating salted fish with high nitrosamine levels. In any event, genetic factors are very important in skin cancer. The darker the skin, the less likely one is to develop skin cancer. An example of how complicated this area is may be seen by looking at cancer of the lung. Most smokers do not develop lung cancer, but if a person has the genetic makeup to rapidly oxidize certain drugs, the risk of developing smoking-related cancer of the lung is much higher. This could be the result of metabolizing various compounds to active carcinogens.

There are more than 200 single-gene disorders linked to neoplasia. These make up a very small fraction of cancers associated with rare syndromes. Genetic testing may be offered to the patient with cancer and their families in cases in which a well-defined inherited cancer syndrome may exist and early screening or other medical intervention may be useful. When syndromes such as familial adenomatous polyposis (FAP), multiple endocrine neoplasia (MEN), retinoblastoma, von Hippel-Lindau (VHL), hereditary breast/ovarian cancer syndrome (BRCA1, BRCA2 mutations), hereditary non-polyposis coli syndrome (HNPCC), and Li-Fraumeni syndrome are suspected, patients should be referred to a genetic counselor. Although cancers tend to occur early in most of these syndromes, elderly patients in the proper clinical setting should be screened, as this information is useful for other family members to plan early screening to prevent development of malignancy. It is necessary to test the proband (individual with the disease) as there may be specific mutations associated with these syndromes in different families or ethnic groups, but there may also be polymorphisms (a common variation; a non-deleterious mutation in DNA).

Principles of Carcinogenesis

The classical view of carcinogenesis was that it was a two-'hit' process – initiation (genetic) and promotion

(epigenetic). However, this is too simplistic and it is now realized that there may be six or more independent genetic mutational events. The newer theory of carcinogenesis is that it is a multistage process driven by both genetic damage (initiation) and other cellular changes (promotion). Tumor initiation begins in cells through genetic mutations that may be caused by chemical carcinogens, viruses, and physical agents. These mutated cells respond differently to their environment and have a selective growth advantage. The newly initiated tumor may be less responsive to negative growth factors, terminal cell differentiation, or programmed cell death (apoptosis). The initiated tumor cells will grow (or expand; 'clonal expansion') if there is physical disruption of the cells' normal microenvironment outside of genetic damage. This stage, promotion, also occurs from chemicals, viruses, and physical agents and results in further selective clonal expansion and proliferation of the initiated cells. The tumor promotion stage, while resulting in proliferation, will also cause further genetic mutation either by increasing cell proliferation or by the nature of the promoting agent (virus, chemical, physical) itself.

As the cells continue to proliferate with repeated genetic changes such as activation of proto-oncogenes, inactivation of tumor suppressor genes, and inactivation of antimetastatic genes, the tumor will transform into a malignancy. This multistage theory of carcinogenesis helps explain why the elderly are so susceptible to cancer. Time is an important element in carcinogenesis, as it takes multiple 'hits' to change a cell into a malignancy. The hits are both genetic and epigenetic, which explains why one may also need multiple risk factors. Thus, the elderly person has been exposed for years to various potential chemical, physical, and viral carcinogens.

Cancer Prevention

Diet and Exercise

Animal studies support a cancer-promoting role for fat, and in humans, epidemiological data strongly suggest that dietary fat intake may be associated with incidence and mortality of cancers of the breast, colon, rectum, and prostate. There are also data implicating fat in cancers of the ovaries, uterus, pancreas, and lung, but the evidence is not as strong. There is still a debate as to whether it is total dietary fat, specific fats, or total calories that are involved in carcinogenesis. In any event, cancers of breast, colon, and prostate are highest in North America and western Europe and lowest in Asia, and are directly related to the intake of total fat in the diet even when adjusted for total calories.

Increased saturated fat intake is associated with an increased incidence of breast, colon, and prostate cancer. High total polyunsaturated fats seem to increase the incidence of breast and prostate cancer. High fiber intake reduces cancer incidence, particularly for colon cancer. In countries where there is a high olive oil intake (a monounsaturated fat), breast cancer is less prevalent. Certain fats, such as the longer chain, highly polyunsaturated omega-3 fatty acids, such as those found in fish, offer protection against cancer. For example, Inuit who consume large amounts of fat from fish are at low risk of developing cancer, including breast cancer.

Migrant group studies show that as the migrants' diet switches to one more typical of the new country in terms of fat intake, the cancer rate also increases to that of the new country. For example, major increases in breast, prostate, and endometrial cancer incidence occurred among four immigrant groups in Hawaii – Chinese, Japanese, Filipinos, and Whites. When studies were done over time in Japan, it was found that from 1957 to 1973 the fat in the diet doubled, as did the total number of breast cancer deaths.

High fat intake also seems to be associated with colorectal cancer. Most studies support the role of saturated fat in carcinogenesis rather than polyunsaturated fat or monounsaturated fats. There have been other studies that implicate high beef and other animal protein intake.

In other cancers, such as prostate, ovary, pancreas, and lung, there may also be a connection with fat. However, studies on this possible connection had methodological problems and are far from conclusive. Most experimental animal studies have suggested that dietary fat acts as a cancer promoter, but there is also some evidence that it may be an initiator as well. It may be that fat acts by changing cell membrane characteristics or by changing the neuroendocrine system. With cancer of the colon, it has been postulated that fat influences the metabolic activity of fecal microflora and the concentration of sterol substrates in the colon. As a consequence, secondary bile acids, which are carcinogens, form in the colon.

The problem with the fat hypothesis is that the dangers of fat may result from childhood eating patterns. Similarly, it is not clear whether modification of the diet in adulthood or in the later years is of benefit. Furthermore, it is difficult to separate dietary fat from calories. Diets high in fat tend to be associated with obesity. The syndrome of insulin resistance in obese individuals raises

circulating insulin levels that may directly cause susceptible tissues to give a growth signal or may act through induction of potent growth factors such as insulin-like growth factor 1 (IGF-1). Obesity could conceivably be the risk for breast and endometrial cancer by raising estrogen levels through peripheral conversion by aromatase inhibitors. Caloric intake is inversely related to physical activity, and obese people usually do not exercise as much. Regular exercise appears to lower the risk for cancer, particularly breast, colon, and ovarian cancer. Studies have shown that even when breast cancer has occurred, women have a lower recurrence rate and live longer if they adopt a low-fat diet and exercise.

Fiber

A diet low in dietary fiber is associated with high cancer rates. Burkitt was the first to suggest that the low rate of colon cancer in Africa resulted from high fiber intake and large stool bulk. Non-starch polysaccharides, as found in fruits and vegetables, are the type of fiber that seems to correlate best with low cancer incidence.

Micronutrients

Since fruits and vegetables are high in micronutrients, it may be that it is not just fiber but also these micronutrients that protect against cancer. Cancer of the lung seems to be lower in populations that have a high beta carotene intake; other carotenoids may also be involved. Vitamin C may protect against certain cancers such as gastric cancer by blocking formulation of nitrosamines. Indole compounds found in cruciferous vegetables may decrease colon cancer, and allyl sulfide in garlic and onions may lower the risk of gastric cancer. It has been suggested that high calcium and vitamin D intake protect against colon and breast cancer. Selenium appears to protect against gastric, esophageal, and prostate carcinomas. Vitamin E and folic acid also may play roles in protecting against cancer. One cautionary note is that although a diet high in fruits and vegetables may be beneficial, it is not clear whether supplements give the same benefit. In a large Finnish placebo controlled trial looking at the effect of daily supplementation with vitamin E, beta carotene, both, or placebo on the incidence of cancer development in smokers showed no risk reduction with vitamin E and, unexpectedly, a higher incidence of lung cancer in those receiving beta carotene. The SELECT trial (Selenium and Vitamin E Cancer Prevention Trial) is a research study currently accruing patients to determine if selenium and vitamin E can help prevent prostate cancer.

There are also concerns that various food additives and contaminants are carcinogenic.

Exogenous Hormones

Taking exogenous hormones may increase the incidence of certain cancers. Estrogens have been implicated in uterine cancer and possibly in breast and ovary cancer. Testosterone is involved in cancer of the prostate. Certainly in people taking hormonal replacement, screening procedures for the cancers are essential.

Alcohol

High alcohol intake is associated with cancers of the oral cavity, pharynx, esophagus, and larynx, particularly in people who smoke. A smaller risk seems to exist between alcohol and liver, rectal, pancreatic, and breast cancers. A safe recommendation is to limit the intake of alcohol to moderate amounts such as one to two drinks per day.

Tobacco

Tobacco smoking is the most modifiable carcinogenic risk. Smoking is firmly linked to cancer of the lung, larynx, mouth, pharynx, esophagus, bladder, and pancreas. It also seems that smokers are more likely to develop cancer of the kidney, cervix, nose, stomach, and leukemia. The anti-smoking campaign in the United States and other countries is directly aimed at this problem.

Cancer prevention, in summary, currently emphasizes cessation of smoking, limiting alcohol intake, modifying diet to include avoidance of obesity, decreasing fat intake, increasing fiber, particularly fruits and vegetables (to a minimum of eight servings a day), consumption of whole grains, and avoidance of food additives and contaminants. Whether or not additional micronutrients should be added to our diet is being studied. Regular exercise during most days of the week for at least 30 min is also recommended.

Molecular Biology of Cancer

Gene Regulation

The sequencing of the human genome was begun in 1990 and completed in 2003. The International Human Genome Sequencing Consortium (2004) reduced the estimated number of human protein-coding genes from 35 000 to only 20 000–25 000. Each cell in the body contains the same genetic material, but only a few genes are expressed in each cell, which determines its phenotype. A gene consists of deoxyribonucleic acid (DNA). The gene will

transcribe a ribonucleic acid (RNA). In the nucleolus the RNA transcribed is ribosomal RNA (rRNA), and in the nucleoplasm the RNA transcribed is messenger RNA (mRNA) and transfer RNA (tRNA). The DNA gene acts as a template to form RNA.

Through a process called translation the cell forms protein. In this process, mRNA serves as the information source, and ribosomes move along the mRNA, adding amino acids carried by specific tRNAs to the growing peptide. At the end of this process, the newly formed protein is released and undergoes post-translational modifications necessary for function of the protein. Both transcription and translation are exquisitely controlled by a large array of cellular factors, which in turn are products of gene regulation, transcription, and translation. These factors regulate gene expression and ultimately determine what the cell will manufacture, how it will grow and function, and how long it will live. If these controls are disturbed, the cell will not grow and differentiate normally; the ultimate disarray is cancer.

Spontaneous human cancers arise from a series of somatic genetic cellular changes caused by abnormal deletions, rearrangements, amplifications, or point mutations. These DNA changes result in failure to regulate transcription and thereby disorder translation. The cell, therefore, becomes cancerous.

Oncogenes

Oncogenes are damaged versions of normal genes ('proto-oncogenes') that control cell growth and differentiation. It is important to realize that a proto-oncogene is a normal gene; it is only through pathological processes that it becomes an oncogene. Cancer is a multistep process in which multiple genetic alterations must occur, usually over many years. Thus, only after a long span of time will cell differentiation, division, and growth be changed. In human cancers, inherited mutations are relatively rare. Most oncogenes are acquired in the form of chromosomal translocations, deletions, amplifications, inversion, or point mutations. Oncogenes may act as transformers of cells and therefore act as positive regulators of growth. Oncogenes may also arise from normal genes that suppress tumor growth (recessive oncogenes). In this situation, the alteration results in lack of uncontrolled cell division and growth.

Oncogenes have been identified by studying transforming retroviruses and common sites of retroviral insertion, study of the transforming genes in DNA tumor viruses, DNA-mediated gene transfer in cell culture, identification of genes at translocation breakpoints in human cancer, and isolation of tumor suppression genes in chromosomal deletions.

Tumor suppression genes (anti-oncogenes), particularly the p53 gene, play a central role in tumor formation. p53 is located on chromosome p17, and alterations of this gene locus are found in a large percentage and wide variety of tumors. Change in p53 is the most common alteration in human cancer. Normal p53 gene activity seems to suppress tumor growth, and inactivation of its activity (such as by viruses) allows uncontrolled division and growth.

Work has shown that most of the genes whose alterations or deregulation lead to cancer are involved in cell division and the control of the cell division by signal transduction. To achieve coordinated growth, differentiation, and adaptation, cells must have complex pathways from the outside of the cell to the inside. These pathways initiate and amplify signals (signal transduction) from outside the cell to specific targets within the cell, such as the nucleus and cytoskeleton. These signals start at the extracellular cell membrane, where all surface receptors interact with ligands (growth factors) that are soluble or are on other nearby cells. Growth factors, therefore, initiate the signal that tells the cells to proliferate and grow by entering the cell cycle.

Apoptosis and Cancer

Much of cell death is genetically programmed by the process called apoptosis. In apoptosis, when the cell is damaged, the DNA initiates cell destruction, or suicide, and the cell is slowly broken into small packages that are removed by phagocytic cells, and there is no inflammation. In cancer, not only does proliferation occur, but apoptosis is blocked, resulting in accumulation of abnormal cells.

Scientists are beginning to investigate mechanisms of restoring and inducing apoptosis in cancer cells. Several approaches are being sought; one is to introduce apoptosis signals, allowing the cancer cells to die while rescuing the normal cells. Another is to reintroduce into the cancer a normal gene involved in setting off apoptosis, such as the normal p53 gene; a third method is to shut off proliferation genes (such as mutated Ras), which by itself inhibits apoptosis. If the mutated Ras gene is shut down, apoptosis will start up again and cancer cells will die.

Cancer Metastases

Cancer kills people because the tumor both invades and metastasizes. Approximately 30% of patients newly diagnosed with a cancer have detectable metastatic disease. About another 30% have occult

metastases (micrometastases) that will become evident in time. Thus, 60% of cancer patients will have multiple dormant metastases and will ultimately fail therapy and die of the cancer. The formation of metastases begins early in the growth of the primary tumor and increases with time. Small metastases up to 1 mm in size receive nutrition by diffusion but need to have new blood vessels (neovascularization) to grow larger. There has been a long search for the angiogenic 'switch.' Some target molecules and new therapies are being developed to thwart this neovascularization.

Cancers can have very different metastatic potential that depends upon their histologic type and intrinsic aggressiveness. It appears that metastasis occurs soon after the primary tumor vascularizes. Metastasis is a process separate from tumor formation. The genetic changes that lead to tumor formation do not by themselves cause erosion and metastases (see **Table 5**). Invasion involves substances such as proteases, adhesion receptors, and motility cytokines. Metastases also involve these.

Table 5 Progression of cancer and the positive and negative influences on its growth and spread[a]

	Growth	*Spread*
Positive influences	Activated oncogenes	Proteases
	Growth factors (cytokines)	Adhesion receptors
		Motility cytokines
		Angiogenesis
Result	Uncontrolled proliferation	Invasion and metastases
Negative influences	Tumor suppression genes	Metastatic suppression genes
	Growth inhibitors	Protease inhibitors
		Immunologic rejection
		Proteosome inhibitors
Result	Decreased or no growth	No invasion or metastases

[a] NCI SEER Program.

The Cell Cycle

In every population of cells there are three types of cell. The first group consists of cycling cells, which continuously proliferate by going from one mitosis to the next. The second is composed of terminally divided cells, which will die without ever dividing again. In the third group the cells are not dividing, but can re-enter the cell cycle if the appropriate stimulus is supplied. This phase is termed G0.

The cell cycle itself has four different phases: G1, S, G2, and M (**Table 6**). For a cell to go from G0 to G1, multiple genes must be expressed (i.e., C-MYC and C-FOS). Then during G1, as the cell begins to grow, in order to progress other genes are activated (e.g., ornithine decarboxylase, C-MYB). The critical point in G1 is called the restriction point; to pass through this, IGF-1 and the GFI receptor gene must be activated. G1 cyclins are also produced either before or after IGF-1; these proteins are necessary to allow the cell to carry on DNA synthesis or enter the S phase. During the S phase, all of the DNA synthesis genes are activated, including the DNA polymerases. Tumor suppression genes (anti-oncogenes) such as p53 seem to work at this step, either before DNA synthetic genes are activated or between appearance of the IGF-1 receptor and the transcription of the DNA synthesis genes. After the chromosomes are replicated, the cell enters the G2 phase, when the genes necessary for mitosis (or meioses) are activated. During this phase, products such as $P34^{cdc2}$, cyclins A and B, and C-Mos are produced. The cell then enters the M phase and the cell divides. All of the genes that are activated during the cell cycle are proto-oncogenes. Mutations in these genes can lead to abnormal growth; they would then be termed oncogenes. The suppressor factors are then the anti-oncogenes. In addition, genes coding for growth factors (cytokines) are also proto-oncogenes, and their mutations are oncogenes.

Table 6 The cell cycle and associated production of selected gene products

Phase of cell cycle	*Activity of cell*	*Examples of genes activated*
G0	Resting	As enters G1
		C-MYC and C-FOS and others
G1	Growth to prepare for DNA synthesis	Ornithine decarboxylase
		C-MYB
		Insulin-like growth factor 1 (IGF-1)
		IGF-1 receptor
		G1 cyclins
S	DNA synthesis	DNA polymerases
	Chromosomal duplication	All other DNA synthesis genes
G2	Growth to prepare for mitosis (or meiosis)	$P34^{cdc2}$
		Cyclins A and B
		C-MOS
M	Mitosis or meiosis	

Growth Factors (Cytokines)

Growth factors are proteins that regulate the cell; they function by binding to specific receptor

molecules in the cell membranes and thereby stimulating receptor-mediated activation of intracellular signal transduction pathways. These pathways are activated beginning with stimulation of tyrosine kinase to phosphorylate other proteins. These are both stimulatory and inhibitory growth factors.

Many oncogenes are analogues of cellular proto-oncogene that code for growth factors, their receptors, or pathways mediated by tyrosine kinase activation. Some viral oncogenes have been shown to be derived from animal cell proto-oncogene and work via these growth factor and receptor pathways. Expression of viral oncogenes is sufficient to induce malignant transformation in certain cells. Many other oncogenes have been found that apparently are not viral in origin that work at these sites of growth factors and receptors and signal transduction.

Chromosome Abnormalities

Cancer is often associated with specific chromosomal abnormalities. Many of the genes involved in consistent chromosomal rearrangements have been identified. Some of the resultant alterations in gene structure and function have been found. It is clear that as a rule, multiple genetic changes are usually required to transform a cell from its normal state to a malignant one. The simplest chromosomal change is a gain or loss of a whole chromosome. Structural changes are translocations (exchange of material between two or more chromosomes), deletions (loss of DNA from a chromosome), and inversions (a single chromosome is broken in two places and the central portion is inverted). Translocations are the most common chromosomal abnormalities found in human cancer, but some deletions have also been described. In some cancers, the chromosome appears normal, but there is extra genetic material (amplification) or a point mutation.

Many proto-oncogene are located in the chromosomal bands that are involved in consistent translocations. Because of the translocation, the proto-oncogene is either not in the right place or is altered so that it functions as an oncogene.

Chromosomal analysis helps us to define the type of malignancy, as specific cancers have specific chromosomal abnormalities. It is hoped that in the future we will be able to type a tumor to make a genetic diagnosis and direct therapy toward the specific genetic defect. With the new gene chip, automated analysis of many genes is possible; this technique holds promise.

Molecular Markers

Molecular biological tests will be available to identify the genetic and cellular alterations of each specific cancer by about 2015. Multiple tumor suppressor genes, oncogenes, genetic translocations, deletions, and amplifications have been described. Some genetic alterations are found on gene chips as 'signatures.' A signature is a particular clustering of genes. Many of the genes found in these clusters control proteolysis, angiogenesis, cell adhesion molecules, and hormone receptors, but not all have a known function. It may be the interplay of multiple gene products that gives the resultant behavior characteristics. Further complicating the delicate interplay in the cell are epigenetics, which are heritable changes in gene function that occur without a change in the DNA sequence. Multiple epigenetic mechanisms such as DNA methylation, histone acetylation, and RNA interference have effects on gene activation and inactivation. These mechanisms are also areas being studied for possible therapeutic intervention. A histone deacetylase inhibitor, desipeptide, is in cancer clinical trials in humans.

We do not have complete knowledge as to how age affects tumor growth or spread. We also have little knowledge of proteogenomics, which looks at the effects of drugs on the molecular machinery of cells and the effect of age.

Common Cancers in the Elderly

Lung Cancer

Lung cancer is the leading cause of death in the United States for both men and women. It accounts for 31% of male and 27% of female cancer deaths. Half of all lung cancers occurs in people age 65 and older. At age 50 in men, the incidence of cancer is 100/100 000, while at age 70 it is 500/100 000. For smokers, the risk of lung cancer continues to rise with increasing age. However, for men over 80 and women over 75, the incidence of lung cancers decreases in the general population, reflecting lower smoking prevalence.

Cigarette smoking causes 80–90% of all lung cancer. There is a direct relationship between the total number of cigarettes smoked in a lifetime and development of cancer. In addition, passive exposure to cigarette smoke is a risk. The positive aspect of this is that it is never too late to stop smoking. Elderly people who stop smoking will have a lung cancer risk reduction to a degree as high as in young people. It is pivotal for health-care workers to advise all people to stop smoking.

Tobacco smoke contains at least 20 carcinogens that can act as either initiators or promoters of cancer. Asbestos exposure increases the risk of cancer 3- to 5-fold in non-smokers and 80- to 90-fold in

smokers. A family history of lung cancer also raises the risk of developing lung cancer about 2.5-fold. There are also numerous other substances such as nickel, chromium, arsenic, polyvinyl chloride, isopropyl oil, and various hydrocarbons that have weaker causal links to lung cancer. Ionizing radiation, particularly in miners, acts synergistically with cigarette smoking.

There are four main subtypes of lung cancer: squamous cell, small cell, adenocarcinoma, and large cell. Small cell lung carcinoma (SCLC) is the most lethal and aggressive of all lung cancers, and often the others are described collectively as non-small cell lung carcinoma (NSCLC). Most lung cancers are linked to cigarette smoking. However, the risk of SCLC and squamous cell is 20–25 times greater in smokers than in non-smokers. The risk of adenocarcinoma and large cell is about three times greater in smokers.

SCLC arises from primitive basal epithelial cells of neuroectodermal origin, the Kulchitsky cells. One characteristic of this type of cancer cell is that it sometimes secretes peptide hormones such as adrenocorticotropic hormone (ACTH) or antidiuretic hormone (ADH). The cell of origin progresses through metaplasia, atypia, and, finally, carcinoma. The cancer grows as a submucosal infiltrate and often causes extrinsic airway compressions with postobstructive pneumonia. SCLC grows rapidly, metastasizes early, and is rarely surgically curable. It is the lung cancer that most commonly causes superior vena canal syndrome and recurrent laryngeal nerve paralysis (hoarseness).

Squamous cell lung cancer is also highly linked to cigarette smoking. This type of cancer arises from respiratory epithelial injury with replacement of columnar epithelial cells with metaplastic squamous epithelium. The process continues with progression through atypia to carcinoma. It arises in large central airways and often presents with cough, hemoptysis (coughing of blood), and postobstructive pneumonia. This is the slowest growing of the lung cancers and is the most likely to be surgically curable.

Adenocarcinoma and large-cell lung cancers typically present in peripheral locations outside of the airways. Adenocarcinoma is associated with preexisting lung scars. Bronchoalveolar carcinoma is an uncommon variant of adenocarcinoma and is not linked to cigarette smoking. It has the best prognosis of all lung cancers. Both adenocarcinoma and large-cell have a much better prognosis than SCLC.

With increasing age, the relative proportion of squamous cell cancer increases while that of adenocarcinoma decreases. In people under 55, about 30% of lung cancers are squamous cell, while in those over age 70, close to 50% are. This implies that surgical cure rates would potentially be greater in elderly people.

Lung cancer is usually symptomatic at the time of diagnosis. It may present as cough, wheezing, chest pain, shortness of breath, pneumonia, or coughing-up of blood. Many patients with lung cancer will have systemic symptoms such as loss of appetite, weight loss, fatigue, and weakness. In SCLC, patients can have sodium problems due to increased ADH secretion by the tumor or Cushing's syndrome from ACTH secretion. When there are metastases, the patient can have a wide variety of symptoms referable to where the tumor is, such as bone pain, abdominal pain, or confusion. It is important in older people to investigate these non-specific symptoms and not just attribute them to 'old age' or to comorbid conditions. New targeted therapies have been developed including monoclonal antibodies against vascular endothelial growth factor (VEGF) and epidermal growth factor receptor (EGFR).

Colorectal Cancer

Colorectal cancer is the third most common malignancy in the United States. This cancer occurs mainly in older people; only about 10% is found in people younger than 50. Age is the leading risk factor for colorectal cancer, and risk doubles each decade after age 50 until age 80.

A major risk factor is the presence of colonic adenomatous polyps. About 5% of adenomas become malignant, with villous adenomas being more likely than tubular adenomas to turn malignant. The larger the adenoma (more than 1 cm), the more likely it is to become cancerous. Also, the more polyps that are present, the more likely there is to be cancer. If there is one cancer of the colon, there is a greater likelihood of developing a second. Patients with familial polyposis are at greater risk of developing colorectal cancer.

Inflammatory bowel disease also predisposes one to cancer of the colon. About 3–5% of patients with ulcerative colitis will develop cancer. The risk of developing cancer increases with duration of the disease and the extent of bowel involvements. Granulomatous colitis also carries an increased risk of cancer, even though the risk is less than with ulcerative colitis.

Lifestyle is very important in the development of colorectal cancer. A high-fiber, low-fat diet seems to be protective. Beer drinking and sedentary lifestyles have been also suggested as possible risk factors. Strangely enough, cigarette smoking seems to be protective.

Most colorectal cancers can be classified as one of five morphological types: adenocarcinoma, mucinous (colloid) adenocarcinoma, signet-ring

Table 7 Clinical stages of colorectal cancer[a]

Stage	*Characteristics*
Stage 0 (Duke's A colon cancer)	Cancer is found only in the innermost lining of the colon (carcinoma *in situ*)
Stage I (Duke's B colon cancer)	Cancer has spread beyond the innermost tissue layer of the colon wall to the middle layers
Stage II (Duke's C colon cancer)	Stage IIA: Cancer has spread beyond the middle tissue layers of the colon wall or has spread to nearby tissues around the colon or rectum. Stage IIB: Cancer has spread beyond the colon wall into nearby organs and/or through the peritoneum
Stage III (Duke's C colon cancer)	Stage IIIA: Cancer has spread from the innermost tissue layer of the colon wall to the middle layers and has spread to as many as three lymph nodes Stage IIIB: Cancer has spread to as many as three nearby lymph nodes and has spread: ● beyond the middle tissue layers of the colon wall, or ● to nearby tissues around the colon or rectum, or ● beyond the colon wall into nearby organs and/or through the peritoneum Stage IIIC: Cancer has spread to four or more nearby lymph nodes and has spread: ● to or beyond the middle tissue layers of the colon wall, or ● to nearby tissues around the colon or rectum, or ● to nearby organs and/or through the peritoneum
Stage IV (Duke's D colon cancer)	Cancer has spread to other parts of the body, such as the liver or lungs

[a] Adapted from http://www.cancer.gov. Duke's staging system has been largely replaced by TNM staging. T (tumor), N (nodes), and M (metastases) staging systems for all cancers are available through the American Joint Committee on Cancer (AJCC).

adenocarcinoma, scirrhous, and carcinoma simplex. The more differentiated the tumor is histologically, the better the prognosis.

Anatomic staging has been very useful in carcinoma of the large bowel, as this is a late metastasizing tumor. The TNM (tumor size, nodal status, presence of metastases) staging system is the one most commonly used and translated into clinical stages (**Table 7**). This system prognosticates how the patient is likely to do. Age does not affect prognosis, nor does it affect treatment outcomes. Thus, in older people it seems important to screen for cancer of the colon with digital rectal exams, checking the stools for blood, and, in patients with family histories of blood in the stool or a history of polyps, examination of the colon. It is not yet definitively clear what combination of screening tests should be used. Unfortunately, virtual colonoscopy using computed tomography (CT; computerized X-ray images) and sigmoidoscopy (which looks at only the left side of the colon) miss many lesions. The incidence of right-side colonic lesions is increasing, so colonoscopy every 10 years beginning at age 50 may be the best screening tool, albeit very expensive and labor intensive.

Prompt recognition of cancer of the colon is very important. If the cancer is in the left side of the colon, it will present with crampy abdominal pain, signs of obstruction, or bleeding. Rectal cancers bleed, and the patient complains of constipation, a sense of incomplete evacuation, and urgency. Cancers of the right side of the colon can present with abdominal pain, but often present as iron deficiency anemia (weakness). This has led many centers to use a complete blood test and serum ferritin as screening tests in the elderly and to examine the colon with barium enema and sigmoidoscopy or colonoscopy in all patients with iron deficiency.

Breast Cancer

Breast cancer is the most common invasive malignancy in women and increases in incidence with advancing age. Over 50 000 women over 65 years of age are diagnosed annually in the United Stated out of 180 000 new cases of breast cancer. The incidence of invasive breast cancer has leveled off and appears to be decreasing, probably secondary to screening and treatment of earlier lesions.

Breast cancer is characterized by a long duration and a marked heterogeneity among and within patients. In general, breast cancer is one of the slower-growing tumors, with a long preclinical (nondetectable) phase. Even when the cancer is apparent and metastasized, the life span of the patient may be for many years. In spite of this, some patients have a more aggressive form of the disease and die rapidly. As a general rule, older patients have more estrogen receptors (better-differentiated tumors) and fewer cells in the S phase of growth or slower growth. These factors should indicate a better prognosis, but elderly women often present with more extensive disease and metastases. Thus, one cannot prognosticate in an individual patient on the basis of age alone. Overall, histologic type, location, and stage are the same at all ages.

A unifying hypothesis to explain breast cancer with age is the theory that most breast cancers arise in the premenstrual period, when the breast is proliferating under the cyclic influences of gonadotropins, estrogen, progesterone, and prolactin. It is

during this period that the initiation and promotion of neoplasia are likely to occur. Since overall most breast cancer grows slowly, it will take many years to show up, and will do so in the postmenopausal years. The better-differentiated tumors (estrogen and progesterone receptor positive) have fewer cells in the S phase, will take many years to grow, and are the ones that will show up in older ages. Conversely, the faster-growing tumors will become clinically apparent in the premenopausal years.

The risk of a woman in the United States developing breast cancer during her lifetime is 11%; 3–4% will die from this disease. Overall, 70% of breast cancer patients do not have any identifiable risks. The risk factors that have been implicated include family history, early menarche, late menopause, not having children, first pregnancy over the age of 30, possibly high-fat diet and high alcohol intake, sedentary lifestyle, and exposure to ionizing radiation.

Multiple mutations on chromosome 19 (BRCA) have been identified in families with breast and ovarian cancer. This accounts only for 10–20% of breast cancer cases.

The role of hormonal use is still not clear. In both young women taking oral contraceptives and postmenopausal women taking estrogens, there may be a very slight increased risk of developing breast cancer. However, this is not definitive, and in any event it seems to be a very small risk, if existent at all.

Breast cancer is classified histologically as either ductal or lobular, corresponding to the ducts and lobules of the normal breast. It is believed in spite of this that most tumors arise in the terminal duct sections of the breast. Breast cancer can present as an intraepithelial neoplasm (carcinoma *in situ*) and is either lobular or ductal. Of the invasive carcinomas, about 75% are ductal, 10% lobular, 9% medullary, and 3% minimally invasive ductal; the remainder are a variety of histological types. Lobular tumors tend to be multicentric and bilateral. A poor prognostic finding is inflammatory breast cancer in which tumor cells block lymphatic channels in the breast. Paget's disease refers to a neoplastic eczemoid change of the nipple. Its prognosis is determined by the underlying neoplasm.

Non-invasive carcinomas are almost always cured by mastectomy, as they rarely metastasize. Ductal carcinoma *in situ* can be palpable but is more likely to be found by mammography as microcalcifications. It is often unilateral and unifocal but occasionally can be extensive throughout the breast. It is usually found in older women. In contrast, lobular carcinoma *in situ* is invisible on mammography, as it does not calcify, is usually multicentric and often bilateral, and is found in younger women.

Clinical staging is based upon the size and extension of the tumor, spread to lymph nodes, and metastatic sites (**Table 8**). The chance of cure worsens with the higher stages and the absolute number of involved lymph nodes. The larger the tumor, the worse the prognosis. Tumors with a high content of estrogen and progesterone receptors relapse slightly less and are more receptive to hormonal manipulation, and therefore patients with this tend to live longer. Younger women also do worse than older women, and obesity is a risk for worse prognosis.

Breast cancer usually is found as a painless mass, often first felt by the woman. At the time of discovery, the average size of the lesion is 2.5 cm, and 50% of invasive lesions have already spread to the axillary nodes on the same side (stage II or greater). In contrast, the average size of the breast cancer lesion found on mammography is 0.5 cm and is much less likely to have spread. Mammography, however, has a 10% false negative rate; any mass should be biopsied if there is any doubt to its benign nature. Men with breast cancer may also carry BRCA mutations and should be offered genetic counseling and screening. The carrier status information is important to both the patient and the family, as carriers of BRCA2, the more common mutation in male breast cancer, have a 15–20% lifetime risk of developing breast cancer, and there is an association with familial pancreatic cancer and prostate cancer.

At the time of initial diagnosis, even many early breast cancers have already spread within the breast or have metastasized (metastases too small to be felt). This is why in many cases the patient, after removal of the tumor, is given radiation to the breast (if lumpectomy was chosen rather than mastectomy) and adjuvant chemotherapy to eradicate micrometastases. Tamoxifen (an anti-estrogen to the breast) had been useful particularly in the elderly woman with estrogen receptor-positive tissues. Tamoxifen use is being challenged by a class of drugs known as aromatase inhibitors, which suppress estrogen levels in postmenopausal women by blocking the conversion from androgens, which is the only estrogen source when ovarian function ceases. In a large randomized clinical trial there was prolonged disease-free survival and reduction in the number of contralateral breast cancers in the anastrozole (an aromatase inhibitor) group. There is a decreased incidence of vascular events and endometrial cancer using the aromatase inhibitors, but increased osteoporosis. Aromatase inhibitors are the first recommendation in treatment for metastatic breast cancer, but the current recommendation is to begin with tamoxifen and consider switching after

Table 8 Clinical stages of breast cancer[a]

Stage	*Characteristics*
Stage I	The tumor is 2 cm or smaller and has not spread outside the breast
Stage II	• No tumor is found in the breast, but cancer is found in the axillary lymph nodes (the lymph nodes under the arm), or • The tumor is 2 cm or smaller and has spread to the axillary lymph nodes, or • The tumor is larger than 2 cm but not larger than 5 cm and has not spread to the axillary lymph nodes
Stage IIIA	• No tumor is found in the breast, but cancer is found in axillary lymph nodes that are attached to each other or to other structures, or • The tumor is 5 cm or smaller and has spread to axillary lymph nodes that are attached to each other or to other structures, or • The tumor is larger than 5 cm and has spread to axillary lymph nodes that may be attached to each other or to other structures
Stage IIIB	The cancer may be any size and • has spread to tissues near the breast (the skin or chest wall, including the ribs and muscles in the chest), and • may have spread to lymph nodes within the breast or under the arm
Stage IIIC	• The cancer has spread to lymph nodes beneath the collarbone and near the neck, and • The cancer may have spread to lymph nodes within the breast or under the arm and to tissues near the breast In operable stage IIIC breast cancer, the cancer • is found in 10 or more of the lymph nodes under the arm, or • is found in the lymph nodes beneath the collarbone and near the neck on the same side of the body as the breast with cancer, or • is found in lymph nodes within the breast itself and in lymph nodes under the arm In inoperable stage IIIC breast cancer, the cancer has spread to the lymph nodes above the collarbone and near the neck on the same side of the body as the breast with cancer
Stage IV	The cancer has spread to other organs of the body, most often the bones, lungs, liver, or brain

[a] Adapted from http://www.cancer.gov. T (tumor), N (nodes), and M (metastases) staging systems for all cancers are available through the American Joint Committee on Cancer (AJCC).

2 years to an aromatase inhibitor based on a study showing a benefit of letrozole (an aromatase inhibitor) after tamoxifen. Women need to be carefully monitored with yearly bone density and should take calcium and vitamin D and other medications to prevent bone loss if needed.

Cancer of the Prostate

Prostate cancer is the most common cancer in men and is second only to lung cancer as a cause of cancer death. It is responsible for over 3% of all deaths in men over age 55. The age-specific mortality rate is double in African American men as compared to Whites. In 2005, it was estimated that 232 090 men will be diagnosed with prostate cancer, and more than 30 350 will die from prostate cancer. More than one-half of men diagnosed with prostate cancer die within 10 years. Cancer of the prostate is the most common malignancy in human beings if one looks at autopsy data. Over 40% of men over the age of 75 have cancer in their prostate glands, but over a lifetime only 23% of these men will develop clinical disease, and only 7% of them will die of the disease. Thus, there is a great difference between having histologic evidence of the disease and actual clinical problems from it.

The incidence and mortality from prostate cancer in the United States has climbed steadily since 1970, particularly in Blacks. In American Blacks, cancer of the prostate is more often diagnosed in later stages and is more likely to be poorly differentiated, and survival time is shorter than in Whites. In contrast, Black Africans have a low incidence of the disease. The incidence of cancer of the prostate is low in Asia, but rises in Asian immigrants to the United States. American Inuit have a low risk for prostate cancer as compared to Americans in general or to other native American groups.

Levels of testosterone and diet have been identified as a possible explanation for these epidemiological differences. American Blacks have higher testosterone levels than Whites or African Blacks. The dietary factors that are suspected include quantity and type of fat, low selenium, low carotene, and high protein. It appears that unsaturated fat is a greater risk than saturated fats. Omega-2 fatty acids found in seafood, as eaten by the Inuit, may be protective. Other possible risks include industrial pollutants, high cadmium, and genetic factors.

Cancer of the prostate may be described as either clinically important (threatening the life or well-being of the patient) or clinically unimportant (latent and not a threat to the person harboring it). However, time is critical in determining whether a

cancer that is clinically unimportant becomes important. Many men will have a latent cancer, which, if given enough time, will go through the multistep process necessary to develop into a clinically important malignancy. The latent cancers are usually small, well-differentiated, and non-invasive, and there is a normal serum prostate-specific antigen (PSA) that does not rise. The clinically important cancers are larger, poorly differentiated, and invasive, and the serum PSA is high and keeps rising.

For many elderly men, if there is a life expectancy of fewer than 10 years, or if the patient has a disease that is likely to be fatal in the near future, one does not have to rush to treat the patient. Watchful waiting is indicated in men over the age of 70 if they have a normal to minimally abnormal digital rectal exam, a low Gleason score (<7), fewer than three involved cores with 50% or less tumor involvement on individual cores, and slowly increasing serum PSA (<1 ng/ml/year). Patients with more aggressive tumors should undergo definitive therapy.

The most common type of cancer in the prostate is adenocarcinoma, accounting for almost 98% of all cancers. The tumors may be well, moderately, or poorly differentiated. They are usually clinically staged, as shown in **Table 9**. Most patients with early-stage disease are asymptomatic at the time of diagnosis. As the tumor grows, it may lead to obstructive symptoms of the bladder or urethra, such as frequency of urination, nocturia, hesitancy, and narrow urinary stream. As the disease spreads locally, it may lead to constipation and lymphedema of the legs. It usually metastasizes to bone, and the patient may present with low back pain, which can be mistaken for arthritis.

Cancer of the prostate can be diagnosed by ultrasonography and core needle biopsy if there is an elevated PSA or if a nodule is felt on rectal examination of the prostate gland. Many men taking the PSA test are found to have mild elevations (4–10 mg/ml), which are non-specific, as a benignly enlarged prostate will give these readings. In addition, the test is not very sensitive, as about 10% of men with normal PSA levels have carcinoma of the prostate. Only about 25% of men with PSA levels of 4–10 mg/ml will have cancer, but about 65% of men with a PSA of greater than 10 mg/ml will have cancer of the prostate. Thus, the sensitivity and specificity of the test is not as good as one would like using 4 mg/ml as a cutoff point for abnormal levels. Using a cutoff of 10 mg/ml, the detection of patients with cancer is 25% of patients were stage A, 35% were stage B, 50% were stage C, and 65% were stage D. Unfortunately, in African Americans and patients with a family history the cutoff may actually need to be lower. The velocity of PSA rise and PSA density may prove helpful.

Table 9 Clinical stages of cancer of the prostate[a]

Stage	*Characteristics*
Stage 0	Cancer is limited to the mucosa (carcinoma *in situ*) and is found only during surgery for other reasons, such as benign prostatic hypertrophy (BPH)
Stage I	Cancer is found in the prostate only. It cannot be felt during a digital rectal exam and is not visible by imaging. It is usually found accidentally during surgery for other reasons, such as BPH. Stage I prostate cancer may also be called stage A1 prostate cancer
Stage II	The cancer is more advanced than in stage I, but has not spread outside the prostate. Stage II prostate cancer may also be called stage A2, stage B1, or stage B2 prostate cancer
Stage III	Cancer has spread beyond the outer layer of the prostate to nearby tissues. Cancer may be found in the seminal vesicles. Stage III prostate cancer may also be called stage C prostate cancer
Stage IV	Cancer has metastasized (spread) to lymph nodes near or far from the prostate or to other parts of the body, such as the bladder, rectum, bones, liver, or lungs. Metastatic prostate cancer often spreads to the bones. Stage IV prostate cancer may also be called stage D1 or stage D2 prostate cancer

[a] Adapted from http://www.cancer.gov. T (tumor), N (nodes), and M (metastases) staging systems for all cancers are available through the American Joint Committee on Cancer (AJCC).

Cancer of the Bladder

More than 50 000 new cases of cancer of the bladder are diagnosed annually in the United States; about 10 000 people die of it. The older one gets, the more likely he or she is to develop bladder cancer, and the survival rate is lower with advancing age.

Cancer of the bladder is more common in men, and is related to occupational exposure to aryl amines such as those found in workers in the organic chemical, dye, rubber, and paint industries. The strongest association is found in cigarette smokers. Other associations are in people with chronic inflammation of the bladder. There have been fears that artificial sweeteners (cyclamate and saccharin) may induce bladder cancer, but this has not been shown in humans.

In the United States, approximately 95% of all bladder cancers are transitional cell carcinomas. About 3% are squamous cell, and the rest are adenocarcinomas. Most bladder tumors are papillary

Table 10 Clinical stages of cancer of the bladder[a]

Stage	*Characteristics*
Stage 0	Cancer is found only on tissue lining the inside of the bladder • Stage 0 is also called papillary carcinoma, which may look like tiny mushrooms growing from the lining of the bladder • Stage 0 is also called carcinoma *in situ*, which is a flat tumor on the tissue lining the inside of the bladder
Stage I	Cancer has spread to the layer below the inner lining of the bladder
Stage II	Cancer has spread to either the muscle wall or the bladder
Stage III	Cancer has spread from the bladder to the fatty layer of tissue surrounding it, and may have spread to the reproductive organs (prostate, uterus, vagina)
Stage IV	Cancer has spread from the bladder to the wall of the abdomen or pelvis, to one or more lymph nodes, or to other parts of the body

[a] Adapted from http://www.cancer.gov. T (tumor), N (nodes), and M (metastases) staging systems for all cancers are available through the American Joint Committee on Cancer (AJCC).

Table 11 Clinical stages of cancer of the kidney[a]

Stage	*Characteristics*
Stage I	Tumor is confined to the kidney and no larger than 7 cm
Stage II	Tumor is confined to the kidney and is larger than 7 cm
Stage III	• Cancer is in the kidney and in one nearby lymph node, or • the cancer has extended to the adrenal gland or in the layer of fatty tissue (perinephric fat) around the kidney, and may be found in one nearby lymph node, or • the cancer has spread in the main blood vessels of the kidney (renal vein) and may be found in one nearby lymph node
Stage IV	• Cancer has spread beyond the layer of fatty tissue around the kidney and may be found in one nearby lymph node, or • the cancer has spread to two or more nearby lymph nodes, or • the cancer has spread to other organs, such as the bowel, pancreas, or lungs, and may be found in nearby lymph nodes

[a] Adapted from http://www.cancer.gov. T (tumor), N (nodes), and M (metastases) staging systems for all cancers are available through the American Joint Committee on Cancer (AJCC).

transitional cell carcinomas. They are classified into three grades. Grade 1 is well differentiated with limited atypia and mitoses. Grade 3 lesions have a marked increase in cell layers and cell size with marked pleomorphism and mitoses. Grade 2 is intermediate. It is believed that cancer of the bladder arises by damage to the bladder endothelium by carcinogens, infections, stones, or other foreign bodies (such as indwelling catheters), which lead to hyperplastic growth and immature cells. This will progress (multiple hits) through metaplasia to carcinoma *in situ*, and finally invasive carcinoma.

Clinical staging of cancer of the bladder is shown in **Table 10**. The lower the stage and grade, the better the prognosis. Cancer of the bladder tends to occur as multiple lesions and tends to recur.

Most patients with cancer of the bladder present with painless hematuria. If any red cells are persistently found on urinalysis, cystoscopy is indicated. Less frequently, the patient will complain of dysuria and frequency. Advanced cancer is rare as a presenting symptom, as most people will go to a doctor when blood is noted in the urine.

Cancer of the Kidney

More than 25 000 cases of cancer of the kidney are diagnosed annually, with close to 11 000 deaths; this represents about 3% of cancer deaths. Cancer of the kidney is more common in men than women, and is most common from age 50 to 70.

The risk factors for cancer of the kidney include cigarette smoking, obesity, and analgesic abuse. Other environmental factors include asbestos, cadmium exposure, and working in the leather industry. Patients with end-stage kidney disease who develop cysts are also at increased risk.

The most common histologic type of kidney cancer is adenocarcinoma. Tumor grading is not used frequently in this type of malignancy. Clinical staging is shown in **Table 11**. In more than half of patients, metastatic disease is present at time of diagnosis.

Cancer of the kidney clearly presents as gross hematuria, pain, and flank mass, but this is found in only about 20% of cases. Many times the disease can be noted by painless microscopic hematuria or is found when the patient presents with systemic symptoms such as anemia, fever, weight loss, and fatigue. Rarely, the patient may have polycythemia. Early disease can be detected only by evaluating any microscopic hematuria.

Cancer of the Ovary

Ovarian cancer is the sixth most common cancer of women in the United States but is the fourth leading

cause of cancer death. More women die from ovarian cancer than from cervical and endometrial cancer combined. Approximately 22 000 new patients are diagnosed every year, and 16 000 women die. Cancer of the ovary increases with age, peaking at age 80. Approximately 1% of all female deaths are from cancer of the ovary.

Ovarian cancer is usually found in industrialized nations, with the notable exception of Japan. Japanese Americans have a higher incidence of ovarian cancer than Japanese in Japan, but the incidence is still lower than in the White population. In the United States, ovarian cancer is most common in White women. Risk factors include a low number of pregnancies (each pregnancy lowers the risk by about 10%), use of anticonvulsant drugs, history of breast cancer, and exposure to asbestos and talc. Birth control pills lower the risk of developing ovarian cancer.

Most cancer of the ovary is of the epithelial type, and in women over 65 this type accounts for 95% of the cases. Cancer of the ovary spreads early by surface shedding, lymphatic spread, and, less commonly, blood-borne metastases. Over 50% of women presenting with this cancer have disease spread outside of the pelvis (stage III or IV). **Table 12** shows the staging used for ovarian cancer. Older women will present with a stage III or IV disease about 65% of the time.

Ovarian cancer is usually asymptomatic until it spreads. By the time the woman notices pain, abdominal swelling, vaginal bleeding, or GI distress, the disease is widespread. The only way to identify disease early is by finding an adnexal mass via a pelvic examination. Any adnexal enlargement in a postmenopausal woman should be considered a malignancy until proven otherwise. Ultrasound is useful in detecting ovarian masses but is considered too expensive to use for routine screening.

Table 12 Clinical stages of cancer of the ovary[a]

Stage	*Characteristics*
Stage I	Cancer is found in one or both of the ovaries and has not spread Stage IA: Cancer is found in a single ovary Stage IB: Cancer is found in both ovaries Stage IC: Cancer is found in one or both ovaries and one of the following is true: ● cancer is found on the outside surface of one or both ovaries, or ● the capsule (outer covering) of the tumor has ruptured (broken open), or ● cancer cells are found in the fluid of the peritoneal cavity (the body cavity that contains most of the organs in the abdomen) or in washings of the peritoneum (tissue lining the peritoneal cavity)
Stage II	Cancer is found in one or both ovaries and has spread into other areas of the pelvis Stage IIA: Cancer has spread to the uterus and/or the fallopian tubes (the long slender tubes through which eggs pass from the ovaries to the uterus) Stage IIB: Cancer has spread to other tissue within the pelvis Stage IIC: Cancer has spread to the uterus and/or fallopian tubes and/or other tissue within the pelvis and cancer cells are found in the fluid of the peritoneal cavity (the body cavity that contains most of the organs in the abdomen) or in washings of the peritoneum (tissue lining the peritoneal cavity)
Stage III	Cancer is found in one or both ovaries and has spread to other parts of the abdomen Stage IIIA: The tumor is found only in the pelvis, but cancer cells have spread to the surface of the peritoneum (tissue that lines the abdominal wall and covers most of the organs in the abdomen) Stage IIIB: Cancer has spread to the peritoneum but is 2 cm or smaller in diameter Stage IIIC: Cancer has spread to the peritoneum and is larger than 2 cm in diameter and/or has spread to lymph nodes in the abdomen or onto the surface of the liver
Stage IV	Cancer is found in one or both ovaries and has metastasized (spread) beyond the abdomen to other parts of the body. Cancer is found in the tissues of the liver

[a] Adapted from http://www.cancer.gov. T (tumor), N (nodes), and M (metastases) staging systems for all cancers are available through the American Joint Committee on Cancer (AJCC).

Cancer of the Uterus

Cancer of the uterine cervix can and does occur in elderly women. However, the peak age occurrence is between age 48 and 55. Hopefully, vigorous annual screening of young women (Pap smears) will result in fewer cases in older women. It is recommended that Pap smears be done in elderly women who have not been adequately screened up to the age of 65. Up to 60% of women over the age of 65 have not had a Pap smear taken.

Cancer of the endometrium is the most common of all gynecologic cancers. The peak age range for developing this cancer is 60–64. It is a relatively easy cancer to detect; it spreads late and Pap smears will detect about 50% of them. The key to detecting gynecologic cancers in older women is them having an annual pelvic exam.

Other Cancers

Cancer can arise in any organ of the body, including the skin and hematopoietic tissues. In all of these systems, the same principles discussed earlier apply: to develop cancer there must be multiple hits resulting in greater degrees of undifferentiation and spread. As a general rule, therefore, given the time necessary to develop a malignancy, the elderly are more likely to have almost any malignancy.

The original histologic grading and clinical staging for malignancy were done in Hodgkin's disease, and then the other lymphomas. These principles are now applied to all cancers and have proven useful in predicting cure rates and in devising therapeutic regimens.

Unfortunately, cure rates for many malignancies are still very low. Cancer of the pancreas, stomach, esophagus, brain, liver, multiple myeloma, and acute leukemia all carry very poor prognoses. As a general rule, in the elderly, cancer presents in a more advanced form and is more likely to have metastasized, and the patient is less likely to be able to tolerate much therapy.

Screening for Cancer

The goal of screening for cancer is to detect disease at an early point and to be able to institute curative therapy at that time. Any screening procedure must meet certain criteria to be used: it must be safe, inexpensive, and easy to do and have high sensitivity and specificity. The illness being screened should be common and a cure must be available.

There are four benefits sought in any cancer screening program. The primary benefit is finding a disease that would be fatal if left untreated. The second benefit is that disease found early requires less harmful therapy. Third, it is cheaper to society if cancer is found early, and finally, those who test negative for the disease are reassured. However, any screening program also has many disadvantages. In many cancers that are detected the prognosis is not changed, so that the morbidity to the patient is actually longer. Second, screening may result in findings that, if left alone, would not have harmed the patient. The third disadvantage is that false-positive tests lead the physician to order many other tests, which causes considerable anxiety to the patient. Fourth, many of the diagnostic tests can in themselves be harmful. The fifth disadvantage is cost to society, and, finally, false-negative tests will falsely reassure the patient.

Due to these considerations, extensive cancer screening is usually reserved for cervix, breast, and colon. While there are advocates for screening for cancer of the prostate and lung, this is not universally accepted. The current (2005) recommendations for screening are shown in **Table 13**. These are in flux, as most screening programs have not shown a reduction in the mortality or morbidity of the cancer being studied. Most people, however, follow these suggestions.

Principles of Cancer Therapy

The mainstays of cancer therapy are surgery, radiation, and chemotherapy. Newer methods of therapy are bone marrow transplantation, use of cytokines, immunotherapy, hormones and anti-hormones, and gene therapy. The elderly are candidates for cancer therapy; indeed, all too often they are denied therapy because either the doctor or the patient and his or her family are misguided as to the benefits of treatment. In many instances the elderly do better with therapy than the young.

Surgery

Surgery is the oldest treatment for cancer and until recently was the only therapy that could cure cancer patients. Surgical treatment has changed drastically since the 1980s. Advances in surgical techniques and a better understanding of the patterns of spread of individual cancers have led to more successful operations, and the development of alternate and adjunct treatment strategies has led to less extensive surgery.

Age is not an independent risk factor for surgery. The determinants of surgical risk include the status of the heart, lungs, kidneys, brain, liver, hematopoietic, and endocrine systems as well as nutritional status and presence of diseases such as diabetes. An elderly patient who is healthy can withstand surgery as well as a young person by using newer methods of anesthesia and postoperative monitoring.

Surgery can be used for six different reasons:

1. Removal of primary cancer
2. Reduction of bulk of residual disease
3. Resection of metastatic disease with curative intent
4. Treatment of an emergency situation in cancer, such as bleeding or infection
5. Palliation
6. Reconstruction and rehabilitation

Radiation Therapy

Radiation therapy may be used as either primary therapy or as an adjunct to surgery or chemotherapy.

Table 13 American Cancer Society cancer detection guidelines

Cancer site	*ACS test or procedure and frequency recommendations*
Breast	Clinical breast exam: self-exam monthly beginning at age 20; physician exam every 3 years at ages 20–39, yearly after age 40 Mammogram: annually after age 40 (?role after age 80)
Cervix	Annual Pap smear within 3 years of vaginal intercourse or by age 21; after age 30 and three negative consecutive smears, perhaps every 3 years with convention of liquid-based Pap plus the HPV DNA. Women over 70 with three normal consecutive Pap tests and no abnormal within 10 years may choose to stop having cervical cancer screening at discretion of physician. Women after total hysterectomy may choose to stop having cervical cancer testing unless the treatment was for cervical cancer or precancer
Colon-rectal	Yearly exam after age 40; yearly fecal occult blood after age 50; sigmoidoscopy every 5 years after age 50; or barium enema every 5 years or colonoscopy every 10 years. All positive tests should be followed with colonoscopy. Higher-risk patients, those with personal history of colorectal cancer or adenomatous polyps, strong family history (first-degree relative younger than 60 or two first-degree relatives at any age), personal history of inflammatory bowel disease, or family history of a hereditary colon cancer syndrome (hereditary non-polyposis colon cancer [HNPCC] or familial adenomatous polyposis [FAP]), should begin screening earlier and more often usually with colonoscopy
Endometrial	Women should be informed about the risks and symptoms of endometrial cancer and should report any unexpected bleeding or spotting to their doctors. Women with HNPCC should be offered frequent screening, with endometrial biopsy beginning at age 35
Lung	Currently no recommendations. Chest X-rays are generally not useful as a screening tool. CT investigation of heavy smokers is ongoing
Prostate	Digital rectal examination of the prostate and PSA blood test yearly beginning at age 50 for men with a life expectancy of greater than 10 years. African American men or men with a family history of prostate cancer in a first-degree relative should begin at age 45 (this recommendation is controversial)
Skin cancer	Counseling on avoiding sun exposure, and skin exam every 3 years between 20 and 40 and yearly after age 40
Testicular	Examination of testicles as part of a cancer-related check-up
Cancer-related check-up	At the periodic health examination, the cancer-related check-up should include examination for cancers of the thyroid, testicles, ovaries, lymph nodes, oral cavity, and skin, as well as health counseling about diet and nutrition, sun exposure, risk factors, sexual practices, and environmental and occupational exposures

Primary radiation therapy is often used in the elderly with multiple diseases who are poor surgical risks, as there is no appreciable acute mortality from irradiation. Associated medical conditions do not contraindicate curative treatments. Other advantages of radiation in the frail elderly are preservation of function in the organ from which the cancer originates, and delivery of curative treatment even when the anatomic boundaries of the tumor are not amenable to surgery.

The disadvantages of radiation therapy include the disturbing side effects, the length of time of treatment (up to 2 months), and the development of secondary malignancies. Secondary malignancies are of less concern in the very old, however.

Newer methods and equipment have made radiation therapy much more tolerable. Certainly secondary or adjuvant radiotherapy with limited surgery and chemotherapy is very attractive to older people. Limited surgery followed by local radiation treatment decreases the morbidity of either treatment alone. Likewise, radiation as an adjunct to chemotherapy allows the physician to decrease the dose of either treatment alone and thus avoid some of the side effects.

Chemotherapy

It has been thought that changes in pharmacokinetics of drugs with age may limit the ability to deliver curative doses of chemotherapy to the elderly. However, there are relatively few studies that have shown this. It is widely accepted that CCNU and methotrexate doses should be reduced in the elderly, and bleomycin toxicity is greater with advancing age. Usually, the limiting factor in delivering chemotherapy is bone marrow reserve, which is decreased in the elderly. However, the wide availability of blood products and growth factors to stimulate bone marrow (such as erythropoietin and colony-stimulating factors) has greatly improved the situation. Bone marrow transplantation has not been well studied in

older people. Bone marrow may be harvested from the patient and retransfused into them after chemotherapy is given (autologous transplantation). Allogenic transplantation from a different donor has not been used in the elderly and is limited mainly to young people.

Chemotherapy is often dreaded by older people because of its systemic symptoms. There is no evidence that the elderly tolerate this form of treatment any worse that the young, nor are there data showing it does not work as well. Many more studies are needed to assess the true value of chemotherapy in the elderly.

Hormonal Therapy

Certain tumors are responsive to hormonal manipulation, notably cancer of the breast and cancer of the prostate. The anti-estrogen tamoxifen has been particularly useful in postmenopausal women with cancer of the breast to palliate metastatic disease and perhaps to prevent development of further disease. Other hormonal therapy, such as oophorectomy, adrenalectomy, and megesterol therapy, has been useful. In cancer of the prostate, orchiectomy, estrogen therapy, the use of luteinizing hormone-releasing hormone (LHRH) agonists to lower testosterone and α-5 reductase inhibitors to block the reduction of testosterone to dihydrotestosterone have been useful in palliation.

Biological Therapy

The use of red blood cell, platelet, and at times granulocyte transfusions and fresh frozen plasma infusions has greatly helped patients overcome the severe effects of anemia, bleeding from thrombocytopenia, and infections from granulocytopenia. Clotting factors, both pooled and recombinant, are available for people who need them. The introduction of recombinant factor VIIa has worked in a variety of hemorrhagic disorders. There are numerous growth factors, such as erythropoietin to stimulate red cell production, granulocyte macrophage colony-stimulating factor (GM-CSF) to stimulate production of both granulocytes and macrophages, granulocyte colony-stimulating factor (G-CSF) to stimulate granulocyte production, and recombinant human interleukin-11 that stimulates production of hematopoietic stem cells and megakaryocyte progenitor cells and induces megakaryocyte maturation, which increases platelet production. Interleukin-3, which increases neutrophils and easinophiles and sometimes basophiles and platelets, and megakaryocyte growth and differentiation factor, which is a thrombopoietin, can increase platelets but are not yet available in the clinic. Studies using combinations of these factors to enable the cancer patient to receive more intensive curative therapies by alleviating cytopenias are in progress.

Immunotherapy in cancer therapy is also being widely studied. Immune cells secrete two types of soluble proteins: antibodies and cytokines. Both of these have the ability to destroy tumor cells. Specific tumor antibodies may be directed against the person's own cancer and are being studied as a means of therapy in designer vaccine trials. The cytokines, which are actually hormones produced in the immune system, are potentially very useful. Studies have been done with interferons and interleukin-2, which are promising in some cancers. Non-specific immunotherapy to increase the immune system has been widely tried with BCG, a modified form of the tubercle bacillus. This has not been very successful, but it is hoped that more-specific immunotherapy with monoclonal antibodies and specific cytokines will be of greater value.

Targeted Therapy

The most exciting advances in cancer therapy come from 'targeted therapy,' which is a type of treatment that uses drugs or other substances to identify and block the growth and spread of specific cancer cells without harming normal cells. Examples of these therapies are monoclonal antibodies, small molecules that block enzymes, antisense molecules, apoptosis-inducing drugs, cancer vaccine, and gene therapy.

Monoclonal Antibodies Cetuximab (Erbitux) is a monoclonal antibody that binds specifically to the human EGFR and that has proven efficacy in metastatic colon cancer as well as other malignancies that express EGFR by blocking this receptor so that the cells do not grow. Bevacizumab (Avastin) is a monoclonal antibody directed against VEGF with efficacy in treating colorectal cancer and other tumors expressing VEGF by interfering with tumor blood vessel formation. Rituximab is a monoclonal antibody against the cell surface receptor CD20 and is used to treat CD20+ lymphomas by coating the cells, resulting in both increased clearance and apoptosis. Ibritumomab tiuxetan (Zevalin) is a monoclonal antibody similar to rituximab linked to a radioactive particle that targets CD20+ tumor cells and kills them. Trastuzumab is a monoclonal antibody used to treat Her2+ breast cancers by targeting that gene product, resulting in apoptosis.

Small Molecules Imatinib mesylate is a small molecule protein tyrosine kinase inhibitor that inhibits the Bcr-Abl tyrosine kinase, the constitutive abnormal

tyrosine kinase created by the Philadelphia chromosome abnormality in chronic myeloid leukemia (CML). This drug is used to treat CML and gastrointestinal stromal tumors (GIST) with the abl tyrosine kinase mutation. BAY 43-9006 (Sorafenib) is another specifically engineered molecule that inhibits RAF kinase in the cancer cells which is part of the RAS oncogene pathway. RAS is a gene that drives cell division and is overexpressed in many cancers, including renal cell carcinoma. This drug has efficacy in treating renal cell carcinoma, may additionally inhibit VEGF and platelet-derived growth factor (PDGF), which are receptor kinases, and may have efficacy in treating a wide variety of malignancies, as RAS mutations are the most common mutations in human malignancy. Erlotinib (Tarceva) and Gefitinib (Iressa) are two other small molecule receptor tyrosine kinases against EGFR shown to be effective in lung cancer.

Drugs That Induce Apoptosis Oblimersen (Genasense) is a molecule directed against the normal RNA responsible for making bcl-2, which promotes cell survival. This drug is currently in clinical trials (2005). Blockade of bcl-2 will lead to apoptosis and increased sensitivity to chemotherapy drugs. Bortebomib (Velcade) causes cells to die by blocking enzymes called proteosomes, which regulate cell function and growth. This drug induces apoptosis and is approved for use in multiple myeloma and cancer of plasma cells, which are one type of the white cells in the body that treats infection.

Cancer Vaccines Clinical trials with vaccines against cervical carcinoma human papillomavirus (HPV) and designer vaccines against lymphoma or melanoma cells, prostate, and colon cancer are some of the ongoing areas of interest.

Gene Therapy

Several goals can be accomplished by gene therapy. Replacement of missing or altered genes with normal genes may prevent cancer from developing and allow the malignant cells to die a normal programmed death; genes can be introduced to improve a patient's immune response to the cancer; genes can be introduced into normal cells to allow the administration of high doses of chemotherapy to kill the malignant cells and spare the normal ones; suicide genes can be introduced into cancer cells and later be turned on by a drug metabolized by the cancer cell; or genes can be introduced to inhibit the formation of new blood vessels. Scientists continue to work on ways to deliver the vector (carrier of the gene into the cell), which is usually done with an altered virus. The danger is that the gene may be inserted into the wrong cell or the wrong location in the DNA, causing a mutation and potentially cancer or another harmful condition. Preclinical research is ongoing.

Supportive Care and Quality of Life

In caring for cancer patients, it is clear that there are numerous problems that must be addressed. Often the patient has considerable pain, is nauseated and vomiting, is not eating, and is depressed. Any cancer program must deal with these issues in order to achieve any quality of life.

Pain

Numerous studies have shown that 30–50% of patients undergoing cancer therapy and 60–90% of patients with advanced disease experience pain. Pain is considered the fifth vital sign. Providers routinely assess patients for pain every time that pulse, blood pressure, core temperature, and respiration are checked. The use of pain scales, either numeric or visual (analog or faces), allows assessment of response to pain control measures in the individual. Patient pain logs correlating medications, activity, type of pain, intensity, duration, and relieving and exacerbating factors help the clinician titrate the medications.

The most effective pain management is a multidisciplinary approach with anesthesiology, neurology, physical therapy, psychology, and oncology. The goal is to allow the patient sufficient relief of pain in order to maintain an acceptable quality of life and continue with the activities of daily living and cancer therapy. For terminally ill patients, the goal is to allow them to function at a level they choose and to die free of pain.

Drug therapy should be effective in virtually all patients. With mild to moderate pain, non-opiate drugs are used, such as acetaminophen and nonsteroidal anti-inflammatory medications. The opioid medications used to treat moderate to severe pain include morphine, fentanyl, oxycodone, and hydromorphone. Meperidine should not be used, as it causes CNS irritability. Fentanyl transdermal patches or oral transmucosal fentanyl citrate, a strong opioid analgesic, have been very useful albeit expensive additions to treat chronic pain. Patient-controlled analgesia (PCA) using an intravenous drip regulated by the patient, once relegated to the preterminal patients, is now a common occurrence in hospitalized patients to achieve quick pain control and an easy switch to an equianalgesic oral and/or transdermal regimen. When using narcotics, it is essential to use the drugs 'around the clock' – in other words, they should be used to

prevent pain, not given only when the pain occurs. This can usually be accomplished with long-acting agents. Combinations of drugs to potentiate the opiates are very useful. All possible approaches should be tried, such as acupuncture, injection of painful sites, physical therapy, nitrous oxide, hypnotism, biofeedback, guided imagery, meditation, and prayer. If need be, surgical procedures such as cordotomy, local blocks of nerves, or implantation of a programmable intrathecal drug delivery pump should be done. In addition to analgesics, other drugs may be used to treat associated depression, sedation, nausea, and constipation. The goal is to eliminate pain.

Nausea and Vomiting

Great strides have been made in the development of antiemetics. The substituted benzaimides that block serotonin receptors (specifically the type 3 or 5-HT3 receptors) are the standard of care. Substance P/neurokinin 1 (NK_1) receptor antagonists are being developed; aprepitant was the first one introduced in the United States. NK_1 receptor blockade augments the central antiemetic effect of 5-HT3 receptor antagonists and dexamethasone, resulting in reduced emesis from highly emetogenic agents, e.g., cisplatin. The phenothiazines, metoclopramide (central and peripheral dopamine receptor agonists), benzodiazepines (lorazepam), butyrophenones (haloperidol), phenothiazines (prochloperazene), corticosteroids, and cannabinoids are also useful.

Nutritional Support

Cancer cachexia is a well-described syndrome of progressive weight loss and anorexia mediated by a variety of cytokines elaborated by the cancer or the host, e.g., TNF. Control of mucositis, nausea and vomiting, pain, constipation, and shortness of breath help to allow the patient to eat and drink, but weight loss may continue. It is essential to offer the patient high-calorie and high-nutrient food supplements, to use intravenous therapy when necessary, even at home, and to consider the use of gastrostomy tube feedings if wanted. Tube feedings may be stopped if and when the patient can eat or no longer chooses this therapy.

Psychological and Social Supports

The care of patients with cancer requires a multidisciplinary team. Most cancer centers provide supportive care, including psychological, social work, nutritional, pain management, physical rehabilitation, and spiritual continuing care programs. These programs have been developed to help cancer survivors as well as dying patients both in the hospital and at home. When the focus of treatment shifts from curative therapy to symptom control and palliative comfort, home-care services, home- and hospital-based teams, and home- and hospital-based hospice care are readily available for the patient and the family. Both the patient and the family need help, supportive psychotherapy, and preparation for death. The team is available 24 hours a day. Nurses, social workers, and physicians work together with the patient and family to achieve comfort and a dignified death. Support groups for the surviving family members and friends are also available.

Cancer: Breast

L Balducci, S Hoover, and H Greenberg, University of South Florida College of Medicine, Tampa, FL, USA

Glossary

Adjuvant Treatment – Treatment given to help the primary treatment succeed.

Lymph Node Mapping – Injection of a supra-vital dye or a radioactive tracer around a tumor, which allows the detection of the first lymph nodes where the tumor lymphatics drain. These lymph nodes are biopsied and if they are free of tumors, no further surgery is necessary.

Neoadjuvant Treatment – Treatment given prior to primary treatment, with different goals, including to reduce the size of the primary tumor and to allow partial mastectomy and organ preservation, as well as to assess the responsiveness of a tumor to systemic treatment.

Introduction

Breast cancer is the most common cancer in US women, and approximately 50% of breast cancers occur in the 12% of women aged 65 and over. With the growth of the older population, by the year 2030 almost two-thirds of breast cancers will affect elderly women. Though breast cancer becomes more indolent with the age of the patient, the mortality related to breast cancer has decreased by approximately 10% for women younger than 65 and has increased by the same proportion for those older, indicating that better control of this malignancy is needed, especially for the older women. Another important consideration is that breast cancer affects preferentially women in good general health, that is, women whose life expectancy is not lessened by comorbidities or functional limitations and for whom breast cancer is a cause of death. After examining potential causes of breast cancer, this article explores the prevention and the management of this neoplasm in older women.

Etiology of Breast Cancer

The most important risk factor of breast cancer is age. At least 10–15% of breast cancers are familial, and a number are clearly hereditary. Of these, the best-defined forms are related to a number of mutations in two genes: BrCa-1 (also associated with ovarian cancer), and BrCa2. The vast majority of hereditary breast cancers are seen in women under the age of 50. Prophylactic mastectomy in individuals at risk prevents the development of hereditary breast cancer. This practice may then minimize the incidence of hereditary breast cancer in older women.

Hormone replacement therapy (HRT) appears a major risk factor in older women, as suggested by several retrospective studies and demonstrated in the prospective and randomized Women Health Initiative, in which postmenopausal women were randomized to receive HRT or placebo. HRT consisted of a combination of estrogen and progesterone for women with uterus, and estrogen alone for those posthysterectomy. The combination of estrogen and progesterone may increase the risk by 50% and is associated with increased breast cancer mortality. The risk increases with the duration of the treatment and abates when the treatment is discontinued. With estrogen alone, the risk of breast cancer and its mortality is smaller, and may not be increased at all.

Obesity, especially the male type of obesity, defined as a ratio between the hip and waist circumference of less than 0.71, is also a risk factor, probably because abdominal fat is rich in aromatase, which transforms ovarian and adrenal androgens into estrogens, and because male obesity is associated with lower circulating levels of sexual hormone binding.

Diet may have a minor role. The role of dietary fat is controversial; while a number of cross-sectional and retrospective studies suggested that high dietary fat may enhance the risk of breast cancer, the Nurse Health Study, a cohort study of nurses followed for more than 10 years, failed to confirm this suggestion. A recent randomized controlled study, however, demonstrated that dietary fat restriction may reduce the risk of breast cancer recurrence after surgery. How this data may apply to the risk of breast cancer is not clear. There is good evidence instead that regular alcoholic intake may increase the risk and that this may be somehow counteracted by the addition of folates to the diet.

Biology of Breast Cancer and Its Relationship to Aging

The most important prognostic factor of breast cancer is stage at the time of diagnosis (**Table 1**). Carcinoma *in situ* is represented by three different

Table 1 TNM staging system of breast cancer[a]

Classification	*Description*
Primary tumor (T)	
Tx	Primary tumor not assessable
T0	No evidence of primary tumor
Tis	Carcinoma *in situ*
T1	Tumor largest diameter $\leq$2 cm
T1a	Tumor between 0.1 and 0.5 cm
T1b	Tumor $>$0.5 but $\leq$1 cm
T1c	Tumor $>$1 but $<$2 cm
T2	Tumor largest diameter between 2 and 5 cm
T3	Tumor largest diameter $>$5 cm
T4	Any size tumor with direct invasion of chest wall and/or skin
T4a	Chest wall but not pectoralis muscle
T4b	Edema, or skin ulceration or satellite nodes
T4c	Both T4a and T4b
T4d	Inflammatory carcinoma
Ge	
Lymph node, (LN) clinical classification (N)	
Nx	Regional LN not assessed
N0	No LN metastases
N1	Palpable axillary ipsilateral LN
N2	Matted (fixed) axillary LNs or ipsilateral mammary LNs in absence of axillary LNs
N3	Infraclavicular ipsilateral LNs
	Ipsilateral mammary LNs in presence of axillary LN metastases
	Ipsilateral supraclavicular LN
Lymph node, pathological classification (pN)	
pNx	Regional LN not assessed
pN0	No LN metastases
pN1	Metastases to 1–3 axillary or mammary LNs
pN2	4–9 axillary LNs or clinically evident mammary LNs in absence of axillary LNs metastases
pN3	10+ axillary LNs, or involvement of infraclavicular or supraclavicular LN or in clinically apparent mammary LNs with positive axillary LN
Metastases (M)	
Mx	Distant metastases not assessed
M0	No distant metastases
M1	Distant metastases present
Final staging	
0	Tis N0 M0
I	T1 N0 M0
IIA	T0 N1 M0
	T1 N1 M0
	T2 N0 M0
IIB	T2 N1 M0
	T3 N0 M0
IIIA	T0 N2 M0
	T1 N0 M0
	T3 N1 M0
	T3 N2 M0
IIIB	T4 Any N M0
	Any T N3 M0
IV	Any T Any N M1

[a] Note: The initial staging is based on the clinical evaluation of the patient. After surgery, treatment is based on the pathological staging, that is, on the presence or absence of involvement of axillary LNs.

pathologies: ductal carcinoma *in situ* (DCIS); lobular carcinoma *in situ* (LCIS), and Paget's disease. For early-stage tumors, the invasion of axillary lymph nodes predicts the risk of systemic tumor recurrence. In addition to stage, other important factors including concentration of hormone receptors, tumor grade, and overexpression of Her-2/neu hormone receptors distinguish two types of breast cancer with different biology. One type, which represents two-thirds of all breast cancer and becomes more common with aging, is dependent on sexual hormones for its growth and is characterized

by the presence of receptors for estrogen and progesterone in the tumor cells; the other type is hormone independent and does not express hormone receptors. As a rule, hormone-dependent tumors are more indolent and produce metastases that are not life-threatening, including bone, skin, and nodular lung metastasis, while hormone receptor-negative tumors are more aggressive and more likely to give origin to life-threatening metastases, such as hepatic, cerebral, and lymphangitic lung metastases. The distinction is not ironclad. Virtually all tumors contain hormone-independent tumor cells, and tumors with low concentration of hormone receptors tend to behave more as hormone receptor-negative tumors. The grade indicates the degree of differentiation of the tumor cells, and Her2/neu is one of the four recognized receptors for the epidermal growth factor. High grade (that is, poor differentiation) and Her2/neu overexpression mark a more aggressive tumor. Thanks to the microarray techniques, a number of genetic profiles of breast cancer have also been recognized with different degree of aggressiveness, but this technique has been limited so far to the research laboratory.

Age may have apparently divergent effects on the prognosis of breast cancer. On one side, the stage at diagnosis may be higher for older than for younger women, while the prevalence of well-differentiated, hormone receptor-rich, Her-2/neu-negative tumors also increases with age. In addition, endocrine senescence may reduce the growth rate of hormone-responsive tumors. This divergence may be more apparent than real, as the fact that older women are diagnosed with breast cancer at a more advanced stage may simply reflect reduced utilization of screening mammography in older women, and increased mortality may reflect both underutilization of screening and suboptimal treatment, both of which are remediable.

Prevention of Breast Cancer in the Older Woman

Cancer prevention is commonly subdivided into primary and secondary prevention. Primary prevention includes elimination of environmental carcinogens or of other conditions that may favor the development of cancer, chemoprevention, that is, administration of substances that may offset carcinogenesis, and prophylactic mastectomy in women at risk for familial cancer. Secondary prevention includes early diagnosis of cancer by screening of asymptomatic individuals at risk and prevention of cancer death by timely treatment.

Primary Prevention of Breast Cancer in Older Women

As a consequence of the Woman Health Initiative, which has demonstrated the association of HRT with breast cancer and cardiovascular complications, the use of HRT had decreased in postmenopausal women. Another possible form of primary prevention may include fat restriction in the diet. This approach was found feasible, but its value in cancer prevention has not been demonstrated. On the same vein, it is legitimate to hypothesize that weight loss may lead to prevention of breast cancer. While reduction in alcoholic drinks may also prevent breast cancer, this beneficial effect may be balanced by a negative effect on the risk of coronary artery disease and on quality of life.

The best studied form of primary prevention has been chemoprevention. At least three randomized controlled studies have explored the prevention of breast cancer with the selective estrogen receptor modulator (SERM) tamoxifen. The NSABP-P1 study involved approximately 13 000 women with a risk of developing breast cancer over the next 5 years of at least 1.67% according to the Gail model of calculating breast cancer risk, and demonstrated more than 50% reduction in the risk of breast cancer in the tamoxifen-treated group. Two European studies did not confirm this effect, but both studies were underpowered due to the relatively small number of patients, high dropout rate, and variation in the risk of breast cancer. The value of tamoxifen and other SERMs in the prevention of breast cancer has also been suggested by other studies:

- A number of randomized and controlled studies showed that tamoxifen prevents systemic recurrence of breast cancer in women with hormone receptor-rich tumors. The same studies demonstrated that tamoxifen reduced by 40% the risk of contralateral breast cancer.
- Tamoxifen prevents the progression of DCIS, a precancerous lesion, to invasive cancer.
- Another SERM, raloxifene, has been studied for the prevention of osteoporosis. In that randomized and controlled trial, the use of raloxifene was associated with a 70% reduction in new breast cancers.

The evidence that SERMs do prevent breast cancer is very robust, but the clinical values of these compounds is debatable. In the NSABP-P1 trial, the prevention of breast cancer was not associated with a decreased breast cancer mortality. In other words, serial mammograms might be as effective as tamoxifen in preventing breast cancer-related deaths. In

addition, tamoxifen was associated with increased risk of uterine cancer, deep vein thrombosis, and cerebral vascular diseases and with a decline in quality of life secondary to hot flashes and sexual dysfunctions. Tamoxifen prevented only well-differentiated hormone receptor-rich tumors, which are generally very indolent, and did not affect the incidence of more aggressive tumors. In a decision analysis Gail concluded that chemoprevention of breast cancer with tamoxifen may be beneficial to a 70-year-old woman only if her chances of developing breast cancer over 5 years were higher than 7%. At this moment, a general recommendation to use tamoxifen in all postmenopausal women for the chemoprevention of breast cancer cannot be made. Another group of hormonal agents, the aromatase inhibitors, which prevent the conversion of androgens into estrogens, are being investigated for this purpose.

In retrospective studies, two groups of medications seemed to have a chemopreventative effect on breast cancer: the non-steroidal anti-inflammatory agents (NSAIDs) and the cholesterol-lowering statins.

Secondary Prevention of Breast Cancer

The best established modality of breast cancer death prevention is early detection through screening of asymptomatic subjects. In women aged 50–70, serial mammography has reduced by 20–30% the breast cancer-related deaths in eight randomized and controlled studies. The benefits of screening mammography after age 70 have been suggested by a retrospective analysis of the Surveillance Epidemiology and End Results (SEER) data, which demonstrated a reduction in mortality in women older than 70 who had undergone at least two mammographic examinations between ages 70 and 80. The reduction in mortality was demonstrable even in individuals with moderate comorbidity. These data support the screening for breast cancer of women with a life expectancy of 5 years or longer, as the initial survival benefits of screening were seen 5 years after the institution of this program. In the authors' opinion, the benefits of screening older women for breast cancer should not be debated anymore. What should still be a matter of discussion is the most cost-effective form of screening. In particular, the following questions should be addressed:

- What should be the interval between screening mammograms? Most studies demonstrated that mammography every 2 years may be as effective as yearly examinations.
- Does physical examination of the breast by a physician or a nurse increase the yield of early breast cancer? Could this approach substitute for mammography? Physical examination of the breast could be performed at a clinic visit without the need of an additional trip for mammograms. In at least two studies, physical examination of the breast appeared as effective as mammography in detecting early invasive cancers.
- Could we the screening be limited to women at increased risk of breast cancer? In a decision analysis, Kerlikowske et al. demonstrated that limiting screening mammography to women in the upper quintile of bone density (i.e., those at the highest risk) would reduce the cost and inconvenience of screening without increasing the mortality or morbidity from breast cancer. This interesting proposal needs confirmation in the clinical arena.
- What is the best form of breast cancer screening? A number of new techniques, including digital mammography and breast MRI, appear more sensitive to the diagnosis of early breast cancer than the standard mammogram and may further decrease breast cancer mortality.

Diagnosis of Breast Cancer

In less than 10% of cases, a woman presents with symptoms of metastatic disease, especially bone pain; in a small number of cases, the woman or her healthcare provider may detect a palpable breast nodule or an enlarged lymph node; and in the majority of cases, the diagnosis of breast cancer is done with a mammogram. Even women who detect a palpable lesion do need a mammogram to study the appearance and the size of the lesion and to exclude the presence of multiple cancers. The radiographic appearance of a lesion indicates the degree of probability that it is neoplastic. For lesions at high probability an immediate biopsy is indicated; for those at intermediate probability a breast ultrasound may help distinguish the benign from the malignant ones; and for those at low probability a repeated mammogram at 6-month intervals is recommended to establish whether they have enlarged. All lesions should be checked for hormone receptors and for HER2neu. Both tests are performed by immunohistochemistry and the results are graded according to the extension of the tumor that is positive. 1+ HER2 staining is considered negative, 3+ is considered positive, and 2+ is considered uncertain and in need of confirmation. For this purpose, the fluorescent *in situ* hybridization (FISH) technique, which is considered the gold standard for assessing HER2neu, is used. Some authors feel that FISH should be used in all patients, as immunohistochemistry may be deceiving: approximately 10% of patients with a tumor negative at

immunohistochemistry are FISH positive and 10% of those with positive immunohistochemistry are FISH negative. The high cost has so far prevented this approach.

The degree of staging necessary at diagnosis is controversial. Immediate staging is conducted if the patients has a locally advanced lesion (stage IIIB or C) or has serious symptoms, such as bone pain, headache, or dyspnea, in which case the imaging of the affected organ is indicated. In the majority of cases staging is delayed until after the initial surgery and is limited to those individuals who have more than three lymph nodes involved, as in all other cases the probability of detecting asymptomatic metastases is low.

The most practical way to conduct the staging may be positron emission tomography (PET) scan, followed by imaging of the organs that are abnormal on PET.

Radioactive bone scan is the most sensitive test to investigate the presence of bony metastases. When doubt persists over whether a positive bone scan indicates bony metastases or inflammatory disease of the joint, other imaging techniques, such as regular radiographs of the bones or MRI, should confirm the presence of metastases. A radiograph of the bones should be obtained every time that a bone scan is positive in the long bones; patients should be referred to an orthopedic surgeon for consideration of surgical stabilization of osteolytic metastases. Metastases to the vertebrae associated with new bone pain should be investigated immediately with an MRI to rule out spinal cord compression.

A number of circulating tumor markers, including the CEA, the CA 15-3, and the CA 27-29, may reflect the course of the tumor. The proper use of these markers is controversial, and most treatment guidelines discourage their use. They may be helpful in patients with multiple metastases undergoing systemic treatment to avoid the discomfort and the cost of repeated imaging, as long as it has been demonstrated that the markers do indeed reflect the progression or the regression of the tumor.

Treatment of Breast Cancer: General Considerations

The treatment of breast cancer varies with the stage of the disease. As for the majority of tumors, the treatment may be local and systemic. After reviewing the various forms of treatment available, a brief description of how these treatments are applied at different stages is provided and the special issues related to the management of the older woman are discussed.

It may be useful at this point to explain the nomenclature that characterizes different forms of treatment:

- Primary treatment is the most important form of treatment: for example, the primary treatment for stage I or II breast cancer is surgery; for stages IIIC and IV, it is systemic treatment.
- Adjuvant treatment, from the Latin *adjuvare,* to help, is treatment given to help the primary treatment succeed. Adjuvant radiotherapy after mastectomy may be used to prevent local recurrences; adjuvant hormonal therapy or chemotherapy may be used to prevent systemic recurrences.
- Neoadjuvant treatment refers to treatment given prior to primary treatment, with different goals, including to reduce the size of the primary tumor and to allow partial mastectomy and organ preservation, as well as to assess the responsiveness of the tumor to systemic treatment and thus establish whether it may be effective as adjuvant.
- Palliative treatment is used exclusively for symptom management, but it should be emphasized that symptom control may also prolong life.

Surgical Treatment of Breast Cancer

Surgical treatment involves mastectomy and axillary lymph node dissection. The radical mastectomy has all but been abandoned and is only used in special circumstances, such as an aggressive tumor involving the pectoral muscles. The modified radical mastectomy, which spares the pectoral muscles, has been replaced in perhaps the majority of cases by a partial mastectomy, which allows preservation of the breast. To prevent the risk of local recurrence, partial mastectomy is generally followed by breast irradiation. Breast reconstruction after modified radical mastectomy represents an alternative to breast preservation.

Axillary lymphadenectomy is associated with long-term complications, including lymphedema and peripheral neuropathy, that may compromise the function of the upper extremities. Since the development of the sentinel lymph node mapping, a complete lymphadenectomy is now required in a minority of cases (approximately 15%).

Lymph node mapping consists of the injection of a supra-vital dye or a radioactive tracer around the tumor, which allows the detection of the first lymph nodes (sentinels) where the tumor lymphatics drain. The sentinel lymph nodes are biopsied, and if they are free of tumors no further surgery is necessary. This practice has now been widely accepted and has markedly reduced the long-term morbidity of

axillary lymphadenectomy. Areas of controversy include the reliability of negative sentinel lymph nodes when the primary tumor has a diameter ≥ 3 cm, and the need to perform a full axillary dissection when the sentinel lymph nodes are microscopically free of tumors, but contain tumor cells recognizable by immunostains for cytokeratin.

Surgery may also be used for the management of metastases, especially single metastases to the brain, and more rarely to the bones, the liver, or the lung. Surgical removal of solitary brain metastases followed by radiation therapy was associated with a more prolonged survival than radiation therapy alone. New techniques including radiosurgery or the use of ultrasounds have largely superseded the surgical management of brain metastases.

Another important surgical intervention involves fixation of lytic bony lesions in long bones, to prevent pathological fractures.

Radiation Therapy

Radiation therapy is used after partial mastectomy and occasionally after modified radical mastectomy to prevent local recurrences. The conditions in which radiation therapy is indicated after mastectomy include a tumor with a diameter ≥ 5 cm, involvement of more than four axillary lymph nodes, extracapsular extension of the tumor in the lymph nodes, and invasion of the chest wall. Ongoing studies explore the use of brachytherapy (radioactive implants) or high-dose intraoperative radiation therapy in lieu of standard external beam irradiation after partial mastectomy. These approaches would prevent the need for daily irradiation for 5 weeks following surgery.

Radiation therapy is invaluable for the symptomatic management of metastases, especially painful bone metastases and brain metastases. One of the problems related to symptomatic management of bone metastases is that painful lesions are generally multiple. In this case the intravenous administration of radioisotopes such as strontium or sumerium may provide prolonged pain relief.

A new radiation technique, called radiosurgery, is commonly used for the management of brain metastases and occasionally of metastases to other organs. Radiosurgery consists of concentrating on the tumors radiation beams coming from several different sources, and in the case of brain metastases appears as effective as standard surgery.

Systemic Treatment

Table 2 illustrates different forms of systemic treatment of breast cancer.

Hormonal Treatment Hormonal treatment has been the mainstay systemic treatment of breast cancer, both in the metastatic and in the adjuvant setting. The aim of hormonal treatment is to eliminate the estrogenic effects on the tumor by antagonizing the estrogen at the receptor level (SERMs, estrogen in high doses), by offsetting the effects of estrogen (progestins, androgens), or by inhibiting the synthesis of estrogen (aromatase inhibitors). Recently, the aromatase inhibitors have become the frontline hormonal treatment for postmenopausal breast cancer, in lieu of the partial estrogen antagonists. The aromatase inhibitors appear more effective, especially because they are also effective in two conditions where the SERMs appear to lose their efficacy: low concentration of hormone receptors and overexpression of HER2/neu. The aromatase inhibitors may also be safer than tamoxifen and toremifene, in that they do not cause endometrial cancer and have lower incidence of deep vein thrombosis; however, they cause bone loss and may increase cholesterol levels. In general, it is recommended to check the patient's bone density at the beginning of treatment and every 2 years thereafter and to institute bisphosphonate therapy for severe osteopenia and osteoporosis. The value of monitoring cholesterol levels is controversial. The activity of the three available agents appears equivalent. The chemical structure of examestane is steroidal while the other two drugs are nonsteroidals. This may be the reason why these agents are not completely cross-resistant. In a small number of patients hot flushes and arthralgia and myalgia may be disabling. Hot flushes are relieved by serotonin receptor agonist antidepressant, and myalgia may respond to vitamin D. The role of the pure estrogen antagonist faslodex is not clear. This drug seems to be as effective as the aromatase inhibitors, but experience with this agent is limited. The main advantage of faslodex is monthly intramuscular administration that may be more convenient and less costly than aromatase inhibitors for patients whose oral medications are not covered by a third-party payer.

Estrogen in high doses and androgens are seldom used; they may be indicated in patients who have failed other hormonal treatments and who do not wish to receive chemotherapy.

Cytotoxic Chemotherapy Cytotoxic chemotherapy is used in patients with hormone receptor-poor tumors, in those whose tumor has not responded to previous hormonal therapy, and in those with life-threatening metastases, such as lymphangitic spread to the lung. Cytotoxic chemotherapy destroys proliferating cells, and for this reason myelosuppression, mucositis, and alopecia are common complications.

Table 2 Systemic treatment of breast cancer

Form of treatment	*Common side effects*	*Other important complications*
1. Hormonal Treatment		
Selective estrogen receptor modulators (SERMs)		
Partial antagonists		
• Tamoxifen • Toremifene	Hot flushes, vaginal secretions, dysuria, myalgia, arthralgia	Endometrial cancer, deep vein thrombosis, cerebro-vascular ischemia, hypercalcemia
Full antagonist		
• Faslodex	Hot flushes, vaginal secretions, dysuria, myalgia, arthralgia	Osteoporosis?
Aromatase inhibitors		
• Anastrazole • Letrozole • Examestane	Hot flushes, vaginal dryness, dysuria, myalgia, arthralgia	Osteoporosis Hypercholesterolemia Coronary artery disease?
Progestins	Weight gain, fluid retention	Deep vein thrombosis
Estrogen high doses	Fluid retention, congestive heart failure, coronary artery disease, deep vein thrombosis	
Androgens	Hirsutism, hair line recession, deepened voice, acne, increased libido	
2. Cytotoxic Chemotherapy	Myelosuppression, nausea and vomiting, mucositis, alopecia	
Anthracyclines		
• Doxorubicin • Epirubicin • Pegylated liposomal doxorubicin (Doxil, Caelyx)		Cardiomyopathy and congestive heart failure Hand and foot syndrome Cardiomyopathy (very rare)
Taxanes		
• Paclitaxel • Docetaxel		Peripheral neuropathy, anaphylaxis Fluid retention
Fluorinated pyrimidines		
• Capecitabine • Fluoro-uracil		Hand and foot syndrome Mucositis
Alkylating agents		
• Cyclophosphamide		Hemorrhagic cystitis, secondary malignancy
Alkaloids		
• Navelbine • Vinblastin		Peripheral neuropathy
Gemcitabine		
Platinum derivatives		
• Cisplatin Carboplatin		Renal insufficiency, peripheral neuropathy
3. Targeted Therapy		
• Trastuzumab (monoclonal antibody against HER2/neu)	Anaphylaxis	Cardiomyopathy, congestive heart failure
• Bevacizumab (monoclonal antibody against vascular endothelial growth factor)	Anaphylaxis, hypertension, bleeding	Visceral perforation

The majority of drugs also stimulate the chemoreceptor trigger zone of the medulla and cause nausea and vomiting.

A number of pharmacological changes make older individuals more susceptible to the toxicity of chemotherapy, including reduced kidney function and decreased functional reserve of normal organs and systems, in particular the hemopoietic system, the mucosas, the peripheral and central nervous system, and the myocardium. The risk and mortality of neutropenic infections as well as the risk of anemia, mucositis, peripheral and central neurotoxicity, and cardiomyopathy increase with age. Anemia is detrimental to the older person in more than one way: it is associated with increased drug-related toxicity and with fatigue that may lead to functional dependence Aware of these pharmacological changes, that National Cancer Center Network (NCCN) has issued some guidelines for the management of older patients with cancer (**Table 3**).

Of particular concern to the older cancer patient are some drug-specific complications that include the following:

- Cardiomyopathy and congestive heart failure from anthracyclines, whose incidence increases with age. Because anthracyclines are among the most active drugs in breast cancer, the prevention of this complication is of special concern. Preventive strategies include combination of doxorubicin and dexrazoxane, a chelating agent, that prevents the formation of free radicals, administration of doxorubicin by continuous infusion or low weekly doses, and substitution of pegylated liposomal doxorubicin (Doxil) for doxorubicin. Other advantages of Doxil include very mild toxicity, with low incidence of alopecia, nausea and vomiting, and fatigue, and for this reason, for some it is the anthracycline of choice in metastatic breast cancer.
- Peripheral neuropathy from paclitaxel, cisplatin, and vinca alkaloid. No effective antagonist exists for this complication. Weekly use of paclitaxel, or substitution of docetaxel for paclitaxel may reduce the risk of neuropathy.
- Mucositis is particularly common and severe with fluorinated pyrimidines (fluoro-uracil, FU). The substitution of intravenous FU with oral capecitabine may obviate this complication. Capecitabine is a pro-drug that is activated directly in the tumor, with the advantage of increased antineoplastic activity and sparing of normal tissues. Together with the anthracyclines and the taxanes, capecitabine is one of the most active antineoplastic drugs in breast cancer and is particularly suitable for older individuals, as the oral formulation allows home administration and dose titration.

Targeted Treatment Targeted treatment indicates treatment aimed at some specific component of cancer. Two monoclonal antibodies, trastuzumab and bevacizumab, directed to HER2/neu and to the vascular endothelial growth factor receptor, respectively, are available for the treatment of breast cancer. Trastuzumab is active only in HER2 overexpressing tumors and may be combined with taxanes or platinum and taxanes. The combination of trastuzumab with anthracyclines has resulted in severe cardiac toxicity, and is currently not recommended. Bevacizumab is ineffective as a single agent but is synergistic with paclitaxel.

Treatment of Breast Cancer: Specific Stage-Related Treatment

Carcinoma in Situ

The treatment of DCIS consists of total mastectomy or partial mastectomy followed by postoperative radiation therapy. When breast preservation is selected, the patient should also receive tamoxifen for 5 years to reduce the risk of local recurrence and invasive recurrence.

LCIS is generally not excised after biopsy. This tumor is generally bilateral, and the chances of a local recurrence are as high, as is the chance of recurrence in the contralateral breast. For this reason some authors recommend bilateral mastectomy. The most common approach is local excision followed by 5 years of tamoxifen.

Table 3 NCCN guidelines for the management of older individuals with chemotherapy

1. Drug doses should be adjusted to the creatinine clearance in individuals aged 65 and older.
2. Prophylactic filgrastim and peg-filgrastim should be used in patients aged 65 and older receiving moderately toxic chemotherapy (adriamycin-cyclophosphamide or adriamycin taxotere) for breast cancer.
3. Hemoglobin levels should be maintained at 12 g/dl or higher.
4. Whenever possible, one should substitute capecitabine for fluorinated pyrimidines and pegylated liposomal doxorubicin for doxorubicin.
5. Some drugs, such as taxanes in low doses, pegylated liposomal doxorubicin, capecitabine, vinorelbine, and gemcitabine, may effectively palliate the symptoms of cancer in frail individuals.

Paget's disease of the breast generally is treated with local excision and radiation.

Early Disease (Stages I–II)

The treatment of early disease generally consists of partial or total mastectomy, lymph node mapping, and full dissection if the sentinel lymph node is involved by the tumor, postoperative irradiation if breast preservation is elected, and adjuvant treatment. Postoperative irradiation to the axilla is administered if more than four lymph nodes are involved by the tumor and/or if there is spilling of the tumor outside the lymph node capsule. Adjuvant treatment is determined by the concentration of hormone receptors and by the involvement of axillary lymph nodes. **Figure 1** illustrates the choice of treatment according to the tumor characteristics.

In postmenopausal women an aromatase inhibitor is currently considered the adjuvant hormonal treatment of choice. Ongoing studies are exploringa the possibility that at least in some patients at low risk of recurrence, sequential treatment with a SERM followed by an aromatase inhibitor may be more effective than the aromatase inhibitor alone. Other studies are exploring the possibility of preventing the aromatase inhibitor-induced osteoporosis with zolendronate, an intravenous bisphosphonate.

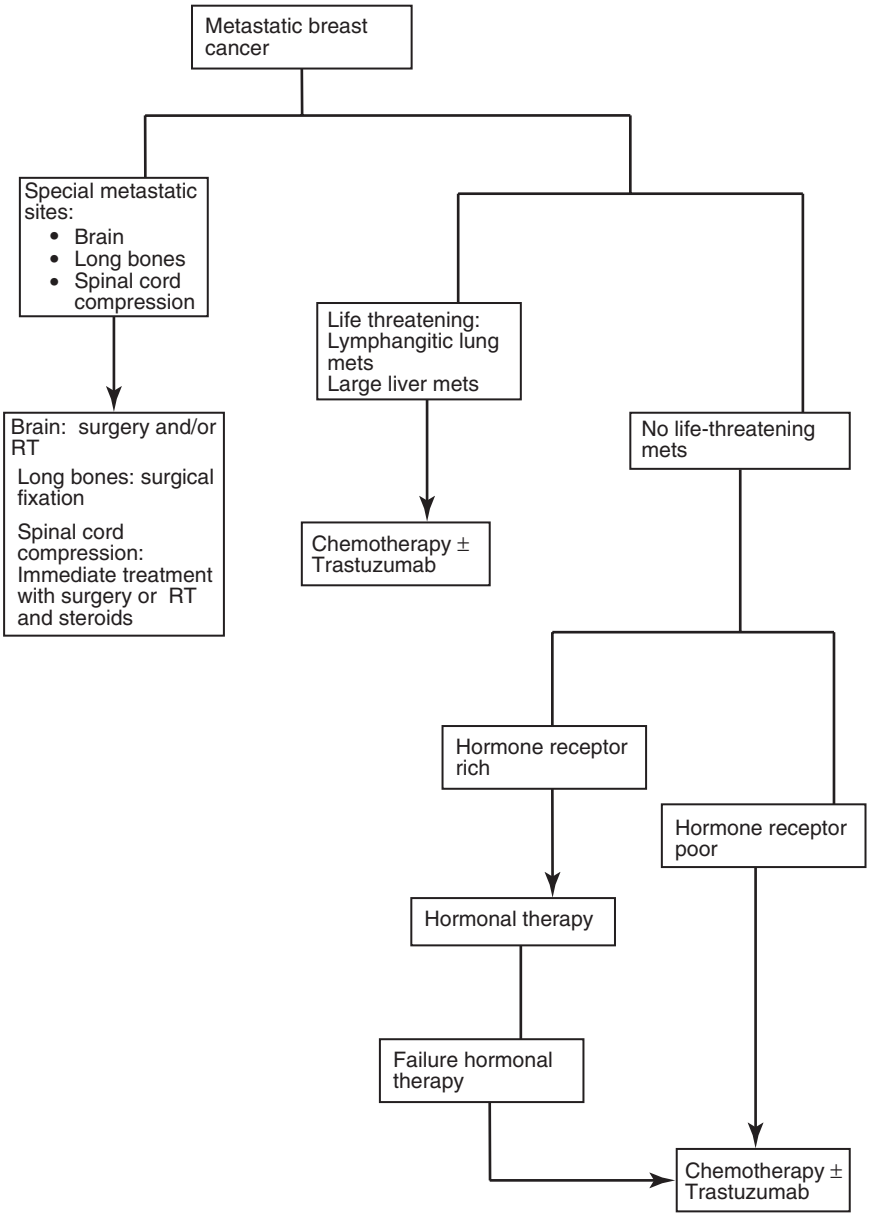

Figure 1 Choice of breast cancer treatment according to the tumor characteristics.

Three recent and yet unpublished studies report that the addition of trastuzumab for 1 year after chemotherapy reduced by more than 50% the risk of systemic recurrence of HER2/neu overexpressing tumors.

Finally, neoadjuvant chemotherapy or hormonal therapy may be occasionally used in these patients to reduce the tumor size and allow breast preservation.

There are a number of age-related controversies in the management of early stage breast cancer:

- Could early breast cancer be managed with hormonal therapy only and without surgery in older women? At least two randomized controlled studies showed that surgery followed by tamoxifen produced a better survival than tamoxifen alone in woman age 70 and over. It is certainly possible that the aromatase inhibitors prove more effective than tamoxifen, but it is not clear whether one more study of this issue is necessary. Mastectomy, even total mastectomy, may be performed under local anesthesia, with minimal risk of complications or quality of life compromise. The benefits of a nonsurgical approach appear negligible or even non-existent.

- Could postoperative radiation therapy be avoided in patients undergoing breast preservation? It is clear that the risk of local tumor recurrence declines with age, and for women over 65 with small tumors (diameter of 1 cm or less), the risk is probably less than 3% at 5 years in the absence of radiation and less than 1% with radiation. The patient may then decide whether this small risk of recurrence is worth the inconvenience and the toxicity (minimal) of the treatment. If brachytherapy or intraoperative irradiation prove effective, this issue of convenience may become irrelevant.

- When is adjuvant therapy indicated? An ongoing meta-analysis of all randomized studies of adjuvant treatment of breast cancer has clearly demonstrated that adjuvant hormonal therapy with tamoxifen (and presumably with aromatase inhibitors) reduces the risk of recurrence of breast cancer by 50% in women of all ages. The benefits of adjuvant chemotherapy instead decline with age and are not apparent after age 70. This is partly due to the small sample size (women over 70 represented 3% of all

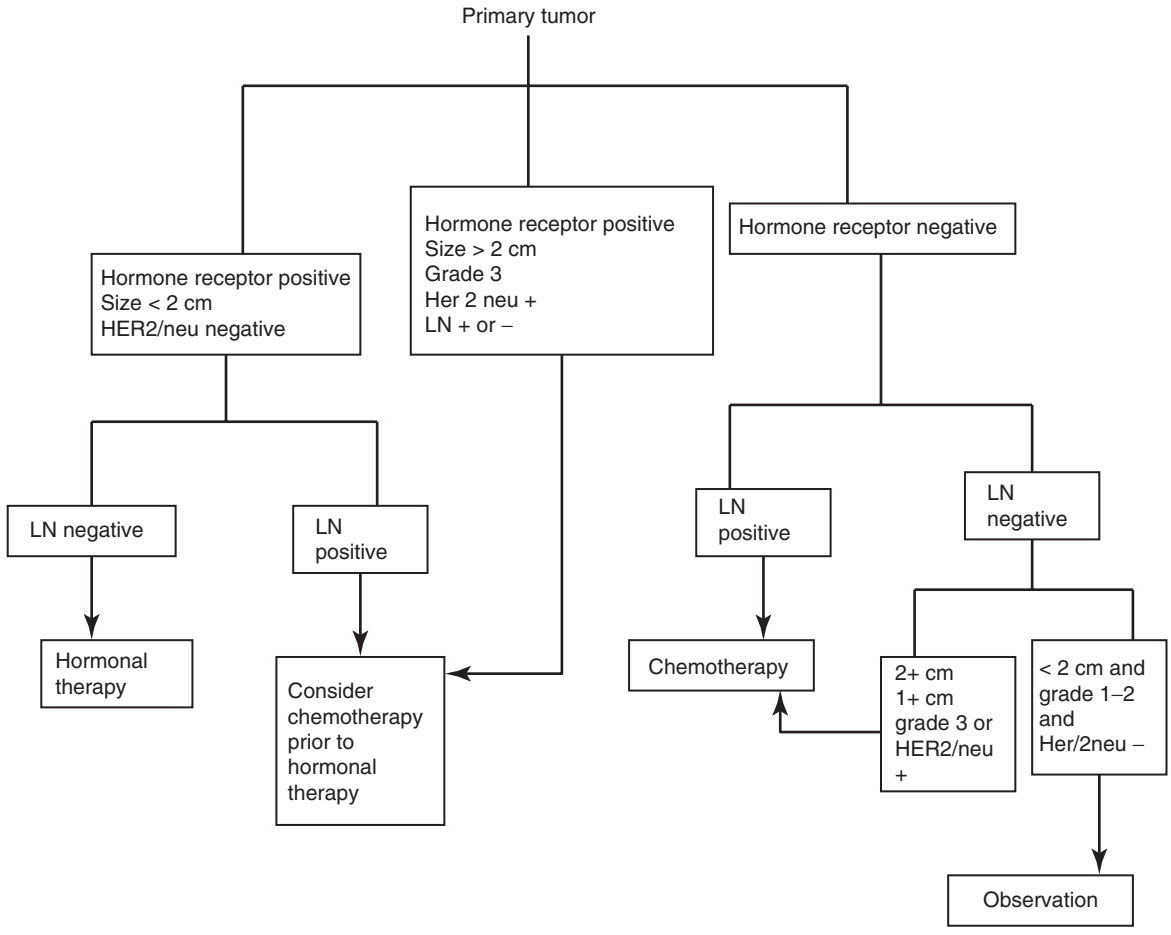

Figure 2 Treatment of metastatic disease.

women included in chemotherapy trials). It is also possible that chemotherapy is less effective in this group of patients with more indolent tumors. Based on current evidence, it seems unreasonable to consider the breast cancer of 70-year-olds different from that of all other postmenopausal women for whom adjuvant chemotherapy is beneficial. A more sensible approach it is to calculate what the effective benefit of chemotherapy is in individual situations based on tumor aggressiveness and life expectancy. This estimate is obtainable with a free online program.

Locally Advanced Disease (Stage III)

In locally advanced disease the initial treatment is systemic (chemotherapy or hormonal therapy for hormone receptor-rich tumors), followed by surgery for stage IIB–IIIA tumors. The benefits of surgery for stage IIIB tumors is controversial. Radiation of the chest wall is always indicated, and radiation of the axilla should be administered for more than four lymph nodes involved by the tumor.

Metastatic Disease (Stage IV)

The treatment of metastatic disease is outlined in **Figure 2**.

As chemotherapy or hormonal therapy does not penetrate the brain in therapeutic concentrations, brain metastases should be resected, when feasible, or irradiated. Stereotactic radiosurgery is now used in the majority of cases in lieu of surgical resection.

Lytic metastases to the long bones, especially to the femur and the humerus, are susceptible to pathological fracture and need surgical stabilization. Spinal cord compression is an oncological emergency requiring immediate treatment to prevent paralysis and incontinence. When only one area of the spine is involved, surgical decompression is the treatment of choice; otherwise, the patient should receive radiation therapy and steroids in high doses.

When the disease is life-threatening, chemotherapy is the treatment of choice, as it acts more rapidly than hormonal therapy.

The choice of hormonal therapy depends on whether the patient has received or is receiving adjuvant hormonal treatment. Clearly, if the metastases occurred while the patient was receiving adjuvant hormonal treatment or shortly (2 years) after completion of adjuvant treatment, an alternative form of hormonal therapy is indicated.

It is also important to add that patients with bone metastases benefit from intravenous bisphosphonates (pamidronate or zolendronate) in addition to their systemic treatment. These agents delay the progression of bony metastases and reduce pain and the risk of bony complications (including fractures and need for palliative irradiation).

Conclusions

The risk of breast cancer increases with age, at least until age 80. Currently 50% of all breast cancer occurs in women ages 65 and over, and this percentage is expected to increase with the aging of the population.

The screening of asymptomatic women for breast cancer reduces the risk of cancer-related mortality and should be continued in all women with a life expectancy of at least 5 years, irrespective of age. The benefits of chemoprevention of breast cancer in older women are not established, with the exception of women at very high risk. It is possible that common medications of widespread use, such as cholesterol-lowering statins or NSAIDs, may also lower the incidence of breast cancer.

The principles of breast cancer treatment do not change with age. However, in older women, postoperative radiotherapy after partial mastectomy may not be necessary; adjuvant chemotherapy should be used only in women in whom it may produce a reduction in mortality; and the toxicity of chemotherapy may be increased. The NCCN guidelines for the management of cancer in older patients may help ameliorate the complications of chemotherapy.

Cardiovascular System

W S Aronow, New York Medical College, Valhalla, NY, USA

Glossary

Afterload – The resistance to ejection of blood by the left ventricle.

Arterial Compliance – The distensibility of the arterial wall.

Atherosclerotic Vascular Disease – A disorder affecting medium and large arteries in which the subintimal deposits of lipids and connective tissue cause a reduction or an obstruction of blood flow through the arteries. This disorder may cause coronary artery disease, peripheral arterial disease, carotid arterial disease, cerebrovascular disease, and abdominal aortic aneurysm.

Contractility – The intrinsic ability of the heart to generate force.

Heart Failure – A disorder in which the cardiac output is not adequate to meet the metabolic needs of the tissues despite an adequate left ventricular filling pressure.

Hypertension – An increase in blood pressure.

Peripheral Vascular Resistance – Measured by dividing mean arterial pressure by cardiac output.

Preload – The filling volume of the left ventricle.

Introduction

Age-related changes in the cardiovascular system, overt and occult cardiovascular disease, and decreased physical activity affect cardiovascular function in the elderly. With aging, there is a loss of myocytes in both the left and right ventricles, with a progressive increase in myocyte cell volume per nucleus in both ventricles. With aging, there is an increase in intimal media thickness and endothelial dysfunction accompanied by both luminal dilatation and a decrease in arterial compliance or distensibility, with an increase in vascular stiffness. Increased vascular stiffness is an independent predictor of hypertension, atherosclerosis, cardiovascular events, and mortality in elderly persons. With aging, there is a progressive reduction in the number of pacemaker cells in the sinus node, with 10% of the number of cells present at age 20 remaining at age 75. With aging, there is also an increase in the prevalence and complexity of supraventricular and ventricular arrhythmias and an increase in the prevalence of left and right bundle branch block.

Afterload

Afterload is the resistance to ejection of blood by the left ventricle. Afterload is composed of two components: (1) peripheral vascular resistance, which is the steady-state component and the opposition to steady blood flow, and (2) characteristic aortic impedance, which is the dynamic component and the opposition to pulsatile blood flow. Peripheral vascular resistance is measured by dividing mean arterial pressure by cardiac output and is inversely proportional to the cross-sectional area of the peripheral vascular beds. Characteristic aortic impedance is measured as the time variation in mean arterial pressure/flow through the aorta and is inversely proportional to the arterial compliance (the distensibility of the arterial wall). An indirect measurement of afterload is the pulse wave velocity, which measures the propagation speed of pressure waves traveling from proximal to distal arterial segments and which increases as arteries become less compliant.

With aging, the large elastic arteries become dilated with a decrease in compliance. Progressive

thickening of the aortic media and intima are associated with aortic enlargement. There is an age-associated increase in arterial stiffness caused by changes in the arterial media such as thickening of the smooth muscle layers, increased fragmentation of elastin, an increase in the amount and characteristics of collagen, and increased calcification. These structural changes are associated with a decrease in aortic distensibility due to increased aortic stiffness with an increase in pulse wave velocity. These structural changes in the arterial wall are independent of coexisting atherosclerosis. An increase in pulse wave velocity with age has been found in a population with a low prevalence of atherosclerosis. The age-associated increase in stiffness and reduction in distensibility of large elastic arteries are not observed in distal arteries.

Impedance spectral patterns have demonstrated an age-related increase in characteristic aortic impedance and in peripheral vascular resistance. The decrease in arterial compliance contributes more to the age-related increase in afterload than does the loss of peripheral vascular beds. Peripheral vascular resistance is not age related in older persons without clinical or occult coronary artery disease but increases with age in persons with coronary artery disease. Arterial stiffening appears as an increase in pulse wave velocity and is associated with degeneration of the vascular media independent of atherosclerosis. Arterial stiffening causes earlier occurrence of wave reflection from peripheral sites to the ascending aorta during left ventricular ejection. Therefore, aortic and carotid phasic pressures increase to a greater magnitude at a later time during left ventricular ejection, causing an increase in systolic and pulse pressures and a delayed peak in the aortic pressure pulse contour.

Circulating levels of catecholamines increase with age, especially with stress. However, β-adrenergic vasodilation of vascular smooth muscle is decreased with aging. α-Adrenergic vasoconstriction of vascular smooth muscle is not changed with aging. The impaired vasodilator response to β-adrenergic stimulation with age is most important during exercise and contributes to the increased afterload associated with aging.

Increased afterload causes an increase in blood pressure. With aging, there is an increase in systolic blood pressure and a widened pulse pressure. A slight decrease in diastolic blood pressure occurs after the sixth decade. The increase in systolic blood pressure is due to interactions of aging, cardiovascular disease, and lifestyle factors such as dietary sodium intake, level of physical activity, and body weight. An age-associated increase in the index of aortic stiffening is not found in normotensive persons on a low sodium chloride diet. The increase in carotid augmentation index (which is an index of aortic stiffening) in highly trained elderly men is one-half of that expected on the basis of age alone.

As aortic compliance is reduced with aging, the transfer of kinetic energy from the blood ejected during left ventricular systole to potential energy stored in the elasticity of the aortic wall is reduced. Consequently, the return of the potential energy stored in the elasticity of the aortic wall back to the kinetic energy of blood flow during diastole is also reduced. Therefore, the left ventricle must eject its stroke volume into a less compliant aorta with greater pressure and force to achieve an adequate cardiac output. The increased pulse wave velocity also causes the pressure in the aorta to increase and peak later in systole, contributing to the increased systolic blood pressure and widened pulse pressure.

Posterior left ventricular wall thickness increases with increasing age in normotensive men and women without coronary artery disease. The increase in left ventricular wall thickness associated with aging is mediated by an increase in systolic blood pressure. Aging is also associated with an increase in the prevalence of hypertension and cardiovascular disease. Therefore, the prevalence of echocardiographic left ventricular hypertrophy increases with age.

Age-associated left ventricular hypertrophy is caused by an increase in the volume but not in the number of cardiac myocytes. Fibroblasts undergo hyperplasia, and collagen is deposited in the myocardial interstitium. Increased afterload increases left ventricular systolic stress with the addition of sarcomeres in parallel. This causes increased left ventricular wall thickness with a normal or reduced left ventricular wall thickness.

It was reported in 2001 that echocardiographic left ventricular hypertrophy was present in 44% of 1881 women, mean age 81 years, and in 43% of 924 men, mean age 80 years. Echocardiographic left ventricular hypertrophy was present in 72% of hypertensive Blacks, in 56% of hypertensive Whites, and in 53% of hypertensive Hispanics. However, echocardiographic left ventricular hypertrophy was present in only 2% of elderly persons without hypertension or overt cardiac disease.

Regular aerobic endurance exercise attenuates age-related reductions in central arterial compliance and restores levels in previously sedentary healthy middle-aged and elderly men. Regular aerobic endurance exercise also can prevent the age-associated loss in endothelium-dependent vasodilation and restore levels in previously sedentary middle-aged and elderly healthy men. These are mechanisms by which regular

aerobic endurance exercise contributes to a decreased risk of cardiovascular disease in the elderly.

Preload

Preload is the filling volume of the left ventricle. Preload is determined by numerous factors that influence blood return to the heart and by the mechanical properties of the heart during diastolic filling of the left ventricle.

Resting left ventricular end-diastolic volume is not age related in healthy persons, indicating that resting preload does not change with age. However, although resting preload does not change with age, left ventricular early diastolic filling decreases with aging.

Passive filling of the left ventricle occurs during the rapid filling and diastasis phases of early diastole. With aging, left ventricular stiffness is increased, left ventricular compliance is reduced, left ventricular relaxation is impaired, and left ventricular early diastolic filling is reduced. This may cause hypotension if preload is reduced. An age-related increase in systolic blood pressure also impairs left ventricular early diastolic filling, leading to hypotension if preload is decreased. Left ventricular filling during early diastole is reduced 50% from age 20 to 80.

Despite the decrease in left ventricular early diastolic filling with aging, preload is maintained because left atrial contraction becomes more vigorous to increase late diastolic filling of the left ventricle. Augmentation of left ventricular late diastolic filling prevents a reduction in left ventricular end-diastolic volume with aging. The ratio of late diastolic Doppler peak transmitral velocity (peak atrial or A wave velocity) to early diastolic Doppler peak transmitral velocity (peak rapid filling or E wave velocity) increases from approximately 0.6 at 30 years of age to 1.2 at 70 years of age. A reduction in E/A wave ratio with aging reflects a decrease in left ventricular compliance. An age-related increase in left atrial size resulting from increased wall stress due to increased left atrial pressure counteracts the effects of reduced left ventricular compliance with aging. It was reported that 38% of 1881 women, mean age 81 years, and 30% of 924 men, mean age 80 years, had echocardiographic left atrial enlargement.

In the Framingham Heart Study, age was the most powerful independent variable for left ventricular filling in healthy persons. Age was inversely associated with the E wave (peak early diastolic filling velocity) and was directly associated with the A wave (peak late diastolic filling velocity). Other independent variables contributing to a lesser degree of left ventricular filling were heart rate, PR interval measured from the electrocardiogram, gender, systolic blood pressure, and left ventricular systolic function. Increasing heart rate decreases peak early diastolic filling and increases peak late diastolic filling velocity. The PR interval on the electrocardiogram is inversely associated with peak early diastolic filling velocity. Women have slightly higher peak early diastolic filling velocities than men. Left ventricular systolic function is directly associated with peak early diastolic filling velocity. Increasing systolic blood pressure increases the peak late diastolic filling velocity.

A decrease in preload is not well tolerated in the elderly. Decreased intravascular volume, reduced venous return to the heart, vasodilation by drugs or disease states, and use of drugs such as diuretics or nitrates decrease preload and may result in reduced cardiac output and hypotension in the elderly. Reduced compliance of the left ventricle and decreased cardiac and vascular responsiveness to β-adrenergic stimulation cause the elderly to be greatly dependent on the Frank–Starling mechanism to increase cardiac output. The elderly are more susceptible to developing orthostatic hypotension. Impaired baroreceptor reflex sensitivity, reduced cardiac responsiveness to β-adrenergic stimulation, loss of arterial compliance, reduced venous return caused by increased venous distensibility, impaired compensatory mechanisms for maintenance of fluid volume and electrolyte balance, increased incidence of common precipitating diseases and disorders, and the use of multiple drugs contribute to orthostatic hypotension. Elderly persons are also more susceptible to developing postprandial hypotension.

Since left atrial contraction can contribute up to 50% of left ventricular filling in a poorly compliant left ventricle, development of atrial fibrillation may result in marked decrease in cardiac output because of the loss of left atrial contribution to left ventricular late diastolic filling. A fast ventricular rate associated with atrial fibrillation will also decrease the time for diastolic filling of the left ventricle.

The incidence of chronic atrial fibrillation also increases with age. According to one report, chronic atrial fibrillation was present in 16% of 1160 men, mean age 80 years, and in 13% of 2464 women, mean age 81 years. The prevalence of chronic atrial fibrillation was 5% in persons aged 60 to 70 years, 13 to 14% in persons aged 71 to 90 years, and 22% in persons older than 90 years.

Cardiac output is increased during exercise in healthy elderly persons by an increase in venous return to the heart, increasing diastolic filling of the left ventricle, and allowing an increased stroke volume to be ejected during exercise. This is the Frank–Starling mechanism. In healthy persons in the Baltimore

Longitudinal Study of Aging, the maximal heart rate response to exercise was reduced with age. However, exercise stroke volume increased with age to maintain the exercise cardiac output. The increase in exercise stroke volume resulted from an increase in left ventricular end-diastolic volume (preload) by the Frank–Starling mechanism. In contrast, healthy non-elderly persons achieved an increase in exercise cardiac output primarily by an increase in heart rate. Exercise stroke volume increased in non-elderly healthy persons by a slight increase in left ventricular end-diastolic volume and by a large reduction in left ventricular end-systolic volume. The exercise-induced increase in heart rate and decrease in left ventricular end-systolic volume in non-elderly persons are probably mediated by β-adrenergic stimulation. The increase in left ventricular end-diastolic volume during exercise in healthy elderly persons suggests that the age-associated decrease in resting left ventricular early diastolic filling does not persist during exercise.

Contractility

The intrinsic ability of the heart to generate force does not change with age in healthy persons. However, the duration of contraction and relaxation is prolonged in senescent animals. Prolongation of left ventricular ejection time and of the pre-ejection period with aging in healthy persons indicates that prolongation of contraction occurs with aging. Prolongation of the duration of contraction in senescent animals is associated with increased muscle stiffness and with prolongation of the action potential duration. These age-related changes are associated with cellular changes in the excitation–contraction coupling mechanism and may be an adaptive response to preserve contractile function in response to an age-induced increase in afterload.

There is no reduction of resting left ventricular ejection fraction or circumferential fiber shortening in elderly persons without heart disease. Systolic function with exercise is impaired with aging. In the Baltimore Longitudinal Study of Aging, elderly persons showed less of an exercise-induced increase in left ventricular ejection fraction than did younger persons because of an age-related increase in left ventricular end-systolic volume. However, absolute values of left ventricular ejection fraction at maximal exercise in healthy elderly persons rarely decreased from basal values. Age-associated decreases in maximal heart rate and in left ventricular contractility during maximal exercise are manifestations of reduced β-adrenergic responsiveness with aging partially offset by exercise-induced left ventricular dilation.

Diastolic Function

Aging is associated with prolongation of isovolumic relaxation time, a reduction in early diastolic filling of the left ventricle, and augmentation of left ventricular late diastolic filling. Normal aging changes affecting left ventricular diastolic function include an increase in systolic blood pressure, an increase in left ventricular wall thickness, a reduction in left ventricular early diastolic filling, prolongation of left ventricular diastolic relaxation, an increase in left atrial size, and an increase in left ventricular late diastolic filling.

With aging, there occurs a slowing of the rate at which calcium is sequestered by the sarcoplasmic reticulum following myocardial excitation, which results in reduced left ventricular relaxation. Accumulation of calcium at the onset of diastole may impair left ventricular diastolic relaxation and early diastolic filling. Decreased oxidative phosphorylation and cumulative mitochondrial peroxidation occurring with aging may also impair left ventricular diastolic function.

Increased left ventricular stiffness with aging due to increased interstitial fibrosis and cross-linking of collagen in the heart impairs left ventricular diastolic relaxation and filling. Myocardial ischemia in the absence of coronary artery disease may be caused by decreases in capillary density, and coronary reserve with aging further impairs left ventricular diastolic function in the elderly.

In addition to a decrease in left ventricular diastolic relaxation and early diastolic filling caused by aging, elderly persons are more likely to have left ventricular diastolic dysfunction because they have an increased prevalence of hypertension, myocardial ischemia due to coronary artery disease, and left ventricular hypertrophy due to hypertension, valvular aortic stenosis, coronary artery disease, hypertrophic cardiomyopathy, and other cardiac disorders. The increased stiffness of the left ventricle and prolonged left ventricular relaxation time impair left ventricular early diastolic filling and cause higher left ventricular end-diastolic pressures at rest and during exercise in older persons.

In congestive heart failure associated with left ventricular systolic dysfunction, the left ventricular ejection fraction is less than 50%. There is a reduced amount of myocardial fiber shortening, the stroke volume is decreased, the left ventricle is dilated, and the patient is symptomatic.

In congestive heart failure due to left ventricular diastolic dysfunction with normal left ventricular systolic function, the left ventricular ejection fraction is normal. Persons with congestive heart failure and

normal left ventricular systolic function but abnormal left ventricular diastolic function are unable to normally increase stroke volume, even in the presence of increased left ventricular filling pressure. Myocardial hypertrophy, ischemia, or fibrosis causes slow or incomplete left ventricular filling at normal left atrial pressures. Left atrial pressure increases to augment left ventricular filling, resulting in pulmonary and systemic venous congestion. The development of atrial fibrillation may also cause a decrease in cardiac output and the development of pulmonary and systemic venous congestion, because of the loss of left atrial contribution to left ventricular late diastolic filling and reduced diastolic filling time due to a rapid ventricular rate.

The prevalence of congestive heart failure associated with left ventricular diastolic dysfunction with a normal left ventricular ejection fraction increases with age and is higher in older women than in older men. In 674 persons, mean age 81 years, with congestive heart failure, a normal left ventricular ejection fraction was present in 44% of Black men versus 58% of Black women, in 46% of Hispanic men versus 56% of Hispanic women, in 35% of White men versus 57% of White women, and in 38% of men versus 57% of women. The Framingham Heart Study reported that 51% of 73 persons, mean age 71 years, with congestive heart failure had a normal left ventricular ejection fraction. The Cardiovascular Health Study reported that 59% of 186 persons, mean age 73 years, with congestive heart failure had a normal left ventricular ejection fraction. Left ventricular ejection fraction should be measured in all persons with congestive heart failure in order that appropriate therapy may be given. For example, calcium channel blockers should not be administered to elderly persons with congestive heart failure and an abnormal left ventricular ejection fraction. Digoxin should not be used to treat elderly persons with congestive heart failure and a normal left ventricular ejection fraction if sinus rhythm is present. By increasing contractility through increasing intracellular calcium ion concentration, digoxin may increase left ventricular stiffness, increasing left ventricular filling pressure and adversely affecting congestive heart failure due to left ventricular diastolic dysfunction. Elderly persons with congestive heart failure due to abnormal left ventricular ejection fraction tolerate higher doses of diuretics than do elderly persons with congestive heart failure and normal left ventricular ejection fraction. Elderly persons with congestive heart failure due to left ventricular diastolic dysfunction with normal left ventricular ejection fraction need high left ventricular filling pressures to maintain an adequate stroke volume and cardiac output and cannot tolerate intravascular depletion. These persons should be treated with a low-salt diet with cautious use of diuretics, rather than with large doses of diuretics.

Cardiovascular Response to Exercise

The maximal oxygen consumption (VO_{2max}) is the best overall measurement of cardiovascular fitness. VO_{2max} is the product of cardiac output and systemic arteriovenous oxygen difference at peak exercise. Maximal cardiac output is the heart rate multiplied by the stroke volume at peak exercise, and is a more direct measurement of cardiovascular reserve than is VO_{2max}. VO_{2max} is reduced with aging. The degree of decrease of VO_{2max} with aging is affected by physical conditioning, subclinical coronary artery disease, smoking, and body weight.

In the Baltimore Longitudinal Study of Aging, older male athletes had a higher peak exercise VO_{2max} than older sedentary men. The greater peak exercise VO_{2max} in older male athletes than in older sedentary men was achieved by a higher cardiac index and a greater systemic arteriovenous oxygen difference. The higher peak exercise cardiac index in older male athletes than in older sedentary men was due to a higher stroke volume index with similar maximal heart rates.

A reduction in maximal systemic arteriovenous oxygen difference occurs with aging. The decrease in muscle mass with aging may play a major role in the decrease in systemic arteriovenous oxygen difference at peak exercise and in VO_{2max} with aging.

The effect of aging upon peak upright cycle exercise was investigated in healthy sedentary men and women aged 22 to 86 years in the Baltimore Longitudinal Study of Aging. Peak cycle work rate decreased with aging in both men and women but was greater in men than in women at any age. Both men and women had, at peak exercise, reductions in heart rate, cardiac index, and left ventricular ejection fraction and increases in left ventricular end-diastolic volume index and end-systolic volume index with aging. Peak exercise stroke volume index did not vary with age in either men or women. The exercise-induced decrease in left ventricular end-systolic volume index and increases in cardiac index, stroke volume index, and left ventricular ejection fraction from rest were greater in older men than in older women.

Therefore, the cardiovascular responses to exercise in healthy elderly persons include the following. Maximal heart rate is reduced with aging. Exercise stroke volume is increased with aging to maintain cardiac output. Increased exercise stroke volume with aging results primarily from an increase in left

Table 1 Prevalence of some cardiovascular disorders in elderly men and women

Cardiovascular disorder	*Mean age (years)*		*Prevalence*			
	Men	*Women*	*Men*		*Women*	
			No.	*Percent*	*No.*	*Percent*
Coronary artery disease	80	81	502/1160	43	1019/2464	41

Left ventricular hypertrophy	80	81	393/924	43	831/1881	44
Left atrial enlargement	80	81	278/924	30	709/1881	38
Idiopathic dilated cardiomyopathy	80	81	10/924	1	19/1881	1

Data from Aronow *et al.* (2001, 2002).

ventricular end-diastolic volume by the Frank–Starling mechanism. The reduction in muscle mass with aging plays a role in the age-associated decreases in systemic arteriovenous oxygen difference and in VO_{2max} at peak exercise. The left ventricular end-diastolic and end-systolic volumes increase during peak exercise with aging. The peak exercise left ventricular ejection fraction is reduced with aging. The exercise-induced decrease in left ventricular end-systolic volume index and increases in cardiac index, stroke volume index, and left ventricular ejection fraction from rest are greater in elderly men than in elderly women.

Cardiovascular Disease

In addition to age-related changes in cardiovascular function and deconditioning due to a sedentary lifestyle in many elderly persons, elderly persons also have a higher prevalence and incidence of cardiovascular disorders that impair cardiovascular performance than non-elderly persons. Aortic valve calcification, aortic sclerosis, and mitral annular calcification are degenerative processes, accounting for their high prevalence in elderly persons. **Table 1** lists the prevalence of some cardiovascular disorders in elderly men and in elderly women.

Careers in Aging

C J Grabinski, AgeEd Mount Pleasant, MI, and Eastern Michigan University, Ypsilanti, MI, USA

Glossary

Geriatricians – Primary care oriented physicians, initially trained in family practice or internal medicine, who gain expertise in caring for older people through completion of a geriatrics fellowship, the board certification examination, and continuing professional education related to geriatric practice.

Gerontological Specialist – Persons from numerous professions and disciplines who devote the major portion of their professional time to working with, for, or on behalf of older persons.

Gerontologist – Graduates of programs offering a bachelor's master's or doctoral degree programs in which the major field of study is gerontology or aging studies.

Gerontology Worker – Persons who work directly with older adults or indirectly on behalf of elders, but who do so without training or education specific to aging.

Introduction

Gerontology is the study of the biological, psychological, and social aspects of aging. From early beginnings in research and theory, gerontology developed into a multidisciplinary field of study and, more recently, into a professional field commonly known as the field of aging. This article identifies key factors that influenced the development of gerontology as a professional field, differentiates three categories of gerontological workers and professionals, delineates generic job roles for gerontological specialists, briefly reviews professional opportunities for gerontological specialists in several traditional fields, provides a glimpse into numerous emerging career paths, and offers recommendations necessary for further career development in the field of aging.

Key Factors in Career Path Development

Three key factors in the development of career paths in the field of aging have been the enactment of federal legislation aimed at improving the quality of life for older persons, growth in the elderly population in the United States, and the advent of gerontology and geriatric education programs in higher education.

Federal Legislation

The first legislation to open a career path in the field of aging was the Social Security Act in 1935, although Social Security Administration personnel usually are not thought of as gerontology specialists. Thirty years later, the Older Americans Act (OAA) of 1965 led to the development of an aging network through which OAA-mandated programs and services are delivered to older adults. Many professionals in the field of aging are employed in this formal aging network. Funding of OAA programs and services flows from the federal level through the Administration on Aging (AoA) to the state-level offices, bureaus, or departments on aging, where state funds may be added to meet the specific needs of a state's elders. These funds then travel into a state's network of Area Agencies on Aging (AAAs), which carry out the functions of needs assessment and funding funnels (i.e., based on the needs assessment of elders in an AAA region, AAA staff issue requests for proposals and award grants to the county and local agencies that will deliver the programs and services). The only direct service to elders generally delivered by AAA staff members is care management. Most program and services delivery is carried out at the county and local level through county or city commissions or departments on aging and other local agencies and facilities. Services delivered include information and outreach, nutrition services, in-home services, activities and leisure programs, employment and volunteerism opportunities, family support, and education about aging and aging-related issues.

Elderly Population Growth

The population of elders in the United States is growing, both in number of older adults and in the proportion of the total population. Population projections show additional increases through 2030. These actual and projected population statistics have multiple implications for the delivery of goods, programs, and services for this population segment. For example, the US Department of Labor Bureau of Statistics predicts an increased demand for occupational therapists, psychologists, physical therapists, social workers, pharmacists, and nurses who have specific education and/or training to work with older persons who are becoming more frail due to physical

conditions, mental health problems, and social service needs. It also is likely that the demand will increase for gerontology-educated professionals to work with persons who are aging well, remain active, and have needs or interests outside of the health-care realm (e.g., products, programs, and services related to advocacy and legal services; architectural services and housing; banking, insurance, and other financial management services; career training, counseling and placement; retirement planning; travel and leisure; product development; transportation).

Gerontology Education in Higher Education

Title V of the original Older Americans Act authorized grants and contracts to public agencies, organizations, and institutions, including institutions of higher education, for training that would prepare persons to carry out the programs and services specified in the act. Such training could be for already employed personnel or for persons preparing for employment in aging-related agencies and organizations. Title III provided grants for community planning, services and training of personnel for programs and centers to offer leisure time activities, as well as services related to information and referral, health, welfare, counseling, and volunteerism of older adults through civic and community services. The first director of training for Title V programs was Clark Tibbitts, a long-time advocate for the inclusion of gerontology curriculum in higher education, especially for graduate-level degree programs in fields such as public administration, recreation, and social work. Tibbitts was also receptive to the idea of degree programs in gerontology. He encouraged program development within universities to meet three career needs and objectives to which AoA assigned high priority: administration of homes for the aged and similar institutions; planning, administration, and coordination (public administration) of programs at federal, state, and community levels; and administration of multiservice senior centers, including positions for recreation specialists in aging.

Title V funding provided seed money for the development of gerontology education programs and centers across the United States; however, not all gerontology education programs in existence today began with AoA funding and some of the AoA-funded programs have not survived. Peterson et al. reported in 2004 that over 50% of US community colleges, 4-year colleges, and universities offer gerontology and/or geriatric courses, while more than 500 US institutions of higher education offer a formal gerontology program (e.g., undergraduate minor in gerontology; graduate certificate in gerontology or specialization in aging; bachelor's, master's or doctoral degree program in gerontology or aging studies). In May 2005, Derek Stepp, Director of the Association for Gerontology in Higher Education (AGHE), indicated that approximately 18 associate, 41 bachelor's, 58 master's, and 9 doctoral degree programs currently are gerontology specific. AGHE has developed standards and guidelines specific to each level and type of program, as well as a review process to help in program development and evaluation. Programs that meet or exceed the AGHE standards and guidelines are eligible for Program of Merit designation. AGHE publishes and regularly updates a *Directory of Educational Programs in Gerontology and Geriatrics*, with updated information about formal credit and postdoctoral training programs in gerontology, geriatrics, and aging studies offered by institutions of higher education in the United States and AGHE members schools in other countries.

Gerontology Workers, Gerontological Specialists, and Gerontologists

With the advent of professional education and training programs in aging studies, gerontology, and geriatrics, it is possible to categorize persons who work with and/or on behalf of older persons as gerontology workers, gerontological specialists, or gerontologists. These categories, however, are neither firmly established across the field of aging nor commonly used among those who serve older adults.

Gerontology worker refers to persons who work directly with older adults or indirectly on behalf of elders, but who do so without training or education specific to aging. For example, certified nursing assistants (CNAs) work directly with elderly clients in long-term care facilities and receive training in direct care processes, but their training does not include content related to the aging process or the elderly population.

Gerontological specialist describes persons from numerous professions and disciplines who devote the major portion of their professional time to working with, for, or on behalf of older persons. Education in gerontology or aging studies, at the associate degree level or higher, means these are professional personnel who understand the aging process and have acquired specific skills to use in working with or on behalf of elders. For many positions, graduate study at the master's or doctoral degree level is required. Gerontological specialists come from a wide array of disciplines (e.g., biology, physiology, sociology,

psychology, history, economics, political science, anthropology, philosophy, religion) and professional fields (e.g., nursing, medicine, occupational and physical therapy, speech pathology and audiology, social work, counseling, pharmacy, dietetics, long-term care administration, political science and public administration, business administration, education, recreation, housing, architecture, interior design, clothing and textiles, family studies and family therapy, journalism, advertising and marketing, music or art therapy). Gerontology is more likely a secondary field of study for gerontological specialists; they tend to major in a discipline or professional field, but also complete academic work specific and/or related to gerontology. For example, a director of social work for a county commission on aging or in a long-term care facility usually holds a degree in social work (BSW or MSW), but also may have completed an undergraduate minor or graduate certificate in gerontology. It is the college degree, plus the specialized education in gerontology, that qualifies this social worker as a gerontological specialist.

Gerontologist is a relatively new professional title that is emerging due to the advent of bachelor's, master's, and doctoral degree programs in which the major field of study is gerontology or aging studies. Technically, it is only graduates of these programs who are eligible to call themselves gerontologists; however, this title continues to be misunderstood and is often used inappropriately. Based on both their formal gerontology education and the nature of their work, gerontologists also may be seen as gerontological specialists. Without the same formal educational background, however, not all gerontological specialists are gerontologists. Since gerontologist is not yet a clearly defined designation and is not yet consistently used within the field of aging, the term gerontological specialist is used in the following discussion.

Employment Settings and Job Roles

Where do gerontological specialists work? What type of job roles do they play? In what ways and situations do they work with older adults?

Employment Settings

Although it is possible for persons with educational backgrounds in gerontology or aging studies to work in almost any setting, it is likely that most are employed in the following:

- Organizations, including professional organizations (e.g., American Society on Aging), organizations that serve specific populations of or issues for older persons (e.g., Alzheimer's Association, American Association of Homes and Services for the Aging, National Caucus and Center on Black Aged, National Hispanic Council on Aging, National Indian Council on Aging, Older Women's League), or senior citizen membership groups (e.g., AARP, Gray Panthers)
- Institutions (e.g., adult day care, assisted living, long-term care, or residential facilities; hospitals, outpatient clinics, and mental health facilities; colleges and universities; churches)
- Corporations (e.g., health-care companies, insurance companies, investment firms, retailers)
- Government agencies (e.g., county commissions, Area Agencies on Aging, state offices on aging, or National Association of Area Agencies on Aging; Social Security Administration or Medicare and Medicaid service centers; health departments; Department of Veterans Affairs; Administration on Aging or National Institute on Aging).

Job Roles

Before exploring some specific professional opportunities, it is important to consider the types of job roles carried out by professionals in the field of aging. Peterson *et al.* identified seven role categories that gerontological specialists commonly fulfill:

1. Advocacy: Professionals in the field of aging are advocates both directly for older adults (e.g., in ombudsperson roles within long-term care settings) and on behalf of older adults (e.g., through policy development, critique, and evaluation).
2. Direct service provision: Gerontological specialists determine needs, develop plans, find resources, and solve problems through their use of processes such as assessment, treatment, counseling, case management, therapy, education, and rehabilitation.
3. Education and training: Gerontological specialists plan, teach in, administer, and evaluate educational programs for and about elders through a variety of venues (e.g., older learner programs and institutes; credit-based courses and gerontology programs in colleges and universities; continuing education and community-based programs; health promotion workshops, seminars, and educational materials; staff development for personnel in agencies and facilities that serve older adults and their families).
4. Management and administration: Gerontological specialists serve as the managers and administrators

of agencies and facilities (e.g., nursing homes and other long-term care facilities; county, state, and federal program, including Area Agencies on Aging) where they assess needs and interests of elders, then develop programs and services to meet the identified needs and services. Gerontological specialists serve as administrators of educational programs and research centers in institutions of higher education.

5. Marketing and product development: As more persons live into later life in better physical and mental health, there is a need for professionals to develop products that improve quality of life for elders. There also is a growing market for products that assist elders with activities of daily living (ADLs) and instrumental activities of daily living (IADLs). Gerontological specialists work in a variety of settings as developers and consultants for new products or product improvement; they also work in advertising, marketing, and sales for these products.
6. Program planning and evaluation: Much of the work of gerontological specialists in the formal aging network is related to the design, implementation, and evaluation of programs to meet the needs of older adults. Such tasks, however, are not restricted to governmental agencies; they are also responsibilities for program administrators and staff in community-based organizations (e.g., senior centers, city recreation programs, adult and community education programs, college/university-based programs for older adults).
7. Research: The earliest gerontological specialists were researchers seeking to gain a better understanding of the processes of aging and the implication of aging for older individuals and the broader society. Research continues to be a primary role for gerontologists with doctoral level education in gerontology-specific or -related disciplines and professions. There also is a growing role for gerontological researchers in applied research.

Gerontological Specialists in Traditional Career Fields

Although an increasing number of new professionals in the field of aging have a gerontology-specific educational background, most current and future professionals come to the field with discipline- or profession-based degrees other than gerontology or aging studies. As a result, they are more likely to seek a position related to their degree that also allows them to work with or on behalf of older persons. Gerontological specialists work in an array of traditional fields, described in the following sections.

Social Work

Social work is one of the fastest growing fields that serves older adults. Social workers provide direct services to elders and their families; they also link their clients with additional programs and services to meet needs (e.g., meal programs, legal services, senior centers, visiting nurse and other in-home services, transportation systems). They consult with, counsel, and educate their elderly clients. They function as discharge planners, casework supervisors, agency and program administrators, policy developers and analysts, ombudsmen and advocates, researchers, client and staff group leaders, and family and in-service trainers. They are trained to be sensitive to population diversity (e.g., ethnic/racial background, socioeconomic status, sexual orientation, spiritual diversity). They work with elders in a variety of settings, such as adult day care centers, adult protective services, alcohol and substance abuse services, Area Agencies on Aging, assisted living facilities, bereavement services, child welfare agencies (related to grandparent caregiving and other family issues), educational institutions, elder abuse programs, employment and volunteer programs, faith-based organizations, family service organizations, home health care, hospice, hospitals or medical centers, information and referral agencies, life care communities, mental health centers, mental retardation and developmental disabilities services, nursing homes, nutrition programs, ombudsman programs, outpatient primary care settings, planning agencies, prisons, private clinical practice, private geriatric care management, protective services, public social service agencies, rehabilitation centers, research centers, respite programs, senior centers, senior housing facilities, and veterans' services. Some gerontological social workers work in non-traditional settings for social work, such as banks and investment firms; corporate eldercare and employee assistance programs; group medical, mental health, and dental practices; insurance companies; law firms and legal or paralegal services; public utilities companies; and labor unions. A baccalaureate degree (BSW) opens the door to direct service with elders in some settings; however, a master's degree (MSW) is required in most clinical settings. The Council for Social Work Education (CSWE) accredits social work degree programs; professional credentials are granted through the National Association for Social Workers (NASW). Social workers also are governed by state licensure regulations. Education about aging

and working with elderly clients is available in more than half of the existing degree programs. There is, however, a shortage of social work faculty with gerontological or geriatric expertise. To address this shortage, one component of the Geriatric Social Work Initiative (GSWI) is the Hartford Doctoral Fellows Program, administered by the Gerontological Society of America (GSA) with funding from the John A. Hartford Foundation. As many as 15 Hartford Doctoral Fellows in geriatric social work are selected each year.

Nursing

Nurses with gerontological educational backgrounds work in hospitals, nursing homes, and other long-term care settings; clinical medicine practices with physicians and other health-care professionals; geriatric assessment centers; hospice programs/facilities; visiting nurse organizations; in-home health-care programs; and other settings where older adults seek medical care. There are three levels of nursing certification that are gerontology specific:

- Associate degree/diploma level: gerontological nurse (registered nurse, certified)
- Baccalaureate level: gerontological nurse (registered nurse, board certified)
- Advanced practice level: advanced practice nurse (registered nurse, board certified) as either a clinical nurse specialist in gerontological nursing or a gerontological nurse practitioner.

Two recent initiatives are aimed at increasing the number of gerontological nurse specialists and improving the quality of gerontological nursing services offered to older adult clients. The John A. Hartford Foundation Institute for Geriatric Nursing is a nurse-led organization intent on helping to shape higher quality health care for older Americans by promoting geriatric nursing through efforts in four areas: nursing education, nursing practice, nursing research, and nursing policy. Nurse Competence in Aging (NCA) is a 5-year collaborative initiative involving the Atlantic Philanthropies (USA) Inc., the American Nurses Association (AHA) through its American Nurses Foundation (ANF), the American Nurses Credentialing Center (ANCC), and the John A. Hartford Foundation Institute for Geriatric Nursing at New York University's Division of Nursing in the Steinhardt School of Education. NCA is committed to the enhancement of geriatric activities by national specialty nursing associations, promotion of gerontological nursing certification, and provision of a web-based comprehensive geriatric nursing resource center.

Therapeutic Recreation

Until recently, the primary role of recreation therapists in practice with older adults was as activity directors in long-term care and community settings. Recently, however, the National Therapeutic Society (NTRS), a branch of the National Recreation and Park Association (NRPA), outlined new directions and trends for practice, including provision of services to medically fragile elders living at home; use of bibliotherapy to stimulate the cognitive skills of older adults; providing therapeutic recreation services to persons suffering from HCV, HIV, and substance abuse; and partnering with public agencies to provide recreational therapy to emotional and behaviorally disturbed children and their families, including family units in which grandparents or great-grandparents are raising their grandchildren. Members of NRPA's Leisure and Aging Section (LAS) work with elders in camping and outdoor experiences, travel and tourism, retirement communities, wellness programs, long-term care facilities, community recreation programs for well older adults, senior centers, and recreational programs for frail elders.

Geriatric Medicine

The American Geriatrics Society defines geriatrics as the branch of medicine that specializes in aging-related diseases and medical problems of older adults. Geriatricians are primary care-oriented physicians, initially trained in family practice or internal medicine, who gain expertise in caring for older people through completion of a geriatrics fellowship, the board certification examination, and continuing professional education related to geriatric practice. Geriatricians commonly work in interdisciplinary or multidisciplinary teams, sometimes called geriatric assessment teams. Additional team members come from related fields (e.g., other medical or surgical specialists, nurses or nurse practitioners, social workers, psychologists or psychiatrists, physician assistants, pharmacists, physical and/or occupational therapists, speech pathologists, audiologists, dietitians). Current and anticipated future shortages exist for both direct-care geriatricians and academic geriatricians to train medical residents.

Clinical Psychology and Clinical Geropsychology

Clinical, clinical work, and working clinically are terms that recognize clinical psychologists as

professional practitioners who hold a doctoral degree in psychology and, based on this degree, are licensed or certified, at the independent practice level, by the state in which they practice. Such clinicians are authorized to diagnose or assess individual clients and furnish preventive and therapeutic services. Standards for clinical psychologists are approved by the American Psychological Association (APA) and by the federal centers for Medicare and Medicaid services. The Omnibus Budget and Reconciliation Act of 1987 increased attention on and services for older adult mental health issues and expanded Medicare reimbursement for mental health conditions of older persons. In 1998, the Commission for the Recognition of Specialties and Proficiencies in Professional Psychology (CRSPP) recommended, and the APA Council of Representatives approved, recognition of clinical geropsychology as proficiency in professional psychology. Recommendations from a 1992 APA national conference on clinical training in psychology and the improvement of psychological services to older persons led to formation of the Interdivisional Task Force on Practice in Clinical Gerontology by APA Division 20: Adult Development and Aging and Section II: Clinical Geropsychology of Division 12: Society of Clinical Psychology. Charged with providing guidance for clinical practice with older adults, task force members developed guidelines related to six practice aspects: attitudes; general knowledge about adult development, aging, and older adults; ethical issues; assessment; intervention, consultation and other service provision; and education. These guidelines are now in effect through August 31, 2010. Additional support for clinical practice with elders has come through two additional venues. The California State Senate Bill 953 of 2002 requires graduate-level or continuing education coursework on aging and long-term care as a prerequisite for licensure to practice as a clinical psychologist. In 2003, Congress appropriated funding, through the Graduate Psychology Education (GPE) Program in the Health Resources and Services Administration's Bureau of Health Professions, for training in geropsychology to overcome a public health shortage in this area. In spite of these initiatives, there remains a shortage of clinical psychologists and geropsychologists to meet the needs of older persons. This shortage is partially due to inadequate education or training in geropsychology for psychology interns, externs, and practicing clinical psychologists. Further initiatives targeted at mental health issues for older adults may spur interest among current and future psychologists. For example, the funding from the Substance Abuse and Mental Health Services Administration (SAMSHA) for the Older Adult Mental Health Targeted Capacity Expansion (TCE) Grant Program is aimed at helping communities build the necessary infrastructure to provide direct services that meet the increasingly diverse mental health needs of older adults.

Rehabilitation Therapy

Rehabilitation therapy is a broad category of professions, including physical therapy, occupational therapy, speech pathology, and audiology. Although these professionals may choose to work in a gerontology- or geriatric-specific setting, most work with persons of many ages who have physical, mental, or developmental disabilities. Their older clients have suffered strokes or hip fractures; had joint replacement, cardiac, or other surgeries; experienced disabling illnesses or accidents; or been afflicted with chronic diseases (e.g., arthritis, Parkinson's disease) or dementia (e.g., Alzheimer's disease). Most frequently, rehabilitation therapists work in clinical settings such as hospitals and long-term care facilities. Most of these professions require a master's degree, and some have licensure requirements that must be met through examination and completion of a set number of years in clinical work. While some rehabilitation therapists have a gerontology education background, it is not required, nor has it been built into their professional education program at the graduate level. In 1978, however, the American Physical Therapy Association (APTA) established the concept of specialist certification programs, and certification in geriatrics is now available.

Long-Term Care and Residential Facility Administration or Management

Some gerontological specialists serve as administrators of an entire residential or long-term care facility, while others serve as the division or departmental directors or managers. They work in settings such as nursing homes, adult foster care homes, adult day care facilities or programs, retirement and continuing care retirement communities, home health-care programs, and other types of residential centers for older adults. These professionals are regulated and licensed by the state in which they work. Many have no formal preparation for the job except their experience as administrator trainees, while some work their way up the ladder from positions such as director of nursing or human resources manager. Others come to the position having completed specific short-term training programs or degrees in fields such as gerontology,

health-care administration, human resources, or personnel administration. A key professional organization for facility and residential administrators and managers is the American Association of Homes and Services for the Aging (AAHSA), which has a research institute and a center for Medicare education. More diverse housing interests of elders means that new types of public and private housing complexes are needed. Gerontological specialists with backgrounds in housing, architecture, facility planning, interior design, and business management are filling positions created by the opening of retirement communities by hotel corporations (some are located on college campuses), age-segregated residential complexes and public housing programs, and grandparent houses to house grandparents and the grandchildren they are raising.

Gerontology Education

Since the advent of gerontology and geriatric education programs in higher education starting in the late 1960s, academic faculty members have been engaged in delivering gerontology coursework and academic programs to students at community colleges, 4-year colleges, and universities. Most faculty members work from within a traditional department (e.g., biology, sociology, psychology, social work, nursing, health administration, interior design, nutrition and dietetics, human development, family studies); however, some are based in a gerontology program, department, institute, or center on aging or research center at their institution. Most have completed doctoral degrees in their discipline or professional field. It is becoming more common that they also have completed some type of formal education in gerontology or aging studies. In the future, some faculty administrators will enter academe with graduate-level gerontology-specific degrees. AGHE, the educational unit of the GSA, is a primary professional organization for gerontology educators and program administrators. GSA and AGHE co-sponsor an annual careers in aging week that encourages activities held on campuses across the country. AGHE publishes booklets and brochures on careers in aging, and works closely with Sigma Phi Epsilon, the gerontology honor society. The theme of the 2005 AGHE annual meeting and educational leadership conference was careers in aging.

Research

Perhaps the longest-standing career option in gerontology is research. Gerontological specialists are involved in the design and conduct of research on every aspect of aging. Early gerontology researchers were primarily discipline based (e.g., biology, sociology, demography, and psychology of aging), used quantitative methodology, tested various theories of aging, and added considerably to the base of knowledge on aging. Various longitudinal studies on aging, such as the Longitudinal Studies on Aging (LSOAs), a joint project of the National Institute on Aging (NIA) and the National Center on Health Statistics (NCHS), and the Duke Longitudinal Study on Aging, have combined quantitative and qualitative methodologies. Gerontology is among the first professional fields to understand the value of qualitative research, as well as other forms of research, including needs assessment, program evaluation, and treatment outcomes research. Research training is built into an increasing number of gerontology education programs; many students in gerontology study programs complete research and have the opportunity to serve as research assistants. The primary settings in which gerontology researchers work are academe, independent or governmental research centers, and medical centers, although some work in corporate and community settings. Gerontology research is funded through governmental programs, foundations, and corporations, which has created career opportunities related to grant writing, grantsmanship, and fundraising.

Emerging Career Paths in the Field of Aging

With continuing growth of the aging population, greater access to gerontology coursework or programs for students at more institutions of higher education, and integration of aging studies into more disciplines and professions, new career paths related to aging are emerging. Among these emerging aging-related career opportunities are the following.

Elder Law

In 1993, the American Bar Association (ABA) developed and adopted a set of voluntary national standards and procedures to accredit a number of specialty certification programs. The National Academy of Elder Law Attorneys (NAELA), a non-profit organization intent on developing and improving lawyer competence in the area of elder law, then founded the National Elder Law Foundation (NELF). Rules and regulations for certification of elder law attorneys were developed by NELF; applications for certification were first accepted in 1994. In February 1995, the ABA House of Delegates approved NELF as the certifying entity for the elder law specialization. For

purposes of certification, elder law is defined as legal practice in the form of counseling and representing older persons and/or their representatives in regard to the legal aspects of physical and mental health status and care, including long-term care planning; legal capacity of the older adult; surrogate decision making (e.g., guardianship and conservatorship); public benefits; estate planning, disposition, and administration; abuse, neglect, or exploitation of the older person; and legal matters related to housing, insurance, employment, retirement, and long-term care. Elder law attorneys also must be familiar with appropriate professional and non-legal services and resources, appropriate standards of professional conduct, and ethical practice. Although many law schools do not yet have elder law degree programs, an increasing number of schools do offer courses related to this specialization or integrate relevant content into existing courses. Most certified elder law attorneys are in private practice, but some are judges, law professors, and staff attorneys in corporate and medical settings. Some attorneys combine family and elder law in their practice or in consultation with public social services and aging agencies.

Financial Gerontology

Around 1990, financial gerontology began to emerge as an applied field that linked applied research, gerontology, and financial professions. In 2002, the American Institute of Financial Gerontology (AIFG) was founded, in partnership with Widener University and the American Society on Aging (ASA), to create educational programming for financial professionals who work predominantly with older individuals. AFIG currently offers two different educational programs in financial gerontology. The registered financial gerontologist (RFG) program is for practicing financial professionals (e.g., accountants/certified public accountants, insurance agents, attorneys, financial planners, reverse mortgage lenders, bank trust officers). RFG candidates complete a multidisciplinary curriculum of four core courses (the new science of wealth span planning; basic processes of aging: physical, psychological, social; serving the older client: values, ethics, and life development; and financing longevity) and two of six possible elective courses (families and aging: resources for professionals; the aging network and the long-term care service delivery system; long-term care solutions; financial preparedness for later life; and successful marketing to the 50+ consumer). These courses are scheduled to coincide with the annual joint conference of ASA and the National Council on Aging (NCOA) in the spring of each year. Candidates also take the RFG comprehensive examination, complete service learning activities, accept the RFG pledge of ethical practice, and pay dues for the Association of Registered Financial Gerontology (includes membership in ASA and in ASA's Business Forum on Aging). AIFG's other program is foundations of financial gerontology, which is designed to meet the needs and interests of non-financial professionals. This curriculum consists of three of the core courses from the RFG program. Participants are awarded a certificate of completion from AIFG and ASA.

Intergenerational Studies

One of the newest gerontology-related fields of study is intergenerational studies, which has grown out of the interest in programs and services that link older adults with youth. Generations Together at the University of Pittsburgh and Generations United have provided key leadership in this field's development. The first certificate program in this field, the continuing education certificate for intergenerational specialists, is a joint effort of Generations Together and the School of Social Work at the University of Pittsburgh. Two major steps in the development of this new field are the establishment in 2001 of the International Consortium of Intergenerational Programs (ICIP) and the publication, starting in 2003, of the *Journal of Intergenerational Relationships: Programs, Policy and Research* (JIR).

Older Drivers Rehabilitation Therapist

The Association for Driver Rehabilitation Specialists (ADED, an acronym retained from the organization's original name, Association of Driver Educators for the Disabled) certifies driver rehabilitation specialists (DRSs). A DRS is a professional who assesses the driving ability of disabled persons, then develops, implements, and coordinates driving rehabilitation services with those persons. The DRS evaluation involves clinical assessment, including a functional (on-road) evaluation, followed by communication of assessment results and recommendation of an appropriate driving status to the client. The evaluation also includes a passenger vehicle assessment, and DRSs consult with the client and relevant agencies about vehicle purchases or adaptations. While DRSs come from a variety of professional backgrounds (e.g., physical therapy, kineseotherapy, driver education, psychology), it is the field of occupational therapy that is taking leadership. The American Occupational Therapy Association (AOTA) is developing a specialty certification for driving rehabilitation, with one emphasis in older driver rehabilitation therapy. AOTA already offers continuing education

on older driver rehabilitation through online courses, workshops at AOTA conferences, and ASA web seminars.

Other Potential Professional Opportunities

New aging-specific or aging-related career paths are emerging out of an array of professional fields. Each of these appear to hold considerable promise to create new avenues for gerontological specialists and gerontologists to work with, for, or on behalf of older adults in exciting new ways.

K-12 Curriculum and Teacher Education Infusion of aging education into the K-12 curriculum has received considerable support over the past 10–20 years, most notably through integration of aging content into existing courses or development of aging-specific curricula for specific subject matter areas (e.g., social studies, health). Gerontology educators have collaborated with K-12 teachers and curriculum specialists to develop curriculum materials and to gain the approval of accrediting agencies and state education departments for the new curricula. Ideally, another effort should infuse aging education into the teacher education and educational administration curriculum by developing a teaching minor in gerontology, accepting some gerontology courses as electives in the degree program, or offering in-service workshops for teachers and administrators. Toward such efforts, gerontological specialists can serve as curriculum developers and consultants or as providers of the in-service training programs.

Music Therapy, Art Therapy, and Writing Program Recent research shows the value of music therapy, art therapy, and writing programs for community-dwelling and institutionalized older adults, especially for those with depression and dementia. These findings open the door for links between gerontology and the humanities in academic education programs and the development of additional career opportunities for gerontological specialists as therapists, program designers, and program leaders.

Applied and Clinical Sociology Some sociology departments are in the process of developing applied or clinical sociology programs at the bachelor's and master's degree level; a few of these programs include tracks in aging. Applied sociology involves the application of sociology knowledge in understanding and solving social problems. Clinical sociology extends knowledge application to the level of intervention and guidance of change processes. Applied and clinical sociologists have expertise in using the techniques of impact assessment, evaluation, mediation, and conflict resolution, counseling, and facilitation. Gerontological specialists in applied or clinical sociology should be able to find career paths in media outlets and mass communication as researchers, news and policy analysts, and pollsters and poll analysts. With mediation and conflict resolution skills, they might work as ombudspersons in long-term care and residential centers for elders, in family mediation, and in community development.

Substance Abuse and Chemical Dependency While some aging persons bring with them into old age the substance abuse problems from across a lifetime, others develop substance abuse and chemical dependency problems in later life. This opens up new career opportunities for gerontological specialization in professional fields such as law enforcement, pharmacy, nursing, medicine, and counseling.

Family Gerontology Emerging from within the field of family studies, family gerontology recognizes the impact of changes in family structure, processes, and relationships on older family members. Current hot areas of professional practice with elders and their families relate to caregiving for elderly family members, grandparents raising grandchildren, and grandparent visitation rights. This opens new career path opportunities for gerontological specialists as family life educators and program administrators, family and elder law attorneys, family mediators, family therapists, and family gerontology policy specialists.

Entrepreneurial Gerontology Gerontological specialists often look for niche opportunities to meet the needs and interests of older adults in unique and creative new ways. Entrepreneurial gerontology allows professionals to develop new tools, products, programs, and delivery systems through their positions as consultants, product developers, project or program managers, and small business owners. For example, one gerontological specialist in interior design now assists older persons with housing transitions, while another consults with small town chambers of commerce and business owners interested in helping their clientele age in place. A former gerontology program director is a traveling professor who teaches condensed-schedule and distance learning niche courses (e.g., sexuality and aging, women and aging) on campuses where resident expertise is not available. A burned-out adult protective services social worker now presents elder abuse prevention seminars and workshops. A new graduate with a bachelor's degree in clothing and textiles and a minor

in gerontology created a position with a long-term care facility to design and make adaptive clothing for elderly residents and dementia patients. Yet another gerontological specialist trains managers and staff members of chain restaurants in regard to employment of older adults and providing age-appropriate services for older clients. These real and hypothetical situations only hint at the possibilities for gerontological specialists in entrepreneurial gerontology.

Conclusion

The field of aging is a tremendously diverse field that offers a wide array of professional career paths. As noted, some of these paths are through traditional career positions within traditional professions and academic disciplines. New career options also are emerging in both traditional fields and emerging subfields of gerontology or related professions. Yet other career opportunities are available in disciplines and professional fields not addressed here (e.g., anthropology, history, spirituality and religion, marketing, advertising, public policy). Also, persons interested in working with, for, and/or on behalf of elders can now develop their own niche practice as entrepreneurial gerontologists and gerontological specialists. Increases in life expectancy and a growing population of elders with diverse needs and interests should encourage the development of even more and different types of professional practice in the field of aging.

With many existing professional positions in the field of aging and the potential for development of yet more types of career paths related to aging, it is vital that adequate gerontology education opportunities exist to prepare new professionals in a wider array of academic disciplines and professional fields. Toward this end, it is necessary to more clearly define what a gerontologist is and what a gerontological specialist is. Development of a career ladder for the field of aging is recommended. Along with degree- and certificate-based career paths, this career ladder needs to include paraprofessional positions that require gerontological content in the training programs. To be effective in such a diverse career field, the ladder must combine the best features from both continuum and hierarchical models so that it allows for increasing complexity and responsibility, as well as for parallel but differentiated career paths. Gerontology program administrators and faculty members must work harder to introduce students to gerontological career options earlier in the students' college experience. Faculty members from more departments and programs across campuses need assistance in identifying gerontology-specific and -related opportunities that are possible in their disciplines and professions. It is vital that university administrators (e.g., deans, provosts, presidents, chancellors) gain a broader understanding of the importance of gerontology education for all students and support gerontology-specific career path education that exists or could exist on their campuses. Finally, it is necessary to educate the general public about the value of adequately educated professionals in the field of aging and the benefits gained through working with gerontological specialists in many, if not all, aspects of their lives.

Caregiving and Caring

C J Whitlatch and L S Noelker, The Margaret Blenkner Research Institute, Cleveland, OH, USA

Glossary

Care Receiver – A person who requires day-to-day assistance due to illness, accident, or disability.

Community-Dwelling Adult – An adult who lives in a private home rather than in an institutional setting.

Formal Caregiver – An individual associated with a service organization or independent contractor who is paid to provide or manage care for persons with chronic illnesses or disabilities. Volunteers associated with a service organization are also considered formal caregivers.

Informal Caregiver – A family member or friend, typically unpaid, who provides or manages care for a person with a chronic illness or disability.

Long-Term Care – Assistance provided over an extended period of time due to chronic illness or disability either at home or in an institution.

Introduction

Caregiving is the act of providing assistance or care to a family member, friend, or client with a chronic illness or disability so that she or he can maintain an optimal level of independence with dignity. This assistance can be instrumental or hands-on, affective, financial, or otherwise of value or necessity to the care receiver. Caregiving varies in its intensity and duration, ranging from 1 hour per day, or one weekend per year, to 24 hours a day for years at a time. Caregiving can occur within a community or home setting, an institutional or assisted living setting, or from a distance. Although providing care can be stressful to both caregivers and care recipients, the effects on caregivers can be long term, lasting for many years after care responsibilities have ended.

Background on Caregiving

Research on informal and formal caregivers has grown dramatically in both quality and quantity over the past decades. With increasing sophistication in both theory and methodology, caregiving research at the beginning of the twenty-first century is characterized by its continued advances in theory, methodology, interventions, and application for policy development. To appreciate the growing significance of caregiving research, it is important to understand caregiving's prevalence and impact as well as current conceptual frameworks that guide and evolve from empirical findings.

Prevalence of Caregiving

The growing percentage of adults age 65 and older in the United States, and particularly those over the age of 85, has a dramatic effect on the prevalence of caregiving. In 1980, 11.2% of the population was 65 years of age or older, and in 2000 this percentage had increased to 12.4%. Moreover, it is projected that by the year 2050, over 20% of the US population will be at least 65 years old.

It is estimated that more than 7 million of the 33.3 million adults in the United States age 65 and older require assistance with personal care or daily activities such as bathing, dressing, and housekeeping. By and large, families and friends provide the majority of assistance with hands-on care as well as emotional and financial support. Specifically, 71% of all long-term care is provided to older adults in the community by an estimated 5.8 to 7 million family members and friends. These estimates are based on the 7 to 8 million community-dwelling elderly with at least one functional disability or with Alzheimer's disease or other type of degenerative dementia. When younger disabled persons (i.e., those age 20 and older) are included, the estimated number of informal caregivers rises to 52 million. An additional 1.69 million informal caregivers continue to provide some level of assistance to their relatives when they are institutionalized.

Types of Care

Empirical research documents the wide variety of help required in relation to the characteristics of both the caregiver and care receiver. One critical factor is the type of functional impairment and the nature of the debilitating disease. For those over age 65, impairments include sensory (14.2% or 4.7 million), physical (28.6% or 9.5 million), mental (10.8% or 3.6 million), self-care (9.5% or 3.2 million), or difficulty going out of the home (20.4% or 6.8 million).

Another factor is presence of cognitive impairment, because these adults have different care needs compared to physically impaired adults who are

cognitively intact. For example, caregivers of adults with physical impairments (e.g., stroke, multiple sclerosis) report providing substantial assistance with self-care activities such as bathing, dressing, and walking. In addition to assisting with self-care activities, caregivers of adults with cognitive impairments (e.g., Alzheimer's disease, degenerative dementia) report spending a great deal of time and energy dealing with their relative's problem behaviors, such as agitation, memory loss, and wandering.

Additional factors that affect care provision include social network characteristics, household income, and access to community services. It is often assumed that caregivers use formal services only after they have exhausted all sources of informal assistance. While this is true for many families, access to services is also linked to factors related to social network characteristics such as its size, the proximity of network members, and their knowledge of community resources. Income level also is associated with use of formal services because most community-based long-term care is paid out-of-pocket. Thus, income and network characteristics are interrelated and instrumental to the accessibility of services.

Providers of Care

Informal Caregivers

The care received by millions of older adults comes from a variety of sources. Although informal care is the most preferred and frequently used source of assistance for older adults, formal care services also supply a great deal of support, especially for the millions of older adults who live alone or have no family or friends available to assist. Older adults who have a choice, however, prefer that family and friends help them once assistance becomes necessary.

Primary and Secondary Caregivers When assistance becomes necessary, families often go through a period of reorganization as they restructure their lives. Frequently, one individual, whether by choice, availability, or convenience, becomes the primary caregiver. The job of the primary caregiver, although rarely specified, is to be the direct provider and/or manager of the elder's care. The stressful and long-term nature of providing care causes many primary caregivers to seek assistance from other family members, friends, or service providers. However, it is understood, though not necessarily made explicit, that the primary caregiver is the main person in charge of the relative's care.

A naturally occurring hierarchy seems to exist within families that often leads to a designated primary caregiver. When care recipients are married, spouses will most likely become the primary caregiver. Adult daughters are also likely candidates. According to Spector *et al.*, approximately 13.4% of family caregivers are wives, 10.0% are husbands, 26.6% are adult daughters, 14.7% are sons, and another 17.5% and 8.6% are 'other' female or male relatives, respectively. In addition, the quality of the caregiver's relationship with the care receiver is associated with who will provide care. Family members who have contentious or antagonistic relationships with the care receiver are less likely to provide care than those relatives who are more compatible. Unfortunately, when the caregiver and care receiver are not compatible, it is common for both to experience heightened distress.

The health of family members, proximity to the care receiver, and demands of their daily lives are additional factors that influence whether or not a family member will become the primary caregiver. These factors also influence the level of involvement family members have in the provision of care. If a family member is in poor health or is at risk for worsening health, he or she is less likely to become a primary caregiver. About one-third of primary caregivers assume the role because they live closer to the care recipient, although an increasing number of family members are assuming care responsibilities from long distances. Relatives with multiple or competing family demands (e.g., employment, child care needs) are also less likely to be caregivers. However, even under demanding and stressful conditions, family members are still more likely than service providers to provide care.

In contrast to the primary caregiver, secondary caregivers typically provide unpaid supplemental or intermittent assistance. Most older adults have more than one informal caregiver, although informal caregiving networks tend to be relatively small, averaging two in number. Secondary caregivers typically supplement the help provided by primary caregivers, particularly in the areas of household tasks, personal care, and socialization. In contrast, assistance with money management and medical care appears to remain the responsibility of one caregiver, generally the one who has more expertise in the area. Secondary caregivers also supply important assistance to the primary caregiver as well as the care receiver. They are a prominent source of companionship and emotional support for the primary caregiver as well as a source of respite or relief from caregiving responsibilities. In total, informal caregiving networks supply an average of 7 hours of help daily to community-residing impaired older persons.

Home-Based versus Institutional Care The responsibilities of caregivers were once thought to end once a care receiver entered an institutional setting such as a nursing home. Research indicates that caregivers continue to remain active in the lives of their impaired family members once institutionalization is necessary. Family caregivers visit often and may travel great distances to spend time with their relatives. Caregivers of nursing home residents often perform many of the tasks they did while caring at home, including assistance with eating and walking. In fact, a large majority of caregivers remain active in the lives of their relatives for many years after they enter the institution.

The continued involvement of family caregivers following placement, however, may result in additional or new sources of distress. Once their relative is institutionalized, caregivers must restructure their lives and adjust to their new role. Research indicates that the stresses of caregiving are not alleviated by placement. Although these caregivers are relieved of the day-to-day demands of caregiving, many continue to feel distress, and some exhibit symptoms well above their pre-placement levels of distress. Thus, it appears that placement alters rather than eliminates stress.

Consequences of Caregiving There is substantial empirical evidence indicating that the stress of providing in-home care over the long term affects a caregiver's mental and physical health. Caregivers are more depressed than age-matched controls, exhibit deficits in physical health and depressed immunologic functioning, use prescription drugs for depression, anxiety, and insomnia two to three times as often as the rest of the population, and have higher rates of comorbid health conditions and mortality.

Caregivers also report financial strain as a result of providing in-home or institutional care over the long term. In some areas of the United States, for example, the cost of caring for an adult with Alzheimer's disease has been estimated to be $50 000 per year. Compared to their age peers in the general population, caregivers are more likely to report adjusted family incomes below the poverty line. Adding to this financial strain is the fact that care-related responsibilities often lead to changes in work status. Caregivers often lose time from work, chose to retire early, or give up work entirely while they are helping their impaired relative.

Another potential consequence of caregiving is its negative effects on the caregiver's relationships with family members and friends and decreased time for leisure and social activities. Families that have difficulty problem solving, coordinating their efforts, and communicating often have difficulty planning and managing the long-term care of their relative, as do those with a history of dysfunctional relationships. This often results in family conflict regarding caregiving arrangements and can even lead to the estrangement of one or more family members. On the other hand, family caregivers often complain that they have no personal or leisure time. Hence, their participation in social and recreational activities declines, as does their ability to travel and take vacations, which can lead to social isolation and loneliness. Some caregivers even complain of not enough time to attend to important personal needs such as medical appointments and exercising.

Characteristics of the care receiver's illness are related to compromised health for caregivers. For example, the severity of the care receiver's illness has been found to be the most important predictor of caregiver stress. This finding is similar for caregivers of persons with stroke, dementia, cancer, and other debilitating illnesses. When the impaired persons' behaviors become unpredictable and ambiguous, caregiver distress is often exacerbated. Thus, behaviors such as acting out, wandering, and agitation are associated with increased caregiver distress. Last, cognitive impairment during the early stages of a disease appears to be more stressful for caregivers than cognitive impairment in the later stages.

Despite the extensive evidence about the adverse effects of caregiving, some evidence suggests that caregivers can experience positive effects from the experience. Although far less research has been directed to the benefits of caregiving, existing evidence indicates that caregivers often define the experience as satisfying, one that gives meaning to their lives and provides a sense of personal mastery or self-efficacy. It is important to gain more knowledge about caregiving's benefits in order to have a more balanced perspective on the caregiving experience and to enable clinicians and service providers to use a strength-based approach to service plans that capitalize on caregivers' capabilities.

Formal Care

Compared to persons younger than 65 years of age, older persons disproportionately utilize more acute and long-term health-care services, whether home- and community-based or institutional (hospital and nursing home). Consequently, they and their informal caregivers are more widely affected by legislation that significantly changed reimbursement for health care and led to corresponding changes in health-care provision. In 1983, the implementation of the Medicare Hospital Prospective Payment

System dramatically altered admission and discharge patterns, effectively transferring 21 million hospital days to home and community. The 'sicker and quicker' discharge of older persons from the hospital placed a heavier burden on informal caregivers and spurred the growth of hospital-based and proprietary home-care agencies.

Another important piece of legislation designed to improve the quality of care in nursing homes was the Omnibus Budget Reconciliation Act (OBRA), passed in 1987. It led to an increase in training requirements for nursing home staff and changes in resident care planning and monitoring. OBRA also addressed the pressing issue of the frequent impoverishment of community-dwelling spouses of nursing home residents. It mandated policies allowing these spouses to retain the equity in their home and one-half of their other assets so they could continue living independently. However, it is not clear that these changes actually resulted in improved care, more positive attitudes toward nursing homes, and decreased spousal impoverishment.

The National Family Caregiver Support Program (NFCSP), funded through the Older Americans Act reauthorization in 2000, is the most comprehensive federal legislation that supports caregivers of older relatives, grandparents, and other relatives who care for children 18 years of age and younger, and older adults caring for persons with developmental disabilities. As part of the NFCSP, states are expected to work with area agencies on aging (AAAs) to develop multifaceted systems of caregiver support in five areas: (1) information about available caregiver services, (2) assistance in gaining access to services, (3) counseling and the organization of support groups and caregiver training, (4) respite care, and (5) other services that complement the care provided by caregivers. As yet, it is unclear how these dramatic changes in reimbursement and the organization of health-care systems will affect older persons' patterns of formal service use and their outcomes, alter the role of family caregivers, and affect attitudes toward and patterns of nursing home use.

Prevalence of Community-Based and Institutional Service Use Findings from the 1987 National Medical Expenditure Survey indicate only 36% of the 5.6 million Americans age 65 and over with functional disabilities use community-based services (e.g., home health care, homemaker, day programs, telephone monitoring, special transportation, senior centers offering congregate meals). The majority of this care (75%) is paid for by the individual, while the public sector covers the cost for the remaining one-fourth. More recent information on home-care expenditures following passage of the Balanced Budget Act in 1997 shows the elderly population had the greatest decline between 1996 and 1999 in use of paid home-care services, primarily those reimbursed under Medicare. With negative changes in the US economy since 2001 and shortfalls in state budgets, federal and state dollars available to cover the costs of home- and community-based services are shrinking.

About 20% of disabled older persons rely on formal services, while 16% combine informal with formal care, 35% exclusively use informal care, and 29% have no assistance. Home care is the most widely reported service used, although studies involving the older population in general suggest that services offered by senior centers are more commonly utilized. The most frequently used type of help by disabled elderly is housekeeping and meals; in fact, housekeeping is also the most widely used assistance by elderly without chronic disabilities. Among disabled older persons receiving community-based services, over two-thirds use entirely home-based services. This sizable group of home-based services users is composed largely of the most severely impaired older adults. Another one-fourth of older adults rely exclusively on out-of-home services at senior centers, day programs, and congregate meal sites. A small minority (about 10%) combine in-home with out-of-home services.

Long-term residential care services are used by only 5% of the elderly at any given time. However, 25 to 35% of older Americans can expect to spend some time during their later life in a nursing home. In addition to the problems related to combining private living space with ongoing medical care and generally unfavorable attitudes toward nursing homes, the high cost of nursing home care dissuades many elderly and their families from its use or causes them to use it only as the last option. An alternative to nursing home care is assisted living, which maximizes the older person's lifestyle choices in a less restrictive housing environment that also supplies supportive services (e.g., housekeeping, transportation, meals, and sometimes supervision of medications and personal care) (*see* Long-Term Care).

Predictors of Service Use by Older Persons and Their Caregivers The stressful nature of caregiving has led many researchers to examine the impact of service use on caregiver well-being. Social support models have been adapted and applied to explain the elderly's use of both informal and formal assistance. This approach is based on the recognition that the exclusion of formal service use from models of social support weakens the full effects that

assistance from others has on the individual's adjustment to negative life events. Moreover, these models incorporate the fact that informal and formal helpers often perform similar functions for chronically ill older persons, including emotional support and instrumental help with personal care and household tasks.

Many of the same predictors explain the elderly's use of community-based and nursing home care. These predictors include advanced age, gender (female), cultural background (Euro-American), marital status (unmarried), living arrangement (alone), and level of functional disability. Additionally, the absence of a willing, able, and proximate informal caregiver is a major factor in nursing home placement. This is particularly salient when the older individual has a neurological condition such as a stroke. Generally, family members control the timing of nursing home entry and physicians exert a major influence on the decision, particularly when discharge planning from the hospital is involved.

Research has examined predictors of mixed helping networks for elderly living at home. Formal and informal help are more commonly used when the elderly person is of more advanced age, is living alone, and is more functionally impaired; the informal caregiver(s) is a more distant or unrelated kin member; and more financial resources are available to purchase services. Interestingly, including race as a predictor of mixed helping networks has had little explanatory power once other important factors, namely, functional status and health change, were controlled. Consistent with findings from most studies, women and those living alone are more likely to have mixed networks, Whites disproportionately tend to use nursing home care, and married elderly tend not to use formal helpers. Although African American elderly are less often married, their typically larger households and greater variety of informal helpers are thought to counterbalance the absence of a spouse caregiver.

Since the mid-1980s, services targeted to informal caregivers have been developed and have become more widely available based on the demonstrated stressful effects of long-term caregiving. These services include respite care, peer- and professionally led support groups, educational programs in care-related skills, training in problem-solving skills and behavioral techniques for patient management, and counseling and psychotherapy. Evaluations of these interventions have yielded mixed results, and a number have been compromised by sampling and other methodological limitations. Research studies are focused increasingly on determining the most effective intervention for specific types of caregivers, the most effective timing of these interventions, and the most appropriate duration of use.

One difficulty commonly encountered in evaluations of caregiver interventions is enrolling sufficient numbers of caregivers in study samples, even when the service is provided free of charge. Various explanations offered for the apparent underutilization of care-related services include unfamiliarity with the service, lack of perceived need, reliance on informal helpers for care-related assistance, absence of culturally relevant services, and barriers to the service system and the delivery of services. To date, relatively little empirical attention has been given to the prevalence, sources, and predictors of care-related service use. In general, however, the predictors of caregiver service use are kinship tie (adult child), living with the care receiver, being employed, more perceived care-related stress, and more informal and formal assistance provided to the care receiver.

Heterogeneity among Caregivers

It is well documented that caregivers experience their role differently depending upon their gender, kinship tie, age, and cultural or ethnic identity. Advanced research designs and methodological techniques have led to a better understanding of the interrelationships among the sociodemographic characteristics of caregivers and their impact on care-related outcomes.

Gender and Kinship Ties Studies of caregiving families indicate that women are more likely than men to (1) take on the role of caregiver, (2) spend more time providing care whether they are employed or not, and (3) provide personal care assistance. Male caregivers tend to take on more instrumental tasks such as decision making and financial management. Among men, husbands are most likely to be caregivers; sons and sons-in-law are much less likely to take on the role. In fact, it is more common for an older woman to be cared for by her daughter-in-law than by her son. Women report greater distress than men, regardless of the care receiver's diagnosis and level of impairment and the caregiver's employment status. Studies that compare adult daughter and wife caregivers suggest mixed results: some studies find daughters to be more distressed, while other studies report the reverse or find no differences by kinship tie.

One explanation for these gender and kinship differences draws upon studies of health and well-being in the general population indicating that women commonly score higher than men on indicators of stress, suggesting women may be more comfortable than men expressing feelings of stress. It has also been suggested that the nurturant role developed by

men in later life may be rewarding or act as a form of repayment for the care they received in the past, which in turn helps to counteract the otherwise negative effects of caregiving.

Age The effects of caregiver age are nearly impossible to disentangle from the effects of other caregiver and care receiver characteristics. For example, age and kinship tie are confounded for spouse caregivers who are significantly older than other groups of caregivers. In addition, there is conflicting evidence about the relationship between caregiver age and distress; some studies find older caregivers to be the most distressed, while other studies find younger caregivers to be the most stressed. However, among employed caregivers, especially those with both child- and adult-care responsibilities, younger caregivers are more likely to experience greater distress as well as absenteeism, interruptions at work, and difficulty in combining work and family.

A related issue concerns older generations caring for younger generations. It is common for elderly parents to care for their disabled adult children and grandchildren. Within the African American community, increasing numbers of mid-life and older women have primary responsibility for their grandchildren and great-grandchildren. Typically, a family crisis precipitates a grandparent taking on the caregiving role, such as the incarceration or death of the grandchildren's parent. The conditions under which grandparents generally, and grandmothers in particular, become caregivers often reflect the broader social context within which these older caregivers live. Furthermore, the circumstances resulting in the parent's inability to care for the child often compound the problems that grandparents encounter in caregiving. Some of these problems include little or no child support, low income, inferior family leave policies, and inadequate social support, as well as the caregivers' own physical health problems. Differences in this phenomenon are evident by cultural group: 12% of African American children live with grandparents, compared to 5.8% of Hispanic children and 3.6% of White children.

Ethnic and Cultural Differences Until the 1990s, little was known about the how the caregiving experience varies in relation to cultural and ethnic identities. Advances in cross-cultural research have demonstrated the diversity among caregivers throughout the world, including differences between developing and developed countries, and urban and rural settings.

Within the United States, research indicates both similarities and differences among caregivers depending upon their ethnicity. Some work suggests that for family members caring for relatives with a variety of disabilities, there is no clear relationship between the caregivers' ethnicity and the amount of stress they experience. Yet regardless of the ethnic background or identity of a caregiver, it is clear that across all ethnic groups family care is the most preferred and relied upon source of assistance. Extensive and supportive kin networks have been documented in Americans of all ethnic backgrounds, including Mexican Americans, African Americans, Asian Americans, and Euro-Americans (e.g., Greek, Italian, Polish, Irish).

Currently, the predominant theme in caregiving is to focus on the differences between Euro- and non-Euro-American caregivers with little attention paid to the great heterogeneity within different ethnic groups. For example, Euro-American caregivers are frequently compared to Asian, Hispanic, or African American caregivers. Growing evidence indicates that differences between these groups are less pronounced than differences within the groups. In addition, it has been suggested that group differences may be more related to the length of time since immigration than to specific ethnic background. As a result, there has been a call to shift efforts away from intergroup study and instead to focus attention on intragroup differences.

Theories of Caregiving

The following sections present a brief overview of theories related to family caregiving. These theories, although not exhaustive, represent the conceptual developments that have influenced caregiving research over the past decades. The overview and integration are presented to foster expansion of the theoretical foundation of caregiving research.

Social Functioning

Social Competence and Breakdown Theory The social competence and breakdown theory, presented by Kuypers and Bengtson, posits that the negative consequences of aging (e.g., illness, loss) can lead to a breakdown in the social competence of the elderly. At risk are elderly individuals with a self-concept that has been diminished because of role losses (e.g., widowhood) and negative stereotypes about the elderly (e.g., ageism). When they experience a health or other crisis, it can result in health professionals, family, or others in the social environment labeling the person as dependent. If the older person accepts this definition, it leads to further vulnerability and the negative cycle escalates, with further adverse

consequences to social and psychological competence. In adapting this model to problems facing the aging family, Bengtson and Kuypers suggest that the sudden dependency of an elderly family member can lead to caregiving problems that test the competence of the family as well as the individual. A thorough understanding of the nature of individual–familial–environmental interactions affecting competence can facilitate the identification of interventions that may improve family functioning and reduce the sense of helplessness felt by many caregivers.

Models Linking Formal and Informal Support Several models have been proposed for conceptualizing the relationship between informal (unpaid) and formal (paid) helpers. First, Cantor's hierarchical compensatory model proposes that the elderly's preferences for informal caregivers reflect a normative pattern in the intimacy or closeness of social relationships. Thus, the caregiving role is taken on by the closest family member, with spouses as first choice, followed by children, other kin, friends or neighbors, and formal helpers. In cases of more severe functional impairment, assistance needs, and limited availability of informal helpers, more overlap between informal and formal helpers is likely to occur.

A second conceptualization is Litwak's task-specific model. In this model, the appropriate source of help is tied to the type of task. Informal helpers are best suited to non-technical tasks and those that cannot be scheduled (toileting, transferring); formal helpers can best manage specialized tasks that can be scheduled. As a result, the allocation of tasks between informal and formal tasks reflects a clear division of labor with 'dual specialization' or task segregation. This arrangement minimizes conflict and other negative outcomes occurring between the two types of helpers.

An alternative perspective gave rise to the supplementation model of Edelman and Hughes, who suggest that task sharing mainly occurs between the elderly's informal and formal helpers. Because most assistance needed by disabled elderly is routine help with personal care and daily activities, supplementation by formal helpers alleviates the time-consuming and potentially exhausting demands on informal caregivers.

In contrast, it has been hypothesized that, given the option, formal care would be used by families to substitute for informal care. Greene's substitution model gives pause to planners and policy makers who advocate expanded reimbursement for community-based services because it is widely recognized that the public sector cannot assume the full cost of long-term care for disabled persons. However, there is little empirical evidence that families would abrogate their role as the primary source of assistance to older impaired relatives if service availability is expanded.

Gender Theory The application of gender theories of caregiving has increased since the 1980s. This body of work has been greatly informed by feminist scholarship and has its roots in the gender socialization framework and social role perspective. Gender socialization proposes that gender roles are internalized as stable personality traits and result from gender differences in socialization during childhood. In contrast, a social role perspective explains gender differences in behaviors as the result of a person's current and continuous construction of social realities and the related role demands of these realities. Using a gender socialization framework to understand gender differences in caregiving and caring, one would expect early role socialization and personality factors to be linked to greater involvement of women in caregiving tasks. In contrast, a social role perspective would posit that women are more involved than men in caring activities because women have fewer alternative roles as a result of their limited access to diverse social resources. However, research has moved away from these two views of gender, focusing instead on issues related to inequity and identity. This redirection is due in part to the fact that women, by default, perform more care tasks than men and, in turn, express being more distressed. Moreover, distinct stressors affect women caregivers who often provide care both on the job and at home, which increases their vulnerability to stress. In general, feminist scholars do not promote the view of caring as a universal element of women's identity, or as a human quality, separate from the cultural and structural circumstances that create it. To feminist scholars, caring is a process that maintains and repairs our world and, in turn, one that should be highly valued within our world.

Family and Individual Functioning

A number of researchers have introduced theoretical perspectives that draw upon models of family systems and individual functioning. First, the study of caregiving systems and dyads has its roots in family systems theory and research. For example, Thompson and Walker have studied patterns of attachment, aid, and communication among grandmothers, mothers, and granddaughters, resulting in a rethinking of the unit of analysis in caregiving research (i.e., generations). Kahana and colleagues also use a dyadic conceptualization based on the view that

illness is not singularly experienced and causes diverse patient-family outcomes.

Second, the circumplex model of family functioning, proposed by Olson, Spenkle, and Russel, describes family cohesion and adaptability as determinants of the family's ability to accomplish developmental tasks and cope with stressors (such as long-term illness). Cohesion is the degree of bonding within a family group, whereas adaptability represents the degree of flexibility demonstrated by the family. For optimal family functioning, families should be balanced on both factors. For a family dealing with long-term disability, the circumplex model suggests that poor adaptation is a result of an imbalance of cohesion and adaptability. Although the model does not suggest specific therapeutic techniques for correcting an imbalance, the authors suggest that it is therapeutically useful to share the assessment with the family.

Third, the double ABCX model of illness adaptation of McCubbin and Patterson proposes that an event such as an illness (A), invokes a family's resources (B) and, depending upon how the family interprets the event (C), a crisis may be produced (X). Thus, a family's ability to invoke resources (e.g., community, family, and personal) and coping responses is related to how family process shapes the course and ease of a family's adjustment and adaptation over time. The emphasis on family resources and coping responses is critical to further adapting the ABCX model to the potential crisis of family caregiving. Families with adequate resources and coping responses may not reach a crisis point. In the future, it may prove useful for researchers to use the ABCX model in order to focus their efforts on the study of well-adapted family caregivers.

Last, Pearlin and his colleagues have developed the stress process model of family caregiving with its roots in sociological and psychological theories of stress and coping. They conceptualize the caregiving experience as a 'career,' thus allowing a framework for identifying continuities and discontinuities in the lives of family caregivers. Transitions occur in this career as individuals provide long-term care for chronically ill or demented family members. The stages include (1) role acquisition, when the individual takes on care responsibilities; (2) role enactment, consisting of the in-home care period; (3) the transition to institutional care, when in-home care is replaced by full-time institutional care; (4) death of the care recipient, including the period of bereavement and grief; and (5) social reintegration, when the caregiver works toward becoming reintegrated into the social environment.

This model conceptualizes the experience of caregiving as a chronic stressor that proliferates and reconfigures over time. The model focuses on background characteristics, primary and secondary stressors, and mediators of stress as well as their interaction to produce various outcomes. Background characteristics (e.g., age, gender, ethnicity) exert their influence throughout the caregiving process, whereas primary stressors are the objective and subjective indicators of care-related needs. Secondary stressors (i.e., role strains such as work and family conflict, and intrapsychic strains such as loss of self and mastery) are the products of primary stressors, not because they are less potent than primary stressors but because they grow out of the care process. Over time, as the care receiver's condition worsens, primary and secondary stressors proliferate, which leads to negative caregiver outcomes such as depression and compromised health. Mediating conditions such as social support or services act to limit this proliferation by lessening the negative effects of the stress.

Taken together, primary and secondary stressors and mediating conditions reveal the dynamic and complex nature of caregiving. Clear specification of the interrelatedness of these domains allows the precise delineation of their influences on caregiving outcomes. Moreover, this model provides a framework for the development and empirical testing of caregiver interventions designed to contain the proliferation of caregiving stressors.

Theory Building: Integration and Expansion of Current Theories

Drawing upon overlapping components and empirical findings from the theories described earlier, we propose a theoretical model that directs attention to specific points for intervention in the caregiving process. This model draws heavily upon the stress process model of family caregiving and highlights the importance of multidimensional models, longitudinal designs, and the bridge between research and practice.

From previous research we know that specific components of the stress process model are related and different types of social support work to alleviate many of the negative effects between stressors. For example, **Figure 1** demonstrates the empirically known relationships that exist between stressors and how social support acts to buffer these negative interactions (see dashed arrows in **Figure 1**). Both formal and informal instrumental support as well as emotional support acts to moderate or buffer the deleterious effects of stress at specific points within this model. The dashed arrows of **Figure 1** show that formal support lessens the negative effects of a care receiver's functional loss on a caregiver's feeling of role overload

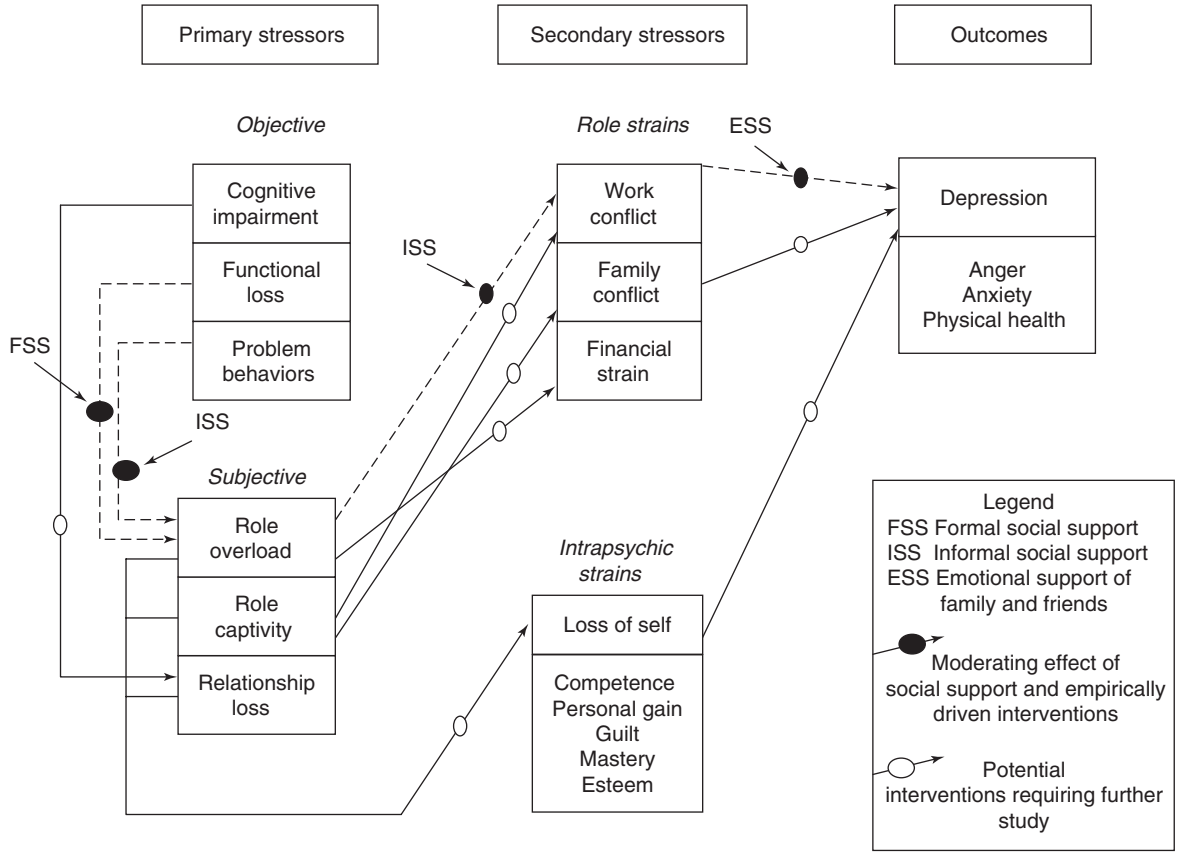

Figure 1 Potential interventions based on empirical findings. From Whitlatch and Noelker (1996) *Encyclopedia of Gerontology*.

(burnout). On the other hand, informal support lessens the negative effects of a care receiver's problematic behavior on a caregiver's feeling of role overload.

Figure 1 also reflects the empirical relationships showing that role overload is associated with increased work conflict that, in turn, relates to increased depression. Here we see the differential buffering effects of support on work conflict and depression. While informal support lessens the negative effect of caregiver overload on caregiver work conflict, emotional support helps to moderate the negative effects of caregiver work conflict on depression. Based on empirical findings, we see that there are a number of points in the stress process where social support can alleviate different types of caregiver distress.

Additional research suggests efficacious points at which social support may act to intervene in order to moderate the negative effects of stressors. The unbroken lines seen in **Figure 1** reflect the results of research suggesting that specific relationships exist among a variety of stressors. For example, research has found that care receiver cognitive impairment leads to a sense of relationship loss for the caregiver. Currently, however, we know little about how social support acts to buffer these and other potentially negative effects.

We also know that subjective primary stressors (i.e., role overload, role captivity, and relationship loss) are related to a caregiver's loss of self. In turn, loss of self is associated with increased levels of caregiver depression. Given that social support ameliorates the deleterious effects of comparable components of the stress model, it is likely that social support could similarly lessen the negative effect of subjective primary stressors on the caregiver's loss of self, and, in turn, lessen the negative effect of loss of self on depression.

These examples illustrate the potential utility of interventions based on related empirical findings. Yet there are numerous pathways within the stress process model that are yet unexplored. For example, we know little about the precursors to caregiving outcomes such as anger, anxiety, and declining physical health. Research that documents the interrelationships among these factors over time, as well as the impact of social support in moderating the effects of these relationships, will help to inform intervention techniques.

Glossary

Apoptosis – Death of a cell through a characteristic pattern including most or all of the following: cell shrinkage, margination of chromatin, fragmentation, destruction of DNA by digestion at nucleosome bridges, and non-inflammatory phagocytosis.

Bcl-2 – An oncogene, named after the cancer in which it was discovered, B-cell lymphoma-2. A B cell is a type of immunocompetent cell. *Bcl*-2 acts by preventing cell death rather than by stimulating cell division.

Fas, Fas Ligand – Fas is a protein expressed by several cells, and fas ligand (FasL) is a cell surface protein similar to tumor necrosis factor. When T cells are activated, they express FasL, inducing apoptosis. Failure of this interaction has been associated with autoimmune diseases and excess proliferation of T cells.

Immunocompetent Cells – Any of several related cells of the immune system, which variously retain memory of foreign proteins that have been encountered, communicate this information to other cells, synthesize antibodies against these proteins, or actively destroy infected, invading, or damaged cells.

Necrosis – Death of a cell by loss of control of energy resources and ion balance, resulting in cell swelling and rupture, producing an inflammatory response.

Nucleosome – Organized grouping of basic proteins (histones) around which DNA wraps. There is approximately one nucleosome for every 180 base pairs of DNA.

Oncogene – Gene involved in cell growth and division, often associated with mechanisms regulating mitosis. The term oncogene (cancer gene) refers to the fact that these normal cellular genes have been captured by viruses, leading to their uncontrolled expression and consequent loss of regulation of growth in infected cells.

Phagocytosis – Consumption of one cell by another. The consuming cell is termed a phagocyte. Some cells (macrophages) are designed to destroy other cells, and are considered professional phagocytes. Others may consume a dead neighboring cell and are considered to be amateur phagocytes.

Programmed Cell Death – Death of a cell by a mechanism involving an identified sequence of steps to its death, often in non-toxic circumstances, and frequently requiring activation of specific genes. In appearance, the collapse is usually but not always apoptotic.

Introduction

The term cell death has three meanings. It refers to a limited potential for division of normal cells in culture, disappearance of cells during the normal life

span of an individual, and the highly controlled suicide of cells. An age-related decline in function of the immune system may reflect the first meaning, the limited life span of cultured cells. The second is poorly defined but presumably results from cell suicide, otherwise described as programmed cell death or apoptosis, which is often controlled by specific genes that protect or destroy cells. This controlled cell death is important in the development of the nervous system and in the differentiation and death of cells in the immune system. Failure of programmed cell death or apoptosis can lead to cancer and autoimmune disease, and excessive cell death can result in immune failure, neurodegeneration, or loss of cells in an infarct. Future therapies are likely to attempt to regulate programmed cell death and apoptosis.

Definition of the Term Cell Death

Cell death, particularly in the context of aging, has at least three meanings for different audiences. First and most familiar to non-research audiences, is loss of cells as an individual ages through pathology or perhaps reasons that cannot be attributed to any specific abnormality other than the passage of time. For the gerontologist, this loss is most critical in the immune system, because it leads to substantial increase in susceptibility to infection; in the central nervous system (CNS), because lost neurons are currently irreplaceable, and in the skeletal muscle, because these cells are likewise irreplaceable. In a less absolute sense, cirrhotic loss of cells in the liver is not followed by regeneration, and this loss also therefore becomes life threatening.

The second major sense of the term cell death is reference to the failure of most normal vertebrate cells to reproduce indefinitely in culture, also described as limited life span of cells in culture. Although they cease mitosis, they may continue to survive for several months in a postmitotic state. Thus this definition tends to be a bit imprecise as an understanding of when the cells actually die, and the relation of cessation of mitosis to actual death remains incomplete.

The third sense of cell death is physiological cell death, variously referred to as active cell death, programmed cell death, or apoptosis. The latter two terms are slightly different but are often considered to be synonymous. Programmed cell death was first described in 1964 in an embryological or developmental context and referred specifically to the identification of a sequence in which a cell destined for death could be observed to mature metabolically toward its fate long before it was committed to that fate. When it was later recognized that programmed cell death could often be prevented by inhibiting protein synthesis, the implied assumption of a genetic control became more explicit, and the first clear identification of a genetics of cell death, in the ascarid worm *Caenorhabditis*, brought the research into the field of molecular biology.

Limited Life Span of Cells in Culture

During the late 1950s and early 1960s, Harry Eagle developed a culture medium that marked the beginning of an era of well-documented maintenance of cells *in vitro*, and it finally became possible to analyze the potential of cells to reproduce and differentiate without the influence of other cells or fluctuating hormones and growth factors or circulation. In 1961, Hayflick and Moorhead reported that, although they had tried all logical parameters, they were unable to maintain normal diploid human cells, as opposed to cancerous cells, in indefinite culture. The medium was adequate to the extent that it supported vigorous growth of younger cells, but no strain of cells survived longer than 50 ± 10 population doublings. (In their terms, a population doubling was regrowth following a 1:2 subdivision of the culture.) This limitation appeared to be consistent among numerous newly started cell lines. Furthermore, cell lines started from fetal or infant tissue survived longer than lines started from elderly individuals, and cell lines started from short-lived animals survived fewer population doublings than lines from long-lived animals. They therefore postulated that there was an intrinsic limit to the life span of normal cells in culture, and that this limit might contribute to the inability of individuals to survive indefinitely. This laboratory contributed the cell lines to the research community. Of these lines, the WI-38 line (for Wistar Institute, where the culture was established) became a national resource material, as did another line, MRC-10 (Medical Research Council, from England). The research that generated from laboratories using these and similar lines of cells has profoundly influenced gerontology. The major principles that have been developed as of 1995 are as follows:

1. When vertebrate cells are cultured, all normal lines of cells show intrinsic life spans. Transition to immortality is typically a sign that the culture has become equivalent to malignant cells.
2. The number of divisions that cells can undergo decreases with the age at which the explant is taken. In genetic diseases often considered to be cases of premature senescence, such as progeria and Werner's syndrome, cells cultured from affected individuals often show extremely restricted potential for reproducing. In these specific cases,

however, the primary defect may specifically affect the fibroblastic cell types that are usually cultured, and the argument may therefore be tautological.

3. The potential for reproduction of fibroblasts such as WI-38 or MRC-10 cells vastly exceeds the number of fibroblasts that can reasonably be expected to be produced in a normal life span. Therefore, it is unlikely that any individual suffers specifically from a lack of fibroblasts. For erythroblasts (the progenitors of red blood cells) and the precursors of thymocytes and peripheral lymphocytes, however, serial transplantation experiments suggest that the limit may be reached if the tissue is transplanted through only a few generations. It is possible, therefore, that the notable decline in function of the immune system, which renders many elderly individuals incapable of resisting infection, is at least partly traceable to their inability to produce immunologically competent cells (*see* Immune System).
4. Failure of the cells to continue to divide does not mean that they have died. In many instances, cells that have ceased to divide can be maintained for many months in culture. The fibroblastic cells that have become postmitotic have differentiated into a different type of cell. This differentiation has attracted the attention of many top researchers. The decision to opt out of mitosis involves several components, including active suppression of mitosis, inactivation of genes that normally initiate a cell division, and the loss of expendable DNA at the tips of chromosomes. (Because of the mechanics of reproduction of DNA, the last little tip at the end of the chromosome is lost with each cell cycle. Organisms compensated for this problem by starting life with a long stretch of meaningless, or non-coding, DNA, called a telomere. When cells use up this telomeric DNA, they lose the ability to divide. Cancerous cells achieve immortality in part by activation of an enzyme called telomerase, which can restore the missing piece.) (*See* DNA and Gene Expression.)
5. Cells in culture that have ceased to divide finally die by an independent process that is thought by many to be equivalent to apoptosis. These cells may signal their fate by activation of specific genes, one of which is called terminin, and which may be seen in many dying cells.

Cell Death *in Vivo*

In spite of the elaborate and frequently exciting cell biology generated by the study of cells maintained in culture, most losses of cells in the body are maintained in culture, most losses of cells in the body are not related to failure of stem cells to continue to divide but are either accidental necrotic deaths, as when cells distal to a clogged artery die from asphyxiation, or the deliberate suicide of cells under stress or deprived of supporting growth factors or hormones. These two types of death, necrosis and physiological cell death, comprise the bulk of the losses considered to be important manifestations of aging.

Programmed Cell Death

The term physiological cell death is a more general description for two terms that are commonly used in the literature: programmed cell death, which implies a specific causal sequence, and apoptosis, which refers to the mechanics and morphology of the death of the cell. Programmed cell death has an obvious morphology or morphologies and specifically differs from necrosis, in which cells, deprived of energy for any reason, ultimately lose control of ion and solute migration across the cell and mitochondrial membranes, imbibe water and calcium, and lyse.

Apoptosis

The morphologies vary somewhat including a graded series of changes, but they tend to group into two major types: one in which the cytoplasm is heavily consumed by autophagic (lysosomal) activity; and a second, common to many vertebrate cells, in which cytoplasmic changes are relatively modest, but nuclear changes are early and dramatic, including coalescence and margination of chromatin, followed by shrinkage of the cell and degradation of DNA in a characteristic manner. DNA is cut between proteins called nucleosomes that bind to it at regular intervals, so that when the cut DNA is separated by size in a process called electrophoresis, the different size classes of DNA line up in a distinct ladder-like pattern. (In an uncontrolled degradation of DNA such as that seen in necrosis, the DNA is cut at random intervals, and the electrophoretic pattern is that of a smear.) The latter, non-lysosomal, type of physiological cell death technically fits the definition of apoptosis. These points are illustrated in **Table 1** and **Figure 1**.

Programmed Cell Death

The concept of genetic programming of cell death was inherent in the recognition that specific regions of embryonic cell death differed among species, for instance that there were patches of cell death in the interdigital regions of the foot palettes of chick embryos, but not in the corresponding regions of foot palettes of web-footed birds such as ducks. Similarly,

Table 1 Characteristics of different types of cell death

Characteristics of necrosis
- Proximate cause of failure is insufficient energy to maintain ionic pumps
- Cause of failure usually involves masses of cells rather than individual cells
- Calcium enters mitochondria and precipitates. Mitochondria swell and lyse
- Cell loses osmotic control, swells, and lyses, releasing intracellular products
- Inflammatory response ensues and cell is destroyed and consumed by phagocytes
- In general, there is no evidence that the cell has time to respond to the challenge or makes any effective response

Characteristics of programmed cell death
- Stage at which cell is deteriorating but death is reversible
- Often best illustrated by developmental or metamorphic events
- Blocked, at least temporarily, by inhibition of mRNA or protein synthesis
- Cell condenses; nucleus condenses at varying times
- Consumption of cell by autophagocytosis or by phagocytosis

Characteristics of apoptosis
- Early nuclear condensation and margination of chromatin
- Fragmentation of nuclei into several pieces
- Fragmentation of DNA as detected by electrophoresis or *in situ* end labeling
- Typically, condensation of cytoplasm with no activation of lysosomes
- Alteration of cell surface proteins
- Phagocytosis by non-professional phagocytic cells (neighboring cells)

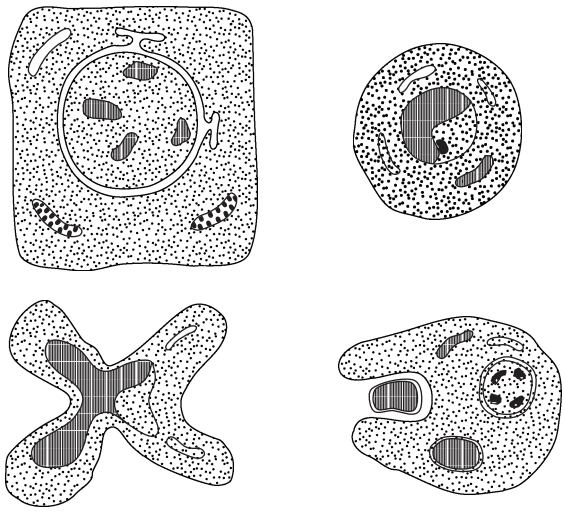

Figure 1 Schematic of changes occurring during apoptosis. In the upper left, a normal cell displays a round nucleus with occasional chromatin patches, an endoplasmic reticulum budding off the nucleus, and mitochondria. During early phases of apoptosis (upper right) the cell rounds and shrinks, while the chromatin aggregates against the nuclear membrane. Other organelles remain intact. The apoptotic cell then fragments into small membrane-bound particles (lower left), which may or may not include portions of the nucleus. Finally (lower right), in cells within the body, the fragments are engulfed by macrophages or by neighboring cells.

certain teratological abnormalities traceable to single genes were thought to derive from abnormalities of cell death. However, the humble ascarid worm *Caenorhabditis elegans* contributed the first unequivocal documentation for a genetics of cell death. In this organism, the origin and fate of each cell is known, and approximately 15% of the cells in the embryo are born only to die shortly thereafter. Several laboratories through assiduous efforts demonstrated that a small number of genes controlled the death of these cells. These genes function at several levels: two classes of genes are necessary, along different pathways, for cells to die, and one class prevents the death of these cells. A fourth set specifies which cells are supposed to die, and others regulate the phagocytosis and digestion of the corpses. The sequence is illustrated in **Figure 2**. A similar sequence is likely to exist in *Drosophila*, where a gene responsible for controlling numerous embryonic cell deaths has been found to exist.

These genes have homologs among mammals. Most notable are the following: the cell death prevention gene *ced-9* is homologous to a mammalian gene, *bcl*-2 (B cell lymphoma-2), which prevents the death of B lymphocytes. These surviving lymphocytes may eventually turn malignant. One of the genes necessary for the death of the *Caenorhabditis* cells is homologous to a specific protease, which is itself required in several experimental forms of cell death. Also in mammals, a gene known to be important in preventing the expansion of tumors, *p53*, acts in a manner similar to that of the cell death genes. Most interesting, in both mammalian cells in culture and in *Caenorhabditis* the anticell death genes *bcl*-2 and *ced-9* may under some circumstances be experimentally exchanged, and variants of the cell death-inducing protease family may likewise be exchanged. Thus it is fair to assume that the mechanisms of cell death have been highly conserved in evolution and that similar processes operate in mammalian cells. As is described below, many other genes may be upregulated in different instances of cell death. However, since causality has not been established and our understanding remained fluid in 1995, excessive attention to many of these genes was not considered appropriate (*see* Models of Aging: Vertebrates).

Apoptosis

Degradation of the Nucleus

The common morphology of dying cells is not yet fully explained. Although there are several well-understood mechanisms that can explain the swelling

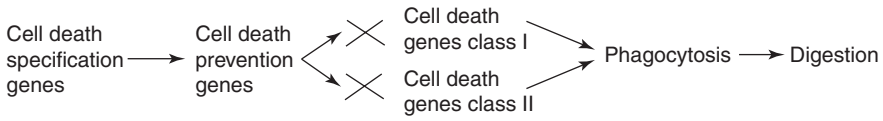

Figure 2 Sequence of control of cell death in *Caenorhabditis*. In order for cells to die by apoptosis, they must contain members of two classes of cell death genes, one of which appears to be a protease. All or most cells are capable of activating these genes, but the death program is suppressed by a cell death prevention gene that is similar to a mammalian oncogene. During development, the cell death prevention gene is turned off in specific cells, allowing the programmed developmental deaths of unique cells. Cells that die are finally phagocytosed by other cells, requiring genes for recognition of the dead cell, nucleases, and perhaps other enzymes.

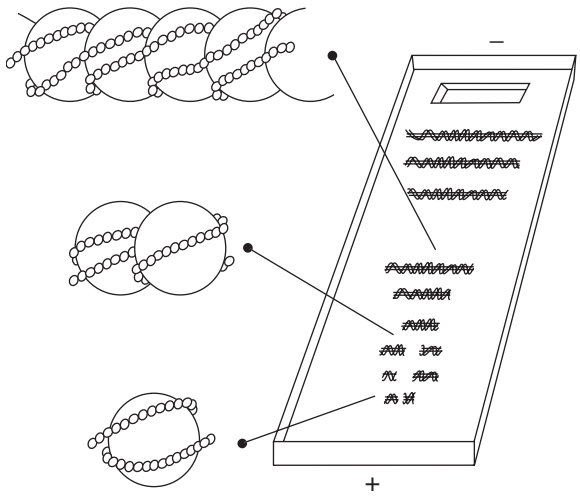

Figure 3 Origin of the hallmark DNA ladder. In normal eukaryotic cells, DNA helices are wound around aggregates of basic proteins (histones). These aggregates are consistent in size and are termed nucleosomes. The DNA in the gap between each nucleosome is more readily digested by certain nucleases than are the approximately 180 base pairs of DNA directly on the nucleosome, breaking the DNA into discrete units differing in size by approximately 180 base pairs. When DNA is electrophoresed or driven by an electric current through an agarose gel, the smaller pieces move more rapidly. Thus, in apoptosis, a distinct 'ladder' of DNA is formed. In necrotic cell death, digestion of DNA is far less organized and a smear rather than a ladder is formed.

and bursting of a necrotic cell, it is more difficult to explain the shrinkage and changes of nuclear morphology that are common to cells dying by apoptosis. Characteristically, the earliest changes are a rapid coalescence of chromatin and its collection along the nuclear membrane. These are frequently associated with degradation of DNA at specific points (**Figure 3**) by an enzyme that may be already resident in the nucleus, suggesting therefore that changed conditions in the cell or in the nucleus allow the enzyme to attack the DNA. Other evidence, however, argues against the idea that cleavage of DNA to nucleosomal fragments is a critical step in apoptosis. Several laboratories have detected damage to DNA prior to its degradation to nucleosomal size, including its release from the nuclear membrane by a possibly proteolytic cleavage. Other research indicates that the morphology and the degradation of DNA may be dissociated, whereas arguments and data from several sources suggest that damage to DNA does not immediately kill the cell. Thus, although the specific destruction of the nucleus may be a hallmark of apoptotic cell death, its origin and significance remain mysterious.

Cell Shrinkage

The second salient characteristic of apoptosis is shrinkage and condensation of the cell, while organelles and cell membrane remain intact. It is not easy to explain this process. In order for a cell to shrink, it must extrude water. Because other cells in the vicinity, unaffected by apoptosis, remain of normal size, the osmotic tension of the extracellular fluid presumably has not changed. Therefore, only three mechanisms are available for it to lose water. It must decrease intracellular solute; it must develop a contractile force sufficient to extrude water against osmotic pressure, or it must actively extrude solute, with water following. It might decrease intracellular solute by cross-linking, polymerizing, or precipitating proteins. The cytoskeleton provides the only known means of contractile force in the cell, and it is doubtful that it can generate the force necessary. One can get an estimate by assuming the cell to be a cube with a striated muscle shortening one dimension. Because most muscles can generate a force of approximately $5\,kg/cm^2$, and it would take a force of approximately $2\,kg/cm^2$ to maintain a volume reduction to half the original cell size, a cell would need a density of cytoskeleton approximately half the density of myofilaments in a striated muscle, with the contractile force of the muscle, to account for the collapse of the cell. Although this force is of the right order of magnitude, it does not appear to be the most logical explanation for the collapse of the cell.

An alternate explanation is cross-linking or precipitation of proteins. There is currently no evidence that the highly condensed proteins are precipitated or insoluble. Proteins cross-linked by transglutaminase are common in many apoptotic bodies, suggesting that cross-linking may play a role in the shrinkage of the cell.

Phagocytosis (Cell Surface Proteins)

Because one characteristic of an apoptotic cell, at least one found in an organism as opposed to one in culture, is that it is phagocytosed by a phagocyte or, more frequently, by a neighboring cell that previously was not considered to be phagocytic, the surface of the attacked cell must carry some markers that identify it as apoptotic. Some of these markers have been identified. Some represent glycoproteins known previously to have been on the surface but now more exposed or exposed in different orientation because of the rearrangement of the cell membrane. Others may identify specific cells as apoptotic and ripe for consumption. Loss of sialic acid from membrane carbohydrates, appearance of phosphatidyl serine on the cell surface, and binding of cell surface receptors all play roles in phagocytosis in specific instances. This targeting is sufficiently effective that the growth of tumors expressing it can be forced to regress by appropriate manipulation of the gene. Another example is fas ligand (FasL), a cell surface protein related to tumor necrosis factor and expressed primarily in activated T cells. Fas is produced by several types of cells. Binding of fas to its ligand induces apoptosis, and failure of the interaction may lead to autoimmune diseases and other immunoproliferative disorders.

How a Cell Dies

The mechanism by which a cell dies a physiological death is not yet well understood. Signaling mechanisms frequently involve growth stimuli or sudden withdrawal of growth stimuli in otherwise congenial environments, and the first responses of cells about to undergo apoptosis are related to those of cells about to reinitiate mitosis. In cells that are subject to many influences, several laboratories have documented that the paths to apoptosis are typically at least partially independent, recalling the dual sets of genes required for cell death in *Caenorhabditis*. Typically, energy resources in a doomed cell remain adequate, and cell and mitochondrial membranes remain intact, until substantial damage has been done to the cell; the irreversibility of death, which tends to be coincident with massive morphological and biochemical damage, is established at a later time than the commitment to the death pathway. These several observations led to the conclusion that cell growth and cell death are tightly linked. For instance, many of the genes activated in growing or dividing cells are proto-oncogenes. Proto-oncogenes are important in the initiation of cell growth or cell division. They owe their names to the fact that they are occasionally captured by viruses. In this virus, they are separated from the controlling genes that typically reside next to them on normal chromosomes, and they therefore cause uncontrolled growth or cancer. One of these proto-oncogenes, *c-myc*, is also activated in many forms of cell death. *c-myc* is well enough known that the exact structure of the gene has been established, and only very limited areas of the gene, a few basepairs in length, actually control the oncogenicity. This precise region of the gene is also influential in apoptosis, suggesting that the product of the gene can stimulate the growth of the cell under some circumstances and can stimulate cell death in other circumstances. A general image of how cell death occurs may be that numerous factors are required for a cell to complete the complex process of growth or mitosis and that, if any of the factors are unavailable, the cell will die.

Cell Death in Aging

Organisms do not die from programmed cell death or apoptosis. Although the limited life span of cells in culture suggests that a decrease in cell division may contribute to decreased function in immunodefense and maintenance of the epidermis, erythroblasts and intestinal crypt cells do not approach their mitotic potential in a normal life span. For postmitotic cells such as neurons and muscle, the consequences of physiological cell death are more important, and because in tumors cell death is a major factor determining the expansion of the malignancy, interest in cell death is high. The most important areas relating gerontology and aging are the following.

Malignancy

Several lines of evidence indicate that cell death is a factor in malignancy. In many tumors, the rate of cell death is a better indicator of malignant potential than is the rate of cell division. Dietary restriction, the only known means of extending life span in mammals, may increase the rate of apoptosis. The *bcl*-2 oncogene acts by inhibiting cell death, and other genes such as *Apo*-1 regulate the rate of apoptosis in a tumor. These observations by themselves argue that study of cell death should be of interest to oncologists. Another consideration is that most chemotherapeutic techniques attempt to kill mitotic cells. In doing so, they necessarily damage other normal but highly mitotic tissues, such as intestinal epithelium, lymphocyte stem cells, and epidermis, as well as cells with high metabolic demands, such as liver and neurons. A chemotherapeutic approach attempting to induce apoptosis in tumor

cells promises to be far less toxic, or minimally to deflect toxicity from normal mitotic cells. (*See* Cancer and Age.)

Gradual Cell Loss

Perhaps the most important suggestion is one derived from a current sense of the biology of apoptosis. As mentioned in the previous section, there is a curious relationship between growth stimuli and responses and apoptosis. Several laboratories have detected homologies between receptors for growth factors and receptors that, when activated by binding a product, trigger cell death. Similarly, as many cells respond to stimuli that will lead to their death, genes normally associated with growth responses, including those required for cell division, are up-regulated. One or more of these genes, such as several cell cycle genes (which are up-regulated during specific phases of cell division) and oncogenes (genes frequently normally used in cell division, which by uncontrolled regulation can cause cancer or cancer-like transformations) are activated in an aberrant manner, and restriction of the activity of these genes may prevent the death of the cell. One interpretation of these results is that the dysregulation is itself a signal, and that cells are programmed to self-destruct if all growth-regulating stimuli impinging on the cell are not completely consistent with the ability of the cell to respond. Particularly among cells that can still undergo mitosis, such a response would be a powerful defense for the organism against potential malignancy. There is at least one claim that the rate of apoptosis declines with age. A low rate of apoptosis could preserve cells but could also heighten the risk of cancer.

Deliberate Self-Destruction in the Immune System

As is described above, cell death in the differentiating immune system is delicately balanced to ensure a wide variety of immunocompetent cells, resting in reserve against a nearly infinite variety of possible antigens, without either attacking self or, by multiplying, draining resources when not needed. The complexity of the controls and stimuli needed to maintain a primary T- or B-lymphocyte is very great, involving a delicate balance of interactions between antigens presented to the cell at specific stages in the differentiation of the immunologically competent cell and the ability of the differentiating and stem cells to recognize those antigens. The complexity may be required to assure the destruction of cells that may form antibodies against one's own body. Other functionally important exploitations of the ability of cells to die are self-destruction of a cell infected by viruses to limit replication of the virus, and self-destruction of a cell that, by virtue of damage to its DNA (mutation) threatens to become cancerous. Among the several steps that cells take toward carcinogenicity, loss of sensitivity to signals to die is an early and ominous one. Nevertheless, the salubrious loss of cells in such circumstances likely contributes to the gradual deterioration of immunocompetence with aging. In a chronic viral infection, for instance, huge numbers of immunocompetent cells may be generated, but a slight imbalance between generation and loss will lead to such a gradual deterioration. Such an imbalance may be seen, for instance, in the progression of acquired immunodeficiency syndrome (AIDS) by gradual loss of specific immunocompetent cells over a 10-year course (representing a net imbalance of 0.03% per day between loss and replacement) or in the difference between imunologically competent centenarians and their less fortunate cohorts. Similarly, an imbalance of 0.004% between the birth and death of hundreds of millions of cells per day could reduce the number of immunocompetent cells by half by the end of an average lifetime. What is startling is that the balance is so precise. As we learn to understand how these controls trigger cell death, we are likely to develop cell death-based therapies either to maintain immunocompetent cells or to prevent autoimmunity, both complications of aging.

Loss of Postmitotic Cells

Loss of postmitotic cells, especially in the CNS, remains a threatening aspect of aging. Many of these losses appear not to be necrotic, derived from circulatory failures, but rather a physiological death of a cell strained beyond its limit. It has become evident, for instance, that loss of cells even in stroke may be by apoptosis, suggesting that cells undergo a prolonged period of agony during which they might conceivably be rescued. A major molecular product generated in senile dementia of Alzheimer type (SDAT), an oxidized form of the β-amyloid accumulated in the disease, is toxic to neurons and, in culture at least, they display such signs of apoptosis as up-regulation of specific oncogenes and protection by experimental activation of the antiapoptosis gene *bcl*-2. Therapeutic considerations remain theoretical. It is likely that the cells that eventually die do so after having passed a considerable period of agony, since postmitotic cells are frequently more resistant to apoptosis than are rapidly replaced cells. Such an explanation would account for the late onset of cell loss in SDAT as well as for other losses less directly attributable to disease. One presumes that the agonizing cell is identifiable before it succumbs and, as in programmed cell death,

passes through a reversible phase. Here a therapeutic goal is to identify the agonizing cell, identify what aspect of its support is inadequate, and to intervene to stabilize it before it dies (*see* Brain and Central Nervous System; Dementia).

Cellular Aging: Growth Factors and Cellular Senescence

C Sell, Lankenau Institute for Medical Research, Wynnewood, PA, USA

Glossary

Growth Factors – Small proteins that bind to specific receptors on the surface of cells. The activation of these receptors drives DNA synthesis to produce a replicate copy of the genome, increased protein synthesis, and an increase in cell size and cell division.

Hayflick Limit – The limit to the proliferative life span of normal cells in culture.

Senescence – When cells lose their ability to divide and enter a nondividing state in which cells enlarge and remain viable for long periods, but they are unresponsive to conditions that would trigger their division when they are 'young' or freshly isolated from the body.

Telomeres – DNA at the end of each chromosome.

Introduction

Human cells have a limited life span when removed from the body and placed into cell culture. This limited life span has been used to study processes associated with aging in a controlled environment in the hope that the mechanisms associated with the aging of cells in culture will provide insight into aging of

the whole organism. Cell culture provides an environment in which multiple variables can be carefully controlled and cell responses can be examined at the molecular level. A great deal of work regarding the aging of human cells *in vitro*, i.e., in cell culture, has been done with human fibroblasts.

When human fibroblasts are removed from the body and placed into cell culture, the cells will divide rapidly when provided with proper nutrients and growth factors. However, following this period of rapid division, fibroblast cells begin to 'age' *in vitro*. This aging process is driven by cell division. As the fibroblasts age, the cells lose their ability to divide and enter a non-dividing state in which cells enlarge and remain viable for long periods, but they are unresponsive to conditions that would trigger their division when they are 'young' or freshly isolated from the body. This non-dividing state is termed senescence and was first described by Leonard Hayflick; the limit to the proliferative life span of normal cells in culture is often referred to as the Hayflick limit. It is important to point out that cell lines derived from cancerous tumors do not display this Hayflick limit and will divide indefinitely. Similarly, normal cells can be induced to bypass the Hayflick limit through the introduction of specific viral proteins. These proteins have multiple functions, but at least one function that is known to be required for the abrogation of the Hayflick limit is the inactivation of p53, a critical regulator of cell response to DNA damage. A particular line of fibroblasts isolated from a skin biopsy will display a reproducible number of cell divisions before reaching the end of its life span and entering senescence. This indicates that there is some reproducible mechanism that underlies the eventual growth arrest or senescence of these cells.

An important point is that rodent cells will spontaneously avoid the Hayflick limit and develop into so-called 'immortal' cell lines similar to cancer cell lines. In fact, recent work indicates that if damage to the cells produced by oxygen can be limited, rodent cells do not exhibit a limited life span and simply divide indefinitely.

What Causes Senescence?

Although many possible explanations for the mechanism that underlies the Hayflick limit have been proposed, it is still not clear what triggers the irreversible growth arrest seen in senescent cells. A loss of telomeres, DNA at the end of each chromosome, has been considered an attractive candidate for the senescent trigger. The hypothesis was that a small amount of the telomere at the end of the chromosome (which is linear) is lost at each cell division due to the directionality of DNA polymerase. DNA polymerase can completely replicate one strand of DNA but cannot begin at the very end of the opposite strand. It needs a small length of primer to begin the replication process, and thus a small amount of DNA is lost at each cell division. This incremental loss of telomere DNA provided an attractive explanation for the Hayflick senescent limit that matched a great deal of experimental evidence. For example, careful studies showed that it was the number of cell divisions, not the length of time in culture, that dictated the Hayflick limit. The loss of telomeres correlated nicely with this information.

Similarly, rodent cells have very long telomeres, suggesting that they would be much less susceptible to a limit to cell division dictated by telomere length. This fits nicely with the ability of rodent cells to evade the Hayflick limit. However, as the telomere structure and dynamics were examined more closely, it became clear that the simple idea that a bit of DNA was snipped off at each division and this eventually caused the cells to stop dividing was not true. One of the first indications that the telomere story was more complex than first thought was that some tumor cell lines survived quite well with very short telomeres. Also, it became clear that telomeres are assembled into complex structures through the interaction of multiple proteins. It was the disruption of these complexes, rather than the loss of telomere DNA per se, that could induce cell arrest. Furthermore, it became clear that many normal cells had the ability to increase their telomeres. This was not originally understood. The initial thinking was that telomere sequences could not be replicated by normal cells.

In the final analysis, it is still not clear what triggers the senescent arrest. It could be that telomeres are involved, and it is fairly certain that regulators of the cell cycle such as p53 and p16 are involved. Interestingly, it has recently been realized that mutations in critical genes involved in cell division may induce a senescent arrest. This has been shown clearly in the case of a gene known as *RAS*. Mutations in the *RAS* gene are quite common in human cancers, and these mutations cause an increase in the activity of the protein. The Ras protein is a central regulator of cell growth, so its activation is thought to be important to the growth of cancer cells. Interestingly, when a mutated *RAS* gene is introduced into normal cells they do not divide more rapidly, as would be expected if they were making the transition to a tumor cell, but rather undergo a senescent-like arrest. This was first observed in the early 1980s when *RAS* was first identified, but the implication of this observation was not fully appreciated until 2001. The presence of a mutated Ras

protein induces the senescent arrest by increasing the expression of specific proteins that regulate cell division known as cyclin-dependent kinase (CDK) inhibitors. As the name implies, these proteins regulate the activity of the CDKs that serve to regulate what is known as the cell cycle. The cell cycle refers to the steps that a cell undergoes during division, growth, DNA synthesis, and cell division. Because this results in the generation of two new identical cells that will undergo the same process immediately if conditions are right, the cell division process is called the cell cycle.

A series of proteins was identified in yeast that are expressed at specific times in the cell cycle; their ordered expression is critical for cell division to occur. These proteins, known as cyclins, are produced by mammalian cells as well and serve a conserved function, to regulate the timing of critical events during cell division. The cyclins bind to, and regulate the activity of, specific proteins within the cell known as CDKs. When activated, the enzymatic activity of a kinase will covalently link phosphate groups from ATP (adenosine triphosphate) to target proteins. ATP is the major energy source for the cell, and this energy is stored in the form of high-energy phosphate bonds that facilitate the transfer of the phosphate group to a target protein by the kinase. Inhibitors of cyclin function, the CDK inhibitors, have been identified. Senescent human cells produce high levels of two of these CDK inhibitors, known as p16 and p21 for their molecular weight. Introduction of these inhibitors into young early-passage cells will induce a senescent-like arrest, and cells that have lost p16 are not arrested in response to a mutated Ras. Thus, it is clear that these inhibitors play a critical role in the senescent arrest.

In addition, several laboratories have shown that a senescent-like growth arrest can be induced in response to several types of manipulations such as increasing the level of ceramide in the cell membrane or blocking growth signals. The upshot of these observations is that the senescent arrest may represent a common endpoint that can be triggered in response to several different disturbances in cell function.

Senescence and Growth Factors

One approach to understanding the senescent growth arrest is to examine the factors that are required for the division of young cells and to determine whether the senescent cells are able to respond to these factors. Any defect in their response would presumably shed light on the mechanism of the growth arrest.

In virtually all cell types, cell division is regulated by the presence of growth factors. Growth factors are small proteins that bind to specific receptors on the surface of cells. The receptors for growth factors contain intrinsic enzymatic activity that is activated by growth factor binding. The activation of these receptors produces a cascade of enzymatic events within the cells to drive a number of events, including DNA synthesis to produce a replicate copy of the genome, increased protein synthesis, and an increase in cell size and cell division. Understanding the factors that drive cell division in general was an area of great interest in the 1960s through the 1980s. Investigators used the fibroblast cell as the model system of choice due to the reproducible way in which these cells would divide following a period of nutrient deprivation. Fetal bovine serum, added in small quantities to a nutrient medium, was found to contain the strongest mix of factors for fibroblast cell division. Laborious work identified the key factors contained in fetal serum that are required for initiating cell division as a growth factor known as platelet-derived growth factor and two closely related proteins known as insulin-like growth factors. As its name implies, platelet-derived growth factor is released by platelets during the clotting process and is contained in serum but is absent from plasma. The insulin-like growth factors are two closely related proteins, insulin-like growth factor 1 and insulin-like growth factor 2. The insulin-like growth factors are produced by the liver and other tissues under the control of growth hormone.

Over time, a number of growth factors have been isolated. They can be grouped into two classes based upon their role in regulating cell division. The first class of growth factors, termed initiation factors, which includes platelet-derived growth factor, is required for initiating cell division in resting cells. The function of these growth factors in terms of cell division (it should be mentioned that the growth factors regulate many aspects of cell behavior such as motility in addition to regulating cell division) is to move a cell out of the resting or quiescent state. The quiescent cell is performing differentiated functions producing proteins specific to its class, and the initiation factors serve to shift the cell away from these differentiated functions and toward cell division. But they are not sufficient to drive cell division on their own.

The second class of growth factors, collectively known as progression factors, includes the insulin-like growth factors and is required at a later stage for the initiation of DNA synthesis and cell division. In general, cells require the addition of two growth factors, one initiation factor and one progression factor, to divide. The specific growth factor that regulates division in a specific cell type is dictated by the cell surface receptor that the cell produces. Like a

lock and key, only the right growth factor will activate a specific receptor. For example, no other growth factor can substitute for platelet-derived growth factor in terms of activating the platelet-derived growth factor receptor. Thus, a cell expressing the platelet-derived growth factor receptor and the insulin-like growth factor receptor will respond to this specific combination.

Senescent Cells are Not Defective in Terms of DNA Synthesis

Senescent cells are unable to respond to the growth factors that drive cell division in young cells. However, a series of key experiments demonstrated that introduction of the viral proteins that will allow rodent cells to bypass the Hayflick limit into human cells will cause the cells to replicate their DNA once and then arrest again. Human cells will not totally bypass the Hayflick limit, but will undergo a single round of DNA synthesis. This is important because it means that the senescent cells are fully capable of dividing, but that there is some intrinsic block to cell division that prevents signals generated by growth factors from initiating cell division. A further implication is that the identification of the mechanisms of the block to growth factor signals would provide insight into the causes of senescence, which is potentially a source of aged cells in the body.

Why do Senescent Cells Fail to Respond to Growth Factors?

Although the evidence is not complete, it seems that the reason that growth factors are unable to drive cell division is that the enzymatic cascade activated by the binding of a growth factor to its specific receptor on the cell surface does not translate into the nucleus. A highly complex series of protein–protein interactions is initiated when a growth factor binds to its cognate receptor. The majority of growth factor receptors possess intrinsic kinase activity, critical to their function, that is activated upon binding of a growth factor. Once activated by growth factor binding, growth factor receptors will use the energy bond in the phosphate bonds of ATP to transfer one phosphate from ATP to a target protein. The sites of this transfer within the target proteins are very specific and have been precisely mapped in many cases. The result of these phosphorylation events is a change in the conformation of the target protein, generally producing an unfolding, since the phosphate group has a negative charge. The conformational change can produce one of several responses in the target protein. An intrinsic enzymatic activity (often also a kinase activity) can be activated. Alternatively, the unfolding may expose parts of the target protein that were previously buried to facilitate specific interactions, or new phosphorylation sites may be exposed. In addition, the phosphorylated target proteins often serve as docking sites for other proteins that recognize the phosphorylation site only when the phosphate group has been attached. This allows the assembly of multi-protein, multi-enzyme complexes that result in the activation of many hundreds of proteins within the cell. This produces a wave of response that affects multiple cellular functions.

In senescent cells, it has been found that the movement of proteins from the cytoplasm into the nucleus is reduced. In addition, it seems that the wave of protein activation initiated by growth factors also has trouble crossing into the nucleus. The result of this block to activation of nuclear responses is that genes essential for cell growth and division are not turned on at the appropriate time. This produces a situation in which the cell completes most, but not all, of the required steps for cell division. For example, the cells will increase in size (senescent cells are known to be abnormally large) but do not replicate their DNA. The end result of this incomplete response is that the cell will stop in an attempt to affect repairs. Since no repairs can be made, the cell must either die or remain in a frozen state. It is this non-dividing frozen state that is the hallmark of the senescent cell. Senescent cells have been maintained for several years by rather stubborn scientists without a loss of viability. This long-term survival is in marked contrast to the response of cells derived from cancerous tumors. The majority of cells that have been studied in culture are tumor cells, which do not display a senescent arrest. Tumor cells will undergo a programmed death if they are not able to complete all the steps required for cell division. This programmed cell death (known as apoptosis) is the basis for most chemotherapy. For example, the use of radiation to treat cancer relies on the fact that the DNA inside cells is broken by the high levels of radiation. Tumor cells divide very rapidly and cannot completely replicate their DNA when radiation damage is present. This triggers programmed cell death. However, the senescent cell is resistant to radiation damage and will not die if exposed to levels of radiation that would kill a tumor cell.

Consequences of the Senescent Arrest

Senescent cells lose the ability to perform normal cell functions but remain viable. It has been suggested that the presence of viable cells that have undergone

a senescent arrest in the tissues of older people will lead to a disruption of normal function in the surrounding area. For example, fibroblast cells normally produce a large amount of extracellular matrix and are important for maintaining tissue integrity. When fibroblasts senesce, the cells no longer secrete extracellular matrix and begin to produce enzymes that can break down the tissue matrix. Theoretically, this will cause a local disruption in the supporting matrix of the tissue. Some investigators have suggested that this may enhance the ability of cancer cells to survive and to metastasize. While the concept that dysfunctional senescent cells alter tissue function is attractive, senescent cells have been difficult to identify in tissues because there is no distinct marker to identify them. There is only one report identifying senescent cells in human tissues, and the marker used for the identification has been tested by other investigators and is not a definitive marker for senescence even though it is consistently produced by senescent cells. This leaves open the question of the presence of true senescent cells in the tissues of older people. No one has been able to verify that senescent cells exist *in vivo,* but given the ubiquitous nature of senescence, it would be very surprising if this type of arrest did not occur in cells as people age.

Summary

The description provided here represents the view of the author and is not representative of all of the viewpoints regarding the senescent arrest. Many investigators would strongly argue that the telomere is the central mediator of the senescent arrest. Others would argue that cell cycle checkpoint proteins such as p53 or the CDK inhibitors are the essential mediators of the senescent arrest. Certainly it is known that p53 phosphorylation is altered in senescent cells. Similarly, it is known that the CDK inhibitors are present at high levels in senescent cells. It is also known that a senescent-like growth arrest can be induced by disrupting p53 activity or introducing CDK inhibitors. However, it is also clear that introducing an oncogene such as RAS will induce a senescent-like arrest, and blocking growth factor signaling will also produce a senescent-like arrest. The major problem is that this produces a chicken and egg conundrum. In senescent cells one can identify specific changes in p53, CDK inhibitor levels, telomere length and conformation, growth factor signaling, ribosome phosphorylation, and protein synthesis, which can all account for the senescent growth arrest. However, each of these changes can just as plausibly be the result of the senescent growth arrest. It is currently impossible to tell which of these changes is the initiator of the senescent arrest and which is the downstream response. In the author's opinion, a key point is that the senescent arrest, or one that bears many similarities to senescence, can be induced by disrupting any one of the critical cellular elements discussed previously. This strongly argues that the senescent arrest represents a default response to cell damage in normal cells. Thus, a normal cell, when faced with DNA damage, telomere erosion, long-term growth factor deprivation, or mutation of a critical gene, will become senescent. It is the universal nature of the senescent arrest and the fact that tumor cells have somehow avoided this critical arrest response that drives the continued interest in senescence. It is clear that understanding the mechanisms of senescence will enormously expand our understanding of basic cellular responses during aging and will certainly have important uses in the treatment of cancer.

Glossary

Cross-Talk – Functional interaction between signal transduction pathways.

G-Protein-Coupled Receptor – Member of a large family of cell surface receptors that contain seven transmembrane spanning regions and function through coupling to heterotrimeric guanine nucleotide binding proteins (G-proteins).

Receptor Tyrosine Kinase – Member of a class of cell surface receptors that relay signals through protein-tyrosine kinase activity intrinsic to the receptor.

Second Messenger – An intracellular signaling molecule generated in response to an extracellular signal.

Signal Transduction – The biochemical events through which extracellular signals are transmitted into cells and converted to physiological responses.

Transactivation – The process by which a G-protein-coupled receptor activates a receptor tyrosine kinase.

Introduction

Postmaturational aging and senescence are accompanied by losses of physiological function, decreased maintenance of homeostasis upon exposure to a variety of stressors, and the emergence of age-associated diseases. Many of the physiological and pathophysiological changes occurring with advanced age may reflect alterations in the coordinated responses of diverse tissues and cells to environmental or intrinsic perturbations. Normal function and even survival of all complex organisms are dependent on the integrity of an intercellular communication system requiring individual cell types to exhibit appropriate biological responses to extracellular stimuli. The term signal transduction is used to describe the biochemical pathways through which extracellular signals are transmitted into cells and converted to physiological responses. In the classical model of signal transduction, binding of an extracellular signal (e.g., a peptide hormone or neurotransmitter) to a specific receptor on the cell's outer or plasma membrane triggers a process leading to the generation of an intracellular signaling molecule, or second messenger, which then initiates so-called downstream signaling events to elicit a cellular response. Relatively recently, the field of signal transduction research has been extended to the elucidation of non-classical signaling pathways underlying the mitogenic actions of growth factors and related processes controlling tissue morphogenesis, maintenance, and regenerative capacity. Moreover, fundamental advances continue to be made in the understanding of the signal transduction pathways responsible for the actions of steroid (and thyroid) hormones, which in the traditional view act exclusively through intracellular receptors but which have also been found to activate membrane-associated signaling cascades. Despite this complexity, the demonstration of cross-talk, or functional interaction, among many individual signaling pathways has to some extent provided a unifying framework for the vast network of messages now recognized to control diverse cellular functions.

Over the years, numerous elements of signal transduction pathways have been examined descriptively with respect to changes during aging; only to a lesser extent have emerging concepts of cellular signaling been applied to questions of aging physiology and pathophysiology. Nonetheless, available data summarized here indicate that functional decline during aging and the development of age-associated diseases are in some instances clearly linked to specific alterations in cellular signal transduction.

Classical Signal Transduction and Aging

Classical Signaling Mechanisms

Among cell surface receptors linked to classical signaling pathways, the largest family is composed of receptors that contain seven transmembrane spanning regions and function through coupling to heterotrimeric guanine nucleotide binding proteins (G-proteins). Upon binding of extracellular signals, or ligands, these G-protein-coupled receptors (GPCRs) function to activate or inhibit specific membrane effectors. The classical example of a membrane effector is the adenylyl cyclase enzyme, which when activated generates the prototypical second messenger cyclic AMP from ATP. Other GPCR-linked effectors include the phospholipase C (PLC) enzyme, which cleaves membrane phosphoinositides to produce the signaling molecules 1,2-diacylglycerol

and inositol 1,4,5-trisphosphate, and membrane ion channels. Of note, GPCRs represent the largest number of pharmacological targets for therapeutic drugs in current use.

Intracellular second messengers elicit diverse, often cell type-specific, physiological responses mediated in many cases by protein kinase enzymes, which modify the activities of critical target proteins by phosphorylation (phosphate group addition) on specific amino acid (serine and threonine) residues. For example, in mammalian fat cells cyclic AMP increases lipolysis, the process by which triglyceride lipid is hydrolyzed to free fatty acids and glycerol, by stimulating a specific protein kinase (cyclic AMP-dependent protein kinase, or protein kinase A) that in turn phosphorylates and activates the lipolytic enzyme hormone-sensitive triglyceride lipase (**Figure 1**). Activation of the same cyclic AMP/protein kinase A pathway in liver cells increases glucose production in part via phosphorylation and activation of the enzymes catalyzing glycogen breakdown to glucose (glycogenolysis) (**Figure 2**).

Altered Lipolytic and Glycogenolytic Signaling During Aging

Lipolysis in Fat Stimulation of lipolysis by hormones and catecholamines declines with age in several species, including humans. Numerous studies have been performed to identify the underlying signaling mechanisms responsible for reduced catecholamine-sensitive lipolysis in aging rats. The results of these studies have varied, depending in part on whether the experimental conditions employed were sufficient to discriminate among the actions of multiple GPCRs that either stimulate or inhibit the lipolytic process. In this context it should be noted that in diverse tissues including fat cells, the naturally occurring catecholamines epinephrine and norepinephrine exert both β- and α-adrenergic functions, mediated respectively by distinct β- and α-adrenergic GPCRs. As illustrated in **Figure 1**, β-adrenergic receptors are coupled to a stimulatory G-protein (G_s) that activates adenylyl cyclase and downstream physiological responses such as lipolysis, whereas α-adrenergic receptors (specifically, receptors of the α_2-subtype) exert an inhibitory effect on adenylyl cyclase mediated by an inhibitory G-protein (G_i). In addition, adenosine is normally generated by fat cell metabolism and is known to reduce lipolysis in rats by binding to a specific GPCR that inhibits adenylyl cyclase via G_i. A comprehensive review of the literature on aging and catecholamine-sensitive lipolysis in the rat implicates three biochemical loci along the lipolytic signaling cascade at which the overall stimulatory action of catecholamines is disrupted over the adult life span: (1) enhanced inhibition of adenylyl cyclase by locally produced adenosine during maturation, but not senescence; (2) a probable increase during senescence of inhibitory α-adrenergic receptor-mediated signaling by catecholamines exhibiting both α- and β-adrenergic activities; and (3) a decline during senescence in the stimulatory action of cyclic AMP on hormone-sensitive triglyceride lipase in fat cells from some anatomic sites (e.g., perirenal fat) but not

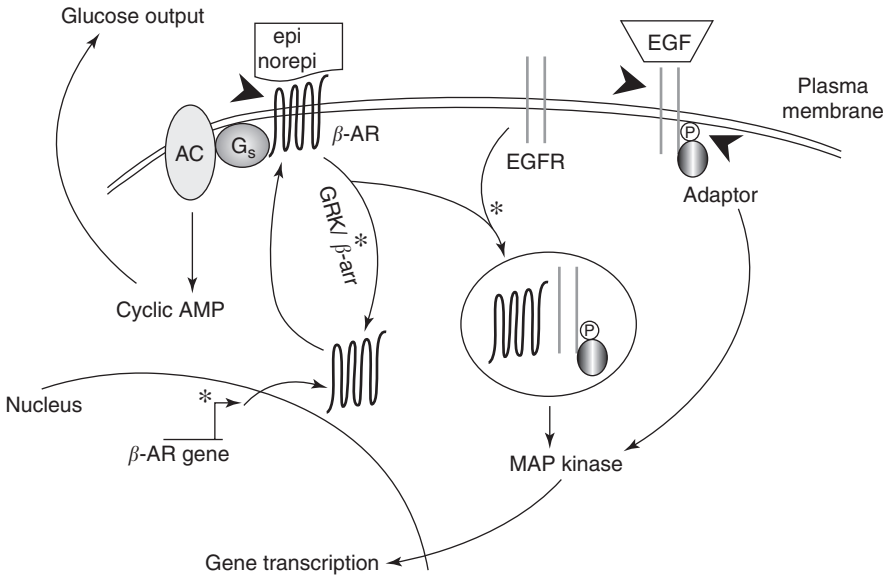

Figure 2 Glycogenolytic and mitogenic signaling pathways in the liver cell. The β-adrenergic responsive glycogenolytic pathway is shown on the left and the epidermal growth factor (EGF) stimulated mitogenic cascade on the right; cross-talk between the two pathways (i.e., β-adrenergic receptor [β-AR]-induced transactivation of the EGF receptor [EGFR]) is pictured in the center of the figure. Arrowheads designate sites at which age-related changes in β-AR and EGFR signaling are known to occur; an asterisk (*) indicates signaling events that *may* be altered during aging (see text). Abbreviations: epi, epinephrine; norepi, norepinephrine; G_s, stimulatory G-protein; AC, adenylyl cyclase; GRK, G-protein-coupled receptor kinase; β-arr, β-arrestin; MAP kinase, mitogen-activated protein kinase.

others (e.g., epididymal fat) (**Figure 1**). The detailed molecular mechanisms determining these age-related changes in rat fat cell lipolysis remain to be clarified. Moreover, the changes of lipolytic signaling found in the aging rat are only variably observed in humans and other species, where in some cases entirely different defects in the lipolytic cascade have been suggested to occur with age. Thus, decreased lipolysis may contribute to accumulation of adiposity during aging in a variety of animal models, albeit by species- and fat depot-specific mechanisms involving diverse changes in the lipolytic signaling cascade.

Glycogenolysis in Liver A second catecholamine signaling pathway characterized by dramatic changes during aging is the β-adrenergic receptor responsive glycogenolytic cascade in rat liver. Early studies limited to young adult male rats indicated that adrenergic responsive glucose output from liver occurs principally by activation of α-adrenergic receptors (i.e., receptors of the α_1 subtype) linked to stimulation of PLC and membrane phosphoinositide turnover. However, subsequent investigations established that postmaturational aging of male rats is associated with progressive increases in β-adrenergic sensitive stimulation of hepatic glycogenolysis via the adenylyl cyclase/cyclic AMP pathway. In liver cells from senescent rats, the glycogenolytic response to β-adrenergic stimuli is greater than that elicited by other stimulatory signals (glucagon and α_1-adrenergic stimuli). The age-related increase in β-adrenergic responsiveness of rat liver can be attributed mainly to an increase in the number of β-adrenergic receptors coupled to adenylyl cyclase in the liver cell membrane (**Figure 2**). Preliminary evidence further indicates that the increased content of membrane β-adrenergic receptors in livers of aging rats is associated with an increase in the expression of the β-adrenergic receptor gene(s). However, it should be remembered that the number of membrane-associated GPCRs, including β-adrenergic receptors, is also normally determined by a complex process in which receptors are desensitized (i.e., uncoupled from G-proteins) and internalized into the cell upon agonist stimulation. Expression of GPCR kinase and β-arrestin, two principal mediators of β-adrenergic receptor internalization, declines with age in rat liver, suggesting that increased numbers of β-adrenergic receptors coupled to classical membrane signaling in livers of aging rats could be caused by defective receptor internalization mechanisms. This possibility (illustrated in **Figure 2**) is of particular interest since sympathetic nervous system activity, as measured by levels of circulating catecholamines, has been shown to increase during aging in both rats and humans. A decline in catecholamine-stimulated functions, which occurs with age in fat and a number of other tissues, may reflect a normal compensatory process of end organ desensitization in response to increased sympathetic tone. Increased β-adrenergic

responsiveness in livers of aging rats might therefore be considered the result of impaired homeostatic processes normally protecting tissues from overstimulation by elevated levels of extracellular signals. At the pathophysiological level, an increase in the content of β-adrenergic receptors coupled to liver glycogenolysis during aging could play a role in the dysregulation of hepatic glucose production that predisposes older people to increasing fasting plasma glucose levels and the development of type 2 diabetes mellitus.

Non-classical Signal Transduction and Aging

Non-classical Signaling Mechanisms

In recent years the field of cellular signal transduction has broadened from considerations of signaling via classical intracellular second messengers to explorations of the mechanisms by which a host of extracellular signals, notably growth factors, promotes the growth, proliferation, differentiation, and survival of cells and tissues. Many growth-promoting signaling proteins, such as epidermal growth factor (EGF), platelet-derived growth factor, nerve growth factor, and fibroblast growth factors, as well as the anabolic hormones insulin and insulin-like growth factor-I (IGF-I), act through a class of cell surface receptors termed receptor tyrosine kinases (RTKs) because of their intrinsic protein-tyrosine kinase activity. Growth factor binding induces RTKs to form dimers and autophosphorylate critical receptor tyrosine residues, which then act as docking sites for adaptor proteins that recruit additional components of a signaling pathway culminating in activation of a family of mitogen-activated protein (MAP) kinases; activated MAP kinases in turn modify cell growth-related processes via phosphorylation of target proteins involved in gene transcription (**Figure 2**). The insulin and IGF-I receptors are tetrameric RTKs that, upon activation by their respective ligands, catalyze the tyrosine phosphorylation of insulin receptor substrate (IRS) proteins and other intracellular intermediates, each functioning to recruit distinct adaptors and downstream signaling molecules resulting in metabolic and mitogenic responses. Interestingly, a number of serine/threonine kinases serving as distal effectors in the insulin signaling pathway also participate in a negative feedback control mechanism that terminates insulin signaling via serine/threonine phosphorylation and inactivation of IRS proteins (**Figure 3**).

In addition to the RTK-mediated signaling cascades, several growth-promoting pathways involving the regulated proteolysis of target proteins play critical roles in cell differentiation and tissue formation during embryogenesis. Of these novel signal transduction systems, signaling through the cell surface Notch receptor appears to be essential for diverse cell fate decisions affecting the development of many tissues and organs. In general, Notch receptors on a given cell are activated by a signaling protein (e.g., Delta) presenting on the surface of a neighboring cell.

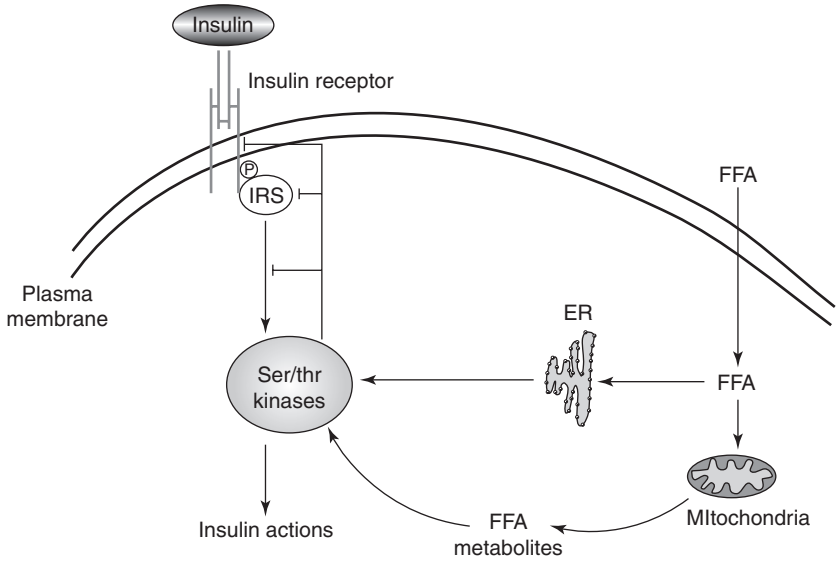

Figure 3 Insulin receptor signaling pathway and potential mechanism underlying insulin resistance. Inducers of insulin resistance (e.g., free fatty acids [FFA]) in type 2 diabetes and possibly during aging may activate mitochondrial and/or endoplasmic reticulum (ER) pathways that block the function of insulin signaling molecules through the actions of serine/threonine (Ser/thr) kinases (see text). IRS, insulin receptor substrate proteins.

Upon binding of the signaling protein, the Notch receptor undergoes proteolytic cleavages that free the cytoplasmic tail of the activated receptor to translocate to the nucleus and activate the CSL family of transcription factors (**Figure 4**). Notch signaling is thought to be involved not only in embryonic development but also in controlling the regenerative capacity of adult skeletal muscle.

Altered Mitogenic and Anabolic Signaling During Aging

The proliferative, or regenerative, potential of many tissues declines with age. A number of studies suggest that impaired regenerative capacity of liver and skeletal muscle in old animals is related to changes in RTK and Notch signaling during aging. EGF and other growth factors acting via RTKs have major effects on liver growth and are thought to play an important role in liver regeneration following liver injury (by drugs, other chemical agents, or viruses) or surgical removal of hepatic tissue. Accordingly, EGF-responsive RTK signaling in rat liver has been studied extensively as a model of reduced cellular proliferative capacity during aging (see **Figure 2**). Liver cells obtained from senescent rats and grown in culture dishes exhibit markedly lower levels of MAP kinase activation by EGF than cells from young adult animals. Levels of EGF receptors do not change with age in cultured liver cells, and the reduction of EGF-induced MAP kinase activation observed in cells from old rats has been linked to an age-dependent decline in autophosphorylation of the activated EGF receptor at a site required for receptor association with an adaptor protein (Shc) that elicits downstream signaling. In contrast to the results using cultured liver cells, a dramatic decline of EGF receptor levels has been demonstrated in whole liver preparations from aging rats. The apparent discrepancy in these findings may be partly explained by observations in early studies suggesting time-dependent loss of activated EGF receptors in liver cells cultured from young rats. Additional investigation will be required to elucidate the mechanisms by which changes in EGF receptor expression and/or function contribute to age-dependent reduction in liver cell proliferation. However, the data currently available in this area of research highlight the fact that studies of complex aging phenomena are subject to a variety of confounding factors, including the experimental conditions utilized.

Recently, investigators have used a mouse model of injury-induced skeletal muscle regeneration to show that impaired proliferative capacity of muscle progenitor cells from old animals is caused by diminished Notch receptor activation, on the basis of inadequate upregulation of the Notch ligand Delta, after injury (**Figure 4**). Notably, in the same series of studies the reduced proliferative potential of both muscle and liver cells in old animals was restored to youthful levels by systemic factors derived from young animals. The identification of these factors, and their role in Notch (or possibly RTK) signaling, may provide fundamental insights into mechanisms of tissue maintenance and regeneration during aging.

In humans the sensitivity of peripheral tissues to the actions of insulin declines during aging,

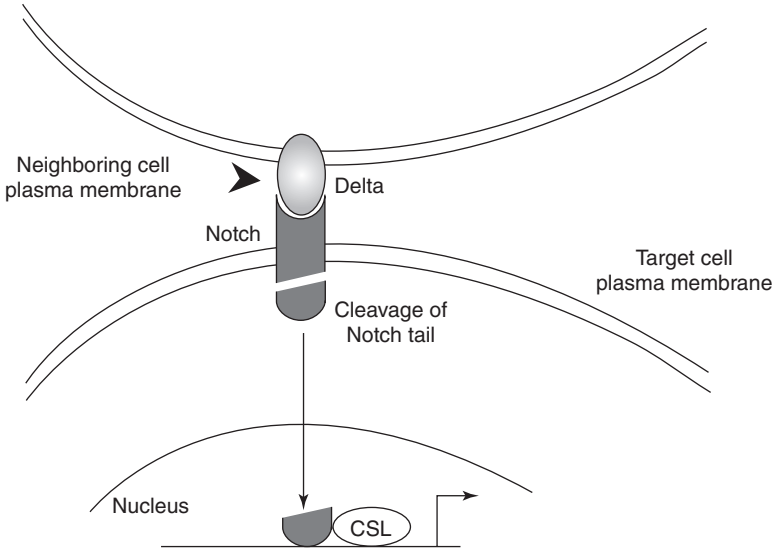

Figure 4 The Notch signaling pathway. Inadequate upregulation of the Notch ligand Delta after injury (arrowhead) appears to play a role in reduced regenerative capacity of skeletal muscle during aging (see text). CSL, a family of transcription factors activating Notch responsive genes.

predisposing the elderly to development of insulin resistance and type 2 diabetes. Considerable research has been focused on the signaling mechanisms underlying insulin resistance associated with aging and diabetes. Animal studies have revealed age-related decreases in early signaling events (e.g., tyrosine phosphorylation of IRS protein) activated by the insulin RTK, although there is no clear consensus relating insulin resistance to any specific defect(s) along the insulin signaling pathway. Accumulating evidence does support a central role for serine/threonine phosphorylation of insulin signaling proteins in the development of insulin resistance. A number of studies, for example, suggest that excess circulating free fatty acids in insulin-resistant states such as obesity and type 2 diabetes suppress insulin signaling by activating serine/threonine kinases – some of which are themselves insulin effectors – that in turn block the function of insulin signaling molecules (e.g., the insulin receptor, IRS proteins, and downstream effectors) through phosphorylation of multiple serine/threonine residues. The cellular pathways underlying fatty acid induction of insulin resistance by serine/threonine kinase activation have been intensively explored, and two non-exclusive proximal mediators have been proposed: (1) fatty acid metabolites accumulating intracellularly on the basis of mitochondrial dysfunction, and (2) signaling events involved in the homeostatic response of the endoplasmic reticulum to protein processing demands imposed by metabolic stressors such as lipid accumulation (**Figure 3**). Evolving research on the interplay of mitochondrial dysfunction, endoplasmic reticulum stress, and control of insulin signaling may identify new pharmacological targets for the treatment or prevention of age-associated diabetes.

The association between insulin resistance and the development of type 2 diabetes, with its adverse consequences, in older people is difficult to reconcile with extensive evidence linking reduced insulin (and/or IGF-I) receptor-related signaling to life span extension in nematodes, flies, and rodents. Data supporting the influence of insulin-like signaling on longevity are derived in large part from mutational analysis, and the extent to which genetic manipulation of metabolic processes can be applied to pathophysiological changes during human aging remains speculative. In this context it should be noted that the metabolic concomitants of insulin resistance, i.e., hyperglycemia and hyperinsulinemia, which are themselves risk factors for diabetic complications and related disorders, are generally not observed in insulin signaling mutants with extended longevity.

Cross-talk between Signaling Pathways During Aging

Numerous instances of cross-talk between signal transduction pathways have been reported. Recent investigations have demonstrated a variety of functional interactions between GPCR and RTK signaling pathways. It has become clear, for example, that a number of GPCRs are coupled not only to G-protein-mediated signaling via classical second messengers, but also to MAP kinase signaling typically responsive to RTKs. In some cases GPCRs induce growth regulatory signals by causing transactivation of RTKs such as the EGF receptor. Interestingly, the process of EGF receptor transactivation by β-adrenergic receptors appears to involve the assembly and internalization of a multireceptor complex containing both the β-adrenergic receptor and the transactivated EGF receptor (**Figure 2**). The mechanisms underlying internalization of the multireceptor complex, including the relationship of this process to GPCR kinase/β-arrestin-mediated internalization of activated β-adrenergic receptors, remain to be clarified.

Little or no information is available on whether interactions between signaling pathways play a role in age-related alterations of tissue responsiveness to extracellular signals. Nonetheless, emerging concepts of cross-talk can provide a useful framework in which to consider at least some changes in signal transduction events known to occur during aging. For example, the increased numbers of adenylyl cyclase coupled β-adrenergic receptors observed in liver cells from old rats may be viewed in the context of cross-talk between the β-adrenergic receptor and EGF receptor signaling pathways. On the basis of evidence that β-adrenergic receptors induce mitogenic signals via internalization in a multireceptor complex with transactivated EGF receptors, and that EGF receptor expression in rat liver declines with age, increasing numbers of cell surface β-adrenergic receptors in livers of aging rats could conceivably reflect a diminished pool of EGF receptors available for co-internalization with β-adrenergic receptors (**Figure 2**). This possibility, though at this point speculative, is likely to be representative of a number of testable hypotheses linking age-related changes in tissue functions to altered cross-talk between cellular signal transduction pathways.

Many of the cellular actions of reactive oxygen species (ROS) appear to reflect mechanisms of cross-talk between the redox state of the cell and cellular signal transduction pathways. Reactive oxygen species generated in mitochondria and other cellular compartments have long been thought to participate

in biochemical reactions causing tissue damage, aging, and age-related diseases. More recently, ROS have also been considered to function as critical regulators of biological processes through complex interactions with classical and non-classical (e.g., receptor tyrosine kinase-mediated) signaling systems. On the one hand, oxidants modulate the activities of a host of signaling pathways presumably through redox modification of reactive cysteine residues on target proteins involved in signal transduction; it should be noted, however, that in many cases the specific signaling targets functionally altered by redox modification are yet to be clarified. Redox regulation of cellular signaling pathways has been linked to control of antioxidant protein expression, insulin signaling, and longevity in a number of animal models. On the other hand, activation of a variety of growth factor receptor and other signaling pathways increases production of ROS, which in turn act as second messengers mediating downstream cellular responses. Mechanisms of bidirectional cross-talk between cellular redox and signaling systems remain incompletely characterized but may well prove to play an essential role in the regulation of gene expression, metabolism, and resistance to stress during aging.

Steroid Hormone Signaling and Aging

Steroid hormones exert diverse actions ranging from regulation of reproductive function to modulation of physiological processes in neural, cardiovascular, immune, musculoskeletal, and gastrointestinal systems. The established model of steroid hormone signaling involves interaction of the steroid molecules with specific intracellular receptors, either cytosolic or nuclear, and a complex of other proteins that together regulate the transcription of certain responsive genes. Whereas the gene regulatory actions of steroid hormones occur over periods of hours to days, it has become clear that some steroid hormone responses occur within a much more rapid time frame (i.e., seconds to minutes). Considerable evidence suggests that these rapid steroid hormone responses are mediated not by transcriptional events, but rather by non-genotropic mechanisms involving second messengers and protein kinases characteristic of plasma membrane receptor signaling pathways. Non-genotropic actions of steroid hormones have been documented in a variety of tissues and are thought to influence the differentiation, physiological function, and survival of numerous cell types. For example, the bone-protective effects of the sex steroid hormone estrogen have been proposed to occur by a non-genotropic mechanism and not by the classical genotropic pathway of steroid hormone action, which – while critical to the control of reproductive tissue functions – may be dispensible for maintenance of bone mass. The genotropic and non-genotropic pathways of estrogen signaling are illustrated in **Figure 5**. In skeletal muscle the anabolic effects of the androgenic sex steroid hormone testosterone reflect hormone actions on both genotropic and non-genotropic pathways. Moreover, in a number of tissues, $1,25(OH)_2$-vitamin D_3, the active form of the

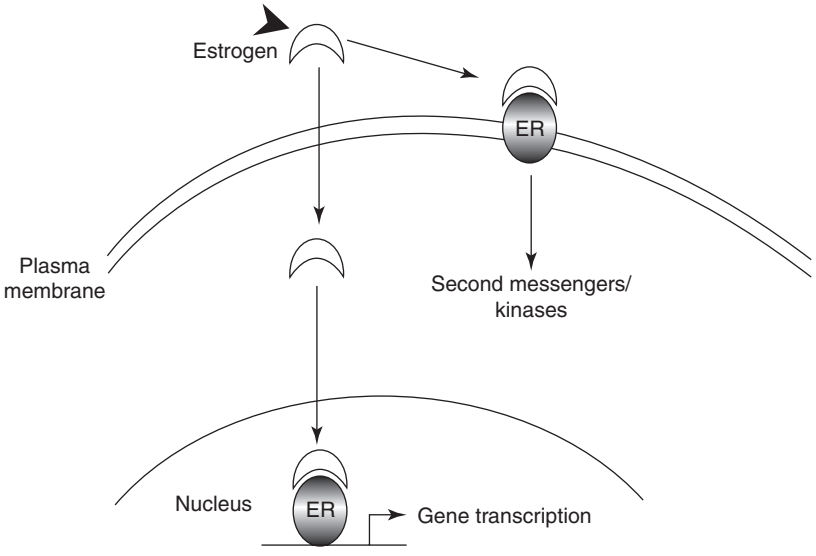

Figure 5 Estrogen signaling pathways. The classical genotropic pathway of estrogen signaling is shown on the left, the non-genotropic pathway on the right (see text). The availability of estrogen (designated by the arrowhead) to bind target cell estrogen receptors (ER) is reduced with age, i.e., at the time of menopause.

secosteroid hormone vitamin D, regulates gene transcription via the classical vitamin D nuclear receptor and also elicits rapid, non-genotropic responses through a plasma membrane-bound vitamin D receptor.

The availability of sex steroid hormones and vitamin D as ligands for target cell receptors is diminished with age in humans. In women, ovarian secretion of estrogen and circulating estrogen levels decline sharply at the time of menopause. In contrast, in men, gonadal sex steroid production and plasma testosterone levels decrease gradually, and to a variable degree, during aging. Low plasma levels of vitamin D are also common in elderly individuals because of limited dietary intake of vitamin D, reduced photosensitive synthesis of vitamin D in the skin during aging, and low exposure to sunlight. Reduced levels of estrogen, testosterone, and vitamin D in older people are all associated with increased risk of age-associated diseases and functional decline. However, steroid hormone 'replacement' may subject aging populations to unexpected, as well as unacceptable, risks. This point was dramatically highlighted by the results of the Women's Health Initiative (WHI), in which large clinical trials of estrogen (and progestin) therapy in postmenopausal women were stopped early because of increased risk of breast cancer and cardiovascular disease in the treatment groups. Several aspects of the WHI study design – specifically, the inclusion of older, overweight women who had no prior hormone therapy and the evaluation of a single estrogen-progestin formulation – have spurred debate over whether the study results are generalizable to other populations and hormone formulations. There is growing awareness that the safe and effective application of therapeutic strategies using natural steroid hormones or synthetic analogs in aging populations will ultimately depend on clinical trials incorporating as yet incomplete insights into the complexity of steroid hormone actions at the molecular level. Fundamental investigations into the tissue specificity of sex steroid actions have already led to the development of selective estrogen and androgen receptor modulators (SERMs and SARMs, respectively), compounds that mimic the beneficial effects of sex steroid hormones on some cell types while antagonizing adverse sex steroid actions on other cell types. Additional research is being carried out to identify new therapeutic agents that retain the favorable, non-genotropic actions of sex steroid hormones on non-reproductive tissues (e.g., prevention of bone loss) without deleterious growth-promoting actions on reproductive tissues (e.g., breast and uterus) via classical genotropic signaling.

Summary

Extracellular stimuli are transmitted into cells and converted into cellular responses by a complex network of signal transduction pathways. Age-related changes at multiple steps along GPCR, RTK, steroid hormone receptor, and other signaling cascades have been implicated in losses of physiological function during aging, as well as in the development of age-associated diseases. Ongoing investigations into the molecular mechanisms of intracellular signaling systems and their involvement in aging and disease will likely lead to the identification of novel pharmacological targets for the treatment or prevention of numerous disorders afflicting older adults.

Glossary

Centenarian – People age 100 years and older.

Supercentenarians – People age 110 years and older.

Introduction

Centenarians are rare, though in industrialized nations they are among the fastest-growing segments of the adult population. Such growth suggests that a greater than once anticipated proportion of people have the potential of achieving extreme old age. This proportion, however, is likely still relatively small because rare combinations of genetic, environmental, and perhaps even stochastic events are necessary to become a centenarian. Centenarian studies are making headway in deciphering these factors and combinations of factors, though these efforts are hampered by the likelihood that many combinations lead to such survival and that these combinations vary according to culture, race, and a myriad of circumstances.

Demography

Prevalence of Centenarians

Among industrialized countries, the number of centenarians is increasing at the rate of about 7% per year. At the turn of the twentieth century in the United States, approximately 1 person per 100 000 was a centenarian, and now it is about 1.2 per 10 000. This dramatic increase is the result of public health measures that have allowed people who would have otherwise succumbed to preventable or treatable causes of childhood or premature mortality, such as waterborne and other infectious diseases, to survive to a much older age. Treatment of now readily reversible causes of death among older people is also making a significant impact. In fact, in recent decades, reductions in mortality at the oldest ages have made significant contributions to increased survival and to the increase in the number of centenarians. As a result, today many more people with favorable genetic and environmental traits achieve their maximum life expectancy.

The 2000 US census listed 1400 supercentenarians, people age 110 years and older (about 1 per 200 000), but this is likely a gross exaggeration due to the 50% annual mortality rate in this group and therefore the likely inclusion of deceased persons as alive supercentenarians. According to an Internet-based interest group that monitors and validates claims of age 110 years and older, the number of living supercentenarians in the United States is generally around 75–100 and worldwide, about 300–450.

Validating Age

The oldest verified age claim is that of Jeanne Calment, who, in 1997, died at the age of approximately 122 years. There have been many claims of older ages, but these either have not been verified with appropriate documentation or have been disproved.

Per the recommendations of the National Institute on Aging's Panel on the Characterization of Participants in Studies of Exceptional Survival in Humans, age verification of centenarians begins with obtaining a birth certificate. In the case of more rare and potentially sensationalized ages, such as claims of 110 years old and older, additional proof that indicates age at different times in the person's life and that is consistent with the age claim is necessary. Such forms

of proof include census records, school report card with age, military record, marriage license, employment record, old passport, and parental age on child's birth certificate. The familial reconstitution method is also employed to determine whether parents, grandparents, siblings, and children are appropriate ages in respect to the supercentenarian.

Mortality Rates

James Vaupel and other noted demographers have indicated that the annual mortality rate of centenarians is generally 30%, though this rate understandably and dramatically differs according to the centenarian's health and gender. There has been significant debate among demographers as to what happens to the rate of mortality at extreme old ages. If selective survival occurs at old ages, then one would expect that the more frail individuals die, leaving behind a cohort who is more fit and better able to survive. The result would be a deceleration of mortality rates at these extreme ages. The dying off of individuals prone to diseases that typically peak in incidence at younger ages, thus leaving behind a cohort of select survivors, is known as demographic selection. The observation by some research groups that the incidence of Alzheimer's disease (AD) plateaus at very old ages is consistent with this phenomenon. Ritchie and Kildea performed a meta-analysis of nine epidemiological studies, finding that the rate of increase in dementia prevalence fell off among octogenarians and plateaued at $\sim$40% at age 95. In a longitudinal study of older people living in Cache County, Utah, the incidence of both dementia and AD increased almost exponentially until ages 85–90, but declined after age 93 for men and age 97 for women.

A genetic example of demographic selection is the decreased frequency of the apolipoprotein E epsilon-4 (ApoE ε4) allotype in the oldest old. Individuals who are homozygous for ApoE ε4 have a risk of developing AD that is 2.3–8.0 times greater than the general Caucasian population. The allelic frequency of ApoE ε4 drops off dramatically in the oldest age groups, presumably because of its association with AD and vascular disease. Interestingly, the effect of the ApoE allotype upon AD incidence appears to decrease with age at these very old ages.

These examples not withstanding, the phenomenon of demographic selection occurring at extreme old ages remains controversial. Some argue that because of marked improvements in medical care and public health measures, such selection no longer occurs. In this case, decreased mortality due to improved health care could lead to an increased prevalence of frailty among older survivors because treatment of existing diseases simply postpones death to older ages.

Gender Differences

Save for a very few exceptions, in most populations, the vast majority of centenarians are women; generally, in industrialized nations, they comprise 85% of centenarians. Michel Poulain has reported that in Sardinia, Italy, approximately 50% of centenarians, particularly those living in the mountainous region of the island, are male. But again, generally speaking, female centenarians outnumber males almost nine to one. Despite the fact that many more women achieve exceptional longevity than men, among centenarians the men generally have better functional status. One explanation for this may be that men must be in excellent health to achieve such extreme old age. Women, on the other hand, may be more adept at living with age-associated illnesses, and thus they can achieve exceptional old age even with significant chronic disability, particularly compared to men of similar age.

These observations might indicate a demographic crossover in which women are better off than men at younger old age, and men, although fewer in number, are functionally better off at extreme old age. The underlying reasons why women generally live longer than men and are, at least before menopause, significantly less likely to develop heart disease and stroke are unclear. Estrogen, which might be a powerful antioxidant, has been implicated as an important reason. The recent findings from the Women's Health Study in which some women who were taking estrogen experienced increased rates of cardiovascular illness bring into question the role of estrogen in longevity. Additionally, it has been noted that premenopausal women who undergo hysterectomy but not oophrectomy experience an increased risk for vascular disease that is similar to men. Another possible reason is that women, because of menses, are more iron deficient than men for a 30- to 40-year period. Iron is a crucial catalyst in mitochondrial production of free radicals as a byproduct of metabolism. Perhaps a reduction in available iron leads to less free radical production. For example, iron deficiency has been associated with significant reductions in levels of oxidized low-density lipoprotein (LDL) cholesterol, an essential component of atherosclerotic plaque production. In addition, diets high in heme have been associated with significantly increased risk of heart disease.

Another potential female advantage studied by scientists relates to the fact that males possess one

X chromosome while women have two. Women thus have the prospect for somatic cell selection with advancing age, in which the more fit of two somatic cell populations survives. Stem cell populations that give rise to highly proliferative cell populations (for example, intestinal and skin epithelium, leukocytes) would be particularly prone to such selection. Among the genes on the X chromosome that are of particular interest are those that effect telomere length, in part because those cell populations that resist oxidative stress better might have longer telomeres. Increased telomere length has been associated with both improved proliferative capacity and decreased mortality.

The Centenarian Phenotype

Personality

The Georgia Centenarian Study examined and compared the personality traits of three age groups: centenarians, octogenarians, and sexagenarians. The centenarians scored higher in suspiciousness, radicalism, fatigue, and depression but lower in intelligence, sensitivity, and stress. Preliminary findings from the New England Centenarian Study suggest that female centenarians score low in the personality domain of neuroticism. The subsequent ability to not dwell on things that are stressful could be an important survival trait.

Functional Status

In the Swedish Centenarian Study, 25% lived in their own home, 37% in assisted living, and 38% in nursing homes. In the New England Centenarian Study, the proportions were not too different, with approximately 15% living independently in their own homes, 35% living with family or in assisted living, and 50% living in nursing homes. While the majority of centenarians appear to have functional disability, this disability appears to be compressed toward the end of life. In the New England Centenarian Study's population-based sample, 90% of centenarians were independently functioning at the mean age of 92 years. Most subjects experienced a decline in their cognitive function only in the last 3 to 5 years of their lives.

Despite delaying disability, a large proportion of centenarians still incurs age-related illnesses for many years. In a study of age of onset of age-related illnesses among 424 centenarians (323 males and 101 females), the subjects fit into three morbidity profiles: survivors, delayers, and escapers. Forty-three percent of the centenarians were survivors, or individuals who were diagnosed with age-related illness prior to age 80 (24% of the male and 43% of the female centenarians). Forty-four percent were delayers, individuals who delayed the onset of age-related diseases until at least age 80 (44% of the male and 42% of the female centenarians). Escapers, individuals who attained the 100th year of life without the diagnosis of an age-related disease, accounted for 13% of the centenarians (32% of the male and 15% of the female centenarians). That most centenarians appear to be functionally independent through their early 90s suggests the possibility that survivors and delayers are better able to cope with illnesses and remain functionally independent compared to other individuals who more readily die from those diseases. Thus, in the case of centenarians, it may be more accurate to note a compression of disability rather than morbidity. This is not the case, as would be expected, with illnesses associated with high mortality risks. When examining only the most lethal diseases of the elderly such as heart disease, non-skin cancer, and stroke, 87% of males and 83% of females delayed or escaped these diseases (relatively few centenarians were survivors of such diseases).

Cognitive Function

The population-based Heidelberg Centenarian Study recently reported that both early education and lifelong intellectual activities correlated with better cognitive performance at age 100 years and older. The study reported that about 50% of centenarians demonstrated moderate to severe cognitive impairment and about 25% were found to be cognitively intact. These proportions are approximately the same as the cognitive function studies reported by the Danish (Jeune *et al.*), Swedish (Hagberg *et al.*), Georgia (Poon *et al.*), and New England Centenarian Studies, which indicated that about 70% of centenarians were cognitively impaired and 30% were cognitively intact. Conservatively, with strict criteria for no evidence of cognitive impairment, about 12–15% of centenarians show no evidence of impairment.

Several centenarian studies conduct neuropsychological testing followed by postmortem neuropathological studies, which have led to several interesting observations. A number of cases have been described of centenarians who were cognitively intact near the time of death, yet at autopsy they were found to have no evidence of neuropathology including neurofibrillary tangles and neuritic plaques. These plaques and tangles, which are the pathological hallmarks of AD, were once thought to be inevitable consequences of aging. These cases might be considered examples of disease-free aging,

and they support the notion that for some people, neuropathology is not an inevitable consequence of aging, nor can aging be blamed as the sole reason for the presence of pathology.

Some researchers have observed that the frequencies of various dementia types are different among people who were nonagenarians or older compared with younger cohorts. The Danish Centenarian Study reported that 50% of the dementia cases among centenarians were due to vascular disease. An autopsy series of 13 Japanese centenarians with at most mild cognitive impairment revealed vascular but not AD pathology. It is likely that rare causes of dementia become more common among centenarians because people who are prone to develop AD die at younger ages, leaving survivors to be prone to clinically express other neurodegenerative illnesses such as vascular dementia, Pick's disease, and Lewy body disease.

Familiality of Exceptional Longevity

Heritability Estimates

Twin studies have estimated the heritability of life expectancy to range from 25 to 30%. These twin studies cannot infer the heritability of living to extreme old age because the oldest subjects in these studies were only octogenarians. In contrast, centenarians who live an additional 15–20 years beyond average life expectancy may require more than an advantage in their habits and environment. They may require a genetic advantage that translates into a significant inherited component to exceptional longevity. Some estimates are higher when the phenotype is more specific, as in the case of cognitive function at very old age. Centenarians and their family members may have or lack certain genetic characteristics that result in a significant survival advantage.

Familiality of Exceptional Longevity

Perls *et al.* analyzed the pedigrees of 444 centenarian families in the United States that included 2092 siblings of centenarians. Survival was compared to 1900 birth cohort survival data from the US Social Security Administration. As shown in **Figure 1**, female siblings had death rates at all ages that were about one-half the national level; male siblings had a similar advantage at most ages, though diminished somewhat during adolescence and young adulthood.

The siblings had an average age of death of 76.7 for females and 70.4 for males compared to 58.3 and 51.5 for the general population. Even after accounting for race and education, the net survival advantage of siblings of centenarians was found to be 16–17 years greater than the general population. Relative survival probabilities (RSP) for these siblings increased markedly at older ages, reflecting the cumulative effect of their mortality advantage throughout life (**Table 1**). Compared to the US 1900 birth cohort, male siblings of centenarians were 17 times as likely to attain age 100 themselves, while female siblings were 8.2 times as likely.

The analysis of death rates indicates that the siblings' mortality advantage does not grow as they get older. Rather, their relative probability of survival is a cumulative measure and reflects their lifelong advantage over the general population born about the same time. Such elevated RSP values support the hypothesis that these family members have genetic

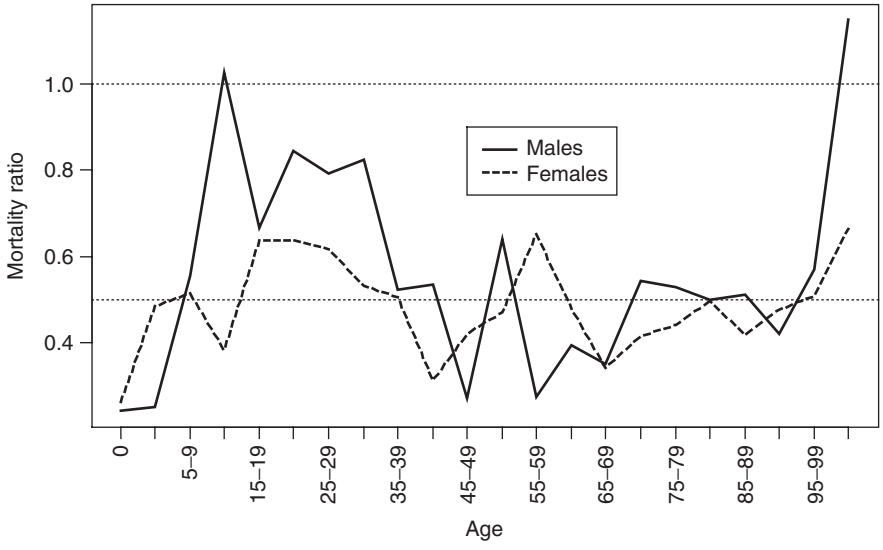

Figure 1 Relative mortality rate of siblings of centenarians compared with their 1900 birth cohort for ages 20 to 100.

Table 1 Relative survival probability (RSP) with 95% confidence intervals (CI) of siblings of centenarians versus US 1900 birth cohort

Age	*Males*			*Females*		
	RSP	*Lower 95% CI*	*Upper 95% CI*	*RSP*	*Lower 95% CI*	*Upper 95% CI*
20	1.00	1.00	1.00	1.00	1.00	1.00
25	1.00	0.99	1.01	1.01	1.00	1.02
60	1.18	1.15	1.21	1.12	1.09	1.14
65	1.29	1.25	1.33	1.16	1.13	1.19
70	1.48	1.42	1.53	1.24	1.21	1.28
75	1.68	1.60	1.77	1.36	1.31	1.41
80	2.03	1.90	2.16	1.54	1.47	1.60
85	2.69	2.47	2.91	1.83	1.73	1.93
90	4.08	3.62	4.54	2.56	2.39	2.74
95	8.35	6.98	9.71	4.15	3.73	4.57
100	17.0	10.8	23.1	8.22	6.55	9.90

variations in common that are important to achieving exceptional longevity. Furthermore, mortality rates of different groups (e.g., gender, race, education, physical activity, socioeconomic status) converge at very old age, and thus such a sustained advantage is unusual. The rarity of sustained mortality differences at older ages in other cases suggests that the mortality advantage enjoyed by siblings of centenarians has some significantly influential etiology, perhaps genetic. The apparent increased probability of exceptional longevity among siblings of long-lived individuals could be inflated by sampling bias. An alternative method, general branching process modeling, has been applied to these data, which can be adjusted to allow for correlations between siblings' life spans, and similar results were obtained. The substantially higher RSP values for men at older ages might reflect the fact that male disease-specific mortality is significantly higher than for females at these older ages, and thus the males experience a greater relative advantage from beneficial genotypes compared with women. Another possibility could be that an even greater, and thus more rare, combination of genetic and environmental factors is required for men to achieve extreme age compared to women. Either possibility could explain why men comprise only 15% of centenarians.

Richard Cutler, in what is now a classic paper in gerontology, proposed that persons who achieve extreme old age do so in part because they have genetic variations that affect the basic mechanisms of aging and that result in a uniform decreased susceptibility to age-associated diseases. Persons who achieve extreme old age probably lack many of the variations (disease genes) that substantially increase risk for premature death by predisposing persons to various fatal diseases, both age-associated and non-age-associated. More controversial is the idea that genetic variations might confer protection against the basic mechanisms of aging or age-related illnesses (the longevity-enabling genes). Centenarians may be rare because a complex set of environmental and genetic variables must coexist for such survival to occur. Based upon studies of centenarian pedigrees, it appears that family members are more likely to have such combinations of factors in common than the general population.

Genes Predisposing to Exceptional Longevity

The discovery of genetic variations that explain even 5–10% of the variation in survival to extreme old age could yield important clues about the cellular and biochemical mechanisms that affect basic mechanisms of aging and susceptibility to age-associated diseases. Until recently, only one genetic variation had been reproducibly associated with exceptional longevity, but even this might vary with ethnicity and other, as-yet-unknown sources of stratification. Schachter and colleagues from the French Centenarian Study noted that the apolipoprotein E $\varepsilon 4$ allele becomes markedly less frequent with advancing age. One of its counterparts, the $\varepsilon 2$ allele, becomes more frequent with advancing age in Caucasians.

Nir Barzilai and colleagues, studying Ashkenazi Jewish centenarians and their families, recently investigated a cardiovascular pathway and gene that is differentiated between centenarians and controls. In this study, controls were spouses of the children of centenarians. Barzilai and colleagues noted that high-density lipoprotein (HDL) and LDL particles were significantly larger among the centenarians and their offspring, and that particle size also differentiated between subjects with and without cardiovascular disease, hypertension, and metabolic syndrome. In a candidate gene approach, the researchers then searched the literature for genes that affect HDL and LDL particle size, and hepatic lipase

and cholesteryl ester transfer protein (CETP) emerged as candidates. Compared with a control group representative of the general population, centenarians were three times as likely to have a specific CETP gene variant (24.8% of centenarians had it vs. 8.6% of controls), and the centenarians' offspring were twice as likely to have it.

Discovering genes that could impart the ability to live to old age while compressing the period of disability toward the end of life should yield important insight into how the aging process increases susceptibility to diseases associated with aging and into how this susceptibility might be modulated. Human longevity-enabling genes are likely to influence aging at its most basic levels, thus affecting a broad spectrum of genetic and cellular pathways synchronously. The centenarian genome should also be an efficient tool for ferreting out disease genes. Comparing single nucleotide polymorphism (SNP) frequencies implicated in disease in centenarians with frequencies in persons with the disease should show clinically relevant polymorphisms. Another approach that researchers are in the early stages of understanding is differential gene expression in models known to slow the aging process, such as caloric restriction. This might prove to be another potent tool for discovering longevity-enabling genes. The hope, of course, is that these gene discoveries will help in identification of drug targets and creation of drugs to allow persons to become more centenarian-like by maximizing the period of their lives spent in good health.

Children of Centenarians

Offspring of centenarians have been found to have lipid profiles associated with lower risk for cardiovascular disease. Other findings include that middle-aged sons of long-lived parents had better systolic pressures, cholesterol levels, and decreased frequencies of the apoE ε4 allele compared to middle-aged sons of shorter-lived parents. Using a questionnaire-based cross-sectional study design, Terry and colleagues assessed the health histories of a nationwide sample of centenarian offspring ($n = 176$) and controls ($n = 166$). The controls consisted of offspring whose parents were born in the same years as the centenarians but at least one of whom died at age 73, the average life expectancy for that birth cohort. The average age at death of the other parent was 77 years, the same as the spouses of the centenarians. Centenarian offspring were found to have a 56% reduced relative prevalence of heart disease (OR 0.44, 95% CI 0.24, 0.80) ($p < 0.01$), a 66% reduced relative prevalence of hypertension (OR 0.34, 95% CI 0.21, 0.55) ($p < 0.01$), and 59% reduced relative prevalence of diabetes (OR 0.41, 95% CI 0.15, 1.12) ($p = 0.01$) in multivariate analyses that controlled for age, gender, years of education, annual income, instrumental activities of daily living (IADL) score, ethnicity, marital status, exercise, smoking, and alcohol use. There were no significant differences in the prevalence of a number of other age-related diseases, including cancer, stroke, dementia, osteoporosis, cataracts, glaucoma, macular degeneration, depression, Parkinson's disease, thyroid disease, and chronic obstructive pulmonary disease. The lack of differences for these diseases may be a function of the sample size or the choice of controls, or it may be that families with exceptional longevity do not have differential susceptibility to these diseases. For the offspring of centenarians who did report hypertension, the age of onset was significantly later when compared to controls. Similar delays were noted for the age of onset of coronary heart disease, diabetes, and stroke.

Conclusion

Centenarian studies are relatively young; formal scientifically rigorous studies began in the 1980s. These studies have grown and new ones have emerged as centenarians have become more common, findings have been reproduced among these culturally diverse studies, and funding studies of the exceptionally old and their families has become a priority. Paralleling this growth has been the development of molecular genetic techniques that are both inexpensive and powerful enough to enable genetic studies of this select cohort that may lead to insights into both environmental and genetic determinants of survival to extreme old age and survival to older age in good health. Centenarians were once thought to be scarce because of a few rare, important determinants. However, it is now suggested that the necessary combination of factors are rare, not the individual factors themselves. An important challenge for centenarian studies is the variability of the combination of factors necessary for different individuals to survive to extreme old age.

Glossary

Arterial Vasospasm – Inappropriate vasoconstriction resulting in the reduction and impairment of blood flow. Vasospastic events result in poor tissue oxygenation and therefore poor tissue function due to impaired blood flow.

Membrane Fluidity – The ease with which lateral mobility of membrane proteins or lipids is permitted along the membrane phospholipid bilayer. Compounds that alter membrane fluidity either increase or decrease lateral mobility of these molecules.

Phenotypic Modulation – In vascular smooth muscle cells, the predominant phenotypic state is the contractile phenotype characterized by robust contractile ability, with reduced protein (matrix) secretion, and little to no replicative ability. In vascular disease, phenotypic modulation occurs in which the smooth muscle cells shift to the synthetic phenotype, which is characterized by marked proliferative activity, augmented protein (matrix) secretion, and reduced contractile ability.

Introduction

The plasma membrane is a lipid bilayer structure separating the intracellular from the extracellular compartments. It provides an important barrier protecting the cell from a variety of molecules present in abundance in the extracellular space. Communication between the cell and its extracellular signals occurs largely through proteins embedded in the bilayer. These integral membrane proteins are held in the bilayer by virtue of a registration of their hydrophobic amino acids with the hydrocarbon core of the membrane bilayer. In this way, the bilayer serves as a two-dimensional solvent system for these signal proteins, which include ion channel proteins, molecular pumps, exchange proteins, and a wide range of cell surface receptors. The ability of these signal proteins to function properly depends on the composition, dynamics, and structure of the membrane solvent features. Changes in bilayer composition have been shown to alter the activity of numerous membrane proteins, many of which play crucial roles in regulating cell function. Age-related

alterations in bilayer lipid composition and dynamics have been described for the plasma membrane in several cell types. Common to most studies is an increase in the cholesterol content of the bilayer. Why this change occurs and the degree to which it disturbs cell function with age needs to be more carefully addressed. This article discusses how cholesterol fits into cell membranes and the molecular interactions it has with the other membrane lipids and how these interactions alter membrane dynamics, structure, and function. In particular, we have focused this discussion on cholesterol's potential involvement in disturbing plasma membranes in cells of the vascular wall and in the central nervous system (CNS), which may contribute to the genesis of cellular defects of two particular diseases that are of special concern in the elderly, atherosclerotic heart disease and Alzheimer's disease (AD).

Background

Membrane Lipid Composition and Physical Characteristics

Many scientists regard the cell plasma membrane merely as the thin black line typically drawn around the cell to delineate the inside of the cell from the outside. Indeed, one of the principal roles of the plasma membrane is to serve as a barrier to keep the cell contents inside and the extracellular contents outside. The membrane bilayer itself is largely resistant to permeation by both charged and most uncharged molecules, as well as a wide variety of extracellular signals. However, the movement of materials and information across this barrier is essential to cell function and is accomplished almost exclusively by membrane proteins that serve transport, diffusion, receptor, and phagocytic processes. Membrane proteins are complex macromolecular assemblies embedded in the membrane lipid bilayer. These transmembrane pathways have been heavily studied and well described. Lost in the interest and activity surrounding the structure–function relations of membrane proteins is the lipid bilayer itself, and the effect that changing the lipid components (i.e., phospholipids and cholesterol) has on the qualitative characteristics of the bilayer. This is a vital issue because the lipid bilayer serves also as a two-dimensional solvent system in which the various membrane proteins are inserted. The proteins are held in the lipid bilayer by virtue of a hydrophobic registration of their lipophilic amino acid residues, with the hydrocarbon core fatty acyl chains. It stands to reason that changes in the composition of the membrane may alter qualitative aspects of the bulk lipid phase and therefore may well have marked effects on functional aspects of the transmembrane proteins. Recent studies described in this article suggest that defects in the bilayer characteristics may have pathogenic roles in important diseases of growing significance to the elderly.

The plasma membrane, like all other membranes in nature is composed of a bilayer of various phospholipids, which include phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylserine (PS), phosphatidylinositol (PI), phosphatidic acid (PA), and sphingomyelin (SP), as well as various glycolipids. At neutral pH, the phosphorus head group is polar, whereas the fatty acyl chains remain neutral. Thus, phospholipids have amphipathic properties and, as such, they spontaneously assemble into lipid bilayers in aqueous media with the polar head groups oriented toward the aqueous phase and the non-polar fatty acyl chains orienting toward each other, thereby excluding water. In addition, nearly all eukaryotic, but not prokaryotic membranes also require sterols. In mammals, this sterol requirement is exclusively for the 3-hydroxy form of unesterified (free) cholesterol. In mammalian plasma membranes the most abundant phospholipids by mass are PC, PE, PS, and SP, and to a much lesser degree PA and PI. The level of SP correlates well with the amount of cholesterol. SP and cholesterol have been suggested to form non-covalent bonds, and SP levels in membranes appear to be driven, at least in part, by the cholesterol content, to the extent that SP levels may even serve to protect cholesterol content in the plasma membrane. Perhaps the greatest variability in membrane lipids is seen in the cholesterol content. The cholesterol to phospholipid mole ratio (FC:PL) ranges from below 0.1 : 1 (10 mol percent) in most intracellular membranes to over 1 : 1 (100 mol percent) in plasma membranes of Schwann cells and red blood cells (RBCs). At a 0.5 FC/PL mole ratio (50 mol percent) approximately one molecule of cholesterol is present for every two molecules of phospholipid. In most mammalian cell plasma membranes, cholesterol is the single most abundant membrane lipid where the FC/PL mole ratio is approximately 0.3–0.5.

The rationale for phospholipids in the bilayer is straightforward; they are ideally suited to forming the thin, pliable barrier enclosing cells. Furthermore, the intrinsic motion of their fatty acyl chains provides a fluid hydrocarbon core permitting conformational changes in membrane proteins as well as lateral movement of membrane constituents. Thus, without exception, all membranes are composed of phospholipids. As for the rationale for specific classes of phospholipids, the problem becomes more complex, because specific functions for the individual

phospholipid classes need to be identified. In this regard, the phospholipids subserving signaling functions are the easiest to explain. The importance of membrane PI in the IP_3/DAG second messenger pathway is well established, as is membrane SP and its hydrolytic products sphingosine and ceramide in the regulation of cell function, in large part through their effects on protein kinase C (PKC) activity.

However, the role of membrane cholesterol in plasma membranes, unlike phospholipids, is less straightforward. To begin with, although free cholesterol is an absolute requirement in mammalian membranes, it is not a requirement for membranes of lower life forms. Indeed, prokaryotes have no sterols in their membranes. So why eukaryotes need a membrane sterol, and why mammals in particular choose cholesterol for their membrane is odd, and perhaps unfortunate because cholesterol's requirement for membrane and hormone synthesis is countered by its potential lethality in the bloodstream. Free cholesterol is highly insoluble in aqueous media so it readily partitions into phospholipid bilayers. In fact, this is its exclusive intracellular location. In mammals 3-hydroxycholesterol is the only membrane cholesterol species. The presence of the 3-hydroxy group confers a specific orientation of the molecule in the bilayer such that the polar hydroxyl group orients this end of the sterol ring near the surface of the bilayer in the polar phosphorus-head group region. The hydrophobic ring structure partitions into the fatty acyl chain region of the phospholipid leaflet where it occupies a position spanning approximately 6 to 15 Å out from the center of the bilayer. The sterol ring is a planar, conformationally inflexible ring structure, and in this position in the bilayer it can greatly hinder the intrinsic motion of the fatty acyl chains, thereby ordering the bilayer and reducing membrane fluidity in native membranes. In addition, kinks in the phospholipid fatty acyl chains are thought to create transient free volume elements or open space regions in the membrane bilayer during acyl chain motion. These free volume elements likely provide pathways for the movement of small molecules like glucose that can diffuse across lipid bilayers, a process that is reduced by increasing the cholesterol content of the bilayer. They may also provide the space or breathing room for protein conformational changes necessary for membrane proteins to mediate transport of materials and/or information from one side of the bilayer to the other. The fractional free volume is therefore reduced by cholesterol in proportion to its concentration in the membrane. In this way, altering membrane cholesterol levels may well hinder activity of some membrane proteins. The functional significance of cholesterol in membranes likely relates, in part, to its ability to set the level of fluidity and fractional free volume. More recently, membrane cholesterol content has also been shown to greatly affect membrane bilayer width, a parameter function with considerable potential consequences to the activity of various membrane proteins. As described below, there is a direct, linear, and highly significant relationship between membrane cholesterol and bilayer thickness. This structural effect of cholesterol on membranes is another interesting and important function of this sterol, and one that is likely integrated into the membrane cholesterol regulatory scheme.

The asymmetrical distribution of cholesterol in cells is another intriguing aspect of this sterol. Several lines of evidence suggest that the greatest fraction of cell cholesterol is located in the plasma membrane where the FC/PL mole ratio is usually around 0.5. This is much higher than is thought to exist in mitochondrial, lysosomal, Golgi, endoplasmic reticulum (ER), or nuclear membranes. In fact, free cholesterol is often used as a marker for the plasma membrane. Using the cholesterol oxidase assay in a fibroblast cell line, Evonne Lange has estimated that over 90% of the cell's cholesterol is in the plasma membrane. However, the cholesterol oxidase technique is not without its shortcomings, and this value may be an overestimate. Nonetheless, current wisdom holds that the plasma membrane is highly enriched with cholesterol relative to the subcellular membranes. Why this asymmetry exists is not clear, but it may be necessary to provide a suitable barrier function of the plasma membrane lipid bilayer. Because cholesterol reduces the fractional free volume of the bilayer, it limits bilayer permeability to small molecules that would otherwise diffuse across it more readily. Lastly, because cholesterol impacts on bilayer structure, it may also provide suitable structural conditions for proper function of the membrane proteins.

Regulation of Membrane Cholesterol

Generally, lipid–protein interactions are regarded as either direct (i.e., a certain lipid species may be required for a protein to function properly) or indirect (as through membrane microviscosity). Both of these interactions have been demonstrated for membrane cholesterol. For any given cell line, the plasma membrane seems to be relatively fixed with regard to its phospholipid profile and cholesterol composition, but significant differences between cell lines are common. Thus, each cell line seems to know what its plasma membrane phospholipid and cholesterol composition ought to be and strives to maintain its

unique profile. This suggests that the plasma membrane lipid composition is carefully regulated, presumably at the genomic level. Although this all makes good sense, it is difficult to understand this regulation because membranes are self-assembled structures. Nonetheless, phospholipid profiles can be generated, at least in part, through their differential synthesis and assembly into Golgi membranes destined for the plasma membrane. Further cell-specific refinement of the phospholipid profile is accomplished through the synthesis and regulation of various phospholipid-active enzymes, such as the various cellular phospholipases and flipases. However, these pathways do not explain the regulation of cholesterol content of the plasma membrane. Nearly all cells have the capacity to synthesize cholesterol, a pathway that is largely held in check in mammals by an abundance of cholesterol that comes to the cell from the outside, primarily by lipoproteins. Cholesterol appears to gain access to the membrane bilayer primarily by aqueous diffusion, as this route has been established for the movement of cholesterol between phospholipid surfaces, between low-density lipoproteins (LDL) and smooth muscle plasma membranes, and between subcellular membranes. Membrane cholesterol levels are determined by the relative rates of cholesterol absorption into and desorption out of the bilayer. In the steady state, these rates must be equal. In non-steroidogenic and non-proliferating cells, the supply of this sterol to cells is almost exclusively through plasma LDL, the level of which is greatly affected by dietary and hepatic factors. Under normal conditions, removal of cholesterol from the membrane is accomplished by high-density lipoprotein (HDL) from the outside (reverse cholesterol transport), a largely unregulated process for cholesterol removal from peripheral cells. Thus, because the extracellular routes for cholesterol to the plasma membrane are unregulated, membrane cholesterol is likely regulated from inside the cell, presumably by the cholesterol esterification/de-esterification pathways (ACAT and CEH). Because these enzymes have only recently been purified through cloning techniques, this regulatory pathway has yet to be defined, and our understanding of the details of how cellular-free cholesterol levels, and therefore also membrane cholesterol, are controlled is meager at best. It is clear, however, that cells are good at regulating their membrane cholesterol levels. For example, in arterial smooth muscle cells (SMCs) in culture, enrichment of the cells with cholesterol using cholesterol donor liposomes increases the membrane FC/PL mole ratio. When the cholesterol-enriched SMCs are then left in culture without the liposomes, the SMC membrane cholesterol content gradually returns back to control levels over 4–5 days. This return is accompanied by an increase in cell cholesteryl esters, consistent with regulation by the ACAT/CEH pathway.

Isolating Plasma Membranes for Study

In any discussion of plasma membrane composition or characteristics, a comment on membrane isolation is essential because the limitations of the technique are important to understand. A major technical problem impeding our understanding of the composition, dynamics, and structure of the membrane lipid bilayer has been the extreme difficulty in isolating and studying it in pure form. On the one hand, membrane function can most easily be studied using transport techniques (i.e., measuring the movement of ions and molecules into [influx] and out of [efflux] cells). However, this type of transport is mediated mostly by large, complex, amphipathic proteins, and the degree to which the lipid characteristics of the bilayer contribute to this process is hard to delineate. For this, the plasma membrane must be isolated, and herein lies the problem. The standard and by far most common approach to isolate plasma membranes is to fractionate the cells osmotically or mechanically, followed by differential ultracentrifugation. This can be applied to intact tissue, dispersed cells, and cells in culture. Differential ultracentrifugation yields a membrane fraction (i.e., microsomes) containing varying degrees of purity relative to internal subcellular membranes. Unfortunately, pure plasma membranes are impossible to obtain. Contaminating the microsomal membrane fraction are the other light membranes such as Golgi and ER membranes. Even with further fractionation, such as gradient ultracentrifugation of the microsomal membrane preparation, contamination is reduced, but not eliminated. Compounding purification by ultracentrifugation, yield is disproportionately reduced as purity is increased. Lastly, even with extreme care and refined procedures, lipid exchange between membrane fractions during the sample preparation cannot be avoided. Hence, what was pure plasma membrane to the cell becomes something less in the test tube. Notwithstanding these difficulties, relatively pure plasma membranes can be prepared and studied, so long as one appreciates that the ideal pure plasma membrane is only a theoretical endpoint. For this reason, the differential distribution of membrane markers is important to demonstrate in any membrane preparation, without which it is impossible to estimate the degree of purification.

Alterations in Membrane Cholesterol: Compensatory Versus Pathological

Compensatory Alterations

Because changes in membrane cholesterol, in either direction, disturb lipid bilayer dynamics and structure, it seems reasonable to suspect that this would also alter membrane and cell function. There is abundant evidence supporting this notion using *in vitro* systems. For example, in cultured arterial SMCs in early passage, increasing membrane cholesterol content, as a single, isolated and independent variable, increases passive membrane permeability to calcium as illustrated in **Figure 1**. In these studies, alterations in membrane cholesterol were accomplished by incubating SMC monolayers overnight with either cholesterol donor liposomes (FC: PL $\approx 2:1$) or cholesterol acceptor liposomes (FC:PL $= 0:1$). It is clear that when membrane cholesterol increased above control levels, calcium permeability increased, and when membrane cholesterol levels were decreased below control levels, calcium permeability also decreased. Moreover, following the shift from either high or low cholesterol levels, if the SMCs were placed in cholesterol-neutral medium, the membrane cholesterol alteration reversed back to control levels, as did passive calcium permeability. Because calcium is an important cell second messenger, these studies suggest that changes in membrane cholesterol levels are likely to have marked influences on cell function.

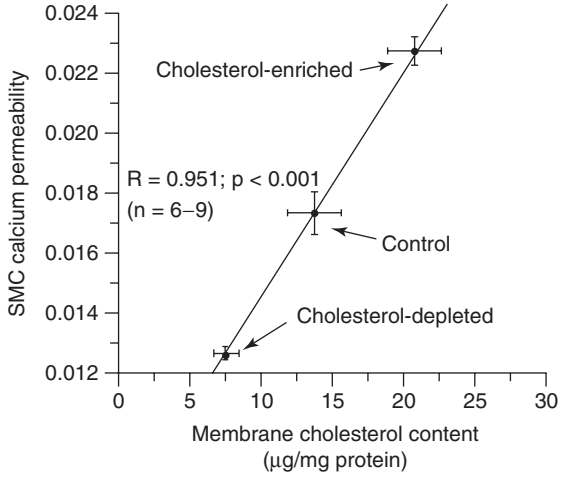

Figure 1 Effects of altering membrane cholesterol content on the permeability of the cell to calcium. SMC, smooth muscle cell. A marked decrease in calcium permeability is seen with decreases in membrane cholesterol content, whereas a marked increase in membrane calcium permeability is seen with increases in membrane cholesterol content. Membrane cholesterol content is expressed as the mass of cell-free cholesterol per milligram cell protein.

However, *in vivo*, it is not always apparent whether changes in membrane cholesterol are pathological or compensatory. This is particularly true in studies of age-related alterations. Several studies have demonstrated an increase in cholesterol content with age including neuronal, cardiac, and arterial SMCs. **Figure 2A** illustrates an increase in the FC/PL mole ratio with age in SMC membranes isolated from the aorta of Fisher 344 rats. In these studies, cholesterol enrichment was evident only in the senescent period. **Figure 2B** illustrates marked alterations in membrane phospholipids from the same samples. These changes in membrane lipid composition with age are accompanied by changes in K^+ permeability as illustrated in **Figure 2C**, which demonstrates an age-dependent suppression of K^+ efflux through the Ca-dependent K^+ channel with adrenergic stimulation. As with free cholesterol (FC) content, this is particularly evident in the senescent period. Studies like this are therefore consistent with the conclusion that, at least in arterial smooth muscle, aging is associated with a remodeling of the membrane bilayer. Remodeling of this type (i.e., an increase in cholesterol and ridigizing phospholipids [PC]) would be expected to reduce membrane fluidity, and this has been reported in other cell lines by other investigators. However, these changes in smooth muscle membrane lipid composition, lipid dynamics, and membrane function with age are apparently not associated with equivalent changes in tissue function, because contractile properties, passive stiffness, collagen, and elastin synthesis do not appear to be altered with age, at least in this animal model of aging (Fisher 344 rat). We conclude from this that these age-related changes in membrane lipids were either unrelated to cell function, or that they constituted a physiologic compensatory response to aging so as to protect cell and tissue function.

Changes in membrane lipid composition in neuronal cells as a function of age have been previously reported. Specifically, an increase in cholesterol content (i.e., increased FC/PL mole ratio) has been reported for cortical gray matter, whole brain lipid extracts, as well as in platelets and lymphocytes derived from aged human subjects. In neuronal microsomes, *in vitro* manipulation of membrane cholesterol content alters the binding activity of various neurotransmitters to their respective receptors. In addition, changes in synaptic membrane signal transduction have also been observed that correlate with increases in membrane cholesterol content. In many cases, the effect of cholesterol enrichment may be reversed with membrane-fluidizing agents, including S-adenosylmethionine, but the degree to which fluidizing the membrane alters membrane structural

parameters has not been determined. Metabolic alterations leading to changes in membrane cholesterol can only be speculated. LDL receptors are expressed on neural cells. Apoprotein E, one of the LDL receptor's two ligands, is synthesized in astrocytes. This suggests that LDL, the cholesterol-rich lipoprotein in humans, may have an important role in cholesterol metabolism in the CNS. Although this relationship has been clearly established for peripheral cells, the relationship between plasma cholesterol levels and neuronal membrane cholesterol content has yet to be defined. However, age-related changes in cell and membrane cholesterol content have been described in several neuronal tissues, but the degree to which these alterations in membrane cholesterol content reflect compensatory or pathological processes is not clear.

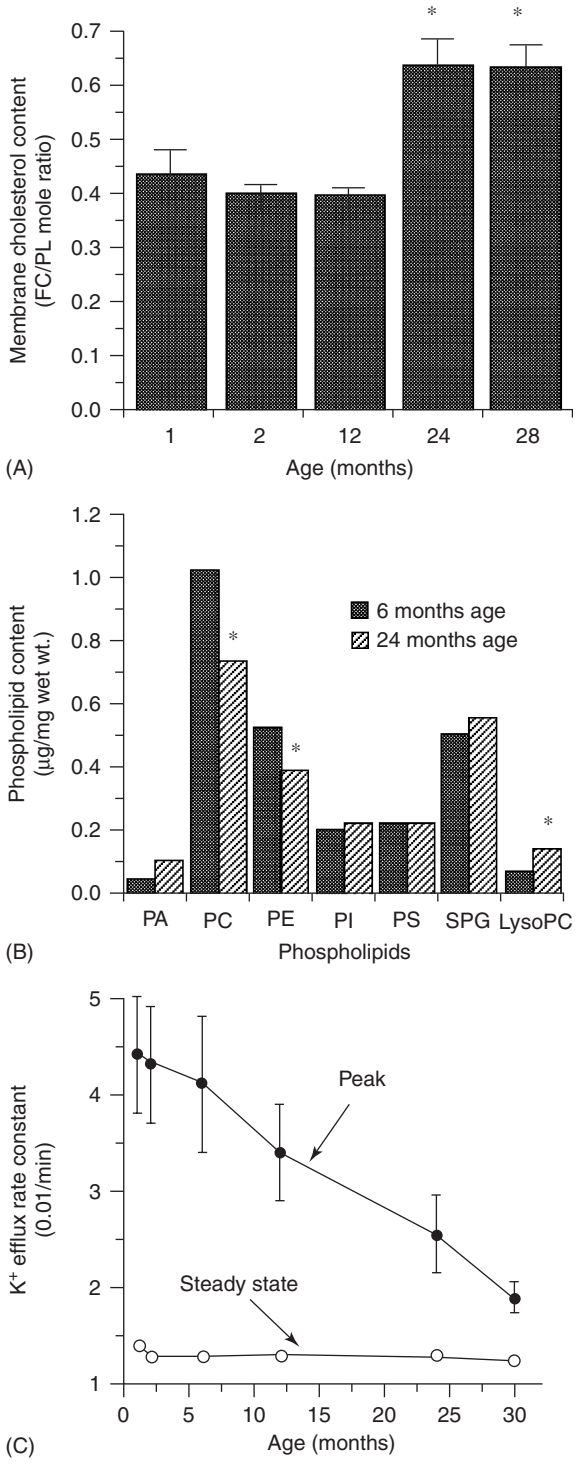

Figure 2 (A) Age-dependent alterations in membrane cholesterol content in aortic smooth muscle isolated from Fisher 344 rats at various ages. There is nearly a 50% increase in membrane cholesterol content in the senescent period (24–30 months). Between 9 and 18 animals were studied in each age group. (B) Alterations in membrane phospholipids with age in aortic smooth muscle isolated from Fisher 344 rats. For simplicity, only the 6- and 24-month ages are illustrated. Note significant reductions in phosphatidylcholine (PC) and phosphatidylethanolamine (PE) at 24 months while lysophosphatidyl-choline (lysoPC) is increased. The significance of these alterations is not clear in that tissue functional parameters (vasoconstriction and stiffness) were not altered at these ages. Between 9 and 18 animals were studied. PA, phosphatidic acid; PI, phosphatidylinositol; PS, phosphatidylserine; SPG, sphigomyelino). (C) Age-dependent decrease in K^+ efflux induced by activation with norepinephrine (NE, 1 μM) in rings of aortic smooth muscle obtained from Fisher 344 rats at various ages. Solid circles indicate peak activation K^+ efflux values and open circles indicate steady-state K^+ efflux values. Currents mediated by K^+ efflux tend to stabilize the cell membrane. In arterial smooth muscle, activation of this current by NE prevents membrane depolarization, which would be expected to limit vasoconstriction. Whether this decrease in K^+ efflux over age alters vasoconstriction to NE is unlikely as force generation to NE was unaffected by age in these experiments. For this reason, these changes are likely compensatory rather than pathological.

Disease-Related Alterations in the Elderly: Alzheimer's Disease

Unlike the alterations in membrane composition and function noted above, which occurred in the absence of alterations in tissue function, notable alterations in certain neuronal membrane bilayers have been seen in conditions clearly associated with functional deficits. A good example of such a potential pathogenic alteration is seen in Alzheimer's disease (AD), a major neurological disorder in the elderly. AD is a neurodegenerative disorder associated with aging that is characterized by progressive loss of higher intellectual function in the absence of focal neurologic defects. A characteristic neuropathological lesion in the cerebral cortex of patients with AD is the neuritic plaque composed primarily of a 42-amino-acid peptide, referred to as beta amyloid (βA4). The number of neuritic plaques generally correlates with the degree of dementia in AD. The

mechanism underlying the elevated formation of βA4 is not well understood, however (*see* Dementia).

The βA4 peptide is derived from a large, membrane-bound amyloid precursor protein (APP) that is broadly expressed throughout the cerebral cortex. Proteolysis experiments indicate that the cleavage site on APP that releases the βA4 peptide fragment is the carboxy terminal end of βA4. The site is normally embedded in the membrane bilayer, and hence, formation of the βA4 peptide fragment is prevented. It is possible that the basis for abnormal APP cleavage that leads to βA4 formation may be related to fundamental changes in membrane lipid composition and structure that could lead to exposure of the βA4 cleavage site.

Alterations in the lipid composition of neuronal membranes in AD has been characterized by various methods, including ^{31}P nuclear magnetic resonance (MRI) thin layer chromatography, and elemental analysis. These studies have demonstrated marked changes in phospholipid composition, including certain metabolites of phospholipid degradation. In addition, biochemical analyses indicate that the cholesterol content of neuronal membranes isolated from an affected cerebral cortical region of AD brain tissue is significantly lower than in corresponding age-matched control and Parkinson's disease samples. The effect of changes in neuronal lipid composition on the structure of plasma membrane lipid bilayers has been directly determined with the use of small angle X-ray diffraction. The results of this analysis showed a reproducible reduction in the overall width of reconstituted AD membrane lipid bilayers relative to age-matched controls. We suggest that this thinning of the membrane bilayer may increase the probability for proteolytic cleavage and release of the βA4 fragment from APP. Interestingly, there was no evidence for changes in lipid composition or structure in neuronal membranes reconstituted from unaffected regions of the AD brain (i.e., cerebellum) relative to control subjects. Furthermore, this reduction in membrane lipid bilayer width could be reversed by adding cholesterol back to the AD samples. Thus, abnormal cleavage of APP may be attributed to basic changes in the architecture of the neuronal plasma membrane bilayer secondary to reduced cholesterol content. Why membrane cholesterol content in these membranes is decreased is not clear and constitutes a clear direction for future studies. Of note is the recent discovery of the expression of an apo E isoform (E_4) in AD patients, the presence of which appears to predict risk and severity for developing AD. However, any link between dysregulation of apo E and altered cortical membrane cholesterol and structure in these subjects has yet to be demonstrated.

Disease-Related Alterations in the Elderly: Atherosclerosis

Another disorder of increasing prevalence with age is heart disease and stroke. Here a link between defects in membrane cholesterol and cell function may also be important. In industrialized cultures, nearly one-half of all causes of death can be attributed to arterial wall disease in which the gradual buildup of fatty lesions and plaque on the luminal surface of large arteries encroaches on organ blood flow. This very gradual, silent process converts in a matter of moments to the acute life-threatening crisis of myocardial infarction or stroke when plaque rupture occurs triggering thrombotic occlusion and ischemia of downstream tissues (*see* Atherosclerosis).

Although cardiovascular mortality is clearly linked with elevated serum cholesterol levels, the cellular basis for atherogenesis is very poorly understood. Moreover, just how molecular cholesterol *per se* fits into the pathophysiology of atherosclerosis has been a total mystery. However, there is a growing belief that serum hypercholesterolemia and/or defects of lipoprotein metabolism lead to the abnormal retention of LDL in the arterial wall. Once there in concentrations greater than can be cleared effectively by the monocyte–macrophage pathway, several biological events likely occur that lead to plaque development and the eventual demise of the arterial lumen and organ blood flow. Recent studies shed new light on the cellular basis of atherogenesis and clearly point to defects in membrane cholesterol levels as a potentially important element in the early pathogenic alterations of arterial wall cells in this disease. Studies from our laboratories have shown that enrichment of arterial SMC plasma membranes with cholesterol augments vasoconstrictor activity by increasing calcium permeability and cytosolic calcium levels. Although these studies were performed *in vitro*, more recent studies have demonstrated very similar findings in rabbits fed a cholesterol-enriched diet for up to 10 weeks. In these studies, atherosclerotic lesions developed in the aorta, and aortic wall segments were isolated and studied for their vasoconstrictor activity and calcium permeability. Again, basal and stimulated calcium permeability and cytosolic calcium levels were elevated. This change in calcium handling was accompanied by an increase in vasoconstrictor activity to adrenergic stimulation and stimulation with serotonin. We concluded from these studies that the augmented vasoconstrictor activity was caused by the elevated cell calcium levels in SMCs, and this defect may explain the common occurrence of vasospastic syndromes in atherosclerotic vessels. Based on our previous studies, we speculated

the increase in SMC calcium permeability was secondary to an increase in SMC plasma membrane cholesterol content. This notion was strongly supported in studies in SMCs freshly dispersed from the aorta of cholesterol-fed animals. We found that the cholesterol content of the SMC plasma membrane increased as a function of time on a high-cholesterol diet. Using small angle X-ray diffraction analysis, we also found that the membrane bilayer width increased over the cholesterol feeding period, and this increase in membrane width correlated very highly with membrane cholesterol content, as illustrated in **Figure 3**. This relationship between membrane width and membrane cholesterol content was preserved regardless of cell origin (i.e., cultured vs. freshly dispersed SMCs) or method of enrichment with cholesterol (*in vitro* with liposomes or *in vivo* by cholesterol feeding to animals). Moreover, this increase in bilayer width and cholesterol content was apparent prior to the appearance of visible lesions, suggesting that the enrichment of SMC plasma membranes in dietary atherosclerosis is an early event in the genesis of atherosclerotic lesions. That excess membrane cholesterol is causally linked to these changes in SMCs during atherogenesis is strongly inferred by our recent observation that they are all reversed back to normal levels following reversal of membrane cholesterol content by incubation of the cells overnight with the human cholesterol acceptor lipoprotein HDL.

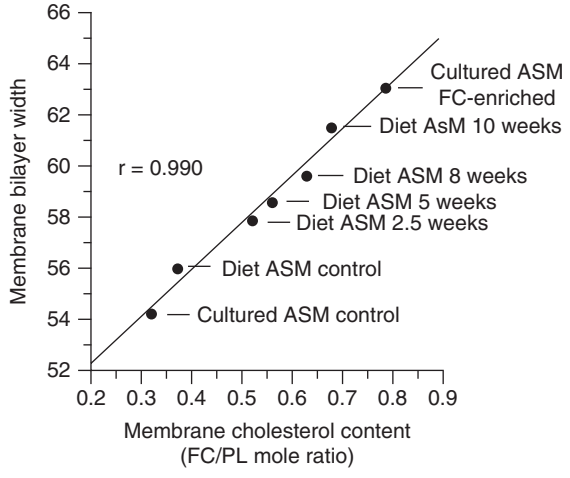

Figure 3 The effects of membrane cholesterol enrichment on membrane bilayer width as determined using small angle X-ray diffraction. Membranes were freshly isolated from smooth muscle cells (SMC) dispersed from the rabbit aorta. Note that the increase in membrane cholesterol tracked with the duration of cholesterol feeding as well as with membrane width. This correlation of membrane width with membrane cholesterol content was preserved for SMC enriched in culture with cholesterol donor liposomes as well as in SMC freshly isolated from rabbits fed cholesterol for up to 10 weeks.

In comparing the membrane and cell alterations that result from acute cholesterol enrichment of SMCs in culture with membrane and cell alterations that are seen in SMCs isolated from atherosclerotic aorta, we have concluded that the phenotypic alterations in SMCs that are seen in atherogenesis may actually be induced by enrichment of the SMC plasma membrane. These membrane alterations common to acute cholesterol enrichment *in vitro* and chronic cholesterol feeding (*in vivo*) include elevated membrane cholesterol levels, decreased membrane fluidity, increased membrane width, increased membrane calcium permeability, decreased membrane Na^+/K^+ ATPase activity, and an increase in unstimulated and stimulated cytosolic calcium levels. The cellular phenotypic alterations induced by cholesterol *in vitro* that are common to *in vivo* hypercholesterolemia include increased cytosolic calcium levels, increased contractile function, increased proliferation rate, and increased mitogen secretion. The ability of human HDL to reverse all these membrane and cell functional alterations strongly supports the hypothesis that they are all driven by enrichment of the SMC plasma membrane with cholesterol. It is clear that excess membrane cholesterol may have broad cellular consequences owing to its ability to induce phenotypic modulation in SMCs. Whether it is also responsible for the increased synthesis of extracellular matrix typical to atherosclerotic lesions is currently under investigation.

In summary, these findings have led us to speculate that enrichment of the SMC plasma membrane with cholesterol contributes to the changes in SMC metabolic activity seen in atherogenesis. Thus, the development of excess membrane cholesterol in SMC secondary to retention of LDL in the arterial wall may play a pivotal and early role in the genesis of the cellular defects responsible for this important human disease.

Summary

It has been known for some time that cholesterol is a major lipid constituent of cell plasma membranes. Although its role there has been regarded largely along the lines of setting membrane fluidity, it is becoming increasingly clear that it also has important membrane structural effects. Changes in membrane cholesterol composition have been demonstrated to induce significant alterations in the activity of various membrane proteins, and therefore also in cell function, including alterations in the phenotypic state, at least in SMC. However, in age-related alterations, it is not clear whether the alterations in membrane cholesterol reflect compensatory alterations or

pathologic alterations. In the case of AD and atherosclerotic vessel disease, two major disorders of prevalence in the elderly, cholesterol may well be playing a pathogenic role. However, in other situations, changes in membrane cholesterol appear to be part of a compensatory response to aging designed to actually protect or preserve cell and tissue function. Thus, molecular cholesterol appears to play a vital role in regulating the healthful activities of cells by its ability to modulate characteristics of plasma membrane that permit optimum performance to the wide array of membrane proteins on the cell surface.

Cognitive-Behavioral Interventions

H M DeVries, Wheaton College, Wheaton, IL, USA

Glossary

Cognitive Triad – Pattern of dysfunctional thinking characteristic of depressed persons in which they hold negative beliefs about the self, experiences, and the future.

Dysfunctional Thought Record – A cognitive-behavioral technique that is used to help individuals identify and monitor cognitive distortions.

Schema – Long-standing underlying assumptions or systems of belief from which the basic cognitive distortions and automatic thoughts emerge.

Introduction

Cognitive-behavioral therapy (CBT) is an approach to treatment of psychological problems that emphasizes the relationship among cognitive processes (thoughts or beliefs), emotions, and behavior. The assumption is that what one believes about an event or experience impacts how one feels and behaves in that situation. Similarly, the activities or behaviors that one engages in will affect mood and thoughts.

Thus, a depressed person is often trapped in a downward spiral of negative thoughts that lead to depressed feelings and disengagement from meaningful and pleasant activities. The approach to treatment assumes that changes in thoughts and behaviors will result in changes in mood. The process of treatment is active and directive, with the therapist and patient working collaboratively to identify and change negative or dysfunctional thoughts and increase participation in meaningful activities. The goal of CBT is to teach the skills needed to change the dysfunctional thinking and behaviors that contribute to negative mood. Thus, CBT emphasizes the teaching of coping skills for dealing with problems rather than 'curing' the problem. The expected consequence of teaching these skills is an increase in patients' sense of self-efficacy, competency, and coping abilities. These skills equip them to deal not only with present problems, but also with future problems. The leading figures in the development of general cognitive therapy approaches to treatment of mood disorders are Albert Ellis, Donald Meichenbaum, and Aaron Beck.

Theoretical Assumptions of Cognitive-Behavioral Therapy

Causes of Problems

CBT assumes that negative emotions are linked to an individual's capacity to distort reality in dysfunctional ways, which often results in withdrawal from meaningful activities. The combination of these processes creates a downward depressive spiral that limits the individual's capacity to respond to life challenges in a functional way. Thus, while everyone experiences stressful life events over the course of a lifetime, it is the individual's subjective evaluation and behavioral response to that evaluation that determine whether they experience psychological distress. The interaction between the experience of a stressful event and the individual's perception and response to that event predicts outcome.

Beck's cognitive model identifies three specific factors that disrupt an individual's capacity to perceive and respond to experiences in a functional way. The first is known as the 'negative or cognitive triad,' an interactive set of negative or distorted beliefs about the self, experiences, and the future. Depressed persons often believe themselves to be unworthy, deficient, or unlovable and interpret negative life events as their fault or as a result of their own inadequacy. Thus, the person who does not get an expected promotion at work might attribute this to the belief 'I am mediocre,' rather than considering alternative explanations (e.g., 'The person who got the promotion had more seniority'). In the same way, beliefs about life events and the future will filter the way an individual interprets his or her experience.

The second factor in Beck's model is maladaptive 'schema.' Schemas are stable organizational patterns of thought that form the basic framework for classifying and evaluating experience. These schemas reflect a kind of world view represented by a set of underlying beliefs about self and others. Often these beliefs, while automatic, are implicit and out of the awareness of the person. Maladaptive schemas impair the individual's ability to objectively evaluate interactions and events, foster a persistent negative response bias, and frequently result in negative affective and behavioral symptoms. For example, following the death of a spouse, the person who holds the schema 'I must have someone to take care of me,' would be likely to endorse such statements as 'I will never be safe (loved, cared for) again.' This schema pushes the individual into an unrealistic appraisal of the situation and to a negative appraisal of self, experience, and the future.

The third factor in Beck's model is that maladaptive schemas lead to errors in information processing and logical thinking. In particular, identifiable patterns in cognitive errors are common and include (1) selective attention (focusing on some details while ignoring other relevant facts of the situation), (2) overgeneralization (assuming that the outcome of one incident will occur in all situations), (3) arbitrary inference (drawing a conclusion in the absence of evidence), (4) magnification or minimization (distorting the importance or significance of a single event), (5) personalization (assuming automatically that external events relate to oneself), (6) 'all-or-none' thinking (categorizing continuous experiences as dichotomous extremes, such as good or bad, loved or hated).

The consequence of these dysfunctional cognitive processes is often a behavioral response that removes the individual from active engagement in enjoyable or meaningful activities. The loss of enjoyable activity contributes to the downward spiral of depression and makes it difficult for the individual to recover from a challenging or stressful life event.

Goals and Strategies of CBT

The goal of CBT is to address the dysfunctional thoughts and beliefs that are causing distress to the older adult and to encourage more adaptive cognitive and behavioral responses. The cognitive component of CBT seeks to identify the dysfunctional thoughts and beliefs that lead to errors in cognitive processing and to teach individuals the skills that permit a more

balanced and accurate view of their situation. The behavioral component emphasizes the relationship between activity and mood and encourages increased participation in pleasant activities, decreased participation in aversive activities, and improved problem-solving and social skills.

To address the cognitive distortions, the process of therapy includes the following components:

1. Identifying the specific negative thoughts associated with a specific event.
2. Establishing the relationship between negative thoughts and feelings associated with that event.
3. Learning specific CB techniques for challenging negative or dysfunctional thinking.
4. Developing more adaptive interpretations and responses to specific situations.
5. Identifying and altering general maladaptive schemas that foster development of depression and/or anxiety.

The concerns of older clients often have a basis in reality but also may reflect biases, distortions, and exaggerations. The therapist helps the client distinguish between realistic implications of their situation and false beliefs about the situation that lead to excessive negative preoccupation and distress.

The behavioral response to awareness of these dysfunctional beliefs will hopefully motivate the individual to engage in activities and relationships that restore pleasure and to generate ways to overcome barriers to enjoyment. The approach to treatment will draw on standard behavioral techniques, including contracting, monitoring of mood, and monitoring of specific behaviors. This approach enables clients to implement new behaviors in gradual, graduated steps and components. These small, incremental, and reinforced steps enable depressed or dependent clients to begin to move out of a cycle of passive inaction and to make important behavioral changes to enhance their well-being. Behavioral approaches emphasize that clients are experts in their own experiences and skills, draw on common sense knowledge, and avoid psychological jargon.

The therapeutic approach of CBT is one of active collaboration between client and therapist. Sessions are structured and emphasize targeting problems, skills training, and problem solving. 'Homework' requiring practice of new skills is assigned regularly and reviewed in each session. Treatment length is generally brief (10–20 sessions). One or two follow-up sessions are sometimes scheduled for relapse prevention and skills maintenance. The strong emphasis on a collaborative relationship between client and therapist requires significant attention by the therapist on establishing a strong therapeutic alliance with the client.

Rationale for Use of CBT with Older Adults

Appropriate for Addressing Normal Problems of Aging

Older adults experience an increasing number of transitions and stressful life events associated with the normal process of aging. Many of the developmental challenges of late adulthood, such as the need to adapt to sensory and perceptual losses, to cope with the loss of significant others, and to adjust to changes in work and family roles, can occur simultaneously or in close succession, complicating the adjustment process. The success with which older adults adapt to these and similar developmental tasks will likely predict their vulnerability to decreased mental and physical well-being.

CBT has been shown to be helpful as a way to support older adults who experience these developmental challenges as problematic and seek treatment to alleviate their emotional distress. In particular, CBT's problem-solving approach, with its emphasis on the development of coping skills, is ideally suited for helping individuals respond to normal developmental and life-adjustment events.

CBT has also been used successfully with older adults to alleviate symptoms of specific psychiatric disorders, including depression, anxiety disorders, and somatic disorders (e.g., insomnia, sexual dysfunction, chronic pain). Thus, this treatment modality has shown promise in addressing a range of problems that an older population might face as they cope with the challenges of aging.

Appropriate for Older Persons

Before the early 1980s, mental health providers often assumed that the elderly would not benefit from psychotherapy. The belief was that older adults were inflexible and incapable of change. Some even assumed that depression and deteriorating mental well-being were normal conditions of old age. These views have been effectively challenged by many studies that have demonstrated the efficacy of psychotherapy for this population. In particular, research has indicated that therapy with the elderly is most helpful if it is (1) not stigmatizing (with emphasis on coping skills, not on psychopathology), (2) structured (so the client knows what to expect), (3) time limited (providing hope that the individual will soon see improvement), and (4) goal oriented (has a problem-solving focus). CBT meets these criteria and provides an excellent

model for addressing the problems experienced by aging adults. In addition, the collaborative stance and present-focused emphasis of CBT generally make it feel more respectful and appealing to an older population.

Recommended Adaptations and Modifications of Standard CBT for Use with Older Adults

Although standard techniques of CBT can be used with older adults, certain modifications in the implementation of treatment are recommended to accommodate age-related changes in personality and intellectual functioning.

Accommodation to the Unique Experiences of this Population

Heterogeneous Population Older adults comprise a widely diverse and heterogeneous population. Variations in educational level, physical health, intellectual functioning, interests, life circumstances, and social history are often greater than those found in a younger population. Such diversity demands added flexibility and sensitivity on the part of the therapist in obtaining a thorough psychological, social, and medical history. Attention to the multiple factors that may be operating in the situation facing the older adult will enhance the therapist's ability to tailor treatment to the appropriate level and unique needs of a specific older adult.

Age Differences An obvious difference between working with older and younger client groups is the likelihood of an age gap between client and therapist. The therapist must recognize and be sensitive to ways in which age compatibility impacts therapy, particularly in the therapeutic relationship and in the identification of appropriate therapeutic goals. For example, a young therapist may find it difficult to accept treatment goals that might be important for someone who has only 5 or 10 years of life left. The tendency may be to aim for long-term personality change rather than helping the client cope or adapt to an immediate situation.

Modifications to Therapy Process

Slower Pace of Therapy Several sensory and developmental changes associated with normal aging require some adjustment to the pace of therapy. Sensory deficits, including decreased visual and auditory acuity, can affect the rate and accuracy of information processing. The therapist should inquire about hearing loss, speak more slowly, and enunciate clearly. Adjustments to the physical environment, including bright lighting and low background noise, will help compensate for many sensory difficulties.

Developmental changes in the elderly also impact their capacity to learn new information and demand a slower pace in therapy. Research indicates that the elderly experience a gradual decline in their ability to absorb and recall new information, learning at a slower rate or in a different way than younger persons. It is helpful to present important information in several different sensory modalities. For example, using handouts and written feedback or having clients frequently repeat major points will enhance encoding of new information. Asking elderly clients to take notes and write down important information during therapy sessions will also improve their capacity to absorb new material. Pre-therapy cognitive screening of older clients to assess level of intellectual functioning is important to ensure that those with gross deficits (e.g., moderate to severe dementia) are excluded from treatment. Clients with only mild cognitive impairment can still benefit from treatment if proper adjustments are made in method and rate of presenting new material.

Active Role of Therapist When working with older adults, the therapist needs to be more active, particularly in maintaining the focus and structure of the session. Older clients sometimes digress from the task at hand to share additional material not related to the therapeutic objectives or to engage in spontaneous life review. The therapist must use clinical judgment to determine when it is necessary to refocus the topic of discussion and redirect the client to the immediate problem under discussion. Taking an active role, however, does not imply an overly directive or 'pushy' style of interaction that patronizes or infantilizes the older adult. A strong therapeutic alliance is critical for successful outcome.

Socialization to Therapy Older adults differ widely in their level of therapeutic sophistication. Many grew up in a culture that viewed psychotherapy as a treatment for 'crazy' people. They often hold the belief that it is shameful or embarrassing to be in therapy. The therapist should explore the older client's expectations, stereotypes, and fears about the process of therapy in order to elicit potentially obstructive assumptions. For example, many older clients think of therapy as a passive process, like going to the doctor to get 'fixed.' It is, therefore, helpful to educate these clients about the active nature of CBT, which requires their participation and collaboration. The therapist should stress the need for a collaborative relationship, the importance of completing

'homework,' and the structured format of individual sessions. In addition, it is often important to review the special 'rules,' conditions, and safeguards of therapy that might differ from the normal rules governing social interactions.

Treatment Approaches

Treatment of Common Life Stage Problems of Older Adults

Most older adults adapt successfully to the multiple developmental and social changes that are common in late life. For those who experience distress or develop psychological symptoms, CBT offers an ideal treatment modality. The emphasis in CBT on the acquisition of coping skills provides older adults with concrete strategies for dealing with areas of problematic adjustment.

Bereavement Multiple losses are common as people age, including deaths of spouse, family, and friends. A less obvious form of loss involves the change in relationship quality with a spouse or friend who may be experiencing physical or cognitive impairment. These losses, as well as the awareness of one's own mortality, often trigger a review and evaluation of unrealized dreams, lost opportunities, and unresolved relationships. This review may activate negative thoughts and maladaptive schema that impede the recovery process. In addition, the loss of meaningful relationships may isolate the older adult and reduce the opportunities for support and social interactions with others. CBT interventions that seek to address these concerns can be helpful in reversing the negative spiral and engaging the individual in a more positive and adaptive response. For example, cognitive interventions that identify negative thoughts and challenge their accuracy will facilitate a more positive grief reaction and process. If the person believes that 'I can't survive alone,' 'My life is a total failure,' or 'I'll never be happy again,' then the person will find it difficult to interpret experience accurately. Cognitive techniques, such as 'examining the evidence' and 'generating alternative thoughts,' will facilitate a more positive recovery from loss. In combination with behavioral techniques, such as increasing pleasant events and interactions with others, CBT helps move the person into a more problem-solving and adaptive response.

Chronic Illness and Disability The majority of older adults (some estimate as high as 85%) have some type of chronic illness, such as arthritis, diabetes, hypertension, or respiratory or cardiac problems. Many also experience a loss or reduction in physical and intellectual abilities that leave them dependent on others for assistance. These physical changes may impose limitations on their lifestyle to accommodate restrictive medical schedules and regimens, cause chronic pain, strain their coping resources, and/or challenge their sense of self-worth, competence, and control. These limitations pose risks for decreasing the individual's engagement in activities and relationships that bring enjoyment and meaning. If older adults also have negative beliefs about themselves and their ability to cope with their illness, there is an additional risk for developing psychological symptoms.

Adjustments to standard treatment protocols (such as simplification of therapy techniques and use of short, frequent sessions) and consideration of the special needs of this population are usually necessary for successful implementation. For example, disabled older adults may need to be seen in facilities that are wheelchair accessible, have elevators, and have rooms large enough to accommodate walkers or wheelchairs. Treatment in the client's home may also be a necessary accommodation.

CBT that identifies negative beliefs about the illness or disability (such as 'Nobody wants to be around a sick person'), that fosters more adaptive thinking about the situation ('My family and friends still enjoy my company'), and that promotes continued participation in pleasant and meaningful activities will encourage better adjustment and coping with the illness or disability. Thus, CBT offers a promising approach for teaching patients to cope with chronic pain or disability, challenges the perception of being a 'burden,' alleviates somatic symptoms, and enhances positive mood.

Changes in Social and Family Roles Older adults face multiple normative transitions associated with aging that result in changes or losses of important social roles. When the individual's personal identity or feelings of self-worth were tied up in a particular role, the loss of that role can be devastating. From a CB perspective, the way an individual perceives these role changes and the beliefs they hold about their own value and importance outside of these roles will impact how well they negotiate the transition. For example, a person who believes that his or her life is meaningful only if they are making money may respond to retirement with thoughts about no longer having value or being needed.

Normative changes in family structure also occur as the family moves through developmental stages. Intergenerational differences and conflicts are bound to emerge as elderly parents and adult children

renegotiate new roles and relationships. Elderly parents may become depressed if ill health or financial constraints force them to become dependent on children. Conversely, parents may feel hurt or abandoned if they perceive that their children are not available to care for them. Identifying an individual's expectations and assumptions abut the nature of late-life parent–child relationships will shed light on why certain family interactions become problematic.

Marital conflicts can also erupt as couples in longstanding relationships undergo changes in patterns of functioning due to retirement, illness, loss of parenting role, and so on. Couples tend to carve out areas of responsibility over the course of their marriage that may be threatened by the change in status of one partner. In addition, life changes (particularly the loss of the shared parenting role) may leave the couple feeling that they have little in common or have lost a sense of shared purpose. CBT can be helpful in challenging unhelpful or negative perspectives on role and relationship changes associated with aging and can encourage the development of new and positive shared activities and relationships.

Ageism and Low Self-Esteem Today's youth-centered culture fosters a stereotype of old age that is less than flattering and optimistic. Some older adults accept these stereotypes as inevitable truths and believe that being old means being undesirable, unattractive, and unwanted. These beliefs can lead to a sense of futility about the future, a passive acceptance of problems, and a withdrawal from engagement in the larger community. Clearly, CBT that challenges and dispels the myths about aging can help activate the individual into a more positive coping response to these hurtful messages.

Treatment of Psychiatric Disorders

CBT has been used to treat a range of psychiatric disorders in older adults. The most common of these include depression, anxiety, drug and alcohol abuse, and somatic complaints, such as insomnia and chronic pain.

Depression Depression is the most common mental health problem in the elderly. While the incidence in community-dwelling older adults is no higher than in the general population, the risk increases significantly with medical illness or institutionalization. Depression is probably the best researched of the psychiatric disorders in the elderly, with epidemiological evidence indicating that older adults have the highest suicide rate of any age group (one-fourth of all suicides are carried out by persons age 60 or older). There is also a growing awareness of 'silent' suicides among older adults who determine to die through non-compliance with medical treatment or self-starvation. Because depression is the principal risk factor for suicide, it is particularly critical to diagnose and treat depression in the elderly.

Depression is not a normative condition of old age, but is rather a treatable psychiatric disorder in the elderly. Significant research literature indicates that CBT is an effective treatment modality for depressive disorders in both younger and older adults. CBT was specifically developed for the treatment of depression and has been standardized into well-documented treatment protocols. It is often used in combination with pharmacotherapy or supportive or family therapy.

A challenge facing the therapist working with older clients who are depressed is differentiating symptoms of depression from underlying medical problems. In addition, there are several differences in the presentation of symptoms found in depressed older adults that may prevent accurate diagnosis of depression. Specifically, depressed older adults are more likely to report somatic rather than psychological symptoms and to seek medical services rather than psychiatric services for treatment of depression. The typical symptoms of depression often overlap with normative changes associated with aging, such as alterations in sleep, appetite, and physical health. Thus, older adults may go to their physician complaining of physical symptoms such as weight loss or lack of energy without recognizing an underlying depression. In addition, depressed elderly tend to withdraw from social activities, confine themselves to bed, neglect bodily functions, and evidence symptoms of apathy and self-deprecation.

Most CBT techniques have been shown to be helpful in treating depression in older adults. The use of the dysfunctional thought record to monitor the occurrence of negative automatic thoughts, to illustrate the relationship between thoughts and emotions, and to challenge the thoughts related to the patient's negative mood is an effective tool. Behavioral techniques, such as daily monitoring of mood and increased participation in pleasant events, are often helpful early in treatment to break through the depressive inertia, improve mood, and create positive expectations for therapy. Assertiveness training frequently restores a sense of self-efficacy and control for those whose depression is linked to issues of dependency.

CBT for the treatment of depression is usually offered in individual therapy. However, there is a growing body of literature suggesting that CBT approaches work well in group formats for the treatment of depression, especially depression linked to a

specific precipitating event (e.g., loss/bereavement, caregiving for a family member with dementia, coping with a chronic illness). In particular, psychoeducational groups designed to alleviate depressive symptoms through the acquisition of cognitive and behavioral skills have shown promising results. Group approaches have the added advantage of increasing social interaction and contact for isolated or lonely individuals. Research suggests, however, that older adults with severe levels of depressive symptoms would most likely not benefit from a group format for treatment and should be treated with individual therapy.

A current area of interest is the effectiveness of CBT in treating depression in early stage Alzheimer patients. Because depression has been shown to impair cognitive functioning, treatment of depression in Alzheimer patients is warranted and, although not halting the disease progression, can help reduce excess disability in functioning. Cognitive techniques help early stage patients to reduce cognitive distortions and generate more adaptive ways of viewing situations and events. Behavioral interventions are helpful with more moderately or severely demented adults and seek to modify the person–environment interactions by increasing positive activities and decreasing negative ones.

In summary, CBT for the treatment of depression in older adults has a strong research record of effectiveness in alleviating symptoms and enhancing functioning. A multilevel approach is probably most effective for dealing with depression in the elderly, with attention given to both psychological and physical factors.

Anxiety Research indicates that anxiety symptoms are more prevalent in elderly people than in any other age group, occurring at about twice the rate of younger adults. The types of anxiety disorders most common among the older population include generalized anxiety, mixed anxious-depressive symptoms, and phobias (often characterized by exaggerations of rational concerns). More rare are late-life onset of obsessive-compulsive disorder (OCD) and panic disorders.

Treating anxiety in the elderly is particularly important due to the negative impact of anxiety on cognitive functioning. High levels of anxiety can interfere with memory, learning, and attentional capacities in older adults and mimic the symptoms of dementia. Treatment of anxiety is often complicated in older adults due to the frequency of coexistence of depression with the anxiety.

Pharmacotherapy is the most common form of treatment for symptoms of anxiety, despite increasing evidence that the use of benzodiazepines by older patients is associated with increased risk of morbidity, including excess sedation, cognitive impairment, falls, and vulnerability to withdrawal symptoms. CBT, on the other hand, offers a more risk-free approach to management of anxiety symptoms.

Although research into the efficacy of CBT for the treatment of anxiety disorders in older populations lags behind research on the treatment of depression, there is a growing body of evidence suggesting that CBT is effective in managing and reducing symptoms of anxiety. Several different CBT approaches to treatment of anxiety in this population have been described. The target of intervention for most approaches appears to be specific cognitive and behavioral symptoms of worry, specifically excessive worry (especially about aging and related health matters), intolerance of uncertainty, erroneous beliefs about worry, reduced structure of daily life, anxiety over symptoms of autonomic arousal, problem solving, insomnia, and cognitive avoidance. Some interventions also included learning and memory aids designed to enhance the impact of the treatment (e.g., homework reminder and troubleshooting calls, weekly review of all concepts and techniques). Results from these studies are promising, but suggest that standard individual CBT may not be optimally effective and may require enhanced treatment that includes support, reminders, and problem-solving strategies.

While these results show promise in treating symptoms of anxiety in older adults, more work is needed in the development and evaluation of CBT for treating anxiety disorders in this population. The advantages of a non-pharmacological approach to treatment of anxiety in older adults are clear and support the need for further development of alternate models of treatment.

Drug and Alcohol Abuse Abuse of drugs and alcohol is not uncommon among the elderly. The high rate of prescribed medication use, increased physiological sensitivity to drug effects, and the danger of interaction effects of multiple medications and/or alcohol place older adults at high risk for deliberate or accidental misuse of drugs or alcohol. In addition, some older adults turn to alcohol to help cope with stressful life events, thus increasing the risk of addiction or toxic interactions. The risk for addiction may be high due to the relative isolation of older adults who often drink in the privacy of their own home and do not have to keep work schedules that would be noticeably impacted by hangovers or intoxication. Heavy use of drugs or alcohol will place the older adult at increased risk for depression,

illness (including risk for falls and accidents), and cognitive impairment.

While few studies exist documenting CBT protocols specifically designed to treat substance use/abuse issues in the elderly, the CBT model seems an appropriate one for dealing with these concerns. CBT approaches for treating real or potential substance abuse problems might include (1) education regarding the importance of monitoring drug and alcohol consumption, (2) development of strategies for managing complex drug regimens, and (3) acquisition of coping skills for managing negative emotions and stressful life events. Individuals who have a long history of chronic alcohol and drug abuse problems would not be suitable for this treatment approach.

Somatic Complaints (Insomnia, Chronic Pain) CBT approaches to managing the distress associated with physical/somatic problems show much promise. As with anxiety disorders, the treatment of somatic complaints of older clients with pharmacological interventions poses risks. Multiple drug interactions, risk of sedation leading to loss of balance or falls, and addiction are problems that come with use of medication as the sole treatment for these problems. A growing literature on alternate methods of treating or managing these problems suggests that CBT is a promising addition to traditional treatments. For example, common CBT techniques used to treat insomnia include daily sleep diaries, establishment of 'bedtime routines,' and tracking of symptoms with clinical rating scales. CBT approaches to treatment of chronic pain often include relaxation training, use of scaling techniques, and use of distraction or imagery techniques.

Effectiveness of CBT with Older Adults

Research documenting the efficacy of CBT in treating the psychological problems of older adults is encouraging. CBT has been shown to reduce symptoms of depression, anxiety, and somatic complaints (e.g., chronic pain, insomnia) in multiple controlled studies. However, research also has indicated that there may be multiple variables to consider in determining whether CBT is the best approach to use with a specific patient and a specific problem. For example, differential effectiveness of CBT compared to other forms of psychotherapy is less certain. Most studies comparing outcomes across different treatment modalities have limitations that make conclusions problematic. In general, data support that some form of treatment is better than no treatment, thus emphasizing that the elderly can benefit from therapy with success rates that are comparable to those with younger patients.

In addition, a few studies indicate that, although there is little difference across treatment modalities at the conclusion of therapy, long-term maintenance of gains is more likely with CBT. The assumption is that the acquisition of coping skills will generalize to other situations and will enable older adults to adapt more successfully to ongoing life stressors. More controlled studies are needed to test this assumption.

Research examining outcome variables in CBT suggests that certain patient-specific and therapist-specific variables may be linked to successful outcome. For example, some studies have demonstrated that the role of the therapeutic alliance is critical in developing the collaborative stance required for successful CBT and may be the key element in whether the intervention is successful. A mismatch between client and therapist may undermine the effectiveness of therapy. Other studies have explored patient-specific variables that seem to be related to outcome, such as (1) initial intensity of depressed mood, (2) presence of a personality disorder in addition to the depression, (3) depth and quality of social and emotional relationships with friends and/or family, and (4) acceptable level of intellectual flexibility and functioning (e.g., absence of severe cognitive decline or rigidity).

A study comparing CBT and psychodynamic interventions for older depressed family caregivers was one of the first to document a specific patient-by-treatment interaction in predicting outcome (length of time caregiving $\times$ type of therapy). Specifically, the longer the time spent as a caregiver, the more positive the outcome with CBT compared to other treatment modalities. The suggested explanation is that early in caregiving, older adults respond best to an intervention that acknowledges and explores the sense of loss associated with the many changes in current and future plans caused by the illness (psychodynamic therapy). Long-term caregivers, however, whose social and emotional resources are dwindling, may respond better to highly structured, skill-oriented interventions that focus on coping rather than emphasizing their losses (CBT).

Other patient-specific variables associated with CBT outcome with depressed older clients have been noted. For example, individuals who generally respond well to CBT are those experiencing reactive depression in which a clear precipitant can be determined and whose depression can be seen as a response to the specific event or situation. Patients with chronic depression, or with a depressive episode superimposed on dysthymia, can be treated effectively if the goals are modest and the general aim is for improved affective status, rather than complete remission of the disorder. The use of medication in conjunction with CBT and the extension of treatment

to 30 or 40 sessions may also facilitate the rate of improvement in the chronically depressed patient.

Therapist-specific variables that are associated with outcome have been less studied. As mentioned earlier, outcome studies have underscored the importance of establishing a collaborative therapeutic relationship with the client. For a therapist working with older adults, attention to certain issues may enhance their capacity to form a therapeutic relationship with the older client. In particular, it is important that therapists examine their own attitudes toward the elderly for potential biases that might negatively impact the therapeutic relationship. Therapists need to convey respect for the life experiences and accomplishments of the older client rather than making their sole focus the client's current difficulties.

In conclusion, CBT is an appropriate and effective intervention for psychological problems in the elderly. Although modifications to the standard course of treatment may be necessary to accommodate the older client (particularly the format and pace at which new information is presented), older adults treated with CBT seem to show an improvement rate similar to that of younger adults. Additional research into specific factors that contribute to outcome will be helpful in developing more comprehensive CBT models for treating the psychological problems of older adults.

Comparative and Cross-Cultural Studies

C L Fry, Loyola University of Chicago, Chicago, IL, USA

Glossary

Cross-Cultural Research – Research of an open-ended and qualitative nature within a meaningful ethnic group or community of a specific culture.

Cross-Ethnic Research – Research within one or more distinctive cultural groups within a nation using both quantitative and qualitative instruments to compare the responses for specific contexts. These cultural groups may also have minority status.

Cross-National Research – Research using survey instruments on probability samples to compare the responses of people across nations.

Holocultural Research – Research using a standard sample of world cultures based on secondary data reported ethnographically and organized within the Human Relations Area Files.

Introduction

Gerontology has always had a healthy respect for comparative research. Elders from one context have

been compared with their counterparts elsewhere in order to determine what is universal about growing old and to distinguish what is specific to a particular population and sociocultural circumstance. Although all research is based on comparison (male–female, young–old, rich–poor), cross-cultural research involves a distinctive research design. At a bare minimum, two or more populations with known biological or cultural properties are systematically examined to evaluate hypotheses about how differences shape experiences of aging. Beyond this basic criterion, comparative research is by necessity quite diverse, reflecting the problem under investigation and the variety of contexts in which people live. This article examines the importance of cross-cultural research, the variety of comparative research designs, specific issues that have been investigated among older people, the meaning of old age and the life course, and needed comparative research.

Importance of Comparative Research

Why engage in comparative research? Coordinating data collection and analysis from around the globe is expensive and time intensive. What is the payoff? There are a number of very compelling reasons for comparative research. First, curiosity is a property of the human intellect. What is it like in faraway places, and do they do things better or worse than us? Second, and more important, diversity helps us formulate and clarify questions. If everything were uniform, there would be virtually no reason to ask questions. For instance, if everyone had the same skin color, why would we want to determine the purpose of skin color? Because skin colors range from dark to light, we want an explanation, and thus discover the positive functions of dark skin and ultraviolet ray protection. Likewise, we find that light skin has positive functions in tanning and vitamin D production for bone metabolism. With cultural phenomena, differences are even more important in challenging world views that seem natural and the only way of understanding and doing things. Just like skin color, issues related to old age, such as retirement, pensions, nursing homes, or even Alzheimer's disease, are seen as one way of doing or understanding things, not the only way. Third, by encompassing the full range of human experience, we enrich and strengthen our scientific theories about that experience. For gerontology, if we limit our investigations to nations where old age has been declared a problem, then we are likely to perpetuate the myths these societies have about themselves. By including the full gamut from small-scale foraging societies to the most industrialized societies of Europe and North America, we gain in diversity and challenge the models generated by one societal type. Furthermore, we strengthen our theories by being able to isolate the social and cultural forces that shape the experience of aging in distinct settings. In the end, we can separate what is universal from what is culturally specific to the experience of aging. Finally, we want to learn something about ourselves. We want to see ourselves as 'the alien.' In the relief of other cultures, we comprehend our own with more understanding.

Comparative research is not without its pitfalls. What has become known as the comparative method can be abused. All data collection and analysis must meet standards of data quality control. Most familiar are issues of validity and reliability. Validity is an assurance that the indicators selected are actually measuring what they should be as suggested by the theory under investigation. Reliability is the confidence placed in procedures to abstract from the data through coding to reduce distortion of the idiosyncrasies of the coders on the resulting data. In other words, the coders should have sufficiently explicit understanding of coding categories so that one coder could replicate the work of another coder with minimal variation in results. In addition to validity and reliability, cross-cultural analysis requires guarantees of comparability. With issues of measurement resolved, we still must consider whether what we are comparing across sites is even similar in meaning. For something as fundamental as old age, can we define it in a way that is meaningful to both corporation executives in New York City and peasant farmers in rural Mexico? Generally for primary data, collected first hand by researchers, comparability problems are made explicit through discussion and negotiation. Secondary data taken from existing records present more challenges since investigators must interpret the meaning of the records.

Comparative Research Designs

Comparative research designs fall into two broad categories: cross-national and cross-cultural. Distinguishing these types of research are distinctive methodologies and units of analysis.

Cross-national Research

The intent of cross-national research is to compare people living in different political units or nations. Thus, the unit of analysis is a country sometimes differentiated into rural/urban or into ethnic groups. Researchers select the people who will participate through national probability sampling. These individuals are then asked either to complete a questionnaire or to agree to be interviewed by a

survey researcher using a standardized interview guide. Most often the questions are designed to be efficiently answered and recorded in a closed-ended format. In this format, various answers to the questions are determined in advance so they may be checked off on the questionnaire and transferred to electronic form for data analysis. In contrast, open-ended questions permit more variability in responses, which in turn presents more challenges in categorizing variation. Results from cross-national research are presented using statistical tables to document national differences on a wide variety of issues such as health, family support, and retirement.

Cross-cultural Research

Comparing entire nations is beyond the intention of cross-cultural research. Instead, the units of analysis are more homogeneous cultural units such as ethnic groups, villages, or urban enclaves. Investigators focus on how cultural understandings and context shape the way aging is perceived and experienced. Research strategies are more open ended and involve the use of qualitative methods (as compared to the quantitative designs of survey research). Although quantitative techniques may be used, results are presented in an ethnographic form describing the cultural context along with any statistical information.

Specific research designs for cross-cultural research are quite variable. At one extreme are large-scale research projects involving a team of investigators using the same research design and adapting protocols to several cultural settings. On the other extreme are single researchers designing their research to shed further light on an existing problem or to redefine that issue by investigating it in a different cultural context. Because primary data are sometimes expensive and difficult to obtain, secondary data are very attractive. Existing ethnographies are systematically organized and mined for information relevant to a topic. The most comprehensive endeavor to use published reports as comparative data is the Human Relations Area Files (HRAF). A distinctive comparative approach has evolved that is known as holocultural. This method is based on a sample of 186 cultures that are relatively independent of each other and ethnographically well documented. Alternatively, ethnographic case studies may be selected by a criterion such as region or by societal type to elucidate a topic on a comparative basis.

Old People

Comparative studies of older people began, like gerontology itself, with an assumption that old age was a problematic state of affairs. Among the first tasks were to demographically document the percent of older adults in a society and to ascertain how well they were doing. Subsequently, topics of investigation became more diversified once we understood old people to be among the most heterogeneous of populations.

Demography

Demography is among the most comparative endeavors. The vital statistics and demographic profiles of one nation are interesting but take on new meaning when contrasted with the population statistics of other nations. Through comparison we can understand the dynamics of fertility, mortality, and migration and the factors shaping population size and structure.

Within the past two centuries, world population has been most impacted by the industrial revolution. Increased productivity and demand for workers, combined with improved sanitation and medical technology, resulted in high fertility and remarkable declines in mortality, especially among infants and children. The net result was an exponential increase in world population, with a doubling in every 50 years. Comparative demographics reveal the continuing shock wave of industry. The populations of the nations that experienced industrialization the earliest are now considered to be aging. Initially, their populations were young, but as the rewards for large families declined and child-rearing costs increased, fertility declined. With further reductions in mortality, the formerly youthful population aged, since there were fewer children replacing their parents and grandparents. This phenomenon has been identified as the demographic transition. In nations that experienced industrialization more recently, the demographic transition has not yet occurred; populations are still youthful and expanding. According to projections, the world population will continue to expand until the twenty-second century, when the effect of industry will stabilize with a world population of 14–19 billion.

If advances have been made in extending life and reducing mortality, how long is it possible for a human being to survive? Demographic profiles indicate that surviving to over 100 is rare even in industrialized countries, but is increasingly possible. In at least three non-industrialized village/ethnic groups we find reported extreme longevity of up to and possibly over 130 years. This is an enticing prospect given molecular biological evidence that humans could potentially have life spans of 120–160 years. However, research among the Abkhasians in the

former Soviet Union state of Georgia, the Ecuadorians in Vilcabamba, and the Hunzakut of the Himalayas reveals that people in these areas grow old, but not as old as they claim. Assuming identities of parents to avoid military conscription or using age escalation to claim attention and respect leads a few elders to affirm they are far older than they actually are. In the absence of birth certificates, evidence of real age is difficult to prove without multiple documentations through baptismal records, marriage certificates, birth histories, and connections to known regional and national history. Thus, aside from reports of superlongevity, the nations where people are surviving to become centenarians are the industrialized nations of Europe, North America, and Asia. From this work, we are reminded that age is not just a simple biological or demographic fact, but can be manipulated and is a potent factor in the politics of daily life.

Well-Being and Successful Aging

As gerontology crystallized into a field of specialization, researchers accepted a societal definition that saw aging as problematic. Thus, one important task was to document how well or poor older adults viewed their own lives. Well-being measures, morale scales, and life satisfaction indexes became a major methodological focus and area of inquiry. Cross-cultural research presented immediate challenges to psychometric scales attempting to measure morale because of inherent cultural assumptions about psychological well-being. Comparative research focused on questions about the status of older people, how they are treated, and what is available to them to maintain a position within a community.

It was hypothesized that older people are better off in smaller-scaled tribal and peasant cultures as compared to their counterparts in the industrialized world. A rather obvious point of difference is that older people in industrial countries are expected to retire from the workplace, which removes them from production and a major activity of adulthood. In tribal societies, work is subsistence based and largely domestic. Productive actives are within a family unit and are lifelong until one is no longer able to perform them. This paradise lost hypothesis has not received much substantiation, however. Retirement has not produced social isolation and a life stage that has limited possibilities. Quite to the contrary: due to medical technology, labor-saving devices, and the economic supports in Social Security and pension plans, old age is full of opportunity and possibilities. It is a time of freedom from the responsibilities of younger life stages.

In smaller-scaled cultures, life is less technologically buffered. Where amenities such as indoor plumbing are absent, water must be hauled from a water source instead of turning on the tap. Fuel must be collected instead of setting the thermostat higher. Likewise, a trip to visit a relative may involve a several kilometer walk instead of a ride in a car. Physical demands are higher for everyone, including older adults. In old age, some individuals may well find themselves unwillingly physically active through expectations of their families.

Although we generally find older people to be well-treated and respected members of their societies, abandonment and killing are not rare. In about half of the technologically simple societies, we find practices resulting in the hastened deaths of some older people. Many of these societies are foraging groups who during the harshest seasons may be forced to sacrifice their least productive members for the survival of the group. On the other hand, many of these societies are agriculturalists in temperate climates. Cross-cultural research has revealed that intact, contributing older people are supported and cared for. Once an individual becomes severely impaired and feeble, support is withdrawn. It is a very difficult family decision, often effected at the request of the person who will die. Death may occur violently, as when a son murders his parent, or may happen by abandonment or by withholding food and water.

With older adults experiencing considerable support in most societies, especially in technologically advanced societies, what promotes a good old age? One obvious factor is the physical condition of one's body. As health declines, it becomes increasingly difficult to work and to do one's daily routine. Another factor is security. To be assured that the material basis of life (food, shelter, warmth) will continue into the future and at a level one is accustomed to is a very important component of successful aging. A safety net of support, usually from family, is another ingredient for aging well. Health, security, and support are near universal in their desirability, but how they are actualized and the consequences of deficits in these areas are highly variable. We discuss these in the sections that follow.

Health In promoting well-being, health is very important. Declines in health status are universally feared. Yet on a cross-cultural basis, health is not just the physical status of the body. Health and its understanding are culturally mitigated. Body states are interpreted though cultural knowledge, as is exemplified by menopause. In the late 40s or early 50s, women experience a change in hormones accompanying the

cessation of ovulation. However, across cultures we find major differences in the symptoms signaling the change. In Japan, the most frequent complaints are of shoulder stiffness, headaches, backaches, constipation, chilliness, and irritability. Women in North America report problems with hot flashes, palpitations, night sweats, and tiredness. Unless Asian and European women have different physiologies, changing body states are given cultural meaning.

Across cultures, declining health means decreased functionality. Difficulty in moving, loss of strength, and loss of perceptual acuity are threats to adult status. If one can no longer do that which is expected of most adults, then full participation in social life is compromised. Comparative research again reveals the impact of culture in at least two ways.

First, functionality is culturally defined. Older Americans have to be able to do certain things because of their technological environment and cultural expectations. When one must be able to read and when a significant portion of recreation and information comes from television, then impaired vision is isolating. Likewise, when one can no longer negotiate stairs, cleaning, cooking, shopping, or managing finances, then the ideal of maintaining an independent household is compromised. In other cultures in which literacy is rare and households are jointly organized with extended families, difficulties in vision and in domestic activities are not as threatening.

Second, culture compensates for human frailties through people and technology. Again, we find variation. In technologically simpler cultures, people are more likely to be mobilized. For instance, if one can no longer haul water, the presence of a grandchild who can resolves the problem. In more complex societies with many labor-saving devices, physical frailty is buffered through technology. Not only do machines save time, but also the need of physical strength is reduced. In addition, prostheses such as pacemakers, wheelchairs, glasses, hearing aids, and walkers directly enable people with impairment to continue to do their daily activities. Ironically, even with the ability to reduce the effects of declining functionality with technology, people still fear the frustrations that come with disability.

Security Control over a resource that others value is certainly a very direct way of promoting one's well-being and security. Comparative research has revealed that when older adults are in control of wealth, land, food, the labor of others, and even information, they are elevated in status and face very secure futures. In old age, relatively few can hold on to enough wealth to be able to manipulate kin through the promise of a sizable inheritance. In any culture, we find people who are more than comfortable while others are in need. We also find some economies that work against material accumulation. Under these circumstances, old age can become very trying. When physical abilities have declined, one's access to the very basis of life, food, is at risk. In the abundance of industrialized societies, we find marked wealth differentials, but we also find old age to be economically stabilized through Social Security and social welfare policies. In North America and Europe, older people are less likely to see material issues as threatening their old age.

Kinship and Support Caregiving and support of older people is a major social issue, but it is primarily a family issue. Families look after and, when needed, care for their older members. Cross-cultural studies of kinship have encountered such tremendous variation in family organization that it is almost impossible to come up with a simple definition of marriage or what constitutes a family. Families reflect the economies in which they are located. In nonindustrial societies, kinship plays a much larger role in people's lives. Families are both political and economic units anchoring one in a larger society. Interdependency is reinforced by a domestic division of labor whereby the kin unit manages its affairs for the good of its members, including those who are old. In contrast, kinship diminishes in industrial economies. Lower fertility reduces the number of kin. But more importantly, occupational structures come to dominate people's lives. Individuals participate in industry through an extensive division of labor within bureaucratically organized corporations. With increased wealth, families no longer maintain and rely on a family fund as households become financially autonomous. Families continue to be very important, but the meaning of kinship is quite different. Kin are cherished for their personalities and friendship, not for how much support they can contribute. Parents invest very heavily in fewer children to encourage them to meet their full potential. Very few parents expect their children to return home in adulthood. In fact, a returning adult child can be seen as very problematic.

For caregiving, the preceding contrast would appear to work against older adults in industrialized society. Families have been the traditional safety nets for older people. In industrialized societies, families are smaller. Households are residentially separate and are financially autonomous. Solidarity is based on affect, which is not necessarily the best way to mobilize people because sentiments can change very rapidly. Yet the news is not all bad. Families in North American and Europe go to great lengths to care for

their older members. Also, as states and economies became more complex, a new safety net appears in the market. Virtually everyone in an industrial economy satisfies their basic needs – food, clothing, shelter – by purchasing them in the marketplace. For older adults, the market is basic and continues to complement what family members contribute. Domestic help, lawn services, and even home care can be hired, which help in reducing the caregiving burden for kin. A rather obvious catch-22 is that there must be sufficient financial resources to access the market.

Old Age

Definitions

One of the most striking aspects of age on a worldwide basis is the limited distribution of its explicit use in organizing social life. Aging is a temporal process. Time is culturally configured. With technological sophistication, time can be measured and finely calibrated from milliseconds to millennia. Hours, days, and years are the more meaningful units. For most of human history and the majority of small-scaled cultures, time is not an important dimension of life. Only bureaucratically organized industrialized cultures use time to organize daily schedules and age to regulate their populations. In these cultures, people need to know their ages and thus are issued birth certificates. People of specified ages are expected to be in school, serve in the military, be able to drive, drink, and vote, and be entitled to Social Security. For people living in these contexts, age is very important.

Also on a comparative basis, old age has been difficult to define. Most industrialized societies set their pensionable ages in the early to mid-60s. Thus, old age has a chronological marker. Gerontologists, however, were quick to point out that in spite of its impartiality; chronological age was a poor predictor of ability. Functional age is far more meaningful in terms of what people can do in their daily lives. In cultures in which chronological age is rarely known, functionality is what defines old age. In nations with youthful populations and in which vital statistics are kept, chronological thresholds are lowered to the mid-50s or even the 40s.

Life Course

One of the major theoretical breakthroughs in gerontology has been the emergence of the life span perspective. Initially, gerontology coalesced with a focus on old age. Old age and all its diversity cannot be isolated from the rest of adulthood. Consequently, the life course became a major unit in gerontological research. Cross-cultural research challenges the way we have modeled the life course.

A long-standing problem in social anthropology suggested ways in which age can be formalized into an explicit principle of social organization. A number of small-scale societies make relative age a criterion by which the males are organized into age-stratified groups. Cohorts of boys are initiated into an age class. These classes are sometimes called age sets or generation sets and are bounded groups that are opened for recruitment and then closed once they are complete. A more junior set is then opened. All men are members of a set, and sets are ranked in seniority – boys, warriors, householders, elders, and so forth. The specifics of how the age classes are organized are quite variable, but in the formality of age organization such concepts as age grading, age stratification, and age norms were documented in simpler social contexts and sharply defined.

Life courses are seen as role courses ordered by age norms and expectations. Cohorts enter adulthood upon completing a finely age-graded system of formal education. Jobs and marriage signal full adult status. Within families, generations become more distinctive due to lower fertility and childbearing occurring most commonly in the 20s or very early 30s. Within jobs, we find seniority and for some career ladders based on seniority, experience, and greater responsibility. A new stage is entered with retirement and an exit from the labor force. Although individual role courses are variable, life courses are seen as sequenced and staged. The life course is divisible into intervals distinguished by age-sensitive status transitions.

Age class systems and a staged life course appear to be parallels in differing cultural contexts. Beyond defining graded categories, the similarity vanishes. Age classes are political institutions organizing males in a public arena. For the most part, they are most salient in the junior classes; they see diminishing significance for the more senior males. Age classes do not organize all of life and usually only indirectly affect women. The staged life course is a near-universal expectation from youth to old age. This view of the life course is also restricted to industrialized societies, especially to the middle classes of those societies. People in small-scaled societies do not see life as sequenced through life stages. Age-sensitive roles are not clearly demarcated. Formal education is rare and not universal, thus there are no finely age-graded classes. Wage labor is intermittent, and there is no real job market. No one retires from subsistence activities. Fertility is higher, and families are

much less differentiated by age, with siblings who may be separated by 20 or more years. Under these circumstances, people have life courses that note youth and old age, but they are more functionally and individually defined. Even in industrialized societies, people who are marginalized in poverty aspire to, but find difficult to attain, a sequenced life course.

Needed Research

Gerontology is at a very important juncture as a discipline. In the half century of work thus far, the multidisciplinary effort in gerontology has evolved an ambitious agenda involving research, application, and advocacy. Those who invented gerontology did so working from disciplinary perspectives that set out to define the problem of old age and how to improve quality of life, both physically and socially. From our current perspective, it is not too surprising that we found no modal old person, but incredible diversity in the experience of growing old. We are just now on the threshold of discovering processes that define age and shape how people experience aging. Now more than ever comparative research is needed.

Research

Comparative research reminds us that world populations are remarkably diverse biologically and culturally. With the mapping of the human genome and breakthroughs in molecular biology, we know that populations differ genetically. Biological models of aging are dealing with an intrinsically difficult problem in differentiating genetic from environmental factors. Unfortunately, most of our models are either based on animal data or from people in North America of European descent and who are predominately male. Given the technology available, more progress can be made by examining human variation and diversity over the life span in genetically diverse populations.

Social and cultural research emphasizing diversity is also required. Our understanding of age and life courses is primarily rooted in one type of social context, urbanized industry. To more fully understand the processes that result in age being such an important aspect of these complex nations, we must examine other contexts. Smaller-scaled societies, developing nations, ethnic diversity, minority groups, and local level communities provide a natural laboratory in which to investigate the meaning of age and the role it plays in people's lives. Likewise, we should explore the meanings people who are old find in their lives. Since meaning is cultural, diversity will further add to our understanding of the linkage between cultural context and personhood.

Societal Transformation

Much of our interpretation of global differences in aging has been couched in a theory of modernization. Underlying most of this thought is the optimism of the 1960s, which spawned economic development programs with the intent of hastening the transformation of underdeveloped countries to become industrialized. By the 1990s, we realized that this has not happened and probably will not happen. On the other hand, we recognize that economic change continues, but not as predicted by modernization. Globalization of the world economy is changing life in both the developed and underdeveloped world. Automation has eliminated many jobs in heavy industry and in the service sector. Jobs are being sent overseas to industrial zones in Asia and Latin America. In what is becoming a global assembly line, what happens to age? How are these changes affecting people who are now old in both the developed and underdeveloped world? How are altered life chances shaping the lives of those who are entering adulthood, and what are the implications for their aging? The time to study a phenomenon is as it is happening.

Globalization itself is a force that is altering the use of the comparative method. Very few people live in small-scaled societies and engage in subsistence agriculture or pastoralism or even forage for a living. By the middle of the twentieth century, the young and middle-aged had found wage labor in the cities or in commercial agriculture. Tribal peoples became peasants and peasants became an urban poor. The exoticness of tribal societies is increasingly replaced by the ordinary life of working people. Cross-cultural is more and more cross-ethnic and cross-minority research. Regardless of the global spread of capitalism and the attractiveness of markets, however, cultural diversity will never disappear. As the world changes, cross-cultural research will also change. New questions will be asked to explore the diverse experience of aging in a globalized world.

Glossary

Classical Conditioning – A type of learning in which a neutral stimulus is paired and becomes associated with a stimulus that consistently evokes a reflexive behavior, and becomes sufficient to produce that behavioral reflex.

Conditioned Response (CR) – In classical conditioning, a learned response to a previously neutral stimulus.

Conditioned Stimulus (CS) – In classical conditioning, an originally irrelevant stimulus that after repeated pairings with an unconditioned stimulus comes to elicit a conditioned response.

Delay Conditioning – A classical conditioning procedure in which the conditioned stimulus is presented prior to and remains activated until after the onset of the unconditioned stimulus.

Interstimulus Interval (ISI) – The amount of time that elapses between the onset of the conditioned stimulus and the onset of the unconditioned stimulus in classical conditioning.

Operant Conditioning – A type of learning in which a behavior becomes associated with and influenced by a consequence.

Trace Conditioning – A classical conditioning procedure in which the conditioned stimulus terminates prior to the onset of the unconditioned stimulus.

Unconditioned Response (UR) – In classical conditioning, the unlearned and naturally occurring reflexive response elicited by the unconditioned stimulus.

Unconditioned Stimulus (US) – In classical conditioning, a stimulus that naturally and consistently triggers a reflexive response.

Introduction

Classical and operant conditioning are fundamental forms of associative learning that enable an individual to adapt to a changing environment across the life span. In classical conditioning, a neutral or conditioned stimulus (CS) is paired in time (commonly preceding it by a half second) with an unconditioned stimulus (US) that reliably elicits a reflexive response termed the unconditioned response (UR). Over training, the subject associates the CS and US to eventually produce learned or conditioned responses (CRs) that are behaviorally similar to the UR but that are elicited by the CS. Classical conditioning procedures

were first described by Ivan Pavlov over a century ago and were subsequently demonstrated in a landmark study by Watson and Raynor in which a laboratory animal (CS) that initially evoked no discernable response was paired with a loud, unexpected noise (US) that reliably evoked a fear response (UR). The naive child subject quickly associated the CS and US to exhibit a learned fear (CR) of the previously non-threatening animal. Classical conditioning has been postulated to explain common phenomena such as phobias and avoidance of dental or medical appointments, and it is currently employed in therapeutic procedures such as systematic desensitization (the extinction or loss of an unwanted CR through non-reinforced exposure to the CS). Operant (or instrumental) conditioning occurs when the probability or frequency of a behavioral response is altered by consequences. The likelihood of a behavior to recur will increase when the consequence is either a desirable event (positive reinforcement) or the removal of an undesirable event (negative reinforcement). In contrast, the likelihood decreases when the contingent event is an undesirable event (punishment). Operant conditioning underlies a considerable proportion of behavioral adaptation across the life span and provides the basis for therapeutic interventions involving behavior modification. Age-related changes in classical and operant conditioning have been extensively investigated.

Classical Conditioning

A common laboratory model of classical conditioning involves the pairing of an auditory (tone) CS with an air puff US delivered to the periorbital region to elicit a reflexive eyeblink (UR). In general, subjects quickly associate the CS and US and develop eyeblink responses to the tone CS with relatively brief training. An extensive review of the rabbit nictitating membrane preparation has been provided by Gormezano, and classical conditioning studies have expanded to involve a wide variety of species (including rat, cat, and human) as well as diverse behavioral responses (including leg flexion, jaw movement, and spinal responses). Parametric investigations have clearly demonstrated a strong impact of stimulus sequence and timing on the acquisition of classically conditioned responses. In classical delay conditioning, there is a short delay between the onset of the CS and the onset of the US (typically on the order of 250 to 500 ms). Generally, subjects quickly and effectively learn in a delay procedure. In classical trace conditioning, a brief gap occurs between the offset of the CS and the onset of the US. Conditioning occurs more slowly with this method, and a significant fraction of apparently healthy, young subjects often experience difficulty or fail to learn the association. The interstimulus interval (ISI), or temporal gap between the onset of the CS and onset of the US, has been shown to have significant effects on the rate of learning. Very short or very long ISIs have been shown to be less effective or ineffective in producing learning. Other procedures, backward conditioning (in which the US precedes the CS) and simultaneous conditioning (concurrent presentation of CS and US) fail to induce learning. The effects of aging on the acquisition and retention of classically conditioned responses have been extensively documented in both delay and trace conditioning procedures.

Studies in Aging Animals

Aged rabbits exhibit a modest impairment in the acquisition of classically conditioned responses when a delay paradigm is employed. An enlightening study by Joan Coffin and Diana Woodruff-Pak revealed that older animals required significantly more trials to reach a criterion of eight conditioned responses in a consecutive nine trial training block, but when the number of conditioned responses given during the entire training period was examined, no significant age difference was found. In contrast, the effects of aging appear to be exacerbated when a trace conditioning paradigm is employed. Solomon and associates directly examined the effects of delay and trace conditioning procedures on different age groups. They found an overall effect of age on the acquisition of CRs, but noted greater impairment in the trace procedure that was evident earlier in the life span. Moreover, the age-related deficit in the trace procedure was far more pronounced than that found in a long delay procedure. Consequently, aged animals show impaired learning in classical conditioning that is influenced by the apparent difficulty of the association; deficits in classical trace conditioning are far more severe than in simpler delay conditioning. In both delay and trace conditioning procedures, age-related differences in acquisition emerge early in adulthood. Numerous studies have reported statistically significant differences in rabbits as young as 2 to 3 years old (in a species with a potential life span exceeding 10 years).

Coffin and Woodruff-Pak also examined the long-term retention of classically conditioned eyelid responses in aged rabbits. They found no significant effect of age on overall retention of CRs at 12 or 18 months after training. However, it was noted that younger subjects maintained a relatively consistent performance level across the training periods; older

subjects showed marked improvement in reaching criteria across the phases of testing. Consequently, aged animal subjects display significant delays in the acquisition of classically conditioned responses but demonstrate intact retention once an association has been formed. Their performance in acquisition is differentially affected by the degree of difficulty inherent in the procedure. While both younger and older subjects require more training to reach criteria when a trace procedure is employed, older subjects are more substantially affected. Effects of aging on classical conditioning of human subjects have been extensively described as well.

Studies in Aging Humans

Analyses of age-related effects on eyeblink conditioning in humans began in the 1960s. Early researchers were surprised to find that older adults were significantly impaired in this simple form of associative learning. More recent studies by Woodruff-Pak and others have confirmed significant impairments in the acquisition of classically conditioned responses using a simple delay procedure. Controlling for extraneous factors, including pathology, sensory, and motor functions, researchers consistently note a significant deficit in older groups. Comprehensive analysis of acquisition performance across the life span has revealed that deficits are apparent in relatively young adults. Acquisition rates decline in subjects in their 30s, are marked in subjects in their 40s, and are relatively stable but remain impaired for the rest of the life span (static rates from the 40s through the 80s). Interestingly, deficits emerge at approximately the same relative point in the life span as in the rabbit studies. It should be noted that considerable variability in performance exists within age groups. Determination of the factors involved in the impairment exhibited by a possible subset of aged subjects may reveal the causes of decline. Regression analysis has shown that the age of the subject is the most salient variable in changes across age groups. Reaction time and implicit memory performance did not account for a significant proportion of variability in learning rates. However, cerebellar function, as measured by a timed-interval tapping task, did account for a significant proportion of variability. Given the prominent role of the cerebellum in classical conditioning, this effect is consistent with findings of studies of the anatomical foundations of classical conditioning.

The exacerbation of an age-related acquisition deficit in classical trace conditioning has been reported in human studies as well. A number of studies have shown a robust decline in performance in older subjects, but findings tend to be less consistent than the animal data and the impact of the trace procedure may be somewhat diminished. Further, interpretation is complicated by relatively complex effects of the ISI on learning rates. In contrast to the delay conditioning procedure, extension of the ISI in trace conditioning of human subjects appears to attenuate age-related changes in acquisition rates. Finkbiner and Woodruff-Pak reported that a deficit occurred only in older and not in middle-aged subjects. With the longer ISI conditions, acquisition rates of younger subjects declined, whereas the rates of older subjects were more consistent across ISI conditions. The researchers suggested that both reaction time differences and the engagement of higher cognitive processes may contribute to these findings in humans.

Ultimately, extensive evaluation of classical conditioning in both animal and human subjects has shown a ubiquitous decline in the initial acquisition of CRs that emerges relatively early in the life span. Similar results are noted in discrimination learning studies wherein a non-reinforced CS is employed to evaluate the ability of subjects to differentially develop CRs to the reinforced CS but not to the non-reinforced CS. Results from fear conditioning studies are relatively consistent with findings in human trace conditioning. When higher order cognitive functions such as awareness and general arousability were accounted for, age-related differences were diminished. Retention of learned responses does not appear to be significantly affected by age, and no definitive change in the extinction of CRs has been reported in older subjects.

Studies in Disease States

Classical conditioning performance has been examined in subjects with a wide range of neurological disorders. In Alzheimer's disease (AD), progressive deterioration of the central nervous system produces a concomitant decline in intellectual and cognitive functioning. Woodruff-Pak and associates have extensively examined acquisition of classically conditioned eyeblink responses in patients with AD. They found that AD patients are markedly impaired in acquisition when a delay procedure is employed and somewhat less impaired when a trace procedure is employed, which is consistent with the general effects of aging on acquisition rates. However, in both procedures, AD patients perform more poorly than healthy older controls. Consequently, classical eyeblink conditioning appears to be a sensitive, inexpensive, and non-invasive test for potential AD.

The ability of classical conditioning to differentiate AD-related deficits from other types of dementing

disorders has been evaluated. Significant differences were noted between AD patients and patients diagnosed with cerebrovascular dementia (CVD). AD was found to produce significantly slower acquisition rates in comparison to the performance of patients with CVD. In addition, AD patients displayed less variability in CR onset latency in contrast to CVD patients. Since CR onset typically follows a systematic pattern wherein onset occurs near the onset of the US and progressively decreases in latency as learning develops, it is feasible that the AD patients display both associative learning and response timing deficits during classical conditioning. The effects on timing could reflect a loss or disruption of the typical pattern of hippocampal neuronal activity that correlates with the amplitude and time course of the behavioral CR. The sensitivity of classical conditioning in detection of early presymptomatic AD is evident in several important findings from Woodruff-Pak and her laboratory. In one study, 62.5% of apparently healthy older subjects with impaired acquisition rates were subsequently diagnosed with dementia within three years of the evaluation. Another report described a case in which a significant deficit in classical conditioning preceded detection of dementia by other screening methods by 6 years. Subsequently, it would appear that AD has early, profound effects on acquisition in classical conditioning and that the severity of the deficit may be capable of differentiating among types of dementia. Eyeblink conditioning would provide a non-invasive and relatively non-threatening means to identify early AD cases and could provide a sample of subjects in which to evaluate potential interventional treatments (see **Figure 1** and **Table 1**).

Operant Conditioning

Common examples of laboratory models of operant conditioning include early studies of pigeon key pecks reinforced by grain or rat bar presses reinforced by food pellets. As in classical conditioning, timing of events has a profound effect on performance. Long delays between the target behavior and the consequence undermines the association. In addition, the schedule of reinforcement influences the rate of learning as well. Under continuous reinforcement, in which every response is rewarded or punished, subjects alter the frequency of the behavior quickly. Intermittent reinforcement schedules slow the initial acquisition of learned behaviors

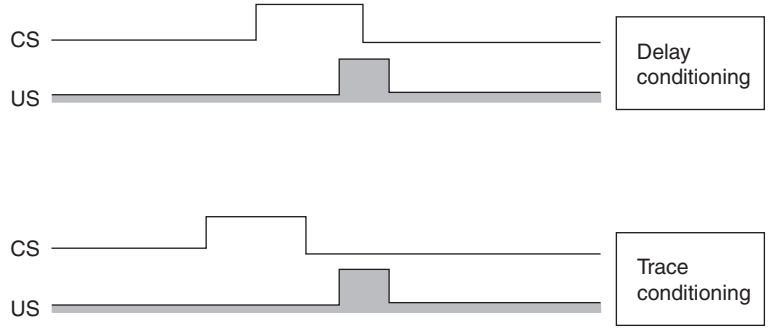

Figure 1 The temporal relationships between conditioned stimulus (CS) and unconditioned stimulus (US) in delay and trace conditioning.

Table 1 Schedules of reinforcement

	Ratio	*Interval*
Fixed	Reinforcement after a fixed number of responses	Reinforcement for first response emitted after a fixed interval of time has elapsed
	Results in a brief pause after reinforcement, followed by a high rate of responding until the next reinforcement delivery	Results in initial slow rate of responding that increases to rapid responding as the time for reinforcement draws near, followed by a pause after reinforcement delivery
	Low resistance to extinction	Low resistance to extinction
Variable	Reinforcement after an unpredictable number of responses	Reinforcement for first response emitted after an unpredictable amount of time has elapsed
	Results in continuous, rapid responding with minimal or no pause after reinforcement delivery	Results in a consistent, slow to moderate rate of responding with minimal or no pause after reinforcement delivery
	Most resistant to extinction	High resistance to extinction

but produce associations that are far more resistant to extinction processes.

In partial or intermittent reinforcement schedules, responding is reinforced only some of the time. In situations that employ ratio schedules, reinforcement depends on the number of responses made by the subject. In contrast, during interval schedules of reinforcement a response is rewarded or reinforced after a specified amount of time has elapsed. A particular schedule of reinforcement determines a subject's pattern of responding. Intermittent reinforcement results in a persistence of responding.

Under a fixed ratio (FR) schedule of reinforcement a reward is delivered after a fixed or predictable number of responses are made. Technically, a continuous reinforcement schedule is a fixed ratio schedule that involves a ratio of one response per reinforcement. Under continuous reinforcement, responding occurs at a steady rate but is interrupted by unpredictable pauses and a drop in the response rate to a moderate level of responding. A different response pattern occurs when a fixed ratio schedule greater than one (i.e., rewarding every second or fifth response) is employed. After each reinforcer is delivered there is a pause in responding, followed by a quick resumption of responding to a constant and rapid rate that is maintained until the next reinforcer is delivered. With a variable ratio (VR) schedule a reinforcer is delivered after an unpredictable number of responses. Reinforcement depends on the number of responses made; however, a variable number of responses is required for the delivery of each reinforcer. A more steady pattern of responding occurs because the response criteria for reinforcement are unpredictable, and pauses in the rate of responding, such as those that occur with FR schedules, therefore are also less likely to occur. Using a fixed interval (FI) schedule the first response after a fixed amount of time has elapsed is reinforced. Reinforcement is available at fixed intervals of time but delivered only if the required instrumental response is performed. Typically the response rate is slow until the end of the time interval. The response rate increases as the time of availability of the next reward draws near. Under a variable interval (VI) schedule reinforcers become available after unpredictable time intervals. The response must be performed after the variable interval in order to gain access to the reward. Variable interval schedules promote steady, stable rates of responding.

Studies in Aging Animals

The effects of age on the acquisition of operant conditioned behavior have been delineated and are strikingly similar to effects seen in classical conditioning studies. Using a continuous reinforcement schedule, we have found that aged rats are markedly impaired in the initial acquisition of appetitively reinforced bar press responses. The magnitude of impairment is similar as well in that aged groups took three or four times as many training days to reach criteria in comparison to the younger group. The impairment appears to reflect an associative learning deficit, in that initial activity levels were equivalent between groups (precluding the potential that younger animals were more active behaviorally and thus produced spontaneous reinforced behaviors earlier in training than the aged subjects). Further, once an association had been formed (meeting a criterion of more than 60 responses in a 20 min training session), response rates were equivalent between groups and precluded the possibility that a lower 'ceiling effect' or maximal response rate in aged subjects had an influence on acquisition performance.

Analysis of the extinction of operant responses in aged rats has revealed no significant difference in comparison to younger subjects. Older subjects were equally resistant to initial extinction via non-reinforced training sessions. Thus, once a behavior was acquired, older animals were unimpaired in maintaining the association. When animals were retrained in the same task, older animals reacquired the response as expediently as the younger animals did. Minimal retraining was required to reintroduce the behavior in both aged and young groups. Cycles of reacquisition and extinction training revealed the expected increased resistance to extinction in both groups as a consequence of prior learning experience. Consequently, the effects of aging on simple appetitive operant conditioning appear to be selectively restricted to the initial learning of the association, and no significant differences are apparent in extinction or relearning of the task.

A differential reinforcement of low rate (DRL) schedule is a more complex appetitive conditioning task wherein subjects must inhibit responding for a period of time to reactivate reinforcement. Commonly, animals are required to inhibit the response for a period of 6 consecutive seconds prior to reinstitution of the reward. Aged animals show a marked impairment in the initial acquisition that is similar to that seen in simple appetitive conditioning. Older subjects experienced significant difficulty in inhibiting responses during the interval. As with many other tasks, once the task was learned, the performance of aged animals was equivalent to younger subjects, and aged subjects were not impaired in the retention of behaviors learned in a DRL schedule.

Aversive conditioning involves the application of punishment to alter the probability of a behavior recurring in the future. In active avoidance conditioning, the subject receives a mild electric shock if they fail to perform the targeted behavior (for example, move to a different location). In passive avoidance, animals are trained to inhibit their natural tendency to explore the environment by punishment for failure to remain at one location in the training chamber. Studies of both active and passive avoidance training revealed a rather marked impairment in aged animals in the initial acquisition phase of training. Once an association is well established, aged animals typically perform as well as younger subjects.

Studies in Aging Humans

Historically, operant conditioning has been used extensively to alter behavior in juvenile and developmentally disabled subjects in the form of behavior modification programs. Early behavioral psychology embraced learning, most often in the form of operant conditioning, as a source of normal and abnormal behaviors and as a method for behavioral change (intervention). However, extensive analysis of performance of adults in operant conditioning has been limited by appropriate control of extraneous variables (motivation, engagement of higher order processes, etc.). Early studies, often using monetary reinforcement, described an apparent deficit in aged subjects that was detected in the initial acquisition phase. Eventually, aged subjects performed as well as younger subjects, and modest to no significant effects were noted in maintenance of conditioned behavior.

More recent analysis of operant conditioning in adult humans has included analysis of patients with traumatic brain injury. Brain-injured adults were found to be somewhat impaired in initial performance, displaying reduced sensitivity to response-reinforcer contingencies. Providing additional 'signal' stimuli enhanced the performance of a subset of the brain-injured subjects, suggesting that some of the deficit may be related to diminished reactivity to the environment in the injured subjects. While data are sparse in comparison to the study of classical conditioning in humans, effects of age on instrumental conditioning appear to be relatively similar. The prominent deficit appears to be restricted to the initial acquisition (association) phase and less prominent to absent thereafter. Considerable effort has been devoted to the elucidation of the neurobiological substrates underlying associative learning. Insight into the fundamental mechanisms mediating classical and operant conditioning may assist in the understanding of and intervening in age-related changes in acquisition (see **Table 2**).

Table 2 A comparison of the effects of aging on the acquisition and retention of classically and instrumentally conditioned responses in both animal and human subjects

		Animal	*Human*
Classical delay conditioning	Acquisition	Aged animals exhibit a modest impairment in acquisition	Older adults exhibit significant impairment in acquisition
		Age-related deficits apparent early in adulthood	Age-related deficits apparent in young adults
	Retention	No significant effect of age on long-term retention	No significant effect of age on long-term retention
		Demonstrate intact retention once an association is formed	Learned responses not significantly affected by age
Classical trace conditioning	Acquisition	Age-related deficits more severe than in delay procedures	Age-related deficits in initial acquisition may be exacerbated in trace procedure
		Impairment apparent earlier in life span; older subjects more profoundly affected	Impairment apparent early in the life span
	Retention	No significant effect of age on long-term retention	No significant effect of age on long-term retention
Operant conditioning	Acquisition	Aged animals impaired in initial acquisition of response under a continuous reinforcement schedule	Aged human subjects exhibit deficits in initial acquisition of conditioned behavior
		Effects of aging restricted to initial learning of the association	Prominent deficit restricted to the initial association phase
	Retention	Once a behavior is acquired and an association established, older animals show no impairment in maintaining the association	Modest to non-significant effects are observed in older subjects in the maintenance of conditioned behavior

Neurobiological Foundations

Considerable basic research has focused on determining the specific neurological networks and changes in brain systems involved in associative plasticity. Pioneering efforts by Karl Lashley, as reported in 1950, were largely unsuccessful in discovering the critical sites in the brain that mediated associative learning. Despite a lengthy, systematic series of studies evaluating the impact of lesioning an array of different brain structures, Lashley was unable to completely prevent the development of learned behaviors in rats. This failure led to his postulate of 'equipotentiality' within the nervous system, which suggested that spared brain tissue adjacent to the damaged region possessed the potential to assume the function previously served by the lesioned area. Subsequently, extensive efforts in describing the fundamental substrates of classical conditioning have led to a relatively impressive understanding of the structural and functional changes in brain systems that appear to form the basis of behavioral changes induced by learning. Studies of operant learning have been markedly less common and fruitful but have revealed some similarity in the processes and brain structures involved in behavioral learning. Examination of these systems and functions in older subjects may help to reveal the sources of the persistent impairment observed during the initial acquisition of learned behaviors.

The Hippocampal Formation

The mammalian hippocampus has long been associated with cognitive processes. Early attempts to control severe seizure disorders in humans by bilateral surgical removal of brain tissue including the hippocampal formation had the unintended result of profound anterograde amnesia. Extensive examination of neurological activity during classical conditioning of the rabbit eyeblink response has led to a comprehensive understanding of the cellular basis of the learned behavior. Early studies revealed a learning-dependent increase in the activity of neurons within the hippocampal formation. Elevated excitability occurred early in training and produced a temporal pattern of activity that was nearly perfectly correlated with the emergence and amplitude of the behavioral conditioned response. However, since classical delay and operant conditioning are unimpeded in animals with bilateral lesions of the hippocampal formation, the relevance of this activity was not clear. Subsequent studies have indicated that the hippocampus (and related neuronal activity) appears to be critically involved in associations in the classical trace procedure. At a cellular level, this learning-related change in activity within the hippocampus is known to be mediated by a subset of glutamate receptors identified as N-methyl-D-aspartate (NMDA) receptors. This associative cellular process, long-term potentiation (LTP) of synaptic efficacy, appears to make a significant contribution to classical conditioning. Experimental induction of LTP has been shown to facilitate, and pharmacological blockade of the receptor sites appears to disrupt, simple classical conditioning.

A number of studies have observed an increased level of hippocampal neuronal activity during operant conditioning. As in classical conditioning, the increase is learning dependent and the pattern correlates with the behavioral response. In appetitive operant conditioning in rats, we have found that initial acquisition by adult subjects is unaffected by pharmacological manipulation of NMDA receptors (agonism and antagonism). Electrically induced LTP also failed to influence the rate of acquisition. However, during extinction of the operant response, an NMDA agonist increased, and an antagonist decreased, the level of responding. Thus, NMDA-dependent hippocampal LTP appears to play a prominent role in the initial acquisition of classically conditioned responses (which is slower in older subjects) but does not appear to have an impact on the initial acquisition of operant behavior (which is also impaired in older subjects).

Examination of hippocampal neuronal activity during classical trace conditioning of aged rabbits was conducted by Woodruff-Pak and associates. Consistent with the previous behavioral studies, aging subjects were significantly impaired in the acquisition of conditioned responses. Thirty-month-old subjects took roughly three times as long as 3-month-old subjects to reach criteria, and 45-month-old subjects took approximately four times as long. In older subjects, hippocampal neuronal activity developed much more slowly but eventually produced the correlated pattern of activity that was observed in younger subjects as a consequence of learning. Consequently, both behavioral and neuronal components of successful classical conditioning are delayed in older subjects, but with adequate training, they develop to the same levels seen in younger subjects. Consistent with a vital role in spatial and higher order cognition, the hippocampal formation appears to play a prominent role in some forms of basic associative learning processes as well. A prominent role in age-related changes in learning is supported by the sensitivity of the hippocampus to stress-related hormonal insult. Indeed, Sapolsky suggested that age-related changes in cognition may be related to an accrual of damage to the hippocampus. The structure

is highly sensitive and reactive to stress hormones, is involved in feedback regulation of stress hormone levels, and shows significant neuronal loss as a consequence of prolonged elevated levels of stress hormones. Anatomical and functional changes within the hippocampus across the life span, along with a prominent role in associative learning, make the structure a prominent candidate for at least some of the age-related differences in learning performance.

The Cerebellum

Historically, the cerebellum has been associated with motor functions, the production of motor programs (coordinated movements) and fine motor control in particular. Richard F. Thompson and associates confirmed an essential, fundamental role of the cerebellum in the acquisition and maintenance of classically conditioned responses in rabbits. Similar to the findings in the hippocampal studies, neuronal activity within the cerebellum produces a learning-dependent pattern of activity that is highly correlated with the amplitude topography of the learned response. Damage to the cerebellar region prior to training blocks the acquisition of CRs, and damage after training produces a loss of conditioned responding that is highly similar to the gradual decline in responding seen in extinction procedures. Intracranial cerebellar stimulation has proven to be an effective CS and US, and is fully capable of producing classically conditioned eyeblink responses. Anatomical data from rats indicate a 15% decrease in the number of Purkinje cells at 2 years of age and a 20% decline by age 3. Thus, similar to the hippocampus, the cerebellum is vitally involved in simple learning and is at significant risk of progressive anatomical decline across the life span.

Analysis of cerebellum volume using MRI was conducted by Woodruff-Pak and associates. It was discovered that cerebellum volume measures in both young and aging subjects were highly positively correlated with behavioral performance in eyeblink conditioning. Specific atrophy within the cerebellum was strongly associated with declining learning performance. The apparently critical requirement of an intact cerebellum for classical conditioning and the well-documented decline in cerebellar structure and function across the life span make the cerebellum of primary interest in age-related deficits in classical and perhaps some aspects of operant conditioning.

Interventional Strategies

Two diverse means of influencing both cognitive processes and related brain functions involve experiential and environmental factors and direct pharmacological manipulation of neuronal transmission. First, profound effects of early environmental deprivation and enrichment on neurological and cognitive processes are extensively defined in developing and younger subjects. In addition, recent cognitive activity may have beneficial effects on subsequent learning performance; this is not entirely unexpected, since learning experience is known to alter functional properties of brain systems subserving cognitive processes. Experientially induced LTP may have effects similar to the facilitatory effects of experimentally (electrically) induced LTP. Second, direct pharmacological manipulation of the neuronal systems affected by aging and contributing to learning processes represents a potential means of attenuating age-related decline in learning performance. Experiential and environmental impact may reflect a naturally occurring facilitation of the same synaptic processes within the brain systems that ultimately mediate learning and memory.

Environmental and Experiential Effects

Animal and human studies have confirmed a lasting and substantial effect of experience and environmental conditions on a wide variety of learning tasks. For example, early handling of rodents appears to have a lasting, positive effect on cognitive performance. It has been suggested that the early experience enhances internal regulation of stress hormones and prevents at least some of the insult to the hippocampus and other structures that may occur across the life span. Other common manipulations used in environmental enrichment studies involve the provision of a changing array of objects to manipulate and explore within the home cage to stimulate cognitive and neurological activity. Positive effects of early exposure to an enriched environment are well documented in a variety of learning tasks; this results in significant changes within the brain structures implicated in cognition. Effects of environmental enrichment on mature animals are somewhat less well defined but are predominantly encouraging.

Long-term exposure to an enriched environment has been found to have substantial positive effects on a variety of learning tasks. Concurrent preservation of neuronal structure and function has been observed within the hippocampus and cortical areas as well. Greenough and associates described attenuating effects of a complex environment on cerebellar neuronal morphology in aged rats. Thus, primary structures involved in cognitive processes appear to be significantly altered by environmental conditions in both younger and older subjects. We have examined the

effects of modest, short-term environmental enrichment on acquisition of operant behavior in an appetitive task in aged rats. Access to a rotating series of simple cage toys for a relatively brief period of several weeks was sufficient to significantly diminish the delay in initial acquisition of operant responses by aging subjects.

While the data from both young and aging animals suggest a powerful effect of environmental condition on learning, the impact as noted in a relatively few studies involving humans has been less promising. Early enrichment has been found to have substantial positive effects, but the results of attempts to improve learning performance in aging humans by environmental conditions has been somewhat disappointing. Differences in the vast ability of the researcher to control the environment in animal studies, and considerably less ability to control the human environment, along with volition issues in human subjects may contribute to the apparent differences.

Prior recent learning experience may influence performance in classical and operant conditioning via the natural induction of learning-related LTP. Potentiation of hippocampal synaptic transmission occurs in most learning situations and has been shown to last for periods of weeks to months after training. Numerous studies have demonstrated the development of LTP during classical conditioning of the rabbit eyeblink. Similarly, we have noted that after aged (and younger) animals are operantly conditioned, synaptic function within the hippocampus is markedly enhanced; no differences in excitability were noted between age groups after training. Control data from untrained subjects indicated a significant reduction in excitability in the naive aging subjects. A subsequent evaluation of trained animals in spatial learning performance, which is normally affected by age, revealed no significant difference between age groups. Evaluation of synaptic function in untrained younger and aging subjects revealed age-related differences in the form of diminished reactivity within the aging subjects. Additional studies have observed that improved learning may occur as a consequence of prior training experience as well. This experiential effect is consistent with the 'use it or lose it' perspective of cognitive and neurological function, and provides an additional potential means of addressing age-related changes in cognition.

Pharmacological Effects

The elucidation of brain structures that mediate associative learning processes and that are significantly affected by aging allows researchers to attempt to ameliorate age-related deficits by pharmacological manipulation of targeted brain regions. In addition to providing a potential therapeutic tool, successful neurochemical intervention further delineates the probable elements underlying age-related decline in performance. NMDA receptors mediate the LTP seen in associative learning, are heavily distributed within the hippocampal region, and are substantially reduced as a consequence of normal aging. Since electrical induction of LTP facilitates simple learning, pharmacological enhancement of NMDA activity should improve learning performance in all age groups.

In classical conditioning, NMDA agonists appear to have a general enhancing effect (while antagonists have a deleterious effect) on acquisition. D-cycloserine (DCS), a potent NMDA agonist, has been shown to markedly improve acquisition in both younger and aging rabbits in a dose-dependent fashion, whereas dizocilpine maleate (MK801), an antagonist, has been shown to impair acquisition. In operant appetitive conditioning, we found that neither DCS nor MK801 had a significant effect on the number of days required by young adult rats to reach a training criterion. However, DCS delayed the extinction process and MK801 accelerated the extinction process in young adult rats. In more complex schedules of reinforcement, such as DRL and fixed interval schedules, NMDA antagonism has a disruptive effect on the performance of young adult rats. It is yet to be determined whether DCS would alleviate the delay in simple acquisition noted in aging rats.

Conclusion

The effects of aging on classical and operant conditioning in both animals and humans have been widely investigated. A pervasive deficit in the initial acquisition of learned behaviors has been noted to occur early in the life span of the subject and persists thereafter. Once this initial impairment is overcome, aged subjects tend to be as competent in the performance level achieved, maintenance, and resistance to extinction as their younger counterparts. The hippocampal formation and cerebellum appear to play prominent roles in both learning processes in general and the age-related decline in acquisition performance. Both structures show marked anatomical and functional changes as a consequence of age. Pharmacological enhancement of hippocampal and cerebellar functions, such as through the use of NMDA receptor agonists, can have a beneficial impact on learning performance. However, both structures also appear to be highly capable of reactive plasticity in response to environmental and experiential factors.

Consequently, in healthy aging subjects, a stimulating environment and persistent history of active learning experience may be the most effective and appropriate interventional strategy. However, the effects of environmental intervention appear to be limited by general health problems (i.e., metabolic or circulatory defects). A continuously active lifestyle (including both cognitive and physical aspects) may be an effective preventative and interventional mechanism. In disease conditions, such as Alzheimer's, classical conditioning appears to be a valuable tool to selectively detect early stage cases. In pathological states, pharmacological supplementation of neuronal function may be of significant benefit and could occur in conjunction with cognitive rehabilitation.

Consumer Behavior

C A Cole, University of Iowa, Iowa City, IA, USA

Glossary

Baby Boom Generation – The approximately 76 million people who were born between 1946 and 1964.

Decision Heuristics – Shortcuts or simplifying strategies for making decisions.

Gerontographic Segmentation – Segmentation of older consumers based on psychological, social, physiological, and lifestyle characteristics.

Marketing Mix – Usually product, price, promotion, and distribution.

Market Segment – Group of consumers with similar needs and wants.

Target Market – A specific market segment or segments that an organization attempts to reach with a marketing mix designed for the needs and wants of the segment(s).

Working Memory – The location where information is stored temporarily and is encoded for transmission into long-term storage.

Introduction

Consumer behavior encompasses mental and physical activities that consumers engage in when searching for, evaluating, purchasing, and using products and services. In the marketplace, consumers exchange their scarce resources (including money, time, and effort) for items of value. A consumer researcher studying how consumers buy long-term care insurance might investigate (1) the characteristics of consumers who buy this type of insurance (e.g., income, age, lifestyle), (2) where they buy it (e.g., from an agent vs. from an 800 number listed in an advertisement), (3) when they buy it (e.g., after a critical event such as a parent's illness or after seeing an ad), (4) how they buy it (e.g., comparing many policies vs. selecting the same one that a friend has), (5) why they buy it (e.g., fear of depleting life savings vs. desire for excellent care in old age), and (6) what happens after they buy it (e.g., satisfaction with the decision and the company).

Motivation for Studying Older Adults' Consumer Behavior

Until recently, business and marketing researchers virtually ignored the older market. Perhaps this neglect arose from inaccurate stereotypes about elderly consumers. However, more and more businesses, governmental agencies, and researchers recognize the importance of the rapidly growing older market. In 2005, there were about 35 million people over the age of 65; by 2010, this number is expected to reach 50 million. By the year 2020, one out of every six Americans will be 65 or older. In this article, we first discuss why businesses, policy makers, and researchers are interested in the growing older market, then we discuss consumer decision making, and finally we discuss how the aging process affects the consumer decision-making process.

Business

Not only is the size of the elderly population increasing, but the financial and health characteristics are also improving. For example, the AARP reported that from 1995 to 2005, Americans aged 50 and over have seen their economic status improve, when status is measured in terms of median inflation-adjusted income and household financial assets. Additionally, in the same time period, the proportion of family budgets available for discretionary items has increased for the 50 + population overall. Census data also suggest that over half the people 65 and over report no activity limitation.

The travel industry illustrates how businesses have started targeting older consumers. Many older travelers are attractive to the travel industry because they are wealthy, with high discretionary income, relatively low consumer debt, and abundant free time. Additionally, they tend to travel greater distances and for longer periods of time than their younger counterparts. Like the younger market, the older market is heterogeneous enough to warrant breaking into subsegments using gerontographic segmentation schemes. For example, the travel industry segments the over 55 market by motivations such as spending time with family, seeking intellectual and spiritual enrichment, meeting other people, and learning new things. Once the market is broken down into subsegments, travel agents, like other business decision makers, select target markets and then tailor the marketing mix to the needs and interests of each market segment.

Public Policy

As the size of the older market increases, increasing numbers of older adults are the targets of unscrupulous business activities. For example, current data suggest that about 34% of the victims of telemarketing fraud are elderly. White House Conferences on Aging and the Senate Special Aging Committee have also identified difficulties elderly people encounter when applying for credit, purchasing food, buying insurance or investments, using prescription drugs, selecting medical services, and using the Internet safely. Statistics cited at the March 2004 Senate Special Aging Committee hearing indicated that 59% of people aged 50 to 64 and 22% of those over 65 have become Internet users. Law enforcement has witnessed a corresponding growth in online fraud targeted toward older users. This fraud includes identify theft, 'phishing' schemes, in which criminals set up emails and websites designed to look like those of legitimate companies and financial institutions, non-delivery of merchandise, and investment fraud.

One possible remedy entails passing legislation to restrict the more unscrupulous business practices. For example, current legislation is being considered to better regulate Internet business practices. Another possible remedy includes increased consumer education efforts, which can not only increase knowledge about consumer rights, but also can prevent inadvertent participation in fraud. An AARP survey suggested that the problems older Americans face

from dishonest businesses are compounded by older adults' lack of knowledge about their rights as consumers. For example, older consumers (those over the age of 65) are much less likely than consumers under the age of 65 to know that you have several days to cancel purchases made from door-to-door salespeople (36% vs. 53%) and that consumers are not able to cancel purchases made by credit card over the telephone (19% vs. 28%).

Both business practitioners and public policy makers, then, are vitally interested in reaching older consumers. Consumer behavior researchers offer insight into how to achieve this through two main avenues: adapting theories of aging from other fields to the marketplace and adapting marketing theories and models (such as consumer decision making) to the elderly. These goals encompass a wide variety of research areas that we have only begun to study.

Theoretical

Theories and models which offer explanations for age differences in consumer behavior are useful to practitioners who would like to predict the behavior of future cohorts of elderly consumers. For example, a practitioner might ask the following question: "As the baby boom generation reaches retirement age, will their general consumption patterns change to be similar to those in the current over 65 market, or will their general consumption patterns remain unique to their cohort?" Answering this question is difficult, but developing theories about how aging affects consumers makes finding the answer easier.

Social aging theories, as applied in marketing, involve understanding how society assigns people to consumer roles across the life span. Consumer roles change as a person passes through different life stages. For example, entering retirement represents a major transition point when people move from one set of activities and social relationships to a new set of activities and social relationships. Businesses can respond to these changing needs. A travel agency might design group trips for older adults that present opportunities to meet new people with shared interests. Similarly, employment agencies might develop services for those one in three baby boomers who are thinking about starting a second career as they rapidly approach retirement. Additionally, one possible effect of retirement might be greater use of the mass media and the Internet during daytime hours to help counteract social isolation. Radio and television networks might develop programming to service this market segment. Social aging theories are useful because they highlight how consumer needs change as people move through different stages in the life course.

Cognitive theories of aging have contributed insights into all aspects of decision making. Cognition entails the mental processes that transform, reduce, elaborate, sort, and retrieve sensory input. One mechanism affecting cognition is working memory capacity. The capacity of working memory is limited in all adults, but the elderly may experience either a decline in the capacity or a slowing down of processing speed. Thus, older adults are not able to store as much information or process as much information as younger adults. Specifically, strategies for encoding information from sources such as advertisements and product labels may take much longer for the elderly to execute than younger adults. As they age, people may experience a decline in their explicit memory, a form of memory that allows us to retrieve pieces of information and their sources consciously (e.g., remembering an advertisement for a car manufacturer, when it was seen, and where it appeared). By understanding age-associated cognitive changes, businesses and public officials can design communication strategies.

Socioemotional selectivity theory hypothesizes that older adults, who perceive their time horizon as limited, place greater emphasis on emotionally meaningful goals (goals related to feelings, such as balancing emotional states) than on knowledge-related goals (goals related to new information acquisitions). This age-related shift in goals could influence the type of information people use to make decisions (affective knowledge versus other types of information), the type of information people recall, and their preference for dealing with familiar suppliers (e.g., a familiar car dealer).

Theories developed to understand aging processes help us understand consumer behavior of all age groups. For example, working memory limitations may affect younger consumers when they face tasks involving very demanding memory loads and fast rates of presentation – as is the case with telephone sales presentations. Although young adults use processing strategies efficiently, at some point, memory loads and time pressure may combine to interrupt the routines that adults typically use.

Dual Process Models of Consumer Decision Making

Generally, there are two routes consumers making decisions follow. In deliberative systematic decision making, consumers make slow, careful decisions. Consumers making such decisions generally pass through five stages: problem recognition, information search, alternative evaluation, purchase decision, and

postpurchase behavior. For example, a consumer buying a new home would generally use systematic decision making. However, in affective/experiential decision making, consumers make intuitive, automatic, and fast decisions. They may pass directly from problem recognition to purchase decision to the postpurchase phase. For example, a consumer deciding which movie to see might employ affective decision making. Individual characteristics, such as personality and information-processing ability, and external events, such as cultural values and exposure to advertising, influence which process consumers use.

Problem Recognition

Problem recognition is the first step toward making an actual purchase. Consumers recognize that their ideal situations differ from their actual situations. It can be as simple as noticing that the coffee is running low, or as complicated as realizing that life insurance is needed. Occasionally marketing itself can trigger problem recognition, such as when a salesperson points out the inferiority of a car without anti-lock brakes.

Information Search and Alternative Evaluation

After recognizing that problems exist, consumers begin to search for information about solutions to their problems. Search can be either internal, in which consumers scan their memory for previous experiences, or external, in which consumers consult a wide variety of informational sources, including advertising. Some would argue that marketing has the greatest capacity to affect consumer behavior during the information search stage.

A great number of factors affect how consumers search. For example, as perceived time pressure increases, search decreases. As knowledge increases, search may decrease. For example, a consumer may quickly search for the usual cereal brand, because she knows it meets her nutrition requirements. However, knowledge may lead to an increased amount of search, especially for non-routine decisions. For example, computer experts who are buying new computers will read more and speak longer with salespeople because they understand bytes, RAM, and processors. By searching, consumers learn about decision criteria and available alternatives. Generally a consumer weighs the perceived payoff from searching against the effort needed to search.

To evaluate alternatives, consumers may systematically combine information about each alternative on the important criteria. Alternatively, consumers may use heuristics to solve their purchase problems. One heuristic might be 'Select the first cereal that is low in sugar and high in fiber.' Such a simplifying rule makes the grocery shopping task easier, but means that the consumer does not consider all the available alternatives or all the available attributes.

When consumers have limited processing resources, they may rely on affective feelings to direct their choice process, rather than cognitions. For example, in one experiment, consumers with limited processing resources were more likely to choose a chocolate cake snack, an option that generates positive affect and negative cognitions about health, than to choose fruit salad, an option that generates negative affect and positive cognitions about health. In a different experiment, consumers who were in a good mood rated a new cookie as better than consumers who were in a bad mood, even though the mood was caused by an unrelated event. In both studies, consumers are quickly relying on affect, instead of cognition, to make choices and form judgments.

Purchase Decision

Consumers might make a brand decision before actually visiting the retail outlet. For example, before grocery shopping, the consumer might draw up a grocery list. Alternatively, the consumer might decide on a destination, such as a mall, and then once at the mall select a branded item such as a dress.

Postpurchase Behavior

Once consumers purchase products, they must decide how satisfied they are with their purchases. Often this involves anxiety or stress about the decision, called cognitive dissonance. Because this stress feels uncomfortable, consumers will often take steps to alleviate their dissonance. At this point, consumers may enter the search stage again, looking for information that confirms that they made the right decision. Many advertisers utilize advertising to help alleviate this cognitive dissonance. Additionally, some research considers how consumers dispose of products that they no longer need.

Age Differences in Consumer Decision Making: Empirical Evidence and Explanations

Although consumer decision-making research spans a broad range of topics, researchers studying age differences in consumer decision making have tended to focus on just a few topic areas. In this section and in **Table 1**, we review the empirical evidence for age differences in search for information, use of advertising information, alternative evaluation, and purchase decisions.

Table 1 Research on age differences in consumer decision making

Topic	*Reference*	*Method*	*Major findings*
Search for information	Lin and Lee (2004) *Financial Services Review* 13: 319–332	Survey	Older adults (OAs) consider fewer sources of information about investment decisions than younger adults (YAs)
	Lambert-Pandraud, Laurent, and Lapersonne (2005) *Journal of Marketing* 69: 97–113	Survey	OAs consider fewer brands, fewer dealers, and fewer models than YAs
	Cole and Balasubramanian (1993) *Journal of Consumer Research* 10: 417–431	Experiment field study	OAs search as much as YAs when the task is familiar; OAs search less when the task is unfamiliar
Advertising	Phillips and Stanton (2004) *Journal of Targeting Measurement and Analysis for Marketing* 13: 7–21	Commercial database with results of 5000 plus copy tests	YAs recall executional elements better than OAs, but OAs are more likely to be persuaded than YAs
	Fung and Carstensen (2003) *Journal of Personality and Social Psychology* 85: 163–178	Experiments	OAs learn more from ads that emphasize emotionally meaningful goals than from other types of ads, while YAs learn the same from all types of ads
	Cole and Houston (1987) *Journal of Marketing Research* 24: 55–63	Experiment	OAs learn less than YAs from TV and print advertising
	Gaeth and Heath (1987) *Journal of Consumer Research* 14: 43–54	Experiment	OAs are less able than YAs to process advertising claims
Alternative evaluation	Kolodinsky, Hogarth, and Hilgert (2004) *The International Journal of Bank Marketing* 22: 238–259	Survey of consumers by Federal Reserve Board	OAs are less likely to adopt phone banking and electronic banking than YAs
	Gilly and Zeithaml (1985) *Journal of Consumer Research* 12: 353–357	Survey	OAs are as likely as YAs to adopt a new technology when the relative advantage is clear
	Gwinner and Stephen (2001) *Psychology and Marketing* 10: 1031–1048	Survey	Cognitive age influences information-seeking behavior and new brand trial
	Reese and LaForge (1995) *Journal of Marketing Theory and Practice* 3: 37–49	Commercial database	Compared to other life cycle stages, older singles are more likely to report using disjunctive rules, and retired older couples are more likely to use conjunctive decision rules
Purchase and postpurchase decisions	Moschis, Curasi, and Bellinger (2004) *Journal of Consumer Marketing* 21: 123–133	Survey	Patronage motives of OAs are different from those of YAs
	Tepper (1994) *Journal of Consumer Research* 20: 503–519	Experiment	Consumers 50–54 are least likely to use senior discounts; consumers 65+ are most likely
	Price, Arnould, and Carsi (2000) *Journal of Consumer Research* 27(September): 179–200	Depth interviews	When discussing cherished possessions and their disposition, OAs express concerns about avoiding intrafamilial conflict, reducing uncertainty, and exercising control over the possessions

Search for Information

Older consumers search for different and often less information than younger consumers. For example, when making investment decisions, older consumers, compared to younger consumers, are more likely to use television media and are less likely to use the Internet for information about investments. In addition, older consumers spent less time searching for investment information than younger consumers. One survey of automobile buyers found that older consumers searched for fewer brands, dealers, and models than younger consumers.

Another study investigated age differences in search behavior in a supermarket setting and in a computer laboratory. Two observers watched consumers buying

cereal in a supermarket. Shoppers inspected very few packages before making a choice, so no age differences emerged in how much people searched. However, when an observer intercepted shoppers and asked them to purchase a cereal that met certain nutritional criteria, younger adults engaged in more search than older adults, who did not change how much they searched. In the laboratory, using a computer search program, older adults searched for less information about unfamiliar cereals than younger adults.

Whether or not age differences in search emerge may depend on task characteristics. Age differences in search may not emerge when consumers perform simple, routine tasks such as grocery shopping because not many people search very much in such situations. When engaging in familiar but complex tasks such as buying a new car, older adults may search less than younger adults because they use their years of shopping experience to design efficient search strategies. However, elderly consumers may restrict search when given a new search problem because of scarce information-processing resources. For example, older consumers with diminished working memory capacity may not easily store information about alternatives in memory. As a result, they may not search for as much information as younger consumers.

Use of Advertising Information

Although older consumers generally recall less information from advertisements than younger consumers, the size of these age differences often depends on the characteristics of the advertisements. For example, one analysis of a large commercial advertising research database found that age differences in recall varied across executional elements of print advertisements. In another study, older adults' recognition of information from advertisements with slogans that promote emotionally meaningful goals was significantly higher than their recognition of information from advertisements with different slogans (either none or those that promoted knowledge-related goals).

Another study found that age differences in recall and recognition varied across media. Younger adults recalled more from the television medium than they recalled from the print medium, but older adults did not realize the learning benefits of television; as a result, age differences were larger in the television medium.

Another studied advertising issue is whether or not there are age differences in the ability to judge truthfulness of claims in print advertising. Suppose an ad says "Brimstone tires will increase the safety of your winter driving." Then viewers are asked whether the statement 'Brimstone tires will increase the safety of your winter driving' has to be true. This procedure represents a test of a direct assertion. However, suppose the ad says "Have a safe winter. Drive on Brimstone tires." Then viewers are asked whether the statement 'Brimstone tires will increase the safety of your winter driving' has to be true. This procedure represents a test of a pragmatic implication. Apparently, there are no age differences when consumers judge statement truthfulness from memory. However, young adults are more likely to correctly judge the truthfulness of implied claims when the advertisements are available during assessment.

Alternative Evaluation

Consumer researchers have studied age differences in how consumers evaluate new products. For many years, marketing practitioners thought that older adults lagged behind younger adults in adopting new products and services. However, survey data suggest that this belief may be a negative stereotype, rather than reality. A 2004 study, which investigated how age and attitudinal characteristics affect consumers' willingness to adopt three types of new electronic banking products, reported that older consumers (over 65) were less likely than other age groups to adopt two of these. In another 1985 survey, younger and older consumers had different adoption rates for three of four new technologies.

What is interesting about both studies is that older consumers were as likely or more likely to have adopted some new technological products, including automatic bill payment and electronic funds transfer. Both sets of authors concluded that like other consumers, elderly consumers will purchase product innovations when the product possesses a clear benefit and meets a specific need.

How consumers choose different brands is another subtopic under alternative evaluation. Research supporting the idea that the older market is composed of subsegments finds that cognitive age, which is based on how old a person perceives him- or herself to be, affects brand choice more than chronological age. A different study found that how people select a brand of financial services depended on life stage, which is based on both age and lifestyle variables. When selecting financial services, older singles were more likely to report using a disjunctive decision strategy ('I chose the financial institution that I rated very good in at least one category') than other life stage groups, whereas retired older couples were most likely to report using conjunctive decision strategies ('I chose the financial institution that I did not rate poorly in any category').

Purchase Decisions

A study of patronage motives for consumers in the selection of food and grocery stores found that those 55 and over differed from those under 55 on the importance they attached to variables such as store location, availability of age-related discounts, availability of personnel to assist consumers, availability of special services, and recommendations by other people their age. These authors concluded that both membership in the identified four gerontographic segments and age were important in understanding patronage motives for grocery store selection.

Some self-report studies indicate that elderly adults say they favor retailers that offer senior citizen discounts, but other surveys show that older adults are reluctant to participate in such programs. A consumer behavior researcher conducted an experiment in order to determine whether or not older adults respond favorably to age-related discounts. In the experiment, consumers learned that a 10% discount was either a senior citizen discount offered to customers over a certain age or a privileged customer discount offered to special customers. Consumers' reactions to the discount varied by age. Respondents in the youngest age group (50–54) were the least likely to use a discount promoted with an age segmentation cue, and adults over the age of 65 were willing to use either of the 10% discounts. The middle age group (55–64) was willing to use the senior discount even though they believed that others would not give senior citizen discount users much respect.

This research resolves prior inconsistencies about consumers' reactions to senior citizens' discounts. Apparently, mature consumers (those in their 50s) are reluctant to accept the label of 'senior citizen,' but by the time consumers reach retirement age, they are willing to accept the label.

Postpurchase Decision Making

One study examined how older adults dispose of favorite possessions. Through depth interviews the researchers studied various aspects of disposition decisions, including precipitating events, emotions associated with decision, meaning of possessions, and tactics for disposing of possessions. Of these, precipitating events seemed most sensitive to age differences, but future research might make additional comparisons.

Summary

Generally, the existing decision-making literature suggests that elderly consumers differ from younger consumers in important ways at each stage of the decision-making process. At the information search stage, the presence of age differences in amount of search and in learning from advertising is not surprising because most of the consumer behavior research is based on extensive prior work in gerontology. At the alternative evaluation stage, a host of unresolved questions center on the decision rules and heuristics that consumers of different ages use when evaluating alternatives. Some processes may differ across age groups because older consumers, with fewer cognitive resources than younger consumers, may perceive higher cognitive costs for certain strategies than younger consumers. Other processes may not differ, when consumers can use familiar, well-practiced heuristics.

The marketing literature has contributed to knowledge by showing that differences found in laboratory research emerge in 'real world' settings. Future research might examine how the older consumer's considerable knowledge and experience moderates any age differences that emerge at each stage of the decision process. In addition, it is important to keep in mind that the older market is diverse and that different segments show these characteristics in differing amounts. Furthermore, even within a segment some consumer tasks may exacerbate or minimize these differences.

Improving Consumer Decision Making

We have described the decision-making process and how elderly adults differ from younger adults with respect to this process. Now we look at intervention programs designed to improve consumer decision making. Specifically, we consider decision aids, training programs, and education.

Improving Use of Information through Decision Aids

A series of studies investigated how age differences in selective attention might affect older adults' ability to use nutritional information contained on product labels. Literature from gerontology and psychology suggests that older adults are more susceptible to interference from the irrelevant components of a stimulus (or other environmental noise) than younger adults. In the experiments, subjects had to select a cereal that met certain criteria. Some subjects learned to circle the relevant information on the nutritional label with a red pen before they made a decision. The decision aid, then, was to highlight the relevant information. Both older and younger adults benefited from the perception aid. However, older consumers remained less able to make good nutritional choices than younger consumers even after being encouraged to focus on the relevant information. In another

experiment, the investigators boxed the relevant information and placed it in a separate location on the label. This time, subjects with moderate, but not severe, disembedding deficiencies were helped, but the field-independent subjects gained little from the aid. Given that the stated aim of nutritional labeling laws is to make nutritional information easy for all consumers to use, this study suggests that such information should be placed in the same spot on all labels.

A different group of investigators tried to aid use of nutritional information by encouraging older and younger adults to write information down as they acquired it from the computer. Using this decision aid, age differences in search intensity were greatly diminished.

Taken together, these two studies suggest that decision aids may successfully improve consumer decision making. Circling or writing down important information may especially help the elderly consumer focus on relevant information. Thus, in an environment where there is information overload, simple decision aids may help.

Improving Decision Making through Training and Education

Through experience, older consumers develop persuasion knowledge, or knowledge about persuasion tactics and methods of resisting persuasion attempts. As such, given their well-developed knowledge structures, older consumers should be able to resist persuasive efforts better than younger consumers. Training programs might increase older adults' ability to recruit persuasion knowledge to resist deceptive marketing practices. However, empirical work indicates that when cognitive capacity is constrained, younger consumers are less likely to recruit persuasion knowledge to resist a sales pitch. This finding raises several interesting questions: Do older adults possess well-developed knowledge structures about persuasion tactics? If not, education programs may enrich their knowledge structures. If so, under what circumstances do they utilize this knowledge structure to resist persuasion efforts? Can training programs improve the accessibility of this knowledge structure?

Regarding training programs, two investigators developed an interactive training program to reduce susceptibility to misleading advertising without increasing consumer suspicion of advertising claims. They found that although training reduced susceptibility to misleading statements in both older and younger consumer groups, it also reduced the younger adults' ability to discriminate between nonmisleading and misleading claims.

The track record for consumer education programs is mixed. Consider, as an example, the private, federal, and state agencies attempting to educate Americans regarding good health practices. These agencies use the mass media as an integral part of most health promotion campaigns. Survey research shows that older adults are interested in maintaining or improving their health. However, many older adults have limited knowledge regarding the relationship between certain lifestyle behaviors and disease incidence. For example, government-sponsored surveys suggest that consumers do not understand why or how controllable risks such as diet, exercise, and weight control are important factors in disease prevention. Thus, there is a need for additional research identifying how to more effectively educate older consumers about health and other topics.

Summary

In summary, efforts to eliminate age differences in decision making have not been entirely successful in equating older adults' performance with that of younger adults. Instead, decision aids, training, and education often help all age groups equally.

To develop a decision aid that differentially benefits the older consumer, consumer researchers must first closely analyze the consumer's task. They then need to identify exactly where in task performance age differences arise. For example, do age differences emerge at the information acquisition stage or at the alternative evaluation stage? Furthermore, the consumer behavior researcher needs a model about why these age differences emerge. Perhaps age differences at the information acquisition stage arise because of working memory differences. Once researchers understand the source of age differences, they can design effective aids.

However, the consumer behavior researcher needs to evaluate the consequences of 'aiding' decision making. For example, when researchers trained subjects to discriminate between directly asserted and implied claims, they worried about increasing younger subjects' skepticism of advertising. Similarly, an advertiser targeting older adults may increase learning in this audience by increasing the number of message repetitions. However, if younger adults are also part of the target market, increased message repetitions may irritate and alienate these consumers.

In addition, the consumer behavior researcher needs to think about whether the aid is managerially relevant. For example, two researchers suggested that consumers should highlight relevant information

before making a decision. However, it is not realistic to recommend that consumers take pens into the supermarket to highlight relevant information on product packages. Retailers would be unhappy if consumers put back on the shelf marked packages that did not meet the consumers' needs.

Future Research Directions and Concluding Comments

Over the life course, consumers build up a repertoire of strategies for solving diverse consumption problems. These problems include routine tasks such as buying cereal at the grocery store and complex tasks such as buying long-term care insurance. Both the consumption problems and the strategies people use to solve the problems evolve over time to reflect a person's changing life experiences and abilities. Decision aids, training, and modified marketing stimuli can make it easier for consumers to use different strategies by reducing the cognitive effort required to execute a particular strategy.

There are a number of unanswered questions about how older consumers adapt their decision-making strategies to changing cognitive abilities, social roles, and task and context demands. Preliminary evidence suggests that the situations in which older consumers are likely to run into difficulties because of changed cognitive abilities are typically new situations with new products or services. Older adults may, for example, encounter difficulties learning new information through advertising; similarly, they may run into problems using new product information presented on a nutritional label. In new situations, older consumers may limit search for information, rely on previously learned decision strategies, and/or resist innovations until the benefits are clear.

Because there is considerable heterogeneity in the over 65 market, it is important to bear in mind that age-related changes in cognitive ability are not the same for everyone and in fact may not occur for everyone. An individual's health history and lifestyle may attenuate the timing and size of changes. Much of the consumer behavior literature points out memory deficiencies in older adults in comparison with younger adults. However, the magnitude of memory deficits appears to vary with task conditions of information processing and how information is placed into or recovered from memory.

Studying the consumer behavior of older Americans has never been more important than it is now in the early twenty-first century. With the impending maturity of the baby boom generation, the size of the elderly consumer market poses a force that businesses, public policy makers, and academic researchers can no longer ignore. The older consumer behaves in ways that are inherently different than the ways a younger consumer does. We have briefly discussed many of these differences in this article. Marketing strategies aimed at affecting older consumers' behavior must then be formulated specifically for the older market.

Creativity

D K Simonton, University of California, Davis, CA, USA

Glossary

Career Age – The number of years a creative individual has been active in a given domain (as contrasted with chronological age).

Cumulative Advantage – The phenomenon in which creators who are initially successful gain advantages that help them become even more successful compared to those who are less successful at the outset.

Divergent Thinking – The mental capacity for generating numerous, varied, or original responses to a given conceptual stimulus.

Equal-Odds Rule – The principle that quality of output (creativity) is a positive and constant function of quantity of output (productivity).

Old-Age Style – The distinctive mode of expression that characterizes the final works of great artists.

Swan Song Phenomenon – The tendency for composers to produce highly distinctive musical masterpieces in the closing years of their life.

Introduction

Creativity is an elusive concept that is not easily defined. The only statement about creativity that can be made with absolute confidence is that creativity has something to do with the production of creative ideas. An idea is said to be creative if it fulfills two conditions. First, the idea must be original in the sense of statistical rarity. Ideas that emerge from only one individual are more original than those that arise in the minds of many individuals. Many people have held down a beach blanket with a shoe, but only one person has revolutionized physics by proposing the general theory of relativity. Second, the idea must be adaptive in some meaningful way. For instance, it must solve an important problem or accomplish a significant task. Without this second requirement, one could not distinguish the bizarre mental ramblings of a psychotic from the breakthrough ideas of a scientific genius. Hence, creative ideas are simultaneously original and adaptive.

When we try to get more specific, however, the consensus disappears. Different researchers will have contrary conceptions of what creativity entails. There are at least three main viewpoints:

1. Creativity is a mental process, or a set of mental processes, that generates creative ideas. These cognitive operations might include insight, intuition, and imagination. This is the preferred definition of cognitive psychologists who study problem solving in laboratory experiments.
2. Creativity is a characteristic of concrete products, such as paintings, poems, or inventions. Those products that satisfy certain standards – such as novelty, elegance, beauty, and technical virtuosity – are called creative. This is the perspective adopted in theoretical and empirical aesthetics.
3. Creativity is a special personality trait, or cluster of traits, in which individuals may vary. For example, individuals who exhibit sufficient intelligence, ambition, determination, independence, and originality may be identified as creative. This is the definition adopted by personality psychologists who examine the traits that distinguish creative persons from everyday populations.

Hence, creativity may be examined as a process, a product, or a person. Despite this conceptual divergence, these three perspectives can overlap and converge in various forms. For instance, researchers might study individual differences in cognitive styles – or preferred modes of information processing. This variation may then correlate with the production of creative ideas. Other investigators may examine individual differences in the output of creative products. Those persons who are the most prolific may be said to be the most creative, according to this criterion. Thus, there exists a tremendous variety of ways that creativity can be examined in the behavioral sciences.

From the standpoint of gerontology, the most crucial issue has always been the relationship between creativity and aging. Does creativity necessarily decline with age? Is the age decrement such that we cannot expect creativity from individuals well advanced in years? What circumstances enable a person to maintain high levels of creativity toward the very end of life? These questions are important for both practical and theoretical reasons. On the practical side, a negative relationship between creativity and old age would provide a strong case for compulsory retirement. At least this argument could apply to those who are employed in positions in which creativity

is essential to effective performance. Professors at research universities and scientists at industrial laboratories are obvious examples. On the theoretical side, furthermore, an age decrement in creativity would have important consequences for our understanding of the aging process. Indeed, the supposed creative decline in later years has often been taken as a sign of intellectual impairments in the final decades of life. If this commonplace conception were shown to be very much mistaken, we would have to draw very different conclusions about the nature of aging.

Because there are multiple definitions of creativity, the relationship between aging and creativity can be examined in more than one way. Actually, researchers have tended to attack the problem from just two different angles. On the one hand, some investigators have defined creativity in terms of performance on measures of the mental processes most relevant to the production of creative ideas. These psychometric instruments are often referred to as 'creativity tests.' On the other hand, other investigators have preferred a more behavioral definition, using counts of creative products as indicators of underlying creativity. The creative achievements in these longitudinal tabulations may include paintings, poems, compositions, patents, books, journal articles, or other discrete items. These alternative research strategies do not always lead to identical conclusions.

Psychometric Assessments

A large number of psychometric instruments exist that purport to assess creativity. However, most investigators have relied on those creativity tests that evaluate a person's capacity for 'divergent thinking.' Measures of divergent thinking examine whether a person can produce a large number of alternative and novel responses to test stimuli. There are several such instruments, each concentrating on a particular process (fluency, flexibility, originality, etc.) or medium (verbal versus visual). Whatever the details, studies using these divergent thinking tests have often found that creativity tends to exhibit a roughly inverted U function with age. That is, the scores may peak somewhere in the 30s or 40s and thereafter decline. Judging from these psychometric inquiries, creativity shows a noticeable and sometimes quite pronounced decrement in the latter half of life. The aging process appears to be antithetical to the demonstration of creative activity.

Nevertheless, these psychometric findings must be interpreted with great caution. These results may not necessarily provide conclusive proof that creativity must decline after an individual reaches middle age. There are three principal difficulties:

1. Most of these psychometric studies rely exclusively on cross-sectional rather than longitudinal data. Instead of actually looking at how test performance changes as an individual gets older, most investigations merely compare the test scores of individuals at different ages. The latter approach is adopted simply for convenience. It obviously takes more time to examine the same subjects for several years in order to gauge the changes more directly. Yet in the absence of a truly longitudinal analysis, the findings can be extremely misleading. The effects of age can be confounded with the effects of cohort. It is possible, for example, that the older persons in a sample came from a generation that attended schools with quite different educational philosophies than those that predominated when the younger persons in the study were educated. These differences alone could account for any observed contrasts in test performance in cross-sectional studies. Hence, it is significant that those few investigations that employ a longitudinal design usually report smaller declines in creativity than normally seen in cross-sectional research.

2. The form of the age curve depends greatly on the specific tests used. It must be emphasized that divergent thinking measures represent only one possible approach to the assessment of creativity. Consequently, different longitudinal trends can be obtained when alternative psychometric instruments are used. For instance, tests that evaluate problem-solving skills in more everyday situations can actually produce scores that increase with age. In addition, measures that impose strict time limits during test administration tend to show greater age decrements than those instruments that are untimed. This difference reflects the fact that the speed of thought processes tends to decline in the later years of life. Timed tests thus put older subjects at a comparative disadvantage.

3. Many experts in the area of creativity research seriously question the validity of all so-called creativity tests. Validation studies usually show that such tests display rather modest correlations with direct measures of creative behavior. The main problem is that most of these psychometric measures assess generic mental processes and cognitive styles. Yet investigators have come to realize that creativity is, for the most part, domain specific. For instance, an individual might be highly creative in music but exhibit no creativity whatsoever in literature. Part of the reason for this differentiation is that creativity in any field requires the acquisition of a tremendous amount of domain-specific knowledge and skills.

Creative individuals must usually devote approximately 10 years to intensive study and training before they have the expertise necessary for the production of ideas that are both original and adaptive. This essential requirement is completely overlooked by tests that assess mental processes or cognitive styles in domains of general information.

These three difficulties suggest that it may prove more fruitful to adopt an alternative strategy. If we wish to learn how creativity changes with age, it might be best to scrutinize how the output of creative products changes during the course of a creator's career. Such inquiries would be inherently longitudinal in design, and the indicators of creativity would enjoy the most validity. After all, the production of creative ideas is the primary criterion against which we must evaluate any measure of creativity.

Productivity Measurements

The scientific study of the relation between age and creative productivity began in 1835, and thus it represents one of the oldest topics in gerontological research. The classic investigations are those conducted by Harvey C. Lehman, especially as summarized in his book *Age and Achievement*, in which he examined the fluctuations in creative output in a wide range of disciplines in the arts, sciences, and humanities. His data show a consistent tendency for creative productivity to follow an approximately inverted-U function with age. Creativity again rose to a peak somewhere in the 30s or 40s, and then progressively declined. The age decrement was very similar to what is observed in performance on the psychometric measures.

Unfortunately, Lehman's work suffered from many methodological deficiencies that rendered his results often ambiguous. These deficiencies caused many behavioral scientists to question the validity of his conclusions. Three problems were especially serious:

1. Lehman's tabulations focused on those products that were the most successful or influential. The total output of works was largely ignored. Critics of his research objected to the value judgment implicit in this methodological decision. The critics argued that a fairer gauge of creativity would require a count of the total output, regardless of whether the product attains acclaim or earns appreciation. When this alternative strategy was taken, productivity in the later years of life seemed more substantial than Lehman's statistics appeared to indicate.
2. Lehman did not make any correction for changes in the number of persons active within a creative discipline. There has been a tendency for this number to increase, sometimes quite dramatically. For instance, the number of scientists has been growing exponentially. As a consequence, the older a creator gets, the more other individuals will be active in the same creative domain. That tendency is tantamount to stating that as creative individuals age, they must face increasingly more competitors. Concert halls can perform only so many compositions, art galleries can exhibit only so many pieces, and journals can publish only so many articles. This puts each creator at an ever-growing disadvantage as they age.
3. Lehman's longitudinal tabulations often failed to introduce corrections for individual differences in life span. Counts of the number of creative products emerging at different ages will automatically show a decline in output if these counts are summed across large numbers of creative individuals, because those creators who die at younger ages will be prevented from contributing works at later ages. There are fewer creative products at the hands of 80-year-olds than 40-year-olds in part because octogenarians are relatively rare. Accordingly, those statistics that fail to adjust for this artifact will exaggerate the age decrement in the advanced years.

Fortunately, more recent research has taken advantage of more sophisticated methods to take care of these and other complaints. At the same time, these modern investigations have verified Lehman's central conclusion: the output of creative products tends to first increase with age until a peak is reached, after which productivity declines. The peak may occur a little later in life, and the post-peak decline may be less pronounced, but an age decrement occurs nonetheless. Even so, this same research also suggests that the prospects for creativity in the later years are not as dismal as they first appeared. The relevant findings concern (1) the magnitude of the age decrement, (2) contrasts across creative domains, (3) individual differences in lifetime output, (4) the contrast between career and chronological age, (5) extraneous influences on productivity, (6) the equal-odds rule, and (7) qualitative transformations in creativity.

Magnitude of the Age Decrement

Even though an age decrement is commonly observed, the size of this decrease is not as substantial as was often thought. Certainly the predicted level of creative productivity rarely drops to zero. In fact, output in the last decade of life can compare quite favorably to other decades of a creative career. For instance, persons in their 70s will usually be more productive than the same persons were in their 20s.

Moreover, this late-life productivity will look respectable even when contrasted with the career peak, when the output rate reaches the maximum. In the typical case, individuals in their 70s will be producing ideas at a pace only 50% below what they accomplished during the high point of their careers. It is trivial to debate whether this percentage means that the creative mind is half empty or half full after it enters the traditional retirement age. The conclusion remains that creative individuals do not necessarily 'dry up' or 'run out of steam.'

This fact alone should help us understand how it is possible for an impressive number of creative achievements to come from individuals who are well advanced in years. To offer some illustrations: Cervantes completed the second part of *Don Quixote* at age 68; Franklin invented bifocal lenses when he was 78 years old; Humboldt wrote his *Cosmos* when he was between 76 and 89 years of age; and Goethe finished the second part of *Faust* when he was in his early 80s. Perhaps the most remarkable example, however, is the case of Henri Chevreul. After a distinguished career as a chemist, Chevreul switched fields in his 90s to become a pioneer in gerontological research. His last publication appeared just a year before his death at age 103.

Contrasts across Creative Domains

Any consideration of the age decrement cannot ignore the considerable variation that occurs across domains of creative activity. The specific shape of the age curve, including the location of the peak and the magnitude of the post-peak drop, varies according to the discipline in which the creativity takes place. In some fields the peak will appear much later in life, sometimes around the 50s or 60s. Moreover, the decline will be very gradual, even imperceptible. Accordingly, octogenarians will be as productive as they were when they were in their supposed prime. This longitudinal pattern tends to hold for philosophy, history, and various forms of scholarship. For example, Kant published his first philosophical masterpiece, the *Critique of Pure Reason*, when he was 57, and his last notable contribution, the *Critique of Judgment*, when he was 66.

Of course, in other fields the age decrement will be accentuated. The career peak might appear in the late 20s or early 30s, and the post-peak decline may be almost precipitous. Such age curves tend to be seen in the output of lyric poetry, abstract mathematics, and theoretical physics. Nonetheless, the picture of late-life creativity is not totally grim. In the worse-case scenario, productivity in the 70s will fall to around 5% of the output rate attained at the career optimum. Thus, creativity is only slowed, not stopped. Nothing prevents individuals in one of these disciplines from coming out with a masterpiece in the final years. Tennyson was still producing notable poems in his 80s, and the last volume of Laplace's *Celestial Mechanics* appeared when he was in his 70s.

Individual Differences in Lifetime Output

There exists extraordinary variation in the lifetime output of various creative individuals. In fact, the distribution of total productivity is much more varied than the distribution of most physical and psychological traits, such as height or intelligence. Typically, the most productive creators in any field are at least 100 times more prolific than their least productive colleagues. So extreme is this contrast that the individuals who are in the top 10% in total output tend to account for about half of all the creative products in a particular domain. For example, only 16 composers account for half of the music regularly performed in the classical repertoire.

The productive elite attain this prodigious output in three ways. First, they tend to launch their careers earlier than normal, often in their late teens or early 20s. Second, they tend to maintain high annual output rates throughout their career, often publishing at two, three, or four times the rate of their less-distinguished colleagues. Third, they tend to continue their prolific output much later in life, most often letting death decide when their careers shall end. These last two components are especially crucial to understanding late-life creativity. Individual differences in creative productivity are so substantial that this variation will largely negate the impact of the age decrement when making comparisons across creators. Hence, highly prolific contributors in their 70s and 80s often display more creative productivity than much less prolific contributors who are active at their career peaks. Indeed, a Nobel prize-winning scientist will make more contributions after age 60 than most scientists make during their entire careers.

Career Age versus Chronological Age

It is a common mistake to conceive of the age curves as expressing creative productivity as a function of chronological age. Almost all of the tables and figures published over the past 150 years take this point of view. Along the horizontal axis of the typical graph, the researcher will usually mark off consecutive decades or half-decades according to age since birth (e.g., 20s, 30s, 40s, 50s). The investigator then counts the number of creative products falling within each time interval. This manner of presenting and analyzing the data is straightforward, but terribly

misleading. The curves expressing the changes in creative output across the life span are not strictly a function of chronological age, but rather of career age. What matters most is how long the individual has been engaged in a given creative enterprise. Hence, to be precise we should not say that an individual peaks at age 40, but rather that the peak is attained about 15 years into a career.

Admittedly, if we are counting creative contributions across a large number of individuals, the distinction between chronological and career age will make little difference. If the average person launches his or her career at age 25, then the average person will attain the optimum at age 40. Furthermore, chronological and career age will correlate very highly with each other. This strong association appears because people usually enter and leave the educational system at about the same ages anyway. Consequently, most beginning creators in a particular field will be in about the same cohort. Nevertheless, circumstances do arise in which the correspondence between chronological and career age breaks down. Some individuals might be 'late bloomers' who did not discover their true calling until they were more advanced in years. Some of these persons may have undergone mid-life career changes, perhaps even going to college as 'reentry students.'

Whatever the causes, those who begin their careers later in life will tend to have age curves that are displaced proportionally later as well. If the peak normally comes 15 years after the career onset, and the person does not get started until age 40, then the optimum will appear around age 55 rather than age 40. In addition, the impact of the age decrement would also not be felt until much later in life. The late starter may have to reach the 90th year of life before he or she showed any clear signs of serious decline.

The career of the Austrian composer Anton Bruckner illustrates this possible outcome. Bruckner spent the first part of his life as an obscure and provincial creator of church music. However, an encounter with the operas of Richard Wagner inspired him to become a symphonic composer with a similar sonic landscape. He therefore did not create his first symphony, a student piece given number 'OO,' until he was 39 years old, and he was 50 before his first masterpiece emerged from his pen. Two more successful symphonies appeared when he was 59 and 60 years of age. He died at age 70, before he could write the concluding movement to his last symphony. Yet that piece is still considered a masterwork. Because Bruckner's entire career was shifted over about 20 years, he was in his prime at an age when many other composers were well past theirs.

Extraneous Influences on Productivity

A large proportion of the decline in output in the last half of life is by no means inevitable. Rather, much of any age decrement can be attributed to extraneous factors. To the extent that these detrimental influences can be overcome, creative productivity can often continue at higher levels than those predicted by the usual age curves. For instance, as a career advances, creative individuals frequently find themselves increasingly engaged in activities that take them away from the studio, laboratory, or writing desk. In academic and industrial settings, these activities often entail time-consuming and stressful administrative responsibilities. Consistent with this adverse impact is the recurrent finding that creative persons will often experience an upsurge in productivity upon retirement. This resuscitation is especially likely in those domains in which knowledge or skill does not quickly become obsolete.

Perhaps the most obvious external constraint on productivity in the later years is physical health. Creative individuals, like everyone else, can suffer from debilitating illnesses in old age. Indeed, some creators have had to make heroic efforts to maintain any level of productivity at all. Johann Sebastian Bach was eventually obliged to compose his works by laborious dictation due to blindness; Matisse attached crayons to bamboo poles so that he could continue to create art from his wheelchair. Hence, any advances in medicine that lengthen the number of years of sound health will probably prolong and intensify the amount of creativity seen in the closing decades of life.

In contrast, certain environments can operate to sustain creativity well into old age. In the sciences, for example, those individuals who are embedded in a rich disciplinary network of colleagues and students tend to display much longer creative careers. This positive influence evidently operates by stimulating the scientists so that they can rejuvenate their creative potential. Likewise, those individuals who maintain a high level of intellectual activity, and who remain open to outside influences, will be able to keep their creative productivity at higher levels. This is one reason that the greatest artists often display multiple periods, each identified with a distinct style. Once these creators have exhausted one aesthetic framework, they will move on to another, and thereby refresh their creativity.

A fascinating illustration is the composer Stravinsky, who went through several musical styles over the course of his long career. At 70 years of age he quite unexpectedly revitalized his creativity by adopting a compositional style that he had hitherto ignored, the

twelve-tone technique of Schoenberg. This dramatic change permitted him to extend his creative life by another 10 years.

Equal-Odds Rule

Earlier it was noted that Lehman's studies were criticized for counting only successful works, while ignoring the often much larger output of unsuccessful products. The critics believed that if total output is examined, the outlook for late-life creativity would appear more optimistic. That is, productivity may remain high in the final years of life even if that productivity does not have an impact on contemporaries or posterity. One problem with this argument harks back to the very definition of creativity. A creative product is an entity that is deemed original and adaptive by other individuals. If an individual continues to produce unoriginal and ineffective works toward the end of his or her career, that does not mean that the person is still being creative. Hence, on analytical grounds, this argument has no relevance to the question of the relation between age and creative productivity.

Yet there is a more important point: The preceding argument assumed that the age curves for total output were different than those for just creative production. Presumably the post-peak decline is less drastic when all potential contributions are tabulated, regardless of merit. Nonetheless, earlier studies making this contention did not use the most appropriate methods. In fact, more recent analyses simply do not support this conclusion. The relation between age and productivity is essentially the same whether we count total output, successful output, or unsuccessful output. The peak occurs at about the same place during the course of the career, and the post-peak decrements are comparable. The ups and downs in the appearance of major products parallel those for minor products. Quality of output is strongly associated with quantity of output.

This concordance might lead to more pessimism about the prospects for creativity in the later years. But such pessimism is unjustified if the longitudinal data are examined from a different angle. The first step is to calculate the ratio of successful works to the total output produced in consecutive age periods. This yields a 'quality ratio' or 'hit rate.' To illustrate, for a sample of scientists this ratio would consist of the proportion of frequently cited articles relative to total articles produced during each age period. The next step is to see how this quality ratio changes as a creative individual gets older. The answer is straightforward: the ratio fluctuates randomly throughout the career. There are good years and bad years, but there is no consistent tendency for the hit rate to either increase or decrease, or display some curvilinear form.

Therefore, the older members of a creative domain boast the same quality ratio as their younger colleagues. This equal-odds rule has obvious implications for any discussion of the connection between age and creativity. Although these creative elders may be generating fewer masterpieces in their last years, they are also producing fewer neglected pieces. Each product has the same chance of success no matter how old the creator was at the time of production. So if creativity is gauged in terms of success rate, there is no rationale for speaking of an age decrement at all. The equal-odds rule thus advises everyone to judge each potential contribution on its merits, for age has no value as a predictor of creative accomplishment at this level.

Qualitative Transformations

One obvious limitation of simply counting creative products per age period is that the procedure implicitly treats all works as virtually identical. This hidden assumption is patently invalid. Clearly, an epic poem should get more credit than a sonnet, while a monograph should earn more points than a research note. The standard solution to this problem is to assign differential weights to the longitudinal tabulations. For example, musical compositions might be weighted according to the amount of thematic material they contain, the complexity of instrumentation, the number and type of movements, and playing time. This would make Beethoven's *Missa Solemnis* count more than his piano bagatelle *Für Elise*.

What makes the implementation of this solution especially urgent is that individuals tend to change their preferred mode of creative expression as their careers advance. A poet might begin with brief lyrics before attempting more ambitious narrative and epic forms; a scientist might start with journal articles and then write increasingly more books and monographs. Because the number of creative ideas found in each creative product thus increases over time, the output of titles will decrease faster than the production of ideas. The weighting procedures allow us to compensate for this crucial shift of growing creative maturity.

However, this methodological improvement ignores another qualitative change that is even more profound. As creators get older, they may grapple with more difficult themes and issues, and thereby make the content of their works more profound, and even devise forms much more rich. For instance, as authors age, their juvenile preoccupations with love

won and lost tend to be replaced with deeper ruminations on the meaning of life, on the place of human existence in the larger scheme of things. By waxing philosophical, creative individuals will often try to say more with less, to concentrate an intense amount of significance within strikingly elegant expression. These life span transitions require a more complex approach to the measurement of creativity. Even weighted counts will not capture the amount of creativity that may be going into each piece.

This point becomes especially urgent when we consider one final empirical finding: creators entering their last years often dramatically alter the approach they take to their creative activities. For instance, visual artists in their concluding years may exhibit a sudden shift toward what has been called the 'old-age style.' Similarly, composers will frequently display the 'swan song phenomenon.' Rather than betray a decline in creative power, these works often serve as last artistic testaments. Practically a creator's entire life and career is summarized within a single, often brief, but highly concentrated masterpiece that serves as his or her career's most worthy capstone. It is as if the greatest creative personalities wish to end it all with a bang, not a whimper. The very fact that an old master can still succeed in such an awesome task is ample testimony to the respectable creative powers that can yet remain in advanced old age.

Theoretical Interpretations

So far the focus has been on the empirical findings that describe the linkage between creativity and aging. Behavioral scientists have proposed a large number of theoretical accounts as well. These theories vary greatly in how well they explain the available data. They also differ with respect to their implications for creativity in the later part of life. These diverse theoretical frameworks fall into four broad categories: psychobiological, sociological, economic, and psychological.

Psychobiological Theories

Creativity obviously takes place in the human brain. Therefore, any biological process that impairs brain function as the body ages will naturally have a similarly negative impact on creative thought. For example, as people get older, reaction time usually tends to increase, as the general rate of information processing gradually slows down. If creativity is assessed by time tests, this neurological shift will necessarily cause inferior performance. Older individuals will simply generate fewer responses in a given unit of time. Hence, only on untimed tests can this inherent disadvantage be minimized. Of course, here we are referring merely to the quantity of ideas produced over a certain period. The quality of those ideas may not necessarily diminish just because the rate of output slows down. Indeed, the equal-odds rule shows that the ratio of good to bad ideas stays more or less constant throughout the life span.

Nevertheless, biological changes may affect the intellect in more subtle ways. Work on IQ tests has established the important distinction between crystallized and fluid intelligence. Whereas the former concerns relatively permanent knowledge, such as a person's active vocabulary, the latter concerns more flexible skills, such as problem-solving ability. For reasons not completely understood, these two types of intelligence have different trajectories across the life span. Crystallized intelligence will often steadily increase, with a relatively minimal age decrement toward the end, whereas fluid intelligence will normally decline somewhat rapidly in the later years. In fact, the divergent thinking tests discussed earlier may be viewed as measures of fluid intelligence, and their age trends follow the same course. This contrast is important because different kinds of creativity may require a distinctive mix of crystallized and fluid intelligence. The nature of this mix may then decide where the career peak tends to be for a particular field. The differences between mathematicians and geologists or between poets and novelists may be partly explained by this principle.

Even so, psychobiological explanations cannot account for many crucial features of longitudinal changes in creativity. Most conspicuous is the finding that creative productivity is principally a function of career age. By comparison, any psychobiological account must be expressed in terms of chronological age. Consequently, it is difficult to use this perspective to comprehend those individuals who enter a creative enterprise later in life, yet still manage to display the expected career trajectories. Perhaps the best conclusion to draw is that various biological factors operate mostly as extraneous influences. Their main effect on late bloomers may be to depress the height of the career peak and make steeper the slope of the post-peak decline. Meanwhile, the specific shape of the age curve will be largely dictated by other factors that have nothing to do with biology.

Sociological Theories

Sociologists adopt a totally different approach to explicating how creativity changes across the life span. Their tendency is to concentrate on objective creative behavior, as gauged by the output of actual products. This productivity is then seen to be largely if not

entirely the function of the prevailing reward structures of a discipline. These structures reinforce certain forms of creative output while discouraging other forms. Output is maintained across the life span when the social rewards for continued productivity are maintained throughout the career. On the other hand, productivity will diminish and disappear when the disciplinary reinforcements are no longer forthcoming.

This explanatory position is best seen in the principle of 'accumulative advantage.' According to this principle, creative individuals live in a very competitive world in which many are called but few are chosen. Not all papers submitted to professional journals will be accepted for publication; only a subset of the art works submitted to a show will be selected by the jury for exhibition. Those who have the fortune to achieve success early will have higher odds of attaining further successes, whereas those who experience the misfortune of early rejection will be more prone to endure further failure. Those in the first group are thereby encouraged to increase their productivity, while those in the second group will suffer discouragement, and eventually drop out of the race. This difference is accelerated because the initially successful will obtain access to social support – such as paid positions, laboratories, studios, contracts, fellowships, and grants – that will be withheld from those who have not yet proven themselves. The upshot is that the rich get richer and the poor get poorer.

The principle of accumulative advantage can explain many of the details of career trajectories. For instance, those individuals who are successful earlier will obtain the resources that will permit them to maintain their productivity at a higher rate and to continue their output until later in their career. In contrast, those less lucky will never become very prolific, and will end their productive careers earlier. This pattern closely approximates what is actually observed. A remarkable feature of this explanation is that it makes no assumptions whatsoever about individual differences in creativity. Even if all individuals entering the contest are roughly equal in native ability, they will eventually stratify according to the length and productivity of their careers. Moreover, persons who are no longer productive in the later years cannot be blamed for their fate. They are simply those who got off on the wrong foot at the very outset of their careers. If they had accumulated the same external resources as their most successful colleagues, they too would be just as prolific in old age.

Although the sociological account has many attractive aspects, it also suffers from numerous explanatory inadequacies. For example, it does not do a very good job of explaining the appearance of creative late bloomers. More seriously, it has problems with accounting for interdisciplinary contrasts in the career trajectories. Why do mathematicians peak early while geologists peak later? In addition, it cannot handle the finer details of individual variation in the career course. For instance, research has shown that the most prolific creators in a discipline attain their productive peaks at the same career age as their less prolific colleagues. The principle of accumulative advantage, in contrast, predicts that the former will peak later than the latter. Hence, the sociological framework may at best capture only a portion of the process underlying age changes in creative output.

Economic Theories

Economists have advanced an interpretation that has a certain affinity with that put forward by sociologists. They also posit that creativity is a behavior maintained by extrinsic incentives. Yet the economists focus more on the individual rather than on the reward structures of a creative domain. Economists begin by assuming that human beings are rational creatures who try to maximize the benefits they receive in life while minimizing the costs. Hence, individuals are always calculating 'cost/benefit ratios' or 'utility functions' in order to decide on a proper course of action. This calculation process becomes complex when a person has to examine the tradeoff between short-term costs and the corresponding long-term benefits. A classic example is education, which consumes much time and money in the short run, but helps ensure a comfortable standard of living in the long run.

Creative individuals face a similar choice. Creativity, according to the economists, requires considerable investment in 'human capital.' That is, creative individuals must devote much time, energy, and expense to mastering the knowledge and techniques of a field before they can generate a creative product. Yet only the products themselves bring benefits in promotions, prizes, and pay raises. Furthermore, creative individuals must continually reinvest their resources in order to maintain productivity throughout their career. Otherwise their expertise will become obsolete, and they will correspondingly fall behind the leading edge or latest fashion. For a person just starting out in a career, the short-term costs of this investment will pay great dividends in the long term. Yet for a person already well advanced in years, the current losses may outweigh the expected gains. For one thing, death may end the person's career before the opportunity has appeared to reap the benefits.

Additionally, the 'marginal utility' of a creative product may decline for those individuals who have already made many contributions. One published poem means more to a young poet with no previous publications than to an established poet who has already put out several volumes of poetry. The net result of these economic decisions is a decline in creative output toward the closing years of the career. The age decrement is thus a natural repercussion of a gradual shift in the incentives and disincentives faced by creative individuals as they get older.

This economic model can explicate many other aspects of the relationship between creativity and age. Nonetheless, this model is not capable of explaining all the details. For example, it is not clear how it would account for the upturn in creativity that is often observed in the final years. What material incentives could possibly induce a dying creator to produce a swan song or final artistic testament? It would seem that the short-term costs of such projects would immensely overwhelm any anticipated long-term benefits. As in the case of the sociologists, economic models can probably account for only a portion of the phenomenon.

Psychological Theories

Psychologists, naturally, place even more emphasis on what is going on in the individual. Presumably the age changes in creativity are some function of cognitive, motivational, or dispositional variables that undergo transformations over the lifetime. For instance, the results of the psychometric studies may be used to explain the findings of the productivity studies. If divergent thinking represents a process fundamental to creative thought, and if scores on tests of divergent cognition decline in the latter part of life, then this trend may underlie the parallel drop in creative productivity. Furthermore, since different forms of these cognitive measures often exhibit distinct longitudinal trends, it is also possible to use these findings to explain the interdisciplinary contrasts in the age curves for creative output. Perhaps creativity in different disciplines requires a distinct mix of cognitive styles, in which each mixture will show an agewise trend that is a weighted average of the separate trends for each mental process entering the mix.

There are three main problems with this particular interpretation, however. First, and as pointed out earlier, the correlation between performance on creativity tests and the demonstration of creative behavior is by no means strong. Second, longitudinal and cross-sectional studies of these psychometric measures have focused on chronological rather than career age. Third, this explanation somewhat begs the core question; if productivity changes reflect underlying changes in mental capacities, the latter changes remain to be explained.

Other psychological interpretations do not suffer from these drawbacks. For example, according to one information-processing theory of creative productivity, the longitudinal trends in output emerge from the very process by which creative potential is converted into actual creative products. This theory predicts that the age curves will vary across disciplines in a manner that corresponds to the complexity and richness of the concepts and skills needed to generate and develop creative ideas. This theory also holds that the age curves depend on career age rather than chronological age. One distinctive asset of this theoretical account is that it makes very precise predictions about longitudinal changes in output across individuals and disciplines. Even so, this theory cannot explain certain details, such as the occurrence of the swan song phenomenon.

In fact, at present there is no theory of creativity that can deal successfully with all of the empirical findings reviewed earlier in this article. The relation between creativity and aging is perhaps far too complicated to permit simple theoretical interpretations.

Crime and Age

E E Flynn, Northeastern University, Boston, MA, USA

Glossary

Cohort – Group of individuals sharing a statistical factor, such as age, in a demographic study.

Crime Rates – The incidence of crime related to the population.

Criminal Careers – Concept describing the onset of criminal activity, the types and number of crimes committed, and the termination of law-violating behavior.

Cross-Sectional Research – Studies groups of people of different ages at particular points in time.

Incidence of Crime – Rate of offending by offenders.

Index Offenses – Also known as Part I crimes.

Longitutional Research – Studies a particular group of people over a period of time.

Prevalence of Crime – Proportion of persons in a population who are offenders.

Property Crimes – Include burglary, larceny theft, motor vehicle theft, and arson.

Recidivism – Relapse into criminal behavior.

Uniform Crime Reports (UCR) – Annual reports on criminal activity collected and published by the Federal Bureau of Investigation (FBI). The reports divide offenses into two major categories: Part I crimes consist of murder, non-negligent manslaughter, forcible rape, robbery, aggravated assault, burglary, larceny, and auto theft. Part II offenses include less serious crimes such as forgery, fraud, embezzlement, sex offenses, and others not meeting the FBI's criteria of seriousness and frequency to qualify for Part I.

Violent Crimes – Include murder, forcible rape, robbery, and aggravated assault.

Introduction

Criminology is the scientific study of crime and delinquency as social phenomena. This relatively young field of study has three principal divisions: (1) the sociology of law, which examines how laws are made and enforced; (2) criminal etiology, which studies the causes of crime; and (3) penology, which addresses society's response to crime and includes the study of the criminal justice system. Criminologists are social scientists who utilize the research methods of modern science to develop a body of general, verifiable principles regarding law, deviance, and crime. Criminological analysis looks upon crime and deviance not as isolated events but as highly complex forms of social behavior. To fully understand the meaning of deviance and crime, the discipline goes beyond the legal definitions of crime and examines the total social context within which deviance and lawlessness arise. In the process of studying the causes of crime, a vast body of research has identified age, gender, ethnicity, social class, family status, and community environments as major social correlates of crime.

This article explores in depth the relationship between age and crime and summarizes current information on this subject. The second section examines in some detail the age–crime curve as it emerges from national crime statistics collected by the Federal Bureau of Investigation (FBI). The third section discusses key statistical properties of the age–crime curve. The fourth section probes the significance of the age–crime curve and reviews the ongoing debate in criminology on the true relation between age and crime. The fifth section explores age as a critical social correlate of crime, along with other key variables. The sixth section considers age as a critical variable in the formation and termination of criminal careers. It also explores current criminal justice system responses to chronic offenders and questions the efficacy of these responses in terms of their potential for crime control and crime reduction. The seventh section investigates the effects of society's age structure on America's crime rate and tracks the expansion of the nation's juvenile population into the twenty-first century. The article concludes by assessing the implications of demographic changes on crime control and criminal justice policies.

The Relationship between Age and Crime

One of the few undisputed facts in criminology is the age distribution of crime. Official crime statistics, supported by victim survey research, show clearly that crime is a young man's game, with most serious crimes being committed by young males between the ages of 14 and 24. Beyond this brief vignette, age–crime curves show reliably that age is inversely related to criminal activity, with crime rates rising

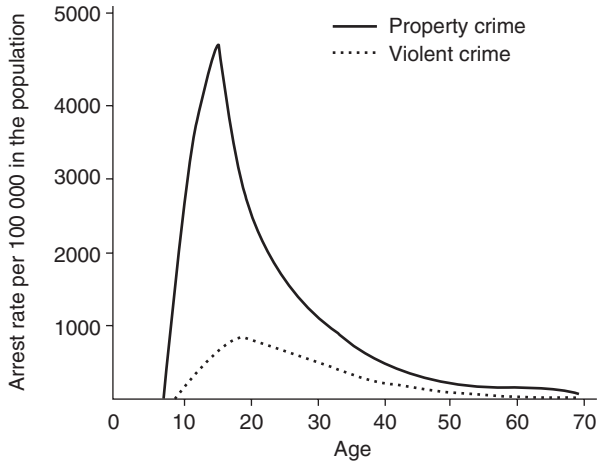

Figure 1 The relationship between age and crime. Property crime arrests peak at age 16 and at 18 for violent crime. There were 746.1 violent crimes and 4736.9 property crimes per 100 000 inhabitants in 1993. (From FBI, 1994. *Crime in the United States, 1993*. Washington, DC: Government Printing Office, pp. 10, 35, 227–228.)

rapidly from the minimum age of responsibility, peaking during adolescence, and then decreasing quickly. The decline is rapid at first, followed by a more gradual downward curve throughout a person's life cycle. **Figure 1** shows the property and violent crime rates for Americans per 100 000 in the population in 1993, as reported by the FBI. Property crime rate peaks at age 16, and the violent crime rate peaks at age 18. The relationship between age and crime is of great interest to criminology and vital to theoretical development in the discipline. Criminologists consider age to be a major correlate of crime, along with gender, ethnicity, social class, family status, and community environments.

Statistical Evidence of the Age–Crime Curve

Juveniles and young adults are arrested at disproportionate rates to their numbers in the general population. According to the FBI's Uniform Crime Reporting Index, youngsters between the ages of 10 and 17 represented 11.3% of the total US population in 1993. But they accounted for 18.4% of all violent crime arrests and for over one-third (33.2%) of all property crime arrests for that year. The disproportionate contribution of the young to the nation's crime problem jumps graphically to the fore when looking at the arrest statistics for all persons under the age of 25. That group makes up only 21.2% of the US population but accounts for more than half (58.3%) of all arrests for index property offenses and almost half (47.4%) of violent crime. The peak arrest age for most offenses is between 16 and 19, with property crime peaking at 16 and violent crime cresting at 18. After age 30, arrest rates decline. From age 50 on, arrest rates become marginal (1.3% and below). The decrease in criminal activity with increasing age is known as maturational reform or the 'aging-out effect'.

Significance of the Age–Crime Relationship: The Age Debate

The persistence of a distinct age–crime relationship has been documented by many studies across time, gender, ethnicity, types of offenses, and different cultures. This phenomenon and the consistency of the data have led some criminologists to suggest that the age–crime curve is invariant. They further believe that this distinct relationship between crime and age cannot be accounted for by changes in other factors with age. As a result, they maintain that age exerts a direct causal effect on crime. Given this causal effect, proponents of this school of thought suggest that the study of the age–crime relationship has little relevance for the study of crime, because all persons commit less crime as they age regardless of ethnicity, gender, social class, family, or any other variable.

On the opposite side of this age–crime debate is another school of thought, pointing to inherent weaknesses in aggregate, cross-sectional statistics, such as those featured in the nation's Uniform Crime Reports. It notes that although these data depict variations in the prevalence of crime, they offer little information on the incidence of crime. In fact, aggregate age–crime curves are singularly unyielding about age–crime curves for individual cases. This is because crime incidence varies considerably between the beginning and end of individual criminal careers. It also varies by the types of crimes that are committed. For example, vandalism or motor vehicle theft are clearly crimes of adolescence. They peak early, when youngsters are between the ages of 15 and 16. By contrast, white-collar crimes such as fraud or embezzlement peak relatively late, when perpetrators are in their late twenties and early thirties. Furthermore, just because the aggregate age–crime curve declines precipitously after adolescence, it does not necessarily signify that the number of crimes committed by every offender declines in a similar fashion. In fact, many cross-cultural, longitudinal research studies have demonstrated that although the frequency of criminal offending does follow the dictates of the age–crime curve for a majority of offenders, some very active individuals continue to violate the law unabated.

Age as an Important Determinant in the Etiology of Crime

Questions of why some individuals turn to crime while others do not and why most youthful offenders 'age out' of criminal activities while others persist in offending, have prompted a good deal of prospective and retrospective longitudinal research on the causes of crime. The results of these efforts indicate that onset, frequency, and cessation of criminal offending varies, depending on a number of biological, individual, and social factors.

Biological and individual factors help account for the shape of the age–crime curve because many criminal activities are contingent upon certain levels of physical and mental development. For example, rising testosterone levels in young males are consistently linked to aggression and violent behavior during adolescence, when immaturity, the pursuit of immediate gratification, and risk-taking behavior are also highly prevalent. As adolescents become adults, physical and mental maturation begin to play key roles in their desistance from crime. In a similar vein, the commission of some types of crimes, such as robbery or rape, is contingent upon certain degrees of strength, force, and agility. With increasing age, these offenders lose their physical power to assault, rob, escape, and avoid apprehension.

Although biology and individual factors do set some of the parameters of the age–crime curve, they fall short of explaining it. Adequate explanations depend on linking the curve to changes in a person's social environment. To that end, criminological research has identified a number of social factors that are of greater importance in explaining the age–crime curve than those focusing exclusively on changes in a person's biological or personal characteristics. The following behavioral factors are consistently associated with very serious, violent, and chronic juvenile crime: (1) dysfunctional families; (2) physical or sexual abuse; (3) delinquent peer groups; (4) poor school performance; and (5) high-crime neighborhoods. As the United States enters the twenty-first century, there is nothing on the horizon in terms of legislation or policy development that effectively responds to any of these factors, which does not bode well for the nation's crime rate or crime control.

Dysfunctional Families

Historically, the family has carried the primary responsibility for the socialization of children. Basic personality traits, perceptions of right and wrong, and personal values are formed within this primary social setting at an early age, long before the other socializing institutions, such as religion, education, or the workplace begin to exert their influence. Socialization is an integrative process of moral internalization and informal and formal education. Successful socialization implies civilization and, by definition, law-abiding behavior.

Most criminologists agree that a stable, secure, and mutually supportive family is exceedingly important in delinquency prevention. Conversely, children growing up in a family filled with violence, abuse, and neglect are most likely to embark on a life of delinquency and crime. The simple truth is that children raised in dysfunctional families have difficulty developing the prosocial identities and values needed to become productive, law-abiding citizens. The following are major indicators of the breakdown of the American family.

The number of children raised in homes broken by divorce, separation, desertion, or death is escalating. The nation's divorce rate is among the highest recorded in the world. The birth rate for unmarried women is fast approaching 50 births per 1000. Teenage pregnancy rates are among the highest in developed nations. The number of households headed by women has more than doubled in less than one generation. More than half of all mothers with school-aged children work outside the home, most out of economic necessity. The result is a steadily rising number of children who find themselves under the care of a single parent, a working mother, a day nursery, and too often, a television set. The percentage of children who do not have full-time parental supervision at home is close to 60% and rising.

Research on the effects of rapid social change and family disruption on crime is extensive and discouraging. Strong ties have been established between parental criminality and delinquency in children. Although the precise causes of intergenerational deviance are not yet known, there is some evidence of a genetic, psychological, and social factor linkage. Much family dysfunction is also related to a growing problem with parental alcohol and substance abuse. For example, there is a strong association between substance abuse, child maltreatment, and infants born with fetal alcohol syndrome or congenital drug addiction. Children raised by substance-abusing adults also have a much greater propensity to develop substance-abuse problems themselves, when compared to youths raised in drug-free home environments. Finally, certain child-rearing practices have emerged as primary factors leading to delinquent offspring. They include inadequate or inconsistent parenting, such as disciplinary practices that alternate between harshness and overindulgence; the use of severe corporal punishment; treating children with coldness and distance; and

exposing children to an incessant barrage of parental conflict.

Physical and Sexual Abuse

The correlation between violent physical or sexual child abuse and delinquency is positive and strong. Although estimates vary, more than 1 million children are abused and tortured in any given year by their parents or caregivers seriously enough to require hospital treatment. Unreported child abuse may be four to six times higher. The number of children who die as a result of parental maltreatment is estimated at between 2000 and 5000 in any given year. Research evidence has consistently linked physical or sexual abuse to risky sexual behaviors, particularly among girls, and to substance abuse, illegitimacy, and suicide. Furthermore, children already vulnerable with neurological and psychological problems seem to become prime candidates for delinquency not only if they are physically abused, but also if they merely witness habitual violence and brutality in their homes. Serious physical abuse can cause neurological or psychomotor disturbances, and children with such impairments have been found to disproportionately exhibit a tendency toward very serious and sometimes brutal violence.

Delinquent Peer Groups

As children mature, the influence and control of parents wanes and peer influence heightens. Crime statistics show that delinquent acts tend to be committed in small groups, rather than by youths acting alone. These statistics coupled with the fact that most children gravitate to forming close-knit peer groups during their early teenage years provide the single best explanation for the rapid escalation of delinquency and crime depicted by the age–crime curve. Although many desist offending, there is ample empirical evidence that youngsters who are involved with delinquent friends, belong to gangs, and otherwise associate with deviant persons are most likely to become involved in delinquency and crime.

Poor School Performance

The failure of schools as an agent of socialization is well documented, especially in socioeconomically deprived urban environments. Even though no clear causal relationship has been established between school failure and crime, there is agreement among criminologists that educational institutions lag in fulfilling their primary socialization function in modern society. The rising level of student violence and vandalism during the past two decades is well documented. When considering the amount of time children spend at school, it comes as no surprise that youngsters are at greater risk of violence in and around schools than anywhere else. Pilfering, assaults, robberies, fights, and racial antagonisms are a major part of school life and especially pronounced in urban schools. With the exception of trespassing and breaking and entering, most crimes committed in schools are perpetrated by the students in attendance. Teacher victimization through property crime and assault is frequent. Poor schooling and negative attitudes toward school are strongly related to delinquency and crime, substance abuse, disdain for authority, increased social fears, racism, and reduced productivity. Absenteeism and lack of discipline are major problems. Too many schools have watered-down curricula and reflect an alienated, prisonlike atmosphere. Many teachers, unappreciated by the public and their charges, are also alienated, demoralized, and prone to burnout. The disruptions, crime, and vandalism have taken their toll. Achievement scores are low, with many schools graduating technological illiterates, and more disturbingly, too many functional illiterates, ill equipped to face a job market requiring ever more knowledge and skills.

High-Crime Neighborhoods

Many of America's inner-city neighborhoods are characterized by poverty, transience, high population density, neglect, and physical deterioration. They are also marked by exceedingly high crime rates when compared to more affluent residential areas. Inner cities have high levels of unemployment, especially for members of minority groups. Even though there is no direct cause-and-effect relationship between poverty and crime (many single parents living in high-risk areas do not produce delinquent children), there is very strong evidence of structural linkages between family disruption, failing public school systems, economic marginality, declining low-skilled, blue-collar employment opportunities, and crime in high-risk, inner-city neighborhoods. Life in such neighborhoods breeds cynicism and alienation. Devoid of positive social control, such areas amplify criminogenic forces and further destabilize these areas. In that light, social, physical, and material conditions of neighborhoods exert an independent effect on delinquency and crime over which individual residents have little, if any, control.

Age and Career Offenders

Many studies analyzing delinquency and crime patterns in cohorts show that any given group contains a relatively small number of repeat offenders who

commit a disproportionately large number of crimes. This 'chronic offender group' (approximately 8%) is responsible for more than half of all the offenses committed, including a large portion of homicides, rapes, robberies, and aggravated assaults. Although the road to a chronic criminal career is highly complex and defies simple explanations, the studies agree on the following points. Most delinquents do not become chronic offenders. A few mischievous and petty delinquencies do not usually lead to an acceleration of serious criminal offending. Compared with conventional delinquent youths, chronic offenders begin their criminal careers at very young ages, often before reaching the age of 10. In fact, age at the onset of offending is the single best predictor of becoming chronic offenders and embarking on adult criminal careers. According to these studies, the younger a person is when first arrested, convicted, or confined for any criminal behavior, the more likely it is for that individual to continue offending. Offense patterns of chronic delinquents are often characterized by excessive violence, destruction, and lack of remorse. Calculations of the average lengths of criminal careers show them to be about 6 years, with career lengths peaking between the ages of 30 and 40. These findings have great potential for crime control and penal policy development. This is because if chronic offenders could be correctly identified and incarcerated for long periods of time, the crime rate should decline considerably.

Responding to these findings, Congress and state governments have passed a wide range of legislative initiatives during the past few years. Rooted in chronic offender research, these efforts are designed to deal more effectively with the nation's mounting crime problem. They do so by targeting high-risk, violent, and persistent offenders for rigorous prosecution. If found guilty in a court of law, such offenders are sentenced to long periods of incarceration, including life without parole. Advocates of longer sentences assume that they will both reduce crime and, ultimately, save taxpayer money. This is because they believe that such sentences will not only decrease the cost of victimization through incapacitation, but will also reduce the substantial costs of rearrest and reprocessing of repeat offenders by the criminal justice system.

Yet in spite of these dramatic legislative changes in sentencing, it is not known whether they will ultimately achieve the desired effect of crime reduction. This is because the research evidence on selective incapacitation is still incomplete. At present, criminologists do not yet have the ability to predict precisely which offenders present unusually high risks for recidivism and violence. Obversely, there is a similar lack of knowledge to correctly predict which offenders represent unusually low risks to society. The result has been legislative overkill. Present sentencing schemes cast too wide a net in their efforts to incapacitate and punish the serious, repeat offender. In the process, too many criminals are incarcerated whose crimes are minor and who do not pose a threat to the community.

The cumulative impact of career offender laws and related harsh sentences for repeat offenders has led this nation to the highest incarceration rate in the world, with over 350 prisoners per 100 000 US residents! To date, prison populations have increased close to a million persons in state and federal prisons. The cost of maintaining these prisoners has risen concomitantly, and will reach $19 billion in 1995, excluding the costs of holding prisoners in the nation's city and county jails. If current trends continue unabated, the costs of incarceration are destined to rise further. This is because of the unprecedented growth of lifers and elderly in prisons, whose healthcare needs double and triple the cost of caring for younger inmates in the general prison population.

Considering what is known about the relationship between age and crime, current developments in criminal justice countervail existing knowledge: statistically speaking, recidivism is known to decline with increases in age. Because offending at an early age is highly predictive of long criminal careers, scarce public resources would be better focused on crime prevention rather than on aging and geriatric inmates, whose criminal careers have peaked and decelerated long ago.

Age Structure and Crime

Because crime varies with age, changes in the age structure of society exert an important impact on the crime rate independent of the other known factors, such as dysfunctional families, schools, peers, and neighborhoods. The Baby Boom after World War II is well known and documented. The twin promises of peace and prosperity accelerated the nation's marriage and birth rates with highly predictable consequences. When the Baby Boom generation reached its most crime-prone years during the 1960s, the country's crime rate rose precipitously. By 1980, the crime rate peaked at 5950 per 100 000 in the population and declined. A decade later, index crimes were down, along with the proportion of juveniles in the total population. Since then, index crimes have been falling, with minor fluctuations. There have been further small decreases in the national crime rate since 1990. However, recent crime rates conceal two highly divergent and troubling trends: although

adult crime rates are declining as the Baby Boom generation ages, juvenile violent crime has increased rapidly. An examination of the nation's homicide rate, calculated per 100 000 inhabitants, illuminates the problem. Since 1985, the homicide rate for adults aged 25 and over has steadily declined from 8 to 5.2% in 1993. During the same time, the homicide rate for young adults aged 18 to 24 has increased from 16 to 26%. Worst of all, for juveniles aged 14 to 17, the homicide rate has more than doubled from 7 to almost 19%. Considering the fact that the nation's adolescent population will expand to 23% by 2005, the problem of rapidly rising serious, violent juvenile crime will only be compounded.

Summary

In summary, the state of criminological knowledge about the relationship between age and crime indicates that current criminal justice policies are misdirected. If today's unacceptably high crime rates are to be reversed, and more importantly, if a new crime wave is to be averted, the focus should be on primary prevention. This is best accomplished by assisting dysfunctional families, juveniles, and school systems outside the criminal justice system and by early intervention programs for youths within the system.

Critical Gerontology

C L Estes and C Phillipson, University of California, San Francisco, CA, USA

Glossary

Aging Enterprise – Term to describe how the aged are treated as a commodity in society and how age-segregated policies fuel this further by singling out, stigmatizing, and isolating the aged from the rest of society.

Humanistic Gerontology (also called Cultural Gerontology) – the study of the interplay and recursive relationships of culture, structure, and agency.

Introduction

Critical gerontology is indebted to a range of theoretical and philosophical traditions, notably those of Antonio Gramsci and the Frankfurt School; conflict theorists including neo-Marxist and neo-Weberian state theorists such as Claus Offe and James O'Connor; feminist theorists, particularly of patriarchy and the state; and theorists of institutional racism and inequality such as Michael Omi and Henry Winant. Other theoretical influences include cultural studies, social constructionism, psychoanalytic perspectives, the sociology of knowledge, and work on globalization and risk.

Each of these theoretical strands has been incorporated into different aspects of critical gerontology. This work has evolved under a number of rubrics, including radical gerontology, political gerontology, the political economy of aging, the moral economy of aging, and cultural gerontology. This article first explores the intellectual origins of critical gerontology; second, identifies its main theoretical strands; and third, considers possible future developments within this perspective.

Origins of Critical Gerontology

The overall project of a critical gerontology has been to provide alternative theoretical frameworks and emancipatory knowledge, addressed toward

concerns of social inequalities and social justice. The initial and most developed area of critical gerontology is the political economy of aging, now considered part of mainstream theory within the field of aging. This approach, which emerged in the late 1970s through the work of scholars such as Carroll Estes in the United States, Peter Townsend and Alan Walker in the United Kingdom, John Myles in Canada, and Anne Marie Guillemard in France, examines the aging process and its social construction as problematic, to be understood only in the context of the larger social forces of politics, class, and social status such as race, ethnicity, gender, and able-bodiedness. From the beginning, the study of ideas and ideology has been central to understanding the social construction of old age and societal aging, the problems defined therein, and the perceived appropriate and feasible lines of public and private action. Power struggles over ideology are understood to reflect and reproduce the dominant social relations that vitally frame the issues of old age and aging, determining how state policy addresses these phenomena in society. As a major vehicle for promoting powerful interests, ideologies reflect a particular world view of later life. Goran Therborn observes, in support of this point, that ideologies delimit public understanding of what is, what is good, and what is possible. In the case of age, they denote first the importance of recognizing and valuing differences between groups of people who are growing old; second, the possibilities for solidarity based on age, across generations, and between social groups with shared interests; and third, the likelihood of developing alternatives to established expectations about the nature of social aging and aging societies.

Critical gerontology uses a conflict perspective to demonstrate how power struggles within society result in various divisions and inequalities, these having significant consequences for the trajectory of the life course and the life chances of individuals in old age. Political economists have criticized the dearth of theoretical and empirical attention to social and structural factors that influence and shape individual aging and the preoccupation of gerontology with features such as life cycle development, individual adjustment to old age, and so-called successful aging.

The critical perspectives in this approach have been twofold. First, they have investigated the institutional roles and powerful structural interests both within and between the state and different corporate sectors as well as the larger economic system of capitalism and other social institutions. This work has examined the impact of the resulting social relations on the family and sex and gender system as institutions, especially with regard to society's least powerful, most disadvantaged individuals. Second, critical perspectives have provided a commitment to social justice and to praxis by linking social analysis to action and political change. Robert Butler's influential book *Why Survive? Being Old in America* anticipated critical gerontology with its attack on ageism and its call for political and social change in defense of older people and a better society. More concretely, the goal of praxis is to understand and change those structures of dominance that produce and reproduce social inequality and injustice.

In Europe and the United States, old age and aging have been constructed and regarded as a problem of the welfare state. With globalization and the increasing strength of financial transnational capitalism, the focus on the state in developed and developing nations is increasingly centered on conflicts over the role of the welfare state in the financing of care and support for groups such as older people. Much of critical gerontology has taken as a central problem the divisions of income, wealth, education, and other resources, with particular interest in their distribution by race, ethnicity, class, gender, and age. A major concern is how the institutions of the family, the market, and the state are organized and function to produce social policy and their related outcomes at the individual, community, and societal levels. Conflicts over the allocation and control of symbolic and material resources are central processes for investigation in order to understand policy formation and the distributional consequences for different segments of the older population.

Carroll Estes has refined the political economy of aging approach, identifying multiple analytic levels, including (1) financial and postindustrial capital and its globalization, (2) the state, (3) the sex/gender system including the family, (4) race, ethnicity, and racism (institutional racism), and (5) the broader public and the individual citizen. Applied to social policy and aging, this perspective seeks to understand and analyze the human and social outcomes of power struggles, especially those occurring on the meso (organizational and institutional) and macro (national and global) levels as they affect the micro level of the everyday lives of people.

Critical Gerontology and the Role of the State

The role of capital and the capitalist system is a key element in the political economy of aging. Major concerns are the relationship between old age policy and the economics and politics of markets.

The power of corporate capital to influence programs and policies for the benefit of business at home, nationally, and around the globe is a key topic of study. An additional area for research is the exercise of ideological, political, and financial might in the service of the privatization of state programs (e.g., Social Security and Medicare in the United States). Of considerable interest are strategies utilized by different financial and industrial sectors to pursue contracting out and other low-wage strategies that weaken the power and economic resources of labor, women, and minority populations. From a political economy perspective, a central issue concerns the effect (real or perceived) that public spending has on the functions of the private economy in terms of ensuring capital flows for profits and investments.

Political economy perspectives view the state as central to the understanding of old age and the life chances of older men and women because of its power to (1) allocate and distribute scarce resources to ensure the survival and growth of the economy, (2) mediate the different needs and demands across different social groups (gender, race, ethnicity, class, and generation), and (3) ameliorate social conditions that could threaten the existing order and/or disturb the power of entrenched vested interests. Within critical political economy, state theory assumes the conflict paradigm, which conceives of the social order as being held together by the dominance of certain groups over others. The outcomes of power struggles are examined in terms of how society is organized and functions. The social order (the status quo) is seen as being held together by constraint (in the sense that some are able to impose their ideas, material interests, and actions over others) rather than by popular consensus. Societal institutions such as work organizations and medicine are examined in terms of how they are organized and operate. The state, in its multiple institutional forms (e.g., legislative, executive, judicial, military, educational) actively participates in these struggles, but also reflects various forms of the interests of the most powerful. Multiple variants of state theory compete and co-exist as explanations in the work of critical gerontologists: elite, managerial, class, feminist, and race theories of the state. At the same time, gerontological work on the state remains limited and has increasingly become the purview of scholars working on the study of globalization (*see* Globalization and Aging).

Critical Gerontology and the Aging Enterprise

An important link between the analytic levels identified previously is found in the different ways that old age and the aged are defined and treated and their relationship both to personal interactions and self-concept, and to the structural arrangements and resource disparities in society. The social constructions of old age and aging are seen as a product of the attributions of others that are differentially influenced by those with the power to impose their particular views of reality, including ideologies and frames about what old age and aging represent. These social constructions produce positive and negative associations with, and connotations of, growing old as well as notions of what it is possible and appropriate to alter or remedy at all societal levels: individual, institutional, and systemic. It is relevant to point out, however, that, in the sense that the experience of old age is socially produced, it is neither immutable nor given entirely by the prevailing distribution of power and constructions of reality. Those who shape and determine the definition of the situation wield disproportionate control over the societal provision of old age benefits, the personal and public costs of care, and the structure of care provision. Nevertheless, individuals retain a strong sense of needing to control their lives and the potential to resist, individually and collectively. This is the human agency that is the driving force behind the development of critical knowledge in the pursuit of social change toward a more just society.

One major product of the relations between capital, the state, and the public that is of major consequence for older people is the development of the aging enterprise, first analyzed in the United States by Carroll Estes (1979) in the late 1970s. This term was introduced to call attention to "…how the aged are often processed and treated as a commodity in our society and to the fact that the age-segregated policies that fuel the aging enterprise are socially divisive 'solutions' that single-out, stigmatize, and isolate the aged from the rest of society." The aging enterprise is constructed through the various agencies comprising the medical industrial complex. This manages problems of aging through (in the United States) the provision of privately rendered medical and high-tech services (usually proprietary) at the individual level and through for-profit nursing homes. The framing (definition) and policy treatment of the needs of the old for health and social support promote the construction of the problem of aging as the need for market goods rather than for a social good such as universal entitlement to the continuity of benefits and a caring community without fear of famine. This framing underscores the key trends in market-driven reform and restructuring, the explosive growth of proprietary care, corporate mergers, for-profit managed care, and pharmaceuticals with increasing

consolidation and concentration of private medical, technological, insurance, and finance capital, not only on the national but also on the global scale.

In both medical and long-term care, major social processes of critical gerontological study include the successful commodification of aging through the biomedicalization of old age and the processes of privatization, competition, rationalization through care (cost) management, and the devolution of federal responsibility to ever lower levels of government and to the individual and family as well as the increasing informalization of care, with the bulk of long-term care provided free by women caregivers, often with the negative consequences of increased stress, morbidity, mortality, and poverty.

Race and Feminist Perspectives in Critical Gerontology

The examination of race and institutional racism is central to understanding both the origins and consequences of old age policy and the effects on diverse racial and ethnic groups, both individually and in the aggregate. State policy is examined in terms of how it is linked with race and ethnicity through both local and global processes of imperialism and immigration policies that facilitate the exploitation and oppression of Blacks and other minorities. Race and institutional racism within social structures and unequal power relations affect the political processing and treatment of different subpopulations, in large part depending upon the relationship to and experience with the dominant cultural, political, and economic systems. Income and wealth inequalities as well as those in health and health-care access are crucial in determining the (multiple) jeopardies and outcomes that may be experienced or endured in old age. Regrettably, analyses of the dimensions of race, ethnicity, and institutional racism in old age and aging societies represent one of the most underdeveloped areas within critical gerontology.

Feminist theory is an essential part of critical gerontology. Gender is a central organizing principle in the economic and power relations of societal institutions as well as social life throughout the life course, shaping the individual experience of old age and aging and the distribution of resources in old age to men and women. The state, the medical industrial complex, women's devalued role in social reproduction and family caregiving, and globalization are each examined as vehicles generating socioeconomic and other inequalities confronting women (and variously so) across the life course. In feminist political economy, attention is given not only to gender relations and sex, but also to social class, race and ethnicity, nation, and age. New principles of feminist economics incorporate non-market activities and the household as loci of economic activity and the concepts of cooperation and caring (not just competition) as appropriate areas for economic analysis.

A number of critical feminist scholars have contended that the state is a major vehicle for the subjugation of women and that the state is in itself a patriarchal institution. Feminist critical gerontologists have demonstrated that older women are more dependent upon the state than older men. A major goal of feminist political economy of aging is understanding how the state, multinational corporations, and capitalism, the sex and gender system, and institutional racism conjointly produce and reproduce the dominant institutions that render a large proportion of older women (particularly minority and non-married women) vulnerable and dependent throughout their life course. Important considerations are how gendered state policies define the problems of aging as individual problems of self-care and private family responsibility predicated on women's unpaid long-term care labor and, when formal care is required and this free care-work cannot be extracted from women, the purchase of care services sold for profit and usually provided by underpaid women. Research examines the relationships between the situation of older women and state roles that advance the interests of capital accumulation, a gender ideology, and the legitimation of capitalist and patriarchal social relations. Work from a critical feminist perspective on old age seeks to advance reflexivity and a feminist epistemology, explicitly working outside the frame of patriarchal thought. Following Dorothy Smith (women's standpoint, ruling relations, and institutional ethnography), Nancy Hartsock (feminist standpoint), and Sandra Harding (the science question in feminism), these approaches extol the value and validity of women's knowledge of everyday life while also challenging mainstream masculinist social science frameworks and methods.

Critical Gerontology and Social Inequality

Reflecting the influence of race and feminist perspectives, a central aim of critical gerontology has been to explore the characteristics of inequality as experienced by older people living within advanced capitalist societies. Patricia Hill Collins' concept of interlocking systems of oppression is part of a broader critical work on social inequality, as it points to the multiplier and layering effects of race/ethnicity, gender, class, age, and disability that reflect

and illuminate social structure and individual experience. Macro-level connections link systems of oppression such as race and gender with the state and other social institutions. At the micro level, intersectionality denotes the processes by which each individual and group occupies a social position with interlocking structures of oppression. Attention to social class has been a major issue for those taking a political economy approach within gerontology, with the view taken that older people are as deeply (or more) divided along class and other structural lines as younger and middle-aged adults. Critical perspectives have begun to clarify the range of processes likely to maintain social divisions in later life. The role of education appears highly influential and may play a crucial role in improving access to stocks of social and cultural capital, thus increasing psychological resources, healthy lifestyles, and general well-being.

An additional approach to understanding social divisions concerns the multidimensional way in which inequality and deprivation might be experienced in old age. In this context, the concept of social exclusion has been helpful in pointing to the range of factors that might limit involvement in mainstream social institutions. The idea of social exclusion is intended to recognize the range of problems experienced by older people living in poverty – material difficulties, certainly, but also social isolation, detachment, and low participation in mainstream institutions. Research in Britain by Scharf et al. demonstrates the extent to which older people living in areas of acute social deprivation (typically inner city metropolitan areas) may face multiple forms of exclusion with clear links operating between different domains of exclusion. In particular, there appears to be a strong relationship between exclusion from social relations and exclusion from material resources, confirming the way in which poverty and deprivation can combine to restrict participation in a range of informal social relationships. Such research raises issues about the role of social institutions in supporting older people's participation in daily life and, conversely, their potential to contribute to disengagement when financial and social resources drop below certain levels.

A central issue concerns future trends in social inequality through the life course. The likelihood is for a continuation of patterns of cumulative advantage/disadvantage, with these patterns constructed around gender, cohort, class, and ethnic divides. Gender is likely to remain a crucial component of inequality, with women especially affected by changes to the organization of welfare and social security. Price and Ginn, analyzing British data, found that divorced and separated women are at a particularly high risk of poverty in later life and that for this group this matches the individual poverty and lack of independent pension building – a situation from which women may find it difficult to recover if they are caring for young children and are in the part-time labor force.

Recognition of growing diversity and inequality within cohorts is another major theme within critical gerontology. Studies of the Baby Boom generation are likely to show wide variations in future income and consumption prospects, reflecting educational, occupational, gender, class, and other social factors. As shown by Johnson and Crystal from their study using US longitudinal data, there is the prospect for high income inequalities among American Baby Boomers during their retirement years, a finding matched in comparable European studies. This may be compounded by changes in employment conditions across the class divide, with improvements in the remuneration of professional and white-collar workers on the one side but with reduced wages, benefits, and job security for blue-collar workers on the other. The driving factors here include the growth of flexible employment (associated with decline in company benefits), changes to pensions with the move from defined benefit to defined contribution schemes, and the further deterioration in manufacturing employment in developed economies. More generally, the inequalities associated with the rise of globalization is an issue for critical gerontologists to address, as foregrounded in work by Chris Phillipson, Carroll Estes, and John Vincent and others (*see* Globalization and Aging).

Humanistic Perspectives in Critical Gerontology

Another important element within critical gerontology is the development of cultural and humanistic gerontology, sometimes referred to as moral economy or more broadly as cultural gerontology. This approach has gained popularity, as the classical theoretical opposition of structure versus agency and culture versus structure has given way to an appreciation of the interplay and recursive relationships of culture, structure, and agency. Cultural gerontology is part of the trend toward theories that reject the sole determinacy of economics in explaining social institutions such as the state and old age policy. The approach reflects a reformulation of the unidirectional causality implied in the classical base superstructure model of Marxism. What has followed is an intensified focus on questions of meaning and experience as applied to later life.

In the United States, scholars such as Tom Cole, Meredith Minkler, Joe Hendricks, and Anne Robertson, working from a moral economy perspective in gerontology, have brought attention to social norms and reciprocal obligations and relations in society and their role in the social integration and social control of the elderly and the workforce. Moral economy scholars examine popular consensus concerning the legitimacy of certain practices based upon shared views of social norms and obligations such as reciprocity and generational equity in relation to distributive and economic justice.

Humanistic gerontology adds yet another dimension to critical approaches to aging by seeking both to critique existing theories and to construct new positive models of aging based on research by historians, ethicists, and other social scientists. Harry Moody has identified several goals for the critical humanistic perspective in gerontology: (1) development of theories that emphasize and reveal the subjective and interpretive dimensions of aging, (2) commitment to praxis and social change, and (3) the production of emancipatory knowledge. Consistent with and complementary to the political economy, feminist, and race theories, this approach centers on the concepts and relations of power, social action, and social meanings as they pertain to aging. At its core, this approach is concerned with the absence of meaning affecting older people and the sense of doubt and uncertainty that is thought to permeate and influence their day-to-day lives and social relations.

A related focus in critical gerontology concerns the relationship between identity and adult aging, including understanding identity as managed and negotiated and representing both a source of restriction and a grounding for social action. In this approach, the varied experiences and meanings associated with old age and aging are the subject of study. This work has emerged as important for understanding emerging forms of human and political agency – and the effects of these on social policy and old age as well as individual and societal aging. Simon Biggs suggests that aging identities have been faced by two forms of excess: an excess of structure that confines the possibilities of adult aging to age stages and stereotypes and an excess of fluidity that disconnects aging from the material bases of experience that can lead to insecurity and risk. Both have served to place restrictions on acceptable forms of contemporary aging.

Three streams of social gerontology – that dealing with the humanistic and experiential side of aging and those attending to the meso institutional and the macro structural movements and forces – are each essential if the goal of understanding differences and inequalities among and between older people and other groups is to be achieved. Critical gerontologists including Jan Baars, Simon Biggs, Dale Dannefer, Chris Phillipson, and Alan Walker variously point to the problematics of postmodern social theory for gerontology. With Baars' concept, reflexive modernization, critical gerontology attempts to rescue the basic modernist ideals of self-fulfillment, solidarity, and human dignity, challenging approaches that remove experiences from the social structural frames within which they are created. Critical gerontologists caution against approaches that (1) individualize social and economic inequalities that dominate everyday life in old age and deflect attention away from the social, economic, and political forces that produce them, and (2) reject universal meta-narratives and truth-telling in ways that ignore or obliterate political power, economics, and sociocultural forces in the structuring of age-related outcomes. The contents, meaning, ideology, and consequences of the postmodern turn and poststructuralism in intellectual circles have produced intense debate within critical gerontology far beyond the parameters of this article; nevertheless, they foreshadow future scholarship in critical gerontology.

Future Developments in Critical Gerontology

Future developments in critical gerontology will be shaped by a commitment of its scholars to the larger intellectual project of critical theory understood as the critique and subversion of all forms of domination. The challenge to social gerontology and critical work therein is found at every level of human existence and analysis: macro, meso, and micro. The forces of accelerating global change, the increasing power of financial capital, deepening social inequalities, and the changing and challenging economic relations between workers and employers and between the people and their nation states are joined by other profound upheavals, cultural and religious conflicts, and the demographics, economics, and politics of societal and global aging – all of which have the potential to unravel the everyday life of groups of older people.

As new, evolving, and ruptured social relations profoundly affect the individual and societal experience of old age and aging, the existing conceptual and methodological tools within gerontology will need to be reexamined. The influences now affecting older people raise profound issues for the quality of their future lives. Important issues for study include developing critical theory and the larger project linking the personal to the political and the economic and the

cultural; theorizing and analyzing old age and the aging society in a global universe with attention to the state, citizenship, and social rights; understanding new social divisions and inequalities; and the critical study of intergenerational relations. In each of these areas, a major task is to illuminate alternative understandings and visions of what is possible in later life. A focus on the ideological is intended to open a critique of all that obscures and mystifies inequality and social injustice, including theoretical, epistemological, methodological, and empirical works. The critical lens aims to open up a distance between what people are told are the choices available to them, and their own views and expressions of their personal and collective needs. The distance facilitates the ability to discriminate between what we are taught to believe and the opportunities to build alternative possibilities for us and for our aging society. The emancipatory project necessitates both critique and distance to encourage a perception of the aging self as a conscious agent in spite of the circumstances in which social actors find themselves. Only then is it possible to discover and build upon common causes rather than disempowering differences between social groups. In this, the issue of solidarity re-emerges as a challenge to the age segregation, ageism, and growing inequalities and divisions in Western societies and across the globe.

Cultural and Ethnic Influences on Aging

S M Albert, University of Pittsburgh, Pittsburgh, PA, USA

Glossary

Culture – Shared beliefs, knowledge, feelings, and objects.

Introduction

Worldwide increases in life expectancy and declines in fertility, nearly universal in extent, make the question of cultural and ethnic variation in the aging experience more pertinent today than ever before. People born in more developed countries today can expect to live 40 years longer than they would have had they been born at the turn of the twentieth century; but even less impressive gains in life expectancy in the developing countries mean large increases in the absolute numbers of elderly. Additionally, declining fertility (which reduces the number of young people entering a population) and increasingly effective medical care (which reduces death rates at all ages) have led to an increase in the proportion of older people alive across the globe.

By 2030, the proportion of people aged 65 or greater will reach 20% in most European and North American countries, and the same trends will result in similar age distributions somewhat later in less developed countries. But the time it takes to reach such proportions of older people will be much shorter in the developing world. For example, in France and Sweden it took 82 years and 114 years, respectively, for the population aged 65 and over to double from 7 to 14%. This same transition took only 18 years for Singapore, 20 years for the Republic of Korea, and 25 years for Japan. A similar process is at work in developing countries; for example, Sri Lanka, Jamaica, and Tunisia will each achieve this doubling over the next 25 years. Unlike the developed countries, these societies are becoming old without the pension, social welfare, and health-care systems of the developed nations, making old age a more precarious experience than it is in the more developed nations.

Increasing immigration from developing to developed countries and the greater birthrates of many immigrant populations also suggest that recognition of cultural and ethnic variation in aging will become increasingly important. How will provision of health care and aging services have to be modified to reach these ethnic minorities? To what degree will clinicians have to alter assessment of elder health and well-being in the face of this increasingly multicultural elder population? What kinds of outreach or innovation in service delivery will be required to close the gap in outcomes between majority and ethnic minority populations?

Defining Culture and Ethnicity

While culture and ethnicity are often used interchangeably, in fact it is important to keep them distinct because they refer to different components of personal identity and social status. For example, in the United States it is possible to self-identify as Asian or Latino, drawing on one's ancestry, appearance, and national allegiance, and yet participate fully in American culture, not know how to speak the language of one's grandparents, and not even know anyone in the home country. Ethnicity as it is usually conceived (as in census records) masks a great deal of variation in acculturation, language, and culture relevant to health behaviors and outcomes in later life. The same is true of race, and indeed many researchers in gerontology and clinical research have given up trying to separate race, ethnicity, and culture and simply speak of ethnoracial, ethnic/racial, or sociocultural groups. But culture and ethnicity do not map together well. In the socially mobile, tolerant United States, it is likely that people self-identifying as an ethnic minority will vary in the extent to which daily life is governed by cultural conventions typically associated with this ethnicity. With assimilation and longer duration in the United States, cultural differences wane, and hence adult children may find themselves facing the severe challenges of cross-cultural communication even within their own families. This challenge may become most apparent when adult children serve as go-betweens between elders and home-care paraprofessionals and clinicians, or when their own expectations for old age clash with those of their parents or grandparents.

By culture, anthropologists refer to shared beliefs, knowledge, feelings, and objects. These kinds of shared experience may differ from those of the majority culture and the expectations of professionals who provide key services, such as health-care providers. For example, medical anthropologists have identified a variety of indigenous conceptions that do not square with modern medicine, such as misconceptions about hypertension or the strength of medications. To this, we might add more general expectations about aging. Are ethnic minorities more or less likely to consider pain, limitation in activity, or cognitive impairment normal in old age? Do they expect more or less from old age than non-minorities? These questions have only recently become topics for research, and the little research available suggests that expectations regarding aging and care in old age may differ across cultures. For example, in the United States, minorities are less likely to use skilled nursing facilities and perhaps are more likely to tolerate dementia and old age disability at home.

More generally, cultures are likely to differ in what they emphasize in the aging experience. We know from gerontological research that the senescence of biological systems typical of late age leads to both positive and negative changes. With each additional decade of life, adults will see declines in strength and walking speed and slowing in reaction time, for example, but they will also see declines in addictive behaviors and crime, reduction in severe psychiatric disorders, and increased contact with close family. American culture stresses the negative features of aging; aging is something to be fought or covered up. In other cultures, the stress may be placed on the more positive elements, as among the Samia of Kenya, who boast of aging as a time to sit by the fire and be fed. Americans, by contrast, consider dependence and need for help in old age worse than death.

One productive approach to cross-cultural variation in expectations about aging is to turn to differences in conceptualization of the life course.

Anthropologists and historians have documented variation in the periodization of developmental processes, that is, how human development over the life span is divided into phases or stages. American ideology stresses discrete stages of adulthood: education, employment, retirement. The transition to retirement may be punctuated by a major journey or long-awaited indulgence postponed during one's career. In Taiwan, by contrast, human lives are likened to the growth cycle of rice. Major stages of life are defined in terms of fertility, decay, and reintegration into the earth. Beyond old age and death is ancestorhood, an important and valued stage of life.

In some social groups age is the dominant principle of social classification. The age-set systems of east Africa, the mandatory age-based clubs of Japan, the junior–senior distinctions in ranking systems (such as the military), and even the freshman through senior designations of colleges and fraternities all use age, or peer groupings roughly based on age, to assign social duties and privileges and to enforce group-wise transitions in status. With age as the prominent element of rank, old age should have greater prestige in such societies or organizations, yet case studies suggest that the position of the elderly in these societies varies considerably.

Relevance of Culture and Ethnicity for the Experience of Aging

When people think of old age, they first think of years or some other indicator of the passage of time (for example, in societies in which people do not use year-based calendars, these indicators might include the number of harvests completed, number of ritual cycles conducted, or number of relocations of dwellings). But even in contemporary cosmopolitan cultures, old age is not simply a matter of chronologic age. Survey results show that the age at which people are considered old varies according to one's own age (the older one is, the later old age is said to begin), gender (women date the start of old age at later ages), and socioeconomic status (old age is said to begin at younger ages among minorities, perhaps out of recognition of shorter life expectancies).

Similarly, when people are asked to group social statuses, chronological age is only one factor affecting ratings. Such cultural dimensions as productivity, vulnerability, and reproductive potential also matter, so that respondents group old people and children together in some cases, distinguishing them from people of middle age. This finding is consistent with research on the infantilization of older people. Baby talk is often used with older people with cognitive impairment or other disabilities, and terms typically reserved for children (for example, diminutives and saccharine terms) are often applied to older people. The reverse is also true: younger adults who are not active, not interested in new experiences or travel, not willing to switch careers, or slow, deliberate, or narrow-minded are often called old. This use of language suggests the negative conception of aging typical of American society. People are old not just because of their age but also because of their behavior, their health, their attitudes, their choices, and even their politics. Thus, in American society, adults can refuse to grow up, and people can insist on not acting their age. Marriages that cross generational lines (so-called May–December weddings) are disparaged and considered nearly incestuous. In many Asian and African societies, by contrast, large gaps in the age of marriage partners (with men much older than women) are not exceptional.

Clearly, these overall evaluations of old age, some subtle, some not, are part and parcel of the status accorded to elders. In all societies and perhaps more so in developing countries, deference and respect for the elderly may be universal (reflected very well in antiquity in Homer's description of a chariot race, in which the trophy is given to the slower elderly warrior just because he is old; the poet remarks that it would be unseemly to give it to the younger, faster competitors). Yet even in societies with well-developed traditions of respect for the elderly, reports of neglect and the precarious status of the elderly are accumulating. In developing countries, migration of young people to cities (or to other countries for employment) reduces the availability of family caregivers and may further jeopardize elders.

Variation in Resources Available upon Entry to Late Age: Health Disparities

Ethnic and cultural minorities enter old age with cumulative disadvantages. They are more likely to report poor health, perform more poorly overall on tests of physical and cognitive function, report a greater number of medical conditions, and on the whole have less wealth and poorer health insurance coverage. Reasons for poorer physical and cognitive performance are not completely clear but likely reflect less or poorer-quality education, more physically demanding occupational exposures over the life span, less access to medical care in child- and adulthood, and many other risk factors associated with lower socioeconomic status. Cultural status may also have an independent effect. For example, Hispanics in the San Luis Valley study are more likely to report

poorer health than White elders, even in analyses that adjust for health conditions and physical performance. On the other hand, minorities may have some advantages upon entry into old age. The Health and Aging Body Composition study found that African American men and women had better bone health than Whites and were less prone to fractures. But the same study has also shown poorer cardiovascular health among African American elders.

In the case of medical conditions, differences between White elders and minorities in the United States are impressive. In the 1990s White and minority elders both saw declines in mortality from heart disease, stroke, lung cancer, and breast cancer (and also in motor vehicle crashes, suicide, and homicide). In some cases, minority elder mortality declined to a greater degree. For example, stroke mortality declined 11.1% among African Americans, 8.2% among Hispanics, and 8.1% among Asian and Pacific Islanders, compared to a decline of 7.2% among White elders. (An exception to this pattern of decline is evident in Native American populations, which saw an increase of 2.6% in stroke mortality over this period.) These trends are welcome in that they reflect progress in eliminating disparities in health service access and outcomes. Still, overall differences in stroke mortality remain impressive. For example, age-adjusted death rates (deaths per 100 000) from stroke at the end of the 1990s were 23.3 for Whites and 42.5 for African Americans. Hispanic mortality from stroke is more similar to rates seen for Whites.

The case of heart disease, the largest source of mortality in old age, shows that some ethnic and cultural groups may face lower risks than the majority group. At the end of the 1990s, risk of death from cardiovascular disease (again, age-adjusted deaths per 100 000) was 123.6 for Whites and 188.0 for African Americans, but 84.2 for Hispanics, 97.1 for Native Americans, and 67.4 for Asians and Pacific Islanders. These figures should be interpreted with some caution, however, since they represent only a single source of mortality, and ethnic and racial minorities also suffer health disparities that increase mortality risk at early ages.

Disparities in the risk of physical disability in old age are also narrowing. Disability has declined 1–2% per year among African American and other elders, at least in the case of highly demanding household tasks. However, ethnic and cultural minorities report greater prevalence of disabilities. In the Health and Retirement Survey, African American elders were more likely than non-Hispanic Whites to report difficulty or need for help bathing (6.7 vs. 2.4%), using the toilet (7.4 vs. 3.0%), transferring from bed or chair (11.1 vs. 4.5%), dressing (12.6 vs. 5.7%), and walking across a room (8.5 vs. 3.5%). Similar differences were found for indicators of upper and lower body strength and dexterity, such as difficulty lifting and carrying 10 lbs (27.8 vs. 14.4%) or using fingers to grasp and handle objects (7.0 vs. 3.9%). These differences were even more pronounced in comparisons of inner city and suburban African Americans.

Some of these differences in prevalence may be explained by lower recourse to use of skilled nursing facilities by ethnic and cultural minorities. The most frail and disabled elderly are likely to reside in nursing homes. If a minority cultural group does not make use of nursing facilities to the same degree as other groups, its community-dwelling elderly will be more likely to include greater numbers of the very disabled. A good illustration of this bias can be seen in the San Luis Valley study of Hispanic elderly, which also found a greater prevalence of disability compared to White elderly when the sample was limited to community-dwelling elderly. However, when nursing home elders from the same survey were included, Hispanic and non-Hispanic Whites did not differ in the prevalence of disability. However, this absence of differences raises an even more intriguing question. How is it that Hispanic elderly enter old age with less income and education, yet do not show a greater prevalence of disability when compared to non-Hispanic Whites in the same region?

The same issues in cumulative disadvantage are evident for cognitive test performance and risk of dementia. Early estimates of the prevalence of Alzheimer's disease among community-dwelling elders were surprisingly high (about 10% of people aged 65 and older), in part because they were based on surveillance in the Italian enclaves of south Boston, a group that also shuns use of skilled nursing facilities. In fact, current estimates suggest about 5% of people aged 65 and older meet criteria for Alzheimer's disease. But the incidence, or risk of Alzheimer's disease, does indeed differ by cultural group status. In one prospective analysis limited to people without APOE-ε4, a genetic risk factor for Alzheimer's disease, Hispanics and African Americans faced a significantly higher risk of disease. By age 75, 2% of Whites and 9% of minorities met criteria for the disease. By age 80, about 9% of Whites and 21% of minorities were affected. These large differences in incidence persisted even with statistical control for differences between the race–ethnicity groups in a great variety of risk factors for Alzheimer's, such as years of school, family history of the disease, number of comorbid chronic disease conditions, and behaviors such as smoking and head injury.

Recalculating incidence using a stricter definition of dementia to identify only clear and obvious cases of Alzheimer's disease (moderate or more severe dementia) also did not eliminate differences between the race–ethnicity groups.

These differences in the risk of Alzheimer's by cultural status raise important questions. Do we overdiagnose minorities (and if so, why?), or do we underdiagnose Whites (and again, if so, why?)? Why should minorities be at greater risk of developing Alzheimer's? Is it because they enter later life already with poorer abilities? Or do they enter later life with abilities similar to Whites, but decline at a faster rate in old age? The first factor suggests an effect in the first 50 years of life, the second an effect in the second half of life.

Evidence suggests the first explanation is more likely to be true. In a study of non-demented community-dwelling elderly, 16.3% of Whites scored in the lowest third of memory performance, but 32.4% of African Americans and 44.4% of Hispanics scored in this range. This difference strongly supports the claim of early life events as a predictor of a key late-life outcome. Minority elders enter later life with less cognitive reserve. By contrast, the slope of memory score change over serial assessments, that is, the mean rate of decline, was not significantly different across the three race–ethnicity groups. Thus, cognitive performance in minorities did not decline at a faster rate. Baseline differences, differences that predate old age, appear to be responsible for the higher risk of Alzheimer's disease among ethnic and cultural minorities.

Variation in Family Caregiving and Intergenerational Exchange

Ethnic and cultural groups differ in their commitment to family care. African Americans are more likely than Whites to endorse the primacy of family care, and accordingly are less likely to make use of formal long-term care, including respite, home care, adult day programs, skilled nursing facilities, and hospice. Similarly, Latinas delay institutionalization relative to Whites; a higher cultural value assigned to family care leads to more positive views of family caregiving, which in turn leads to a more negative evaluation of skilled nursing facilities as an option for dementia or end-of-life care. These differences, however, may be narrowing. With the rise of alternative living situations for the frailest elderly, such as assistive living and continuing care retirement communities, the proportion of White elders in skilled nursing facilities has declined and the proportion of minorities has increased.

Differences in commitment to family care are based on cultural norms of filial piety or obligation. The Chinese concept of *xiao*, or filial piety, is a well-developed element in Chinese culture, which, however, is strongly gendered, so that the burden of such care falls on adult daughters or daughters-in-law, not sons. Caregiving in American families shows a more variegated pattern, both in underlying concepts and in the division of labor (though caregiving to disabled elders remains mostly women's work). Ideas of filial obligation are linked to conceptions of parental dependency. Caregivers who view the obligation to provide care as a matter of reciprocity ("she was a good mother; now I need to take care of her") are likely to view the elders as simply sick, disabled, or in need. Caregivers who view the obligation as a matter of bodily connection ("she is my mother") are more likely to speak of caregiving as a reversal of roles, viewing the parent's decline as a return to childhood. Americans who view caregiving as a matter of reciprocity may be more likely to use the nursing home as a care option. This recourse usually occurs late in the caregiving career, when families perceive that the bounds of reasonable reciprocity (and family ability to meet elder needs) have been exceeded. In the United States, norms of filial obligation are heavily influenced by education, with greater acceptability and use of nursing homes evident among more highly educated people.

With norms of filial obligation and positive appraisals of caregiving demands, ethnic and cultural minorities are more likely to report satisfaction in caregiving. Latina caregivers report lower appraisals of stress and greater perceived benefits of caregiving; they also make greater use of religious coping than Caucasian caregivers. Similarly, African American caregivers report lower anxiety, greater well-being, and more perceived benefits of caregiving than Caucasian caregivers.

Is caregiving an extension of other intergenerational relationships, such as provision of financial and other kinds of instrumental support? A prospective study of relationships between adult child and parents, first when children were in their 20s and parents in their 40–50s (1970s) and again 25 years later (1990s), yields some insight. Parents who spent more time with their adult children and provided greater economic support were more likely to receive instrumental and caregiving support from adult children 25 years later.

Evidence from a number of different settings suggests that this investment or insurance mechanism for intergenerational relationships may hold across cultures. For example, in a Taiwanese sample, the odds of nursing home admission were lower for

elderly who provided instrumental assistance to their families before they were disabled. However, in other settings, where the norm of filial obligation is paramount, the correlation between help provided early in life and the provision of caregiving later in life may be less strong.

It is also worth noting that exchanges of goods, time, and care are also a vehicle for perpetuating continuity across the generations. When elders are no longer able to reciprocate in such exchanges, maintaining continuity of the family becomes more difficult, and this threat may be more or less well managed across cultures. Cross-cultural investigation of this area is relatively undeveloped.

Relevance of Culture and Ethnicity for Assessment of Elderly

Cognitive Status

Despite some thought that ethnic or cultural minorities may differ in the recognition of dementia in elders (for example, finding dementia behaviors more acceptable), in fact such differences appear to be an artifact of knowledge about dementia or access to dementia care. On the other hand, the challenges of cognitive assessment in non-literate or low-literate populations are profound, and, as discussed earlier, reasons for the poorer performance of minorities in cognitive assessment remain unclear. Poorer performance is apparent in non-verbal as well as verbal tests and is visible in even the most basic tests of mental status, such as the Mini-Mental State Examination. Part of the explanation for lower performance lies in the lower educational attainment of minority populations, since education is strongly associated with neuropsychological assessment. However, even when African Americans or Hispanics are matched with Whites of similar educational experience, performance of minorities is poorer, though differences are attenuated. The explanation may lie in poorer quality of education or lower literacy of minorities despite equivalent educational experience.

Physical Function

While ethnic and cultural minorities are more likely to report poorer physical function (such as need for help bathing or lifting groceries), physical assessment does not appear to suffer the same test biases as cognitive assessment. Still, major differences in strength, speed, dexterity, and sensory acuity have been reported for ethnic and cultural minorities. For example, in a New York City sample of elderly Whites, African Americans, and Hispanics, the groups did not differ in grip strength, as measured by a hand dynamometer. Only expected differences by age and gender were apparent. However, when compared to a sample of New Delhi elders, major differences were apparent. The Indian elders demonstrated only about half the grip strength of the Americans, even when the groups were matched by age, gender, self-reported disability, and disease status. Since expected differences were also evident in the Indian sample (women had lower grip strength than men, diabetics had lower grip strength than non-diabetics, etc.), the great difference in grip strength between American and Indian elders likely reflects lifelong effects of poorer nutrition, more challenging manual labor, poorer access to health care, and related factors.

Affect and Mental Health

Mexican Americans appear to be at greater risk for depressive symptoms than Whites in the same geographic region, and the prevalence of such symptoms is strongly related to degree of acculturation. The greater prevalence of poorer mental health (anxiety, depressive symptoms, poorer morale, panic syndromes) has been reported for a number of different ethnic and cultural groups in the United States. However, the difference in prevalence is likely due to the challenges of assimilating to a new and often very different society, and not to features of culture or ethnicity per se. Also, the status of mental health symptoms varies across cultures; for example, it is not clear that feeling anxious or loss of interest mean the same thing to a new immigrant from, say, Cambodia, and an elder American. Indeed, psychometric studies of depression measures suggest that assessment items do not travel well across cultures. Items that typically form a scale in American samples (such as dysphoria or somatic symptoms) do not correlate highly in non-American samples. This has led some investigators to conclude that depression may differ across cultural groups. Different psychometric properties for depression measures have been reported for Korean, Native American, and African American elders relative to White elders. How these differences in the experience of mental health symptoms may matter for mental health service use is another area in need of further research.

Relevance of Culture and Ethnicity for Health Promotion in Late Age

Ethnic and racial minorities are less likely to take advantage of preventive health services, such as vaccinations and cancer screening, even when they are available. Again, it is hard to know how much of

this difference in service use is related to aspects of culture (such as a different understanding of prevention in late life or differences in the degree to which people view health as a matter of personal agency or entitlement) and how much is related to the cultural insularity that characterizes many ethnic enclaves. Cultural insularity in this context refers to restrictions in access to health information related to culture, such as not speaking English, but also religious proscriptions against contact with mainstream culture, for example, watching television or reading English language newspapers. This kind of insularity may have an important significance for health in ethnic communities organized around religious belief. In an orthodox Jewish sample of older women in Brooklyn, New York City, the prevalence of mammography, Pap smears, and colorectal cancer screening was low compared to New York City women of similar age and education. Use of these preventive services was lowest in the orthodox women who reported least exposure to mainstream sources of health information. It is important that ethnic and cultural communities that wish to maintain traditions and yet participate in effective disease prevention and health promotion efforts mobilize community resources, perhaps in partnership with public health agencies, to develop appropriate delivery of information in culturally acceptable ways.

Summary

The older world in the making will be a multicultural older world, with the majority of elders living in developing countries but with greater numbers crossing borders and immigrating to the United States as well. Thus, recognition of ethnic and cultural differences is likely to become more important for understanding variation in aging and how best to address the needs of an aging world. As this brief article has shown, cultural and ethnic differences in aging pose challenges to assessment, treatment, and service delivery. By way of summary, we can now address the questions posed earlier.

How will provision of health care and aging services have to be modified to reach these ethnic minorities? Clearly, service providers will need to understand more about cultural differences to deliver care effectively. Ethnic and cultural minorities may not mean the same thing as a White elder when they report anxiety, they may have lower reserves of physical and cognitive ability even before they develop frank disability, their families may play a greater role in health management, and they may be more resistant to use of available long-term care services. Clinicians and other service providers will need to develop partners in ethnic and cultural communities, or better yet train minorities to deliver care.

To what degree will clinicians have to alter assessment of elder health and well-being in the face of this increasingly multicultural elder population? The challenges of assessing cognitive ability in a nonliterate or low-educated elder are clear. Similarly, culture-specific measures of mood, sensitive to reporting styles, will need to be developed in some cases if we are to target therapies to ethnic and cultural minorities. Other areas of old age experience, such as physical assessment or recognition of dementia, may be less influenced by culture.

What kinds of outreach or innovation in service delivery will be required to close the gap in outcomes between majority and ethnic minority aged populations? Evidence, summarized here, suggests that the gap in access to health services and in health outcomes is closing in the United States. Yet disparities continue to be large in some cases, such as between Whites and African Americans. The availability of an expanding universal health insurance system for the elderly has gone a long way in closing the gap in access. However, the gap in health outcomes is more difficult and remains a challenge for the future.

Death and Dying

R Kastenbaum, Arizona State University, Tempe, AZ, USA

Glossary

Advance Directive – A document that instructs physicians on the type of treatment a person wishes to receive if unable to express his or her wishes at a later time because of impairment; the living will is an early type of advance directive.

Brain Death – A condition in which vegetative processes of the body persist although the capacity for thought, experience, and purposive behavior has been destroyed.

Coma – A state of deep unconsciousness from which the individual cannot be aroused but in which the brain may remain intact with the possibility of recovery.

Death Anxiety – A turbulent emotional state that may be aroused when people encounter a life-threatening situation or reminders of their mortality.

Dying – Process of physical decline that ends in death. This term emphasizes the person who is living through the process, as distinguished from the medical condition itself.

Hospice – An alternative to traditional medical care for dying people that gives highest priority to relief of pain and other symptoms (also known as the palliative care approach).

Life Expectancy – Statistical estimate of the number of years of life a person is likely to have remaining; can be calculated from date of birth or from one's present age.

Minimally Conscious State – Severe impair that is distinguished from coma or vegetative state by limited and occasional evidence of awareness.

Organ Transplantation – Removal of body parts from a person at death to restore function or save the life of another person.

Persistent Vegetative State – The continuation of vital body functions over a period of weeks, months, or even years despite the individual's lack of responsiveness (a condition that is often maintained through the use of a ventilator and/or other life support devices, but that may also exist spontaneously).

Terminal Illness – An incurable condition that will lead to a person's death within 6 months or less. The period immediately preceding death is known as the end phase.

Introduction

Death has become ever more patient in fortunate societies such as the United States. The addition of three decades to the average life expectancy since the turn of the nineteenth century has been achieved mostly by protecting survival of the young (*see* Life Expectancy). Coming later rather than sooner, death is now increasingly associated with long-lived people. The need for informed decision making regarding end-of-life issues has also increased with a growing population that has reached its 'three score and ten' and kept going.

New Questions about Death and Dying

"What is death?" is a classic question that has been much pondered by philosophers and theologians through the centuries. Today, the question has become, "When is this person dead?" Traditionally, this determination was made by observing the lack of respiration, pulse, and response to stimulation as well as by lowered body temperature (hypothermia). A person was considered to be 'dying' when vital functions were failing and his or her doctors conceded there was noting more to be done. This situation changed as a result of three related developments: (1) longer intervals between onset of illness and death, (2) life support technology, and (3) organ transplantation. Financial considerations are salient in all of these developments: medical care that

is prolonged and intensive runs up the expenses, and there are high stakes in the process of organ harvesting and transfer.

In the past, deaths often occurred after an acute illness or traumatic injury. People today are more likely to live with a life-threatening illness for months or years. The distinctions between 'chronic illness,' 'terminal illness,' and 'dying' are sometimes blurred. The terminology remains important because people are treated differently in subtle ways when defined as 'dying.'

Life support technology that maintains respiration and other vital functions has become increasingly available in technologically advanced nations. This technology has helped people recover from acute medical crises. More controversial is its use with patients who are unresponsive and who seem to have little or no chance of recovery. Much confusion surrounds the patient who is unresponsive or nearly so. The doctors may diagnose brain death, but family members may see a person who looks physically intact and who, in some cases, goes through a sleep–waking cycle, moans, and makes non-purposive movements. The absence of electrical activity and blood circulation in the cerebral cortex signifies the loss of capacity for thought, experience, and purposive behavior that led to the introduction of diagnosis of brain death. The situation is complicated by the fact that vegetative functions can persist if lower centers in the brain stem are still operating.

In recent years it has become more widely acknowledged that the diagnostic situation is even more complex. The patient might be comatose, a condition of deep unconsciousness but with the possibility of intact brain and full recovery. Alternately, the condition might be a transient vegetative state, the lack of mental activity having been caused by drugs, extreme cold, or an injury from which recovery is possible. Yet again, the patient might be in either a persistent or a permanent vegetative state (a judgment made when the condition is of long duration). In the less often discussed minimally responsive state, there are limited signs of awareness, suggesting that the underlying brain damage is not total. Perhaps the most harrowing condition is the locked-in syndrome, in which the patient is immobile and non-responsive – but is conscious and able to communicate through eye movements. (This condition is thought to be rare, but its actual incidence has not been firmly established.)

Differential diagnosis requires a high level of expertise. It is not surprising when people without such expertise and access express varying opinions about the status of the patient. Furthermore, opinions can be influenced by the perceivers' values and needs. Conflicting interpretations of the non-responsive patient's situation have often been resolved through discussion. Sometimes, however, they have led to widespread public involvement, including the highest reaches of the executive, legislative, and judicial branches of government. The controversy usually centers on the ethics of continuing or withdrawing life support for a person who is either dead or not dead, depending on the standards applied. The most widely publicized cases have invariably involved young women. This pattern might be taken as another example of age bias in life and death situations (*see* Ageism and Discrimination; Ethics and Euthanasia).

Organ transplantation has further intensified the question of how death should be defined and determined. Those with a stake in successful organ donations are inclined to define 'dead' so as to maximize the harvesting of organs at the earliest possible time. Those involved with the care of a non-responsive patient are inclined to favor more restrictive criteria. Two competent and well-intentioned physicians, then, may have different approaches to defining the same person as either alive or dead, depending on their goals and responsibilities.

The ordeal of grieving and mourning is complicated when the loved one appears to be not yet dead but no longer quite alive. The emotional stress on family and friends makes it difficult for them to carry out their other responsibilities (e.g., parenting, working). As much as they might cherish the patient, they may also feel the need to get on with their own lives, a need that seems in this situation to have been thwarted by medical technology (*see* Bereavement and Loss).

Attitudes and Their Consequences

Mainstream American attitudes have tended to marginalize elderly men and women. Unfortunately, elderly people are also subject to our society's aversive attitude toward dying and death. The risks of bereavement and terminal illness increase with advancing adult age, placing us in double jeopardy of rejection by a society uneasy with both aging and death. Widowed elders may be shunned even by their peers because they have been touched by death. A member of a widowed persons' support group explains: "First, most people don't know what to say to you, so they get tight and jittery around you. But second, and more important, they look at you and think, 'That could happen to me, too!' You just being there reminds them that death is real and husbands die and this could happen to them, too." Fortunately, peer support groups for bereaved people have

become more common in recent years (*see* Widowhood and Widowerhood).

People apprehensive about their own aging often project this negative attitude. For example, my walking companion noticed an elderly couple strolling by a lake. She confided, "I will never be an old woman. I will never let myself become dependent. I will never just sit around and watch the world go by. I will never die slowly and painfully. Let me assure you, I am being serious. One of these days, while I still have my health and independence, I will end my life. And I have it all worked out." This intelligent and robust woman in her early 50s described the specific method she would use to commit suicide. "I have seen plenty of old people," she added for emphasis, "so I don't intend to be one." Meanwhile, the elderly couple who had innocently provided the stimulus for this monologue continued to stroll around the lake, hand in hand. The woman who assumed that aging would be worse than death had not conversed with the couple and had no direct knowledge of their lives: she was a prisoner of the societal stereotype she had imposed on them – and on herself.

The most salient societal attitudes toward elders include the following:

1. Discomfort with one's own future status. American society encourages the development of a self-concept that does not encompass the entire life course. The 'I' who will face bereavement, grow old, and die is excluded from the sense of self. One may cling to the following scenario: "I will never grow old. And I will not be there when I die, because that person will be a stranger, not my real self."
2. Negative characterization of elderly persons and persons who have been touched by death. Elderly persons are assumed to be frail, lethargic, asexual, senile, incompetent, useless, and burdensome. Dying and bereaved persons are presumed to be depressed, bitter, and withdrawn. This negative attitude contrasts with the experiences of caregivers who have discovered that people bring many distinctive personal strengths into the later years of their lives. People who have entered the lives of elders in the role of caregiver or researcher often report that they have themselves received something valuable from the relationship.
3. Legitimization of avoidance strategies. Negative stereotypes provide justification for avoiding intimate contact. These justifications may be expressed in statements such as "It's better to avoid sensitive topics like, well, you know what." Under the surface of these propositions lies the anxiety of confrontation with those who remind us of our own unresolved problems with aging and death.
4. Communication, when it cannot be avoided, that is governed by special rules. When younger adults converse with elders they tend to use 'secondary baby talk,' a simplified speech accompanied by exaggerated intonations and facial expressions. Through this strategy, they attempt to restrict what the other person can say. Studies have repeatedly shown that most people try to keep a greater physical and social distance between themselves and those who are perceived as dying or grieving. Egalitarian give and take is replaced by 'down-talking,' in which the elderly, bereaved, or dying person is treated as inferior in terms of status, power, and value.

The convergence of negative attitudes toward both aging and death is consequential. For example, it is often assumed that the death of an elderly person is relatively unimportant. Little attention was given to the psychological, social, and spiritual needs of the dying person until the introduction of the hospice concept. Elders who reside in institutions are still likely to die alone, however, with sedation replacing companionship. This dismissive approach affects those who participate in the process. Staff members in nursing care facilities report feeling more depressed about their own future because they have seen repeatedly how the deaths – and therefore the lives – of elderly residents have been accorded little respect. This dismissive process also ignores the needs of those who loved and valued the deceased. Societal attitudes that legitimize turning away from the dying elderly person can therefore have long-term adverse consequences.

The death of an aged person is still the occasion for elaborate funeral and memorial observations in some societies, such as the Hmong, both in their homeland (Laos) and the United States. The rites of final passage affirm both the person whose life has just ended and the fundamental values of the group. By contrast, funeral directors continue to report that the general preference among Americans is for services that are brief and 'not too emotional.'

In planning the funeral and memorialization process for elderly people, there are often special circumstances to consider, such as the following:

- Conflicting ideas about the value and purposes of a funeral; generational differences within the family often are the source of dissension
- Unresolved family issues and grievances that are activated by the funeral process
- Uncertainty or conflict in deciding who should make the decisions
- Difficulty or inability of other aging family members to travel
- Financial hardship

Families that engage in open and ongoing discussion about life and death issues are more likely to avoid conflict, confusion, and regrets when the time comes to make these final arrangements.

Individual Orientations toward Dying and Death

We turn now to the elderly person's own view of dying and death.

Death Anxiety

Do we become more anxious about death with advancing age? Not necessarily. Elderly people most often report a decrease in death anxiety over the years. The most frequent explanation is that "I have had a life." A strong marriage, the nurturing of children and grandchildren, and a sense of having met one's responsibilities in all spheres of life are accomplishments that death cannot invalidate. Death anxiety scores generally are higher among young adults, who voice concerns about their plans and desires that might never come to fruition. People who are still searching for their personal identities and sense of worth are more likely to feel threatened about the possibility of a foreshortened future than those who have a firm sense of self, value, and accomplishment. Age, however, is only an indirect variable. Young adults can achieve a sense of living fully and well, and elderly adults can be burdened by a sense of disappointment, regret, and unfulfillment.

Another major contributing factor to reduced death anxiety in the later adult years is cumulative experience with losses and limitations. A person of 80 is unlikely to retain the 20-year-old's sense of invulnerability. Most people learn how to accommodate themselves to the changes that occur over a long life. A person may at first resent the need to acquire glasses or a hearing aid, but then utilize these devices to maintain quality of life. One elder observed: "I stopped being immortal a long time ago. I am in the flow of life, the flow of aging, we all are. This flow, this river delivers us into the great sea. That's life. That's just the way things are."

People who throughout their lives have depended on other people to cope with anxiety-arousing situations are likely to continue to do so when they are faced with death-related situations. This behavioral consistency is also likely for those whose preferred coping technique has been counterphobic (seeking out encounters with sources of fear, e.g., by taking extra risks with their lives), avoidance, or intellectualization. Problems arise when a preferred strategy for coping with anxiety is no longer available or effective. For example, a person who has characteristically bolted from difficult situations and relationships may discover that there is no easy way to escape from a failing body.

Some people do experience heightened death anxiety with advancing age. This is most likely to occur under four circumstances: (1) acute symptomatic episodes, (2) perceived lack of social support, (3) failure of coping strategies, and (4) fear of rejection or punishment by God. In a person with emphysema, for example, who is stricken by alarming episodes of respiratory distress, it is the increasing vulnerability to these episodes rather than age per se that heightens his or her death anxiety. People who feel alone and abandoned are also likely to experience death anxiety more often and intensely. Multiple and unremitting life stresses can overwhelm the individual's confidence and sense of security. A spike of death anxiety in such circumstances does not necessarily signify that the person's life is actually in acute jeopardy. Rather, death has become the symbol of one's feeling of helplessness and dissolution.

Elderly people tend to be more concerned about the manner in which they will die rather than the fact of death per se. Elderly men and women often express concerns about becoming helpless, dependent, and subjected to life support devices. Fears of disfiguration, pain, and clouded consciousness are voiced more frequently and with more intensity than fear of death. By and large, elders seem to come to terms with their mortality, whether through faith in God and survival, or through a philosophical acceptance. Many elders cherish each day's gift of life, neither seeking nor hiding from death.

Living through Dying

Denying the fact of terminal illness used to be a common strategy in the United States and many other nations. Bedside visitors would assure dying people that they would soon be up and around. Ironically, the dying person's hesitancy to share his or her thoughts was often interpreted as denial when it was actually a strategic maneuver intended to reduce the anxiety of family and friends who were themselves hesitant to face the facts.

Dying people also were deprived of reliable communication and social support because they were unwelcome reminders that medicine could not always work miracles. Furthermore, the dying person often suffered unrelenting pain and other stressful symptoms that were not well controlled by the prevailing customs of medical management. Restricted in communicational interactions, rejected as medical failures, and left to their suffering, terminally

ill people were hard-pressed to find comfort and value in the end phase of life.

This pattern of avoidance, suffering, and social isolation is now being transformed by two developments:

1. Death education and counseling. Academic courses and professional workshops on death and dying started to appear in the mid-1960s. The research of Herman Feifel exposed the cultural taboo on death, and the lectures and writings of Elizabeth Kubler-Ross encouraged professional caregivers and family to discuss these topics openly. Counselors willing and able to help people deal with dying, death, and grief have also become more available in connection with the death education movement.
2. Hospice and palliative care programs have proven a valuable alternative to traditional medical management of terminal illness. Compassionate and effective care of the dying person has become a higher priority. Those who select the hospice alternative – especially at a relatively early point in their terminal illness – are likely to benefit from improved techniques for controlling pain and other symptoms, as well as from the opportunity to live at home much of the time. The improved comfort and communication associated with hospice care enables dying people to draw more fully on their own resources and the resources of their most valued companions.

End-of-Life Issues and Choices

Elderly adults are becoming increasingly interested in learning about end-of-life issues and choices. As a woman in her late 80s observed, "I am still responsible for my life. I think I should take some responsibility for my death, too, don't you?"

It may be necessary first to overcome the resistance of adult children to discussing end-of-life issues. Often they need to be reassured that their parents or grandparents are neither depressed nor fragile. Rather, it simply makes sense to discuss death-related issues within the family, make the choices, and then go on with life. The alternative is to be overtaken by events and not have the opportunity to have one's preferences fulfilled. Many families are discovering that by confronting end-of-life decisions they are also becoming more aware of priorities and decisions for making the most of their own lives.

End-of-life decisions include distribution of personal assets, funeral and memorial arrangements, and choice of hospice or traditional medical care. Many experts believe it is the advance directive for health care that deserves the most attention. The current regulations and options evolved from the living will, which was introduced in 1968 as one of the first expressions of the nascent death awareness movement. The living will was intended as an instructive document for health-care personnel should a situation arise in which there was no reasonable expectation of recovery and the patient was too impaired to communicate his or her preferences. The living will requested that physicians administer medication to alleviate suffering, even if this would shorten the patient's life. However, physician were also asked to refrain from trying to keep the person alive by medications, artificial means, or 'heroic measures.'

The living will was received favorably by the American public. However, the document was not legally enforceable: health-care personnel were under no obligation to act in accordance with the instructions. Many physicians who sympathized with the idea behind the living wills hesitated to act upon them, out of concern that they might be accused of malpractice, or even homicide. Additionally, the language was too vague and the instructions too general to serve as guidelines in many situations (e.g., precisely what is 'artificial' or 'heroic'?). These problems were partially remedied as state legislatures passed bills that established some version of the living will as a legal document (often called 'natural death acts'). This was followed by a new generation of advance directives that encouraged the individual to be more specific. Every health-care institution that receives either Medicare or Medicaid reimbursements is now required to ask all clients about their preferences should a terminal illness arise. Patients must be informed of their rights to accept or refuse treatment and to provide their health-care facility with an advance directive if they so desire. The effectiveness of this regulation, however, depends much on the hospital's dedication to presenting the information in such a way that the patient understands the options and has a pressure-free opportunity to consider them. There have been numerous complaints about the manner in which the informed consent process has been carried out.

The major advance directive options (**Figure 1**) may at first appear similar, but the differences can be critical when guiding medical decision making during a crisis. An advance directive that is clear on these options is more likely to be honored by health-care personnel than the more ambiguous language of the original living will. Whether or not an individual intends to authorize an advanced directive, it is a useful learning experience to consider these options and become familiar with their implications.

Yes	No	Options
		1. I want all life-sustaining treatments to be discontinued if I become terminally ill and permanently incompetent.
		2. I want all life-sustaining treatments to be discontinued if I become permanently unconscious, whether terminally ill or not.
		3. I want all life-sustaining treatments to be discontinued if I become unconscious and have very little chance of ever recovering consciousness or avoiding permanent brain injury.
		4. I want to be kept alive if I become gravely ill and have only a slight chance of recovery (5% or less), and would probably require weeks or months of further treatment before the outcome became clear.
		5. I want to have fluids and nutrition discontinued if other life- support measures are discontinued.

Figure 1 Advance directive options.

Elderly adults who make the effort to learn about their end-of-life options are in a position not only to influence future events in their own lives, but also to serve as mentors for younger adults and as an insistent voice demanding that health-care systems give the attention that advance directives deserve.

Decision Making and Everyday Problem Solving

F Blanchard-Fields and A Mienaltowski, Georgia Institute of Technology, Atlanta, GA, USA

Glossary

Abstract Problem Solving – Problems that involve finding the correct solution to a novel task and that incorporate novel stimuli. Examples include concept learning, visual/spatial tasks, and search tasks.

Ecological Validity – A concern with the investigation of processes used in everyday life.

Emotional Salience – The degree to which an individual is emotionally involved in a problem situation.

Emotion-Focused Strategy – Solutions involving covert behaviors that manage or control emotional reactions such as positively reappraising a situation or passively accepting a situation.

Interpersonal Involvement – The degree to which social concerns underlie the context of a problem situation.

Personal Relevance – The degree to which an individual is personally affected by a problem situation.

Problem-Focused Strategy – Solutions involving self-initiated, overt behaviors that deal directly with a problem and its effects, such as taking direct action to alter a situation or seeking information or advice about it.

Problem-Solving Efficacy – The use of effective and adaptive problem-solving strategies.

Introduction

Empirical evidence based on traditional models of abstract problem solving and decision making demonstrates decline in performance as adults grow older. However, researchers have become increasingly dissatisfied with this theoretical and methodological approach as the sole means for assessing adult intellectual functioning. In response to these concerns, a growing body of research has emerged that assesses the skills and knowledge necessary for successful functioning in an everyday context. In contrast to research demonstrating a decline in abstract problem solving, problem-solving competence in adulthood and aging is maintained in socio-emotional or everyday types of situations. This is particularly evident when researchers consider the ways in which an individual perceives and structures the problem situation. In other words, problem-solving efficacy may not simply be a function of how many more 'correct' solutions an individual generates for a given problem. It may be more a function of (1) whether or not the problem reflects situations encountered in daily life, (2) whether or not the circumstances of the problem are personally meaningful or emotionally salient to the individual, (3) how the individual interprets, organizes, and restructures the problem space of the everyday situation, and (4) how adaptive a specific solution is given the individual's goals and context of living.

Approaches to the Study of Everyday Problem Solving

Concerns about Traditional Approaches to Problem Solving

Research examining age differences in abstract problem solving demonstrates more effective problem solving in college-aged and middle-aged individuals as compared to older adults. However, the majority of these studies constrain problem-solving ability to abstract tasks that have only one optimal solution (e.g., concept learning, abstract inferencing, and logical reasoning tasks). Problems that occur in our everyday lives are typically rich with context or individual-specific information that bounds the thoughts and actions of the problem-solver. Thus, context-free, abstract measures of problem solving may not be valid indicators of adaptive skills across multiple domains of adult functioning. Although understanding abstract problem solving is vital to the growth of our knowledge of age-related change in thought processes, measures of everyday cognition that attempt to capture the true lifestyle of individuals are also valuable. Focusing the microscope of vigorous study on the day-to-day tasks and struggles of all individuals can help to inform those clinicians, caregivers, and policy makers who are especially concerned with the well-being and independent functioning of senior citizens.

The Issue of Ecological Validity

One might expect that age-related decline in formal measures of reasoning would lead older adults to be less able to effectively function in their day-to-day activities. However, older adults report that their social reasoning about everyday matters has improved over time despite losses in other areas of cognition. Some researchers argue that a portion of the decline observed in older adults emerges because the skills that are necessary to perform abstract problem-solving tasks in the laboratory are not well practiced in middle-aged and older adults. Thus, a number of alternative approaches to investigating everyday problem solving have emerged, all with a common goal: to identify and measure types of problem-solving skills required for effective functioning in an everyday context during adulthood.

In pursuit of this goal, researchers improved the ecological validity of problem-solving tasks by incorporating more meaningful and realistic materials in their studies. A first approach was to change the content of traditional problem tasks to conform to content that is more relevant in adulthood (e.g., substituting strategies used to solve an abstract numerical problem with arithmetic strategies to select best buys in a supermarket). By improving the face validity of the tasks, it was assumed that the bias inherent in abstract problem-solving tasks would be removed. Although the typical age differences found in more traditional problem-solving studies were attenuated in studies conducted within this framework, a negative linear relationship between age and

problem-solving performance still remained. Also, simply varying the content of these abstract tasks does not eliminate the issue of which criteria are most suitable for judging problem-solving efficacy. It was argued that these tasks reflect only a cosmetic change to content and are still grounded in traditional abstract problem-solving (and youth-oriented) criteria. For example, they still demand a single correct solution and involve the same strategies used to solve astract problems.

Structural Characteristics of Everyday Problem-Solving Tasks

A more current version of the preceding approach structures everyday problem solving as a manifestation of underlying intellectual abilities. That is, problem-solving tasks have been designed to describe psychometric aspects of intelligence within problems that are experienced in daily life (e.g., understanding information on a medication label, using tax return forms). Problem-solving tasks grounded in this tradition tend to be well structured in that (1) the problem situation and the rules to be followed are defined by the experimenter, and (2) a single correct solution to the problem is required. An important but generally overlooked avenue in such tasks is the examination of goals and strategies used by individuals to solve ill-structured or ambiguous tasks. As a function of the social content inherent in these situations, ill-structured problems are unpredictable and are continually in transformation. The resulting ambiguity as to what defines these types of problems requires individuals to generate their own interpretation of a problem situation rather than rely on the structure imposed by others. In addition to multiple definitions of a problem space, there may be multiple solutions to ill-structured problems, all potentially effective depending upon the trade-offs one is willing to make. Finally, unlike traditional time-constrained abstract problems, it may take an extended period of time before one knows whether a decision to choose a particular solution strategy (among many potential candidates) will prove to be successful for an everyday problem (e.g., it may take months or even years to find out if one has chosen a compatible marital partner).

In concert with this approach, current research suggests that everyday problem solving across the life span is inherently interpersonal and thus has a strong socio-emotional component. This finding calls attention to the importance of emotions and other psychosocial factors involved in solving problems that emerge in adulthood. In fact, studies show that as adults grow older, their goals for solving problems become more concerned with other people, intimacy, and generativity. In sum, problems encountered in everyday life appear to be ill-structured, time-extended, and social in nature. These three characteristics of everyday problem situations help to stress the importance of taking a contextual perspective when assessing the efficacy of competing problem solutions.

A Contextual Perspective on Everyday Problem Solving

A contextual perspective enlarges the scope of everyday problem solving by considering the roles that cognitive, social, emotional, motivational, and cultural demands play in how individuals solve problems. For example, the goals of the individual relative to the circumstances (e.g., social demands) of the problem can influence how problems are managed. All of the these factors combine to have an effect on the appraisal and interpretation of a problem. They also influence the motivation behind an individual's decision to employ specific strategies to solve the problem.

For some problems (e.g., traditional well-structured, single-criterion problems), contextual demands act to drastically limit the number of responses that will lead to a successful outcome, so more traditional modes of problem solving are adaptive in this context. However, situations reflecting multiple criteria for potential solutions are more prominent in the problems of everyday living faced by older adults. There are several researchers who have attempted to specify these criteria from various theoretical perspectives.

For example, adaptive problem solving in an everyday context has been purported to entail (1) an awareness that the veracity of the solution to a particular problem is relative to differing perspectives and to the goals of the individual, (2) an awareness of the role of self in interpreting problems, and (3) a recognition that logical reasoning is embedded in a sociocultural matrix. In other words, individuals need to approach problems from a contextual perspective in order to exercise good judgment in problems reflecting uncertainty and ambiguity. From this framework, effective problem solving in an everyday context involves both the flexibility to adapt to the changing demands of one's environment and a system of organization to maintain continuous progress toward a desired outcome. It also suggests an 'openness' on the part of assessment criteria to judge the effectiveness of a problem-solving strategy as a function of the demands of the environment and the goals of the problem-solver in that particular context.

Adult Developmental Differences in Everyday Problem Solving and Decision Making

Criteria for Judging Strategy Efficacy

Following the precedent set by more traditional measures of problem-solving ability, quantitative assessments of strategy efficacy include the number of solutions generated, the number of steps needed to arrive at a solution, and the lack of redundancy in responding on test questions. In this case, both the best response and the criteria used to judge how effective an individual is at producing a solution have been determined by experimenters. It has been suggested that these types of criteria obscure qualitative differences inherent in a set of solutions. They do not take into account differences in the resources available to each problem-solver or qualitative differences in the algorithms used to solve problems.

Another criterion for judging problem-solving efficacy captures the individual's own perspective on problem-solving competence: individuals rate the efficacy of their own solutions. In this way, the criteria for problem-solving efficacy are determined by what the individual perceives to be effective given that she or he is living in the particular context in question. Researchers have also used a criterion group of judges to determine problem-solving efficacy (e.g., individuals' solutions are compared to the ratings provided by population-representative group ratings of expert adults). In essence, this approach provides a prototype (by means of the judges' efficacy ratings) of what is adaptive in a particular context. Solutions offered by participants in the study can be compared to this prototype. However, both self- and judge-perceived scales may be too global to delineate the qualitatively different form and content of an individual's solutions.

Given the importance of examining adaptive everyday functioning across the life span, emphasis has been placed on devising measures that are sensitive enough to capture possible developmental differences in how individuals structure reality and approach everyday problems. To these ends, problem-solving tasks may require the individual to generate her or his own interpretation of the problem situation. This approach considers qualitative differences in an individual-specific problem context and in the form and content of solutions. For example, some scoring systems may assess the type of strategies (e.g., problem-focused strategies, cognitive re-evaluations, emotional regulation) that are used to solve problems that emerge in particular domains of life. By contrast, other scoring systems examine the development of various modes of thought (e.g., self-oriented vs. other-oriented) that are important to reasoning through problem situations.

Age Differences in Problem-Solving Efficacy

In past research, examining age differences in problem-solving effectiveness involved asking young, middle-aged, and older adults to generate solutions for hypothetical practical problems (e.g., "When you open the refrigerator up, you notice that it is not cold inside, but rather it is warm. What would you do?"). Criteria for effective problem solving included the number of 'safe and effective' solutions as well as the number of 'self-initiated' solutions generated. Findings from examinations like this typically suggested that middle-aged adults outperform younger and older adults (who did not differ from each other). In other words, problem-solving performance would improve into middle adulthood and then decline. This trajectory, which resembles that found on measures of traditional intellectual ability, has also been found in a number of studies using psychometric measures of everyday problem solving.

The demonstrated decline in problem solving and decision making in older adults has been interpreted by some to reflect a biologically determined decline in the maximum potential of cognitive processing beginning after early adulthood. Indeed, such tasks are highly related to age-related decline on basic cognitive tasks. Although experience may compensate for this deficit during the earlier portion of adulthood, it is in the older adult years that the decline is sufficient to interfere with even frequently practiced abilities. In contrast to decline in everyday problem-solving ability, other researchers find either equivalent performance among younger, middle-aged, and older adults or linear improvement in problem-solving efficacy and decision making throughout the life span. However, different criteria for judging problem efficacy are employed in these studies. For example, in a number of studies, participants generated a solution to various problem situations (as performed in the previously described studies). In these studies, individuals rated the efficacy of their own solutions. Results indicated no age differences between young, middle-aged, and older adults when self-perceived problem-solving efficacy was assessed.

These findings are moderated somewhat by the relevance of problems to participants' lives. For example, when participants generated their own problems, equivalent self-rated problem-solving efficacy across age groups was found. However, when participants were responding to experimenter-generated

(i.e., hypothetical) problems, young and middle-aged adults provided higher ratings of self-efficacy than they did for their solutions to self-generated, personally relevant everyday problems. Interestingly, older adults viewed their solutions to both of these types of problems as being equally efficacious, indicating that the older participants felt that they were as able to reach successful outcomes in hypothetical problems as they were in problems that they actually face in real life.

In addition to this pattern of results for self-rated problem-solving efficacy, other studies have found improvements in problem-solving efficacy across the life span when comparing the preferred strategies of adult judges to adults of various ages. An Everyday Problem Solving Inventory was developed to assess practical problem solving in everyday situations. The inventory consists of six different content domains in which an adult might experience a problem situation, including consumer issues, home management, interpersonal conflicts with family members, conflicts with friends, conflicts with co-workers, and dealing with technical information. Possible responses were enumerated for each of these situations (including problem-focused action, cognitive problem analysis, passive-dependent behavior, and avoidant thinking and denial) and were evaluated by judges, ranging in age from 24 to 72, as to their potential efficacy. The inventory was then administered to adults ranging in age from 20 to 78 years. Examination of age differences revealed that effective performance on the problem-solving inventory (as defined by the judges) increased with age, whereas performance on more traditional problem-solving tasks declined after middle age. Interestingly, performance on the problem-solving inventory was not related to cognitive abilities, whereas traditional problem-solving tasks were related to cognitive abilities. Consistent with these expectations, studies have demonstrated that older adults are better than young adults at tailoring their strategy choices to specifically meet the demands of the issues that they are addressing (e.g., family, relationship, consumer problems). For example, researchers examining different styles of problem solving in adolescence through older adulthood found dissimilar patterns of results when contrasting participants' responses to instrumental (achievement-oriented) problems and to interpersonal conflicts. No age differences were found for problems representing consumer decisions and home management; all age groups tended to use more problem-focused strategies. In fact, younger adults opted for a problem-focused or cognitive analytic approach to all problems. Older adults, on the other hand, endorsed strategies that evinced an awareness of when to avoid or to passively accept a situation within interpersonal domains (e.g., conflicts with family or friends). Overall, older adults were more likely to endorse emotion-focused strategies than younger adults, who strictly relied on more problem-focused strategies. These results suggest that older adults may choose a diverse array of strategies to specifically target the contextual aspects (instrumental or interpersonal) of problems. Conversely, younger individuals preferred direct, problem-focused action. This was true even in situations in which it may have been advantageous to be more mindful of the complex emotions of all parties involved. It is also important to note that, despite research that suggests that older adults 'lack' the ability to engage in cognitively complex strategies, older adults were just as likely as young adults to endorse problem-focused and cognitive analytical strategies (as evidenced by a lack of age differences or increased use of these strategies). Although advancing age may be associated with declines in performance on timed tasks of cognition, such declines do not necessarily translate into impaired everyday problem-solving effectiveness.

In sum, it appears that everyday problem-solving measures can be critically influenced by the world from which the problems are derived – that of the experimenter versus that of the participant. What constitutes a good solution to a problem may depend on the criteria used to judge problem-solving efficacy (e.g., who is making such a decision, the experimenter or the individual who tried the solution and had to live with the consequences). Finally, although age does influence the types of problems that are volunteered, older adults are no worse than younger adults at solving everyday problems, especially those problems that tap into the social domain. In reality, older adults may compensate for declines in traditional forms of reasoning by carefully selecting how best to invest their cognitive, physical, and emotional capital so as to achieve the best possible outcome given the contextual demands of the problem.

Beyond Strategy Efficacy: Examining Strategic Behavior

In order to better understand qualitative differences in the strategies implemented by young and older adults when solving everyday problems, researchers have designed measures of decision making that allow for the systematic evaluation of online problem solving. These measures include tasks that ask young and older individuals to make decisions (e.g., choosing a new car, apartment, political candidate, or health insurance policy) after considering

information presented on a matrix (i.e., grid with information organized by features and choices). Information-processing strategies are assessed by keeping track of the number of times an individual reads a given piece of information, the time devoted to viewing each cell selected on the grid, and the sequence in which participants view information (e.g., scanning several features of a single automobile versus comparing several automobiles for a single feature such as fuel economy). Using these factors, researchers can get a sense of how an individual arrives at a decision. When presented with information on automobiles, both young and older adults required the same amount of time to choose an automobile. Young adults conducted exhaustive searches, looking at most if not all of the information about a single automobile before moving on to the next. Conversely, older adults reviewed the information so as to narrow their options. They first identified the features of automobiles that were most important to their decision, and then they compared the automobiles starting with the most important feature. Automobiles were ruled out based on whether or not they satisfactorily matched the demands of the older participant.

This difference in the information search strategies used by younger and older participants is often attributed to the limited cognitive resources of older adults. Many researchers feel that, given age-related declines in memory, older individuals must strategically minimize (i.e., satisfice) the number of pieces of information that they simultaneously store and manipulate. However, the older adults' strategic behavior might also be expected if the contextual environment of the task was different for them relative to young adults. For example, older adults might have more experience with purchasing automobiles and thus might have approached the decision with well-defined preferences in mind. Preferences or rules of thumb (i.e., decision heuristics) would allow older adults to select an automobile without examining all of the information on the grid.

Although an individual can inadvertently miss important information when an exhaustive search is not used, the result of a less comprehensive search can be just as positive if the outcome is subjectively appraised as satisfactory. In other words, the effectiveness of one's everyday decisions usually depends on the circumstances under which the decisions are made. For example, studies have shown that older adults may demonstrate equivalent or superior performance relative to young adults when asked to make practical financial decisions. When presented with an opportunity to choose between various consumer discount plans, older adults were more likely than younger adults to choose the plan that best suited their anticipated expenditures. By holding a personally defined preference, the decision heuristic served an adaptive purpose for older adults. Research examining how individuals weigh the pros and cons of choice-related options demonstrates that the degree of personal relevance of the decision alters how likely individuals are to engage in heuristic strategies. Also, when the decision is important to an individual, it elicits strong emotions. These emotions promote careful deliberation and, if unresolved, prolong the selection process so as to avoid regret. Interestingly, decisions that are particularly relevant to one age group may not be as relevant to others. Developmental theories of emotion (e.g., Carstensen's Socioemotional Selectivity Theory) suggest that what is important to an individual changes across the life span: with advancing age comes the desire to maximize emotionally relevant experiences and to minimize emotional setbacks.

Based on this prediction, young and older adults may place different values on the same aspect of a decision. For example, when choosing to rent an apartment, older individuals may place more value than younger adults on how close a given apartment complex is to the residences of their immediate family members. Similarly, when faced with a difficult decision wrought with negative emotions, older adults may be more likely than younger adults to delay the decision in order to avoid the regret associated with making a mistake. For example, a senior citizen who has recently retired may prolong making a decision about possible supplemental insurance policies for fear that the new policy will detract from his or her current policy. On the one hand, maintaining the status quo provides emotional benefits with a minimal investment of cognitive resources. On the other hand, delaying the decision could result in a less than optimal insurance policy. Current studies support the idea that the emotional content of a decision-making task can influence the amount of effort that older individuals devote to information processing. For example, older individuals have been found to remember chosen options as being more positive than the options that were forgone. Future research will tell us under what conditions it is adaptive to increase one's attention to emotional components of decisions and when it is not.

Factors Mediating Age Differences in Everyday Problem Solving

As mentioned earlier, age differences emerge in how an everyday problem is defined due to age differences in appraisals of the problem's context. Consequently,

researchers have sought to more clearly identify those aspects of a problem's context that may mediate age differences in everyday problem solving. Included among these factors are problem appraisal, interpersonal involvement, personal relevance, and emotional salience.

Problem Appraisal

Differences in strategy use for everyday problem solving are shown to be a function of age differences in the underlying interpretations of the problem or decision-making situation. Indeed, effective problem solving depends upon a realistic appraisal of the situation that matches or approximates the unfolding of events. Furthermore, there is a need to examine differences in problem appraisal between younger and older adults in order to understand better strategy use and the potential adaptive nature of such age differences.

For example, one study found that younger and older adults differed in their appraisal of problems as a function of the type of situation and relevance to their everyday functioning (e.g., a visit to the doctor's office and problems arising at a dinner party). On the one hand, older adults interpreted the doctor's office problems as external-social (i.e., something to do with the social circumstances rather than themselves). On the other hand, older adults viewed the dinner party problem more as internal-cognitive (i.e., something to do with their decision making). Younger adults interpreted both problems as internal-affective (e.g., they attributed the problem to their personal emotions). In addition, the way in which both age groups interpreted the problem influenced their subsequent selection of problem-solving strategies. Some researchers propose that mature thinking involves the redefinition of the problem space by accepting inherent uncertainties and resolving them. Similarly, other researchers suggest that this interpretive process in adulthood is characterized by an increased awareness of self as interpreter or the ability to consider multiple perspectives in reasoning tasks of an interpersonal nature. A number of developmental changes in how individuals structure reality and approach a problem situation (e.g., awareness of self as interpreter, cognitive representations of events, cognitive appraisal) have been identified. However, more research is needed to link these changes in problem appraisal with subsequent selection of problem-solving strategies.

Interpersonal Involvement

Researchers interested in everyday cognition have also found that older adults interpret everyday problems differently than younger adults in that they focus on interpersonal concerns of the problem. Some studies have shown that early on in adulthood, interpersonal goals emerge and become as important as competence goals. From middle adulthood to old age, individuals tend to report that the problems that they face occur in more social domains. Problems are more widely distributed across several domains (as opposed to being primarily related to schooling or one's career). Also, across age groups, people who face problems in interpersonal domains (e.g., family and romantic relationships) tend to use strategies that involve regulating and including others in the solution process.

Consistent with these trends, another study on how adults solve interpersonal problems displayed similar results. In non-romantic relationship situations, adults of all ages endorsed problem-focused strategy combinations geared at improving the circumstances of the problem for other individuals involved in the conflict. For romantic relationship situations, however, older adults were more likely than young and middle-aged adults to first try to regulate their own emotions (e.g., by hiding how they truly felt). Conversely, the younger age groups were more likely to first carry out some active problem-focused strategy to deal with the problem (e.g., confront their cheating spouse or pack their bags and move to their mother's house). Although there are age differences in the strategies used to cope with interpersonal problems, it is possible that the preferred strategies of each age group are equally as effective. It is important to remember that, when faced with a standard (empirically derived) hypothetical problem, younger and older individuals each might bring distinct contextual perspectives to the situation. For example, although individuals of all ages would be angry if their spouse were unfaithful, older adults may place more importance on emotion regulation than younger adults because of the immense quantity of resources that they have already invested in the relationship. Based on these studies, young and older individuals differ in how they deal with interpersonal problems. As is discussed later, the emotional nature of interpersonal problems is an important component of these age differences.

Personal Relevance

Besides being influenced by the emotional nature of everyday problems, strategy selection in everyday problem situations is also influenced by the importance or relevance of the problem as seen through the eyes of the problem-solver. Personal relevance, whether it takes the form of age relevance (i.e.,

problems characteristic of the participant's age group) or self-generated problems (i.e., problems described by individuals when asked to discuss issues that they are dealing with), appears to affect whether or not age differences in problem-solving efficacy will also be observed. Although the findings from studies are mixed, older adults seem to be more influenced by perceived relevance of individual problems. First, a number of studies reveal that older adults perform better on tasks reflecting personal relevance and familiarity than on hypothetical tasks. In other words, young and middle-aged adults outperform older adults on hypothetical problems, whereas no age differences emerge when problems were self-generated. In addition, in contrast to younger adults, older adults rate their solutions to self-generated problems as being equally as effective as their solutions for experimenter-generated (hypothetical) problems. As mentioned earlier, older adults may feel more efficacious because they approach problem situations equipped with a lifetime of experience from which they may select those strategies that have proven to be successful for them in the past.

When age-relevant problems were developed for individuals of varying age (e.g., problems relevant to young, middle-aged, and older adults), young and middle-aged adults performed best on problems relevant to their own age group, whereas older adults did not vary as a function of the age relevance of the problems. Some argue that experience and familiarity may compensate for deficits in everyday problem solving. Others suggest that older adults compensate for age-related deficits by taking steps (e.g., heuristically relying on past successful strategies) to minimize the effort that is needed to generate the most efficacious solution to problems. However, life experience is a difficult variable to measure. More research is needed to directly examine the roles that experience and heuristic decision-making strategies play in everyday cognition. At this point it can be argued that familiarity and personal relevance mediate age differences in everyday problem solving. In other words, familiar problems tend to be managed effectively in a similar fashion across age groups.

Emotional Salience

Earlier in this article it was noted that one of the defining characteristics of everyday problem solving was the interpersonal nature of problem situations encountered in everyday life. In addition, a common finding among studies on age differences in problem-solving strategies is that changes in strategy preference are most evident in interpersonal situations that characteristically embody emotional and psychosocial factors. The apparent role that emotion plays in how an individual construes a problem (particularly in an interpersonal context) and, in turn, adopts a problem-solving strategy has recently been addressed in the problem-solving literature. For example, with increasing age, individuals engage in more mature social reasoning (e.g., increased relativistic thinking) in emotionally laden situations; older adults with high affective intensity demonstrate more dialectical thinking; higher levels of ego maturity involving emotional regulation and openness to affective experience relate to more mature coping and problem solving; older adults make more complex causal attributions in problem situations that are high in emotional salience; and emotional salience plays an important role in age differences in coping with stress.

In one study, emotional salience of problems (ranging from low to high) was found to be a critical determinant of the degree to which individuals reported a particular problem-solving strategy. In low and high emotionally salient situations, there were no age differences in the use of instrumental and proactive strategies. However, in high emotionally salient situations, older adults endorsed more passive-dependent and avoidant strategies than either young or middle-aged adults. These findings support the premise that the responses of older adults are related to the nature of the problem situation. Like the other age groups, older adults used more problem-focused strategies in instrumental and less emotionally salient task situations (e.g., returning defective merchandise). When the situations were more emotionally salient (e.g., moving to a new town, taking care of a parent), older adults used more emotion regulation strategies (e.g., suppressing feelings, not trying to alter an uncontrollable situation).

Similarly, a number of studies have shown that, in general, older adults use more emotion-focused styles of coping than younger adults. For example, older adults report fewer negative emotions, and they appear to be better equipped with cognitive problem-solving skills for negative emotions. When the problem situation is appraised as uncontrollable, older adults use more emotion-focused coping than younger adults. Finally, a life span developmental perspective has been proposed with respect to emotional regulation. In the latter half of the life span, individuals find emotional aspects of information more salient. In addition, older adults prefer to focus on the emotional potential in interpersonal relationships. In contrast, young adults do not focus as much on the emotional aspects of information presented.

In interpersonal relationships, they focus more on the information- and stimulation-seeking potential.

Recent studies are consistent with this hypothesis for life span developmental shifts in the implementation of emotion regulation strategies. When young, middle-aged, and older adults were asked to describe the strategies that they used to solve self-generated problems that they experienced with family members, middle-aged and older adults were more likely to report the use of emotion regulation strategies. Interestingly, middle-aged adults used more proactive forms of emotion regulation, whereas older adults used more passive strategies to control their emotions. These results suggest that older adults, when faced with emotional problems that involve others, are more likely to have an internal focus to their emotion regulation. Given their goal of maximizing positive affect, older adults may choose to use passive forms of emotion regulation in order to purposefully maintain the emotional meaningfulness of the relationships that they share with their closest family members. Further support for this hypothesis is found in studies that demonstrate that older adults are less likely to express their anger when coping with a highly emotional problem that they are having with a friend. In stark contrast to the traditional decline in reasoning that is often associated with advancing age, the affective-oriented goals and strategies used by older adults in interpersonal everyday problems portray them to be more complex, flexible, and emotionally mature than one might otherwise assume. Evidence for adulthood changes in the appraisal and regulation of emotion stresses the importance for future research to continue to examine everyday problem solving within an emotional context.

Conclusions and Implications

In conclusion, traditional problem-solving measures that are relatively abstract, are low in ecological validity, or come from a more psychometric tradition demonstrate decreased problem-solving and decision-making ability with age. Such developmental/age differences seem to emerge only on measures that draw upon information processing/mechanistic or intellectual abilities. However, with tasks of high emotional salience, ambiguity, and ecological validity, developmental differences have been documented that are related to qualitative changes in the way the individual perceives their problem-solving efficacy and structures everyday problems.

Therefore, in order to attain a more complete picture of developmental variation in problem solving, both research perspectives are needed. We must be able to differentiate (1) when age differences are due to a production deficiency or a genuine regression on the part of older adults and (2) when these differences can be attributed to discriminative and volitional choices in problem-solving strategy. Developmental differences can exist concurrently in that we see decline in abstract and psychometrically tested problem-solving ability while also finding increased sophistication in the appraisal of problem contexts and in the approaches used to solve real-world problems. Both types of developmental changes can exist in parallel; they may even complement each other.

Delirium

J H Flaherty, Saint Louis University School of Medicine, St. Louis, MO, USA

Glossary

Delirium – Characterized by sudden onset of impaired attention, disorganized thinking, or incoherent speech.

Delirium Room (DR) – A delirium intervention consisting of a specialized four-bed room that provides 24 hour nursing care and observation by at least one nurse in the room and that is completely free of physical restraints.

Introduction

Delirium is a medical diagnosis often referred to by clinicians as an acute change in mental status. Summarizing the *Diagnostic and Statistical Manual of Mental Disorders,* 4th edition, text revision (DSM-IV) criteria for making the diagnosis, delirium is characterized by a sudden onset of impaired attention, disorganized thinking, or incoherent speech. The patient usually has a clouded consciousness, perceptual disturbances, sleep–wake cycle problems, psychomotor agitation, or lethargy, and is disoriented.

Delirium is a dangerous diagnosis because it is common in various health-care sites, it is commonly missed, and it is associated with serious adverse outcomes such as loss of physical function and mortality. The comprehensive approach to delirium involves awareness, diagnosis (knowing how to differentiate between delirium and dementia), evaluation (identifying and treating the underlying causes of delirium), prevention, and management. Typically, the underlying causes of delirium are multifactorial and can be remembered using the mnemonic DELIRIUMS. Examples of prevention interventions include a multicomponent intervention with protocols targeting risk factors to prevent the development of delirium and a geriatric consultation service for patients with hip fracture. An example of a management intervention is a specialized four-bed room that provides 24-h nursing care, called the delirium room. Physical restraints should not be used in patients with delirium, and rarely should pharmacological restraints be used.

Definition and Types of Delirium; Prevalence and Incidence for Various Sites and Situations

According to the DSM-IV, delirium is characterized by a sudden onset of impaired attention, disorganized thinking, or incoherent speech. The patient usually has a clouded consciousness, perceptual disturbances, sleep–wake cycle problems, and psychomotor agitation or lethargy and is disoriented. Although the definition and thus diagnosis of delirium is based on the DSM-IV, it should be considered a medical diagnosis because one of the other diagnostic criteria is that there is evidence by history, physical, or

laboratory findings that the delirium is caused by the physiological consequences of a medical condition, an intoxication substance, a medication use, or a combination of these.

Most studies have agreed that there are two types of delirium: hypoactive and hyperactive. Patients may also have a combination of the two types. Using the available DSM criteria at the time, studies have found delirium in up to 22% of older patients on admission to the hospital and in up to 31% of older patients while hospitalized. Prevalence rates for confusion of any kind during admission have been found to be even higher.

In most studies, surgical patients have been found to have higher rates than medical patients. Postoperative rates were highest among coronary artery bypass graft patients, ranging from 17 to 74%, and rates among orthopedic surgical patients ranged from 28 to 53%. Studies of urologic patients found lower rates, from 4.5 to 6.8%. Anesthesia agents should not be blamed for these high rates, as several studies have found that the route of anesthesia (general, epidural, spinal, regional) was not associated with the development of delirium.

One of the sites with the highest rates of delirium is the intensive care unit (ICU). Rates as high as 80% have been found. For years, this problem has inappropriately been called ICU psychosis or sundowning, and has been considered inevitable and unpreventable, which may partly explain the high non-recognition rates of 66–84%. However, research has shown that delirium in the ICU is similar to delirium at other health-care sites (with associated poor outcomes), and clinical practice guidelines from the Society of Critical Care Medicine now recommend monitoring for delirium among all ICU patients.

Data from postacute care facilities (such as subacute care facilities, skilled nursing facilities, rehabilitation centers, and long-term care facilities) have shown that patients are discharged from acute hospitals with persistent delirium, and delirium at these sites persists for an extended period of time. One study found that 72% of 214 nursing home patients who were hospitalized still had delirium at the time of discharge back to the nursing home, and the delirium persisted for 55% of the patients at 1 month and 25% at 3 months. In a large study of more than 80 postacute care facilities using the Minimum Data Set (MDS) to identify patients with any delirium symptoms, a prevalence rate of 23% was found on admission, and 52% of these patients still had symptoms of delirium at 1 week follow-up.

Two studies that looked at point prevalence within nursing facilities discovered a similarly high rate of delirium, 14% of 324 long-term nursing home patients in one study and 33% of 74 patients in the other.

At least two reasons have been proposed to explain high prevalence rates at various sites. One reason is the higher occurrence of the hypoactive type of delirium compared to the hyperactive. The other reason has to do with patients who have subsyndromal delirium, in which patients meet only some of the criteria for delirium. This type should still be considered serious, as at least one study has shown intermediate negative outcomes when compared to delirious patients and patients without delirium.

Associated Adverse Outcomes

Delirium is one of the most serious diagnoses patients can have or develop. However, it has been reported that it is not identified in 32–66% of the cases, by either nurses or physicians. Hospitalized older persons with delirium compared to those without delirium are more likely to have hospital complications, loss of physical function, increased hospital length of stay, increased discharge to a long-term care facility, and even a higher mortality risk. Mortality rates for hospitalized delirious patients have been reported to be 25–33%, as high as mortality rates for acute myocardial infarction and sepsis.

Even when adjusting for factors such as older age, underlying cognitive impairment, severe acute and chronic illness, and functional impairment, delirium has been found to be independently associated with poor outcomes in most studies.

Associated adverse outcomes among delirious ICU patients have shown prolonged ICU stay, prolonged hospital stay, and increased mortality compared to patients without delirium. Data from postacute facilities have also shown associated adverse outcomes, related to loss of physical function and mortality.

Risk Factors

Numerous risk factors for the development of delirium have been identified. Risk factors can be external (environmental) or internal (depending on the status of the individual). A non-exhaustive list includes underlying dementia, recent surgery, dehydration, renal insufficiency, multiple medications, inadequate pain relief, indwelling urinary catheter, and physical restraints. The most important of these is probably an underlying dementia, which may have to do with the underlying neuropathophysiology of delirium.

Many hypotheses have been proposed, but to date, it is not clear exactly which or how many mechanisms are responsible for the clinical presentation.

Some hypotheses include abnormalities in neurotransmitter systems, vascular mechanisms, and neuroendocrine/immune mediation (e.g., cytokines).

The Comprehensive Approach to Delirium

Since delirium is a multifactorial problem, a multifaceted approach is warranted: (1) awareness: be aware of how commonly delirium occurs and where it occurs, and get others involved in the care of the older persons to do the same; (2) diagnosis: know why it is important to differentiate and how to differentiate between delirium and dementia; (3) evaluation: identify and treat the underlying causes of delirium; (4) prevention: implement strategies or care systems that can prevent delirium; and (5) management: manage patients who develop delirium.

Awareness

Since delirium is so common, and because there are so many risk factors for the development of delirium, health-care sites should consider screening for delirium. Several validated screening tools exist. A few examples of hospital tools are the Clinical Assessment of Confusion A, the Confusion Rating Scale, and the NEECHAM Confusion Scale, which were developed primarily for nursing. The Confusion Assessment Method (CAM) was developed for use by trained nurses and physicians. The CAM-ICU has been validated in ICU patients. The NEECHAM and a Visual Analog Scale for Acute Confusion have been validated in long-term care patients.

The use of the term delirium by health-care professionals in acute care and postacute care may increase awareness. Last, incidence rates and outcomes associated with delirium should be monitored (that is, they should become quality of care measures) at all sites where delirium occurs.

Diagnosis

One of the most important steps in diagnosing delirium is to realize that delirium is not dementia. Although delirium can arise during the course of dementia, the two are worth differentiating because most types of dementia have a progressive downhill course, whereas delirium is reversible most of the time. A mislabeling, or lack of differentiation between these two diagnoses, is thought to be the reason why delirium is missed by physicians at rates as high as 32 to 66% and by nurses up to 69% of the time. Misdiagnosis or late diagnosis may also partly explain why delirium is associated with adverse outcomes. **Table 1** details some of the differentiating characteristics between delirium and dementia, based on DSM criteria. One of the criteria not listed in **Table 1** is that delirium must occur in the context of a medical illness, metabolic derangement, drug toxicity, or withdrawal.

An altered level of consciousness (LOC) is useful in differentiating delirium and dementia because even if the patient's baseline mental status is unknown, one can still determine whether the patient's LOC lies toward the agitated or vigilant side of the spectrum of LOC or toward the lethargic, drowsy, or stuporous side of the spectrum.

Although disorientation can occur in both delirium and dementia, the key in distinguishing delirium from dementia is how the patient answers orientation questions. The delirious patient will often give disorganized answers, which can be described as rambling or even incoherent.

Acute onset and fluctuating course are two of the hallmarks of delirium. This information is usually obtained by close caregivers (family or nurses). The term subacute is used to emphasize that subtle mental status changes can be overlooked by caregivers. Over a period of many days, the patient may appear to be slowly declining mentally due to the underlying

Table 1 Characteristics of delirium versus dementia

Characteristic	*Delirium*	*Dementia*
Consciousness	Clouded Decreased or hyperalert	Usually alert
Orientation	Disorganized	Disoriented
Course	Fluctuating	Steady slow decline
Onset	Acute or subacute	Chronic
Attention	Impaired	Usually normal
Psychomotor	Agitated or lethargic	Usually normal
Hallucinations	Perceptual disturbances May have hallucinations	Usually not present
Sleep–wake cycle	Abnormal	Usually normal
Speech	Slow, incoherent	Aphasic, anomic difficulty finding words

Reproduced with permission from Flaherty JH (2006) Delirium. In: *Principles and Practice of Geriatric Medicine*, 4th edn, pp. 1047–1060. Sussex, England: John Wiley & Sons.

dementia. If left unchecked, the initial delirium may impair other necessary functions, leading to further medical problems, such as dehydration and malnutrition, further complicating the delirium. This snowball effect explains in part why the etiology of delirium is typically multifactorial. Thus, if it is unclear how long the change has been occurring, patients should be put in the category of delirium and an evaluation should be done.

Attention may be especially helpful if the patient's baseline mental status is not known. During history taking, patients may have difficulty maintaining or following the conversation, perseverate on the previous question, or become easily distracted. Attention can also be tested with cognitive tasks such as asking the patient to say the days of the week backward, spell a word backward, or perform other mental tasks that require focus and attention.

Psychomotor agitation or lethargy, hallucinations, sleep–wake cycle abnormalities, and slow or incoherent speech can all be seen in patients with delirium, but these features are not necessary for the diagnosis.

Evaluation

In general, the medical evaluation of patients who are thought to have delirium includes considering all possible causes, proceeding cautiously with appropriate testing, and keeping in mind that delirium is usually caused by a combination of underlying causes.

After a history and physical is performed, which includes obtaining details from anyone considered a caregiver (e.g., family, nurse's aide) and a thorough medication list, the mnemonic DELIRIUMS can be used as a checklist to cover most causes of delirium (**Table 2**).

Drugs are one of the most common causes of delirium. Although drugs with anticholinergic properties are the main offenders, since neurotransmitters involved in delirium go beyond the cholinergic system, a broader approach is warranted. Three general guidelines for the comprehensive approach are as follows: (1) drugs that have any central nervous system activity should be considered deliriogenic; (2) drugs that have recently been started or were started coincidently with the onset of cognitive changes may be the offending agents; and (3) almost any drug has the potential to cause cognitive problems.

Examples of the more common offenders are noted here to give the reader a sense of the preceding guidelines. Although many older reports did not discuss strict delirium criteria, or such criteria were not commonly used, their use of terms such as hallucinosis, paranoia, delusions, psychosis, general confusion, aggressiveness, restlessness, and drowsiness is still useful as they might indicate the presence of delirium due to these drugs. Thus, the following descriptions use these terms when the original reports used them, instead of the recommended term delirium.

Antiparkinsonian drugs probably cause delirium due to a tip in the tenuous balance of the neurotransmitters dopamine and acetylcholine, both implicated in the pathophysiology of delirium.

Although older short-acting antispasmodics (for urinary incontinence) have more of a potential to cause delirium, newer sustained-release agents have been reported.

Motility agents (of which metoclopramide is an example) have peripheral and central antidopaminergic properties. Reported mental status side effects include restlessness, drowsiness, depression, and confusion.

Since psychiatric medications are centrally acting, these are commonly targeted first as offenders of delirium. However, since psychiatric illnesses, especially depression, need to be treated, it is worth noting some of the reports of drug side effects in this area.

Tricyclic antidepressants (TCAs) can cause delirium, with an overall incidence ranging from 1.5 to 20%. The highest rates seem to be among older previously cognitively impaired and medically ill patients. Some TCAs are not as anticholinergic as others (e.g., desipramine) so that the risk of delirium is not an absolute contraindication to their use.

Serotonin selective reuptake inhibitor (SSRI) antidepressants have a much safer side effect profile compared to the TCAs as far as delirium is concerned. However, one of the main side effects of SSRIs, hyponatremia, can present as delirium in older persons. This has been reported with fluoxetine, fluvoxamine, paroxetine, and sertraline. Most reported cases seem to point toward drug interactions as a plausible cause.

Table 2 The multifactorial causes of delirium

D Drugs
E Emotions[a]
L Low O_2 states (hypoxic injury such as myocardial infarction, stroke, pulmonary embolus)
I Infection
R Retention (of urine or stool)
I Ictal (seizures)
U Underhydration/undernutrition
M Metabolic
(S) Subdural

[a] Depression is considered in the differential diagnosis of patients presenting with some features of delirium, although is not a cause of delirium.

Reproduced with permission from Flaherty JH (2006) Delirium. In: *Principles and Practice of Geriatric Medicine*, 4th edn, pp. 1047–1060. Sussex, England: John Wiley & Sons.

Benzodiazepines (BDZs) were introduced in the 1960s and are one of the most widely used psychoactive drugs. Unfortunately, their use is highest among the elderly. In one study of more than 400 hospitalized patients, age 58–88 years, who had normal Mini-Mental Status Examination scores on admission, use of BDZs was associated with a relative risk of developing cognitive impairment of 3.5 (95% CI; 1.4–8.8). Postoperative use of BDZs has also been found to increase the risk of delirium.

Antipsychotics can cause delirium. In one study of patients who were transferred from the psychiatric ward to a medical ward because of delirium, 31% of the cases were due to low-potency antipsychotic agents. Whether the antipsychotic prescribed is considered a typical antipsychotic or an atypical antipsychotic, the clinician needs to keep in mind that none of these drugs has pure mononeurotransmitter activity. Rather, they have varying degrees of activity, either agonist or antagonist to many of the neurotransmitters implicated in the pathophysiology of delirium, such as dopamine, acetylcholine, serotonin, and histamine. Thus, like other geriatric psychiatric medications, antipsychotic drugs can and should be considered a potential cause of delirium. Patients with Lewy body dementia have an increased sensitivity to neuroleptics.

The neuroleptic malignant syndrome is classically described as a triad consisting of fever, elevated creatinine kinase enzymes, and confusion. However, some authors believe that a variant, or rather a clinical spectrum, of the neuroleptic malignant syndrome can be seen in which patients may have only one or two of the triad features and may have only a small degree of these features. For example, patients may have subtle confusion and muscle rigidity, which is intermittent but only mild, or no elevation of creatinine kinase enzymes.

Narcotics can be used safely in older persons with little risk of developing delirium, but a few important details need to be remembered. Meperidine is particularly risky in older persons, likely due to the anticholinergic activity of its active metabolite normeperidine. The main problems associated with the use of narcotics and delirium are usually related to toxicity, overuse, or overdosage in patients with impaired hepatic or renal function, or stopping the narcotic abruptly.

Muscle relaxant is a misnomer because these medications act centrally in the brain, not locally at the muscles. Some of the commonly used muscle relaxants include cyclobenzaprine, methocarbamol, and carisoprodol and have been reported to cause delirium.

Seizure medications have been reported to cause varying types of cognitive impairment including drowsiness, agitation, depression, psychosis, and delirium. The cognitive impairment is thought to be related to serum levels, but clinicians should keep in mind that most anticonvulsants are protein bound, and if the patient's nutritional status is poor then there is potential that the amount of free drug will actually be higher than what is measured by the serum level.

For patients who present with delirium or for patients that are at risk for delirium, the general guidelines in **Table 3** can be used concerning medication management.

The E in the DELIRIUM mnemonic stands for emotions and reminds the clinician that depression, although not considered a cause of delirium, should be in the differential diagnosis of patients who present with features of delirium. This is because depressed patients can have psychotic features as well as other symptoms similar to patients with delirium such as disorganized thinking or psychomotor lethargy.

Low O_2 (oxygen) states in the mnemonic should highlight to the clinician that older patients with hypoxic injuries to the heart, lung, or brain (for example, myocardial infarction, pulmonary embolism, or stroke) can present with delirium. It could be said

Table 3 General guidelines for medication management in patients with delirium or at risk of developing delirium

1. Stop unnecessary drugs until the delirium has resolved, then reevaluate the necessity of these drugs once the delirium has resolved.
2. Use non-pharmacological interventions whenever possible instead of a medication.
3. Do not treat vague symptoms with a medication (for example, do not routinely give H2 antagonists for vague gastrointestinal complaints).
4. Include an assessment of OTC medications as potential offenders.
5. Evaluate all drugs for drug–drug and drug–disease interactions.
6. If a drug is started, decide on the duration of how long that drug will be used. The old rule of start low and go slow needs to be expanded to start low, go slow, and know when to stop.
7. The justification for prescribing medications should be based on therapeutic reasons and not preventive reasons until the patient is no longer at risk for delirium or the delirium has resolved.
8. Do not treat adverse effects of drugs with another drug unless completely necessary (as may be the case with long-acting narcotics and laxatives).

that delirium is as serious as a heart attack, because older patients who are delirious may actually be having myocardial ischemia. Whether it is because patients cannot tell clinicians about chest pain because of the delirium, or whether there exists a cardiocerebral syndrome in which the stress of the myocardial infarction affects the adrenergic system, causing a stress on the balance in the central nervous system, if an older patient is delirious, myocardial infarction should be in the differential diagnosis.

Not only are patients with stroke at risk to develop delirium as a complication of the stroke or the underlying comorbidities associated with the stroke, but delirium also may be the presenting feature of some stroke patients.

Infections are one of the most common underlying causes of delirium among older people. The most common types of infections that cause delirium are urinary tract infections and respiratory infections. However, subtle infections such as cholecystitis and diverticulitis should be considered part of the differential diagnosis if other clues point toward this diagnosis. Although meningitis should be considered, it is not clear whether or not cerebrospinal fluid analysis is warranted in the initial workup of delirious patients without other symptoms that point toward a central nervous system infection.

One of the most common nosocomial infections for older patients is urinary tract infections because of the use of indwelling urinary catheters. Given this risk, indwelling urinary catheters are not indicated for urinary incontinence or urinary retention that can be managed with straight intermittent catheterization and should not be used to monitor input and output unless this monitoring is critical for decision making and outcomes related to this parameter.

Retention of urine causing delirium has been well reported in the literature under the term cystocerebral syndrome. The original report was of three cases, all older men who became acutely agitated and near mute. All three patients had large volumes of urine in their bladder, and in all three patients, the agitated delirium resolved within a short time after emptying the bladder. One of the best ways to quickly evaluate for urinary retention is with a handheld bladder ultrasound. Although these have a fairly high initial cost, cost savings from the reduction in use of straight catheterizations may help balance this issue.

Retention of feces as a cause of delirium has not been reported in the literature. However, since older patients are at risk for fecal impactions for multiple reasons, clinicians should be suspicious of this problem when the delirium is of the lethargic type.

Ictal states are a rare cause of delirium and are not difficult to diagnose clinically for patients with tonic clonic seizures. However, complex partial and simple partial make up over half of the seizures in patients over 65 years. Also, absence seizures may go unnoticed to caregivers and may only seem to have fluctuating mental status changes. Although an EEG is not indicated in the initial medical evaluation of delirium, it should be considered when the pertinent history is obtained.

Underhydration should remind the clinician that dehydration can be one of the underlying causes of delirium. It should also be considered a risk factor for developing delirium. Although there are several circumstances in which an elevated blood urea nitrogen (BUN):creatinine ratio may not truly indicate dehydration, there are data to suggest that a ratio of greater than 17:1 puts patients at risk for delirium.

Undernutrition or malnutrition is considered an underlying cause of delirium related to the issue of medications that are protein bound. Patients who are malnourished may have lower protein stores, and thus protein-bound drugs will have a higher free concentration that puts the patient at risk for delirium. Other proposed relationships between malnutrition and delirium that have yet to be fully elucidated include those mechanisms looking at cytokines.

Metabolic abnormalities that cause delirium are not difficult to identify because of the availability of commonly used laboratory tests. A complete metabolic panel usually will identify abnormalities of electrolytes, liver function, or renal function. Thyroid function tests and B_{12} are typically put in this category.

Using the mnemonic DELIRIUMS with an 'S' emphasizes to the clinician that delirium usually has more than one cause. The S also stands for subdural hematoma, which can cause a change in mental status. Although the mortality rate of subdural hematomas among younger people is quite high, the prognosis for older people is quite good as long as the diagnosis is not missed. The other difference between older and younger patients with subdural hematomas is that older patients may develop the subdural hematoma over a period of a few hours or days. Although there is some debate as to whether or not all older patients presenting to a hospital with delirium should have some sort of brain imaging, most would agree that because this is a very reversible problem that is not reversible if the diagnosis is delayed, it should be looked for if there has been a history of head trauma or falls or any suspicion that there was an unwitnessed fall.

One of the other causes of delirium not represented in the mnemonic is pain. Recognition of pain, now identified as the fifth vital sign, is improving,

and pain should be considered a readily treatable cause of delirium, especially when associated with elective surgery.

Prevention and Management Interventions

Interventions in the area of delirium can have any or all of the following goals: (1) prevent the development of delirium, (2) reduce adverse outcomes associated with delirium in those patients for whom delirium is not prevented, and (3) provide health-care professionals with alternatives to physical restraints and pharmacological methods in the management of delirium.

Delirium is a complex issue, and interventions that are successful will involve several components, many of which are not easily measured. These include education about the risk factors and screening for the diagnosis of delirium, a culture change about how not to use what seems logical and protective (for example, physical restraints or pharmacological sedation), and the realization that multicomponent interventions are not simple but can be done. Thus, the most consistent message about successful interventions is to use an interdisciplinary team approach and follow geriatric principles. Although not all interventions have reported successful outcomes, the following are a few interventions that have.

In a prospective study of a multicomponent intervention to prevent the development of delirium in hospitalized older patients, patients at risk for delirium were identified using the following six risk factors for the development of delirium: baseline cognitive impairment, eye or visual problems, altered sleep–wake cycle, dehydration, restricted or decreased mobility, or hearing impairment. The standardized intervention protocols that were used in the study included the following:

- A protocol for sleep (back massage, relaxation music, decreased noise, warm milk or caffeine-free herbal tea)
- Recognition of volume depletion and treating as appropriate
- Use of an amplifier or the patient's own hearing aid
- Use of visual aids (the patient's own glasses, magnifying lens)
- Ambulation as soon as possible
- Frequent reorientation.

Development of delirium was reduced by more than one-third (15% of 426 usual care patients versus 9.9% of 426 intervention group patients; OR 0.60, 95% CI, 0.39–0.92). The total number of days of delirium and the total number of episodes of delirium were also significantly lower in the intervention group, but the severity of delirium and recurrence rates were not significantly different. The interdisciplinary team included a geriatric nurse specialist, two specially trained persons familiar with the standardized intervention protocols, a certified therapeutic recreation specialist, a physical therapy consultant, a geriatrician, and trained volunteers. The low rate of delirium in the control group compared to previous studies reflects the study being done within one hospital. Some control group patients who were on floors with intervention group patients probably received some of the interventions. Although a multicomponent intervention such as this seems labor intensive and costly, cost-effective analyses have been favorable.

In another study, 126 patients 65 years or older who were admitted for surgical repair of hip fracture, a high-risk group for development of delirium, were randomized to geriatric consultation or usual care. The geriatric consultation was proactive, which meant that the consultation began preoperatively (for 61% of the patients) or within 24 h of surgery. A geriatrician made daily visits for the duration of the hospitalization. Recommendations, based on a structured protocol emphasizing geriatric principles as well as postoperative medical care, covered areas such as treatment of severe pain, elimination of unnecessary medications, regulation of bowel/bladder function (including discontinuing bladder catheters by postoperative day 2), adequate nutritional intake and early mobilization. Overall adherence rate by the orthopedics team to the recommendations was 77%.

Development of delirium was reduced by about one-third (50% of the 64 usual care patients versus 32% of the 62 consultation patients; OR 0.64, 95% CI, 0.37–0.98). There was a greater reduction of severe delirium, occurring in 12% of the consultation group and 29% of the usual care group (OR 0.40, 95% CI, 0.18–0.89).

Another type of intervention, called the delirium room (DR), was developed for patients for whom delirium is unpreventable or who already have delirium on admission to the hospital. The DR is a specialized four-bed room that provides 24-h nursing care and observation by at least one nurse in the room and that is completely free of physical restraints. The main components of the DR are the following. The four-bed DR is an integral part of an acute care for the elderly (ACE) unit. As such, the patients in the DR receive the benefits of the geriatric principles for which the ACE unit has been shown to be effective in preventing loss of functional decline. Nursing inservices and nurse-developed protocols on

how to identify and manage delirious patients are necessary. The DR is not isolated from the rest of the floor; rather, it is the closest room to the main nurses' station. Since awareness is one of the components of the comprehensive approach to delirium (discussed previously), having a location on a busy medical floor called the delirium room can raise awareness for health-care professionals that delirium is a serious diagnosis, with serious consequences. Putting delirious or potentially delirious patients in a room together does not increase agitation, as previous literature might suggest.

The report of the DR showed that over a 12-month consecutive time frame, of the 69 patients with a diagnosis of delirium (according to the *International Classification of Disease*, 9th edition) in the DR, negative associations found in other studies of delirious patients (such as loss of function, increased length of stay, and increased mortality) were decreased. Only 13% of the patients lost physical function, and none of the 69 delirious patients died during their stay in the hospital. Mean length of stay for these patients was not significantly different compared to the length of stay for all other patients over the age of 70 during the same time frame. No physical restraints were used, and only 29% of the patients received new orders for medications considered to be pharmacological restraints (haloperidol, risperidone, or lorazepam), all at total daily doses less than 2.0 mg.

One of the risk factors for development of delirium is the hospital environment. But if patients are sick, how can this be prevented? Two novel studies of home hospital care have shown lower rates of delirium among medical patients cared for in the home compared to similar patients cared for in the hospital. In one study, 100 patients with a mean age of 76 years (70% from home, 25% from nursing homes, and 4% from hostels) and with medical illnesses such as acute infections requiring intravenous antibiotics, deep venous thrombosis, minor cerebrovascular accidents, or cardiac failure were randomized within 24 h of diagnosis to either home or hospital. The researchers used the term confusion instead of the formal diagnosis of delirium. They found a lower incidence of confusion (0 versus 20.4%; $P = 0.0005$) in the home group compared to the hospital group.

Another study of older patients admitted to the hospital with pneumonia, congestive heart failure, chronic obstructive pulmonary disease, or cellulitis randomized patients to either home for continued care or usual care to be completed in the hospital (average length of stay 2.9 days versus 4.9 days). The home care group had an adjusted odds ratio for development of delirium of 0.25 (0.11, 0.58, adjusted 95% CI).

Two other interventions worth mentioning in the areas of prevention and management of delirium are exercise and involving family members in the care of the older patient.

Physical Restraints

Restraint-free care should be the standard of care for patients who are at risk for developing delirium or who have already developed delirium. This is based on several reasons. Studies have shown both that physical restraints are an independent risk factor for development of delirium and that use of physical restraints is significantly related to severity of delirium. Furthermore, the proposed reason for the use of physical restraints among delirious patients, to prevent injury, primarily related to falls, is misconceived. Of three studies in long-term care institutions of restraint reduction programs, two showed no change in fall rate and one showed an increase in fall rate. However, all three studies showed a decrease in fall injury rates. Of two studies in the hospital setting, restraint reduction was not associated with an increase in falls. One of the hospital studies reduced restraint use from 52 per 1000 patient-days to just 0.3 per 1000 patient-days. The other hospital study showed good success on the regular wards but only modest success in two of six intensive care units in restraint reduction ($\geq$20% reduction) but reported that no deaths occurred as a result of a fall or disruption in therapy, including intensive care unit patients on mechanical ventilators.

Restraint-free environments have been achieved in some geriatric departments within European hospitals, ACE units within US hospitals, and some nursing facilities.

Pharmacological Restraints

Based on the available data concerning medications used in the management of delirium and the commonly accepted reason to use them (for patients whose behavior interrupts medically necessary care or puts themselves or others at risk of physical harm), antipsychotics should be considered a form of restraint until further evidence shows otherwise. Currently no antipsychotic or other pharmacological agent is approved by the US Federal Drug Administration for the treatment of delirium.

In patients with schizophrenia, antipsychotics can improve behavior and function, with sedation being a common side effect. However, delirium is not analogous to psychosis, and this may be the reason why antipsychotics have not been shown to do the same in patients with delirium. It is argued that they

Table 4 Use of antipsychotics in delirium

1. There is not enough evidence for the routine use of antipsychotic or other pharmacological approaches in the management of delirium.
2. Based on general geriatric principles, non-pharmacological interventions that have no or less risk should be tried before any pharmacological approach is tried.
3. If pharmacological agents are used, the lowest possible dose should be tried first, keeping in mind that the goal is a manageable and awake, not oversedated, patient.
4. Based on very limited data, the category of drug of choice seems to be antipsychotics, not benzodiazepines or sedative hypnotics.

control behavior, but it is unclear whether this is through the sedation effects of the drugs or through their effect on the neurotransmitters thought to play a role in delirium. One of the main problems with antipsychotic drugs, whether atypical or typical, is that they are not pure in their mechanism of action. For example, although risperidone primarily affects serotonergic (5-HT_2A) receptors, it affects to some extent dopaminergic and α-1 receptors. Although olanzapine affects the 5-HT_2A receptors, similar to risperidone, its sedation properties are probably due to its effect on the histaminic receptors. Clozapine also affects histaminic as well as muscarinic receptors, and quetiapine has varying effects on histaminic and α-1 receptors but also has a small effect on dopaminergic and 5-HT receptors.

The available data for use of antipsychotics in the management of delirium are poor because of the populations studied, the types of studies done, or the presence of the common mistake of not including a placebo group in order to measure the natural course (duration) of delirium without pharmacological intervention. For example, one of the often-referenced studies condoning the use of antipsychotic medications compared haloperidol, chlorpromazine, and lorazepam in 30 delirious hospitalized patients with AIDS, whose mean age was 39.2 years (range 23–56 years). Another study comparing haloperidol and mianserin included 60 patients with a mean age of 65 years and did not have a control group either. Thus, although they reported improvement on a delirium rating scale at 1 week, one questions whether or not patients would have improved by this time anyway. It should be noted that one randomized controlled trial of a non-pharmacological intervention to prevent delirium found that even in the control group patients that developed delirium, the average total number of days of delirium was approximately 2.5.

Newer studies with atypical antipsychotics are also wrought with this error of not taking into account the duration of delirium without medication. A prospective study of 64 patients with delirium who received risperidone reported improvement at day 7. Olanzapine was evaluated in a retrospective study of 11 delirious patients compared to 11 other patients who received haloperidol. It took 6.8 days and 7.2 days, respectively, for the peak clinical response.

The proper dosage of antipsychotics has also never been established. One recent recommendation is that if severe agitation is present, haloperidol doses of 0.25–1.0 mg can be used as often as every 20–30 min, with a maximum 24-h dose of 3–5 mg. This dose is recommended because D2-dopaminergic receptors are saturated at low doses, and thus theoretically doses above 5 mg over a 24-h period are likely to increase adverse events without providing additional clinical benefit. The goal should be an awake patient who is manageable, not a sedated patient, and the drug should be tapered and discontinued as soon as possible. One study of delirious ICU patients, mostly surgical with an average age of 65 years, compared haloperidol and olanzapine. For patients over 60 years, haloperidol was initiated at 0.5–1.0 mg and olanzapine at 2.5 mg every 8 h. Younger patients were initiated at doses of 2.5–5.0 mg and 5 mg, respectively. The delirium index (measure of severity) decreased over time, and clinical improvement was the same in both groups. The study did not detail what percentage of patients was mechanically ventilated.

Table 4 includes conclusions based on the available current data.

Glossary

Dementia – The acquired loss of cognitive abilities in more than one domain.

Introduction

Dementia is the acquired loss of cognitive abilities in more than one domain. It can be progressive or not and reversible or not. The differential diagnosis of dementia includes many conditions such as degenerative and vascular, as well as those associated with movement disorders. Treatment depends upon the kind of dementia but should include both biological and psychosocial approaches.

Dementia, the loss of thinking abilities in more than one intellectual domain, represents a great challenge to individuals and to societies. Not all dementias are progressive, but many are – particularly those that affect the elderly. Dementia is often associated with memory impairment but can present itself in various different forms with quite variable initial symptoms and subsequent courses. Dementias, especially those that progress, can lead to considerable functional disability and dependence on others, as well as eventually contributing to death.

The concept of dementia emerged in the mid-1800s. During this period of medical history, neurology and psychiatry were less differentiated from each other. Confusion reigned as to the causes of and mechanisms for the deterioration in the intellect found in a variety of conditions. What constituted a psychiatric and neurological condition was less clear, although even today mind and brain issues continue to perplex us. The thought disorder in schizophrenia was labeled dementia praecox, although it was not until modern times that the cognitive dysfunction in schizophrenia was fully appreciated. Syphilis was a common cause of dementia (general paresis of the insane) at the turn of the century. In the early 1900s, the field of brain psychiatry emerged, and researchers began to study the brain pathology associated with dementias. Dr. Alois Alzheimer contributed not only to describing the condition that now bears his name, but also to the understanding of vascular dementia, syphilis, and Pick's disease.

In modern times, the concern about dementia has increased because of the growing number of affected people due to a variety of social and environmental issues that characterize modern life. Projections of some of these trends into the future predict that more cases of dementia will burden individuals, their families, and the health-care system in the twenty-first century. Most notable among the social trends is the aging of the world's population. Thus, degenerative and vascular dementias will become more common. As the number of persons with HIV/AIDS increases and current therapies keep people alive longer, more AIDS-related dementias will occur. The likely increase in environmental toxic exposures and infectious diseases caused by industrial pollution and global warming affecting ecosystems will affect larger numbers of people – particularly those grouped in urban areas. Viral and other encephalitides may spread more rapidly, perhaps leading to, for example, another influenza epidemic. More conflicts over resources such as water and oil may lead to an increase in war-related head injuries causing dementia among both military and civilian participants.

Epidemiology

Dementia affects individuals of all ages. By definition, in order to be labeled demented, a person must have had a higher level of intellectual ability prior to a decline. More dementias affect individuals who have been alive long enough to gain intellectual skills and then to lose them. World-wide estimates of the incidence and prevalence of dementia are difficult to obtain because of the difficulty in making the diagnosis and recording cases in the developing world. Moreover, which conditions are included in the category of dementia and what forms of dementia should be included in these surveys vary across the studies. In many texts, it is said that degenerative dementias are the most common causes, with Alzheimer's disease (AD) being the most common in that category. Following AD, conditions such as frontal lobe dementia and dementia of the Lewy body type account for significant percentages (perhaps 10–20% each) of dementia cases. It is also said that vascular dementia is the second most common etiology, particularly in populations at risk for vascular disease, such as African Americans in the United States and some Asian populations. However, it is increasingly recognized that individuals with so-called vascular dementia often suffer from a mixed overlapping pattern with AD. Also, patients with AD often display vascular lesions such as amyloid angiopathy and arteriosclerosis. From a more inclusive viewpoint, however, dementia includes large numbers of individuals who are victims of famines and wars. Individuals whose brains are inadequately nourished or affected by head trauma fit within the definition of dementia and should be included in a full accounting of the dementias. Even in the United States, thousands of young children's brains are damaged by lead; mercury pollution is also a growing threat to neurological health.

Diagnostic Evaluation

As shown in **Table 1**, many different conditions can cause dementia. Such lists of the dementias can range from the 10 most common dementias to huge numbers of rare conditions of various degenerative, metabolic, and infectious disease types. Some dementias that are caused by ongoing irreversible processes in the brain are progressive. Others, such as head injury, are relatively fixed in their course. Although some dementias are irreversible because the underlying pathology cannot be interrupted, they should not be considered untreatable. All dementias are treatable

Table 1 Broad causes of dementia

Type	*Examples*
Degenerative	Alzheimer's disease, Parkinson's disease, Huntington's disease, frontal lobe dementia
Vascular	Multi-infarct, hematomia, white matter pathology
Infectious	Slow virus, chronic meningitis
Metabolic	Thyroid distinction, alcohol related
Head trauma	Missile wounds, closed head injury
Psychiatric	Depression, chronic schizophrenia
Genetic	Storage diseases

with psychosocial interventions, and many can be ameliorated by biological therapies. This article discusses the dementias in two broad categories: reversible and irreversible. It must be recognized, however, that these terms are relative and that even so-called reversible dementias due to metabolic causes may not allow an individual to return fully to their baseline intellectual state. There is tremendous overlap between the different kinds of degenerative dementias and between degenerative dementias and vascular disease. Particularly in the elderly, multiple conditions may affect an individual's brain function contributing to dementia.

Thus, applying the label dementia necessitates that the physician try to determine a more specific cause. The first step is to determine that dementia is the most appropriate label. For children who have never been intellectually normal or who have not deteriorated from a previous baseline, a more appropriate label may be amentia or mental retardation. Children and adults may have an acute metabolic disturbance such as abnormal electrolytes or exposure to toxins such as alcohol. Such deliriums may be fully reversible by treating the underlying metabolic problems. However, delirium can also coexist in persons with dementia.

It is often quite difficult to differentiate psychological or psychiatric causes of cognitive impairment. For example, depression – particularly in the elderly – can manifest as a cognitive retardation and create a picture of dementia. Some have labeled this as a pseudo dementia, but its cognitive impairment is genuine and is best labeled as an actual form of dementia. Once again, these psychiatric causes overlap with neurological forms; thus, patients with AD and Parkinson's disease can be demented from both the underlying neurological condition and depression.

The nosological problems of dementia can be illustrated by the concepts of cortical and subcortical dementia. These terms are falling out of favor but represent an attempt to categorize degenerative and other dementias depending on the alleged primary location of the pathology causing the cognitive impairment. Prototypical so-called cortical dementias include AD and frontal lobe dementias. Prototypical so-called subcortical dementias include progressive supranuclear palsy and Huntington's disease (HD). Although these terms were somewhat heuristic in identifying that there was heterogeneity in the dementias, the pseudo-anatomical nature of the terms is apparent, as subcortical pathologies exist in AD and cortical pathologies in HD, for example.

Moreover, the associated clinical symptoms (for example, motor disturbances) are often the obvious difference between the two categories. The use of the terms cortical and subcortical is falling out of favor even for didactic or educational purposes, which should be based on our best scientific understanding. Certainly much cortical pathology occurs in AD, and the basal ganglia appears to be more of a target in HD. Determining the relative importance of different systems underlying cognitive symptoms and their treatment is difficult. The first drugs approved for AD were based on ameliorating subcortical pathology in the cholinergic basal forebrain.

The clinician should take a careful history to determine the nature and course of the dementia. General physical, neurological, and psychiatric examinations should be given to search for signs of associated illness that might give clues to the cause of the dementia. A mental status exam that covers the domains of attention, executive function, language, praxis, and perception and that considers different types of short- and long-term memory should be conducted. If the degree of cognitive impairment is mild, neuropsychological assessment to establish the presence of cognitive impairment greater than expected for age and education and to determine the patterns of cognitive impairment should be considered. Moreover, in questionable cases of dementia, such a sensitive, detailed assessment can serve as a baseline for subsequent evaluations. For many of the dementias, the boundaries between normal and abnormal or pathological are fuzzy. The concept of mild cognitive impairment has been invented to try to characterize preclinical forms of dementia. However, the term has proven to be quite controversial and should not be used clinically. Some argue that patients prefer the term mild cognitive impairment rather than brain aging; others disagree with early dementia. Any progressive dementia has a phase in which cognitive impairment is present but the clinician does not believe that the functional impairment is sufficient to warrant the label of dementia. Mild cognitive impairment is based on arbitrary thresholds on various cognitive and functional criteria, is inconsistently used by experts, is very heterogeneous, and often does not predict subsequent course.

Once the presence of dementia has been established on the basis of history and the physical examination, it is often important to conduct additional laboratory tests to pinpoint the specific cause. Brain imaging such as computerized tomography (CT) or magnetic resonance imaging (MRI) can determine whether there are any structural lesions that cause dementia, such as strokes or tumors. The use of single photon emission computerized tomography (SPECT) and positron emission tomography (PET) scans (i.e., functional imaging) in the evaluation

of dementia is controversial. Specific patterns of a reduction in blood flow or glucose utilization can be associated with AD (parietal temporal) and frontal lobe dementia (frontal and/or temporal), but the overlaps are considerable. The diagnosis should be made based on the clinical pattern of impairment and not on the imaging. An electroencephalogram (EEG) may be used in rare cases where the cognitive impairment appears to fluctuate in a manner consistent with seizures. Moreover, in some conditions it may provide diagnostic assistance. For example, in Pick's and frontal lobe dementias, the EEG may appear normal later in the course than in AD. In a rare infectious course of dementia called Creuzfeldt–Jacob disease, characteristic sharp wave activity may make the diagnosis more certain. Blood tests should be conducted to make sure that there are no metabolic causes of the dementia, focusing particularly on thyroid and vitamin B_{12}. Finally, in rare circumstances it may be worthwhile to consider a spinal tap to examine cerebrospinal fluid. If suspicion of some inflammatory, vasculitus, or infectious process exists, then examination of fluid may aid the diagnosis. Research studies show lower cerebrospinal fluid (CSF) levels of amyloid and higher levels of tau in AD, but the overlap with normal and other neurological disease controls is considerable. No clinical diagnostic consensus statements recommend their use in routine practice. Finally, in rare cases a brain biopsy may be helpful, particularly in younger people if evidence of vasculitis or a specific metabolic or degenerative process is present. However, it is often difficult to make the diagnosis based on the limited tissue often obtained at biopsy. Moreover, the critical issue to consider is whether the brain biopsy would affect treatment.

Types of Dementia

As mentioned previously, the dementias are discussed in two broad categories, reversible and irreversible, recognizing that there is overlap in these categories and that individual patients often suffer from several different processes manifesting at the same time.

Reversible Dementias

The principal reversible dementias are metabolic. Hypothyroidism and exposure to industrial or environmental toxins should be considered; iatrogenic cognitive impairment due to medications is a common example. Depending on the acuteness and intensity of the metabolic disturbance, the clinical presentation may be more similar to delirium than dementia. These dementias are reversible, but often not completely, depending on the length of exposure of the brain to the abnormal metabolic environment.

Perhaps the most challenging reversible dementia is depression, because it often coexists with a neurological disease. In some circumstances it can be the initial symptom of a condition such as AD. The clinical adages that "people with AD do not complain about their memory problems; their families do" and "the patient with depression actually is the one who complains" are worth considering. All patients with dementia are at risk for depression because of their reaction to the underlying illness. Moreover, patients with vascular dementia and Parkinson's disease may be more at risk because of lesions in areas of the brain that affect emotions. Counseling should be offered to all patients with depression, and a therapeutic trial of antidepressive medications may assist the patient and aid in the differential diagnosis as well.

Normal-pressure hydrocephalus, another rare dementia, is associated with early onset of gait ataxia and incontinence. Abnormal cerebral fluid pressure dynamics can be treated by placing a ventricular shunt and draining fluid from the brain. The principal problem is predicting who will benefit from a shunt. Brain imaging often shows enlarged ventricles out of proportion to the degree of atrophy but is often specific for the diagnosis. Often the removal of a small amount of CSF to see if there are any changes in the patient's gait is the best predictor of whether there will be benefit from the shunt, which carries the risk of infection and bleeding.

Irreversible Dementias

Unfortunately, many dementias are partially or completely biologically irreversible. However, as mentioned previously, it is important to recognize that all dementias are treatable. Some of these irreversible dementias are preventable. For example, automobile accidents in civilian populations and projectile wounds in military populations are common causes of brain damage that cause dementia. Some improvements can occur in these conditions for a period of time after the initial insult, but affected individuals are left with varying degrees of impairment and often severe limitations in function.

Vascular dementias are another large category of irreversible but potentially preventable dementias. The classification of the vascular dementias is complex and has evolved over the last several decades. Multiple small infarcts, hematomas of various kinds, single strategic infarcts, vasculitis, and other disturbances in vascular mechanisms can all cause dementia. They can be differentiated from the

degenerative diseases, although overlapping syndromes are common. Neuroimaging may show strokes, white matter ischemic changes, or other vascular lesions. The onset may be abrupt and the course more stepwise in its progression. Vascular dementia is largely treated by modifying risk factors. Some drugs approved for the treatment of AD may also help patients with vascular dementia, such as the cholinesterase inhibitors and memantine, although these are off-label treatments.

The most common degenerative dementias are AD, frontal lobe dementia, and those associated with Parkinsonism. There is considerable overlap between these different conditions, even in families in which known genetic mutations cause degenerative dementia. Family members with the same mutation can demonstrate different pathologies and clinical course. Motor symptoms, either impoverishment or overactivity, are useful in differential diagnosis. Parkinsonism is characterized by bradykinesia or slow movement, rigidity, and tremor and can be seen in a variety of conditions, including classic idiopathic Parkinson's disease as well as other, rarer neurodegenerative conditions. Dementia of the Lewy body type is characterized pathologically by the Lewy body (found in Parkinson's disease in the mid-brain but in this disease throughout the cortex as well) and clinically by Parkinsonism fluctuating attention and hallucinations. HD is associated with abnormal involuntary movements, such as chorea, and is the prototypical autosomal dominant cause of dementia. AD is usually characterized by initial presentation with memory difficulties followed by other cognitive impairments in the domains of language, perception, and praxis. Frontal lobe dementia is associated with early disturbances in attention and executive dysfunctions such as goal setting, planning, and monitoring one's own behavior. In addition, frontal lobe dementia is often accompanied by disturbances in behavior and emotion. However, the clinical overlap between AD and frontal lobe dementia is considerable.

Treatment

The treatment of any person of any age with any degree of cognitive impairment must be individualized. Clearly, if there are underlying causes and risk factors for deterioration, they must be addressed. It is always important in the treatment of dementia to have clear therapeutic goals established in partnership with the patient and family. Often, the concept of quality of life is an important guide to therapy, as this reflects the values of the individual and his or her family. This section discusses both non-pharmacological and pharmacological treatments of dementia. Remember that non-pharmacological approaches are always appropriate. Pharmacological treatment may be useful in some circumstances but may also contribute to patient dysfunction because of side effects.

Non-pharmacological Approaches

Non-pharmacological approaches include providing educational material, suggesting counseling, and recommending environmental modifications in the patient's home or other residential care environment. A considerable degree of misunderstanding, even in experts, exists with regard to the labels that are used to classify dementia. Hence, informing patients honestly about the uncertainties of diagnosis and prognosis is important. It is helpful to provide patients and families with some sense of the stages that the patient may go through, even though the course of illness can be quite variable. A diagnosis of dementia can be stressful for both the patient and the family. Support groups offered by lay organizations such as Alzheimer and Parkinson's associations are quite helpful to both patients and caregivers in learning practical management skills and sharing means of adaptation. Wherever the patient lives, the environment can be examined for modifications that may improve quality of life, for example, to provide adequate privacy, social interaction, and exercise. The use of household appliances should be monitored. A major safety issue is driving. Patients should be evaluated and counseled to stop driving when appropriate. A wealth of literature is available about modifying environments to prevent wandering and other risks to patients.

Biological or Pharmacological Treatment

As mentioned previously, if a dementia is essentially reversible or has a potentially reversible component, it is important to treat the underlying cause. Many medications can contribute to cognitive impairment, particularly prescribed and over-the-counter medications with anticholinergic and antihistamine side effects. A few drugs have been approved for the treatment of mild to moderate AD, such as cholinesterase inhibitors (donepezil, galantamine, and rivastigmine). Many other dementias have a cholinergic component, including Parkinson's disease and dementia of the Lewy body type and probably vascular dementia. Cholinesterase (ChE) inhibitors might be tried in these conditions even though they are off-label. Moreover, there is evidence that some

patients with vascular dementia respond to this class of agents.

Memantine acts through a different neurotransmitter, glutamate, as a glutamate receptor antagonist. This medication has been approved for moderate to severe stages of AD but can be considered off-label for other degenerative dementias and vascular dementias as well.

Medications can also be used to treat the noncognitive or behavioral symptoms of dementia. Depression, agitation, hallucination, delusions, social inappropriateness, and apathy can disturb patients and caregivers more than the behavioral symptoms. Some evidence suggests that medicines used for treating this phenomenology in psychiatric diseases can be used in patients with dementia. Antidepressants are used for demented patients with depression. Novel neuroleptics are the most widely used drugs for agitation and psychosis, but they have significant risk of side effects.

The holy grail of drug development in dementia is to find medications that actually prevent or modify the biological course of the disease. A variety of approaches, such as estrogen replacement therapy, anti-inflammatory agents, antioxidants such as vitamin E, and statins, have been assessed. Epidemiological and basic science studies suggest such candidates for slowing the biological progression of AD. Since there are overlaps in the pathogenetic mechanisms of AD and other conditions such as vascular dementia, these classes of potential disease-modifying agents may have effects in several dementias. However, no adequately sized and conducted studies have demonstrated any disease-modifying action from any drug. No drugs are approved as agents to modify the progression of a dementia save those that modify risk factors.

So-called complementary and alternative medicine approaches are also often used by patients to prevent cognitive deterioration. However, no such products have been demonstrated in adequate trials to modify the progression of any dementia. Gingko biloba is widely used and is currently being studied but cannot be recommended.

Future Directions

Dementia represents both a tremendous challenge and opportunity to apply powerful new scientific approaches to understanding pathological mechanisms and developing more effective therapies. However, we must be careful about exaggerating the likelihood that progressive dementias will yield quickly to our technologies. The boundary between some degenerative conditions and aging mechanisms is not clear, and thus attempts to slow the biology of these age-related degenerative conditions may be tantamount to finding a neurological fountain of youth. Currently, genetic and molecular biological approaches are exciting and offer hope. But excessive hype leads to the possibility of creating false hope. Moreover, focusing on genetic factors in late life may result in ignoring effective preventative therapies at young ages, such as preventing exposure to toxins. It is remarkable that the consequences of lead poisoning on the brains of young children (i.e., dementia and other forms of cognitive impairment) have been known for centuries but were not adequately acted upon. Even in a wealthy country like the United States, children are still exposed to dangerous levels of lead. Moreover, as we continue to pollute our environment with a variety of manmade chemicals, it is quite possible that environmental causes of dementia will become more common in adults. Thus, the major contributors to the increase in incidence of dementia include the aging of the population and the social and environmental stressors that will contribute to poor cognitive health.

Ethical issues about social justice and priorities for our health-care system will continue to be important. We seem excessively enamored with the power of genomics to create more effective medications. The medical profession has been criticized for its close alliance with the pharmaceutical industry. So, too, the bioethics establishment is said to be coopted by medicine. Safety issues with new medications and studies that show little improvements in efficacy associated with greater costs challenge the viability of current drug development approaches. Many ethical issues remain in research on developing more effective drugs for dementia. For example, most countries have not adequately dealt with the issue of informed consent (i.e., how to use proxies to provide informed consent in patients with no or reduced capacity to do so themselves). Now that the drugs are available on the market, when is it appropriate to use placebos in drug trials? Finally, what are the appropriate goals for treatment, especially in severe dementia? What evidence is there that the drugs have benefit on quality of life or health-care costs?

It has been a century since many of the causes of dementia were first identified by brain psychiatrists such as Alois Alzheimer. Perhaps it is time to reflect on what we have learned about these conditions so that the next 100 years can be guided by greater wisdom than we are currently demonstrating.

Glossary

Alzheimer's Disease – A degenerative brain disease characterized pathologically by cell loss associated with neurofibrillary tangles and plaques.

Delirium – Acute confusional state.

Introduction

Alzheimer's disease is considered a degenerative brain disease and was first described in 1906. As the world's population ages, it will become more common. It is characterized pathologically by cell loss associated with neurofibrillary tangles and plaques. The etiologies are unknown, but genetic factors play a role in the condition. The diagnosis is primarily one of exclusion, and the treatment a combination of pharmacological and non-pharmacological approaches. Future research challenges and ethical issues are considerable.

Alzheimer's disease (AD) is an eponym that has been with us for almost 100 years. Although a single label, it includes a variety of different clinical pictures and biologies. It is most often considered a degenerative brain disease characterized by senile or neuritic plaques and neurofibrillary tangles. In 1906, Dr. Alois Alzheimer described the first case of what became called Alzheimer's disease in a woman who presented progressive cognitive and behavioral impairment at the age of 51. Clinically, AD often presents with memory problems, but subsequently progresses to involve other cognitive abilities and behavioral symptoms such as agitation and even frank psychosis.

Since its original description and naming as a disease by Emil Kraeplin in his psychiatry textbook in 1910, we have come to know much about AD. However, as time has passed the picture has become more complex, not less. As with all degenerative diseases, AD is characterized by a progressive loss of neurons in the nervous system in association with a variety of pathological features. However, it remains controversial as to what are the respective roles of neurofibrillary tangles and senile plaques in contributing to neuronal death. Variable numbers of plaques and tangles are found in individuals with AD. Moreover, a variety of genetic lesions can cause early-onset AD and modify late-onset disease. Thus, heterogeneity of the biological substrate of AD is the watchword.

One of the great historical and current controversies, recognized even by Alzheimer himself, was so-called presenile dementia and whether this condition occurring in younger people was fundamentally

different than senile dementia occurring in older persons. The relationships between the normal processes of brain aging and AD also remain perplexing and controversial.

The term mild cognitive impairment has joined a long list of labels that have been applied to individuals who have cognitive impairment but not of a magnitude sufficient to warrant the label of dementia. Previous terms include benign senile forgetfulness, aging-associated memory impairment, and aging-related cognitive decline. Logically, any degenerative condition such as AD must have a preclinical phase that is characterized by cognitive impairment unassociated with functional decline sufficient to warrant the label dementia. The term mild cognitive impairment is used inconsistently by experts, is based on arbitrary thresholds in impairment, and has heterogeneous features and outcomes. Some patients prefer a label such as mild cognitive impairment to brain aging or early dementia, but because of the controversy it should not currently be used clinically.

AD is said to be the most common dementia worldwide. Alzheimer's Disease International claims that there are perhaps 25 million people with AD around the world. The veracity of this figure is uncertain because of different epidemiological approaches used in different countries. In addition, the arbitrary distinctions among normal brain aging, mild cognitive impairment, and AD produce different results in different studies depending on the criteria used. Nevertheless, it is clear that as the population of the world ages, the number of individuals with degenerative diseases such as AD will increase. However, other forms of dementia associated with social and environmental disturbances, such as war, epidemics, and environmental toxins, will also likely increase in frequency.

Pathology

As with most degenerative dementias, AD is associated with neuronal loss in association with specific pathological features. Widespread pathology in the cortex contributes to atrophy visible at autopsy and clinically on neuroimaging. This cell loss is accompanied by extracellular neuritic plaques and intracellular tangles as described by Alois Alzheimer, but a variety of other changes are also apparent, such as changes in blood vessels, granulovascular degeneration, and Lewy bodies. The senile or neuritic plaque is an accumulation of abnormal proteins, including amyloid, surrounded by abnormal neuritic processes. The neurofibrillary tangle is found inside certain neurons and is composed of tau in a paired helical configuration associated with other proteins. Although AD affects many populations of neurons, it is selective in impairing some more than others, although the pattern is quite variable in different cases. Hippocampal involvement is universal and underlies some of the memory disturbance. In addition to the cortical pathology, changes occur in subcortical structures such as the nucleus basalis of Meynert (cholinergic basal forebrain), noradrenergic locus ceruleus, and serotonergic raphe nucleii. It is said that a definite diagnosis of AD can be made only on the basis of autopsy findings. However, even at autopsy it is sometimes difficult to differentiate normal aging from AD; different neuropathological criteria emphasize different features. The distinction from normal is more quantitative than qualitative. Moreover, many elderly individuals suffer from mixed dementia, that is, a combination of AD changes with vascular and/or Parkinson's features.

Etiology

Shortly after its original description, it became known that AD can be familial. Rarely, the pattern is one of autosomal dominance in which 50% of children on average inherit the gene from an affected parent. The fact that individuals with Down's syndrome or trisomy 21 are more at risk for developing plaques and tangles later in life provided motivation to examine this chromosome in AD. A number of mutations have been described in the amyloid precursor protein, the gene for which is located on chromosome 21, causes dementia in some rare families. These mutations alter the procession of the large (approximately 700 amino acids) precursors, which in turn allows the accumulation of the smaller (approximately 42 amino acids) amyloid protein itself. Secretase enzymes clip the precursor into smaller proteins as a part of normal processing, but mutations affect these shortening activities.

Other mutations have been described on chromosomes 1 and 14 in genes coding for proteins called presenilins (which may be related to the secretases), which are also involved in disrupting amyloid processing. Although these autosomal dominant forms are rare ($<$1–2% of cases), other genes modify the risk for later sporadic forms. The only well-established susceptibility locus is apolipoprotein E (ApoE) located on chromosome 19. ApoE is a cholesterol transport protein and exists normally in several forms. Individuals who have one or particularly two copies of the ApoE4 form of the protein are at higher risk for AD. Other susceptibility genes probably exist but remain to be clearly demonstrated.

A variety of other theories as to what causes AD have developed. Antioxidant theories of AD are similar to those used to explain normal aging. The accumulation of free radicals in the brain is said to damage nerve cells. Of late, inflammatory hypotheses have achieved some prominence, as atypical cellular and chemical inflammatory features are associated with senile plaques. Other studies have implicated the mechanism of excitatory cell death in AD. According to this theory, neurons die through excess stimulation by excitatory amino acid neurotransmitters such as glutamate. Finally, many parallels have been drawn between the potential etiology mechanisms in AD and vascular dementia, focusing on pathology in blood vessels. Amyloid can accumulate in vessel walls. Moreover, alterations in cholesterol metabolism have been claimed to be involved in both conditions.

The major risk factor for AD is advancing age. However, the relationship between normal age-related processes in the brain and AD remains controversial. To date, there is no way to make a diagnosis of AD with certainty in either life or death that does not involve the establishment of some arbitrary threshold in a clinical or biological feature present in both AD and aging but that is more apparent or severe in those with dementia. Cerebrospinal fluid (CSF) markers for tau (elevated) and amyloid (reduced) are affected in AD, but the values overlap with normal aging and other neurological diseases. Hence, well-accepted clinical consensus panels have not recommended their routine use. Combining multiple markers may lead to more definitive diagnostic tests, but they have not done so to date. The often-made statement that AD is not normal aging is more a political than a scientific one. Is AD a form of severe brain aging?

Diagnosis

AD is characterized by the insidious onset and slow progression of intellectual difficulties, usually starting with memory impairment. It can begin with language, praxis, perceptual, or executive dysfunction. The illness is said to evolve through stages from mild to moderate to severe. In late stages, cognitive difficulties are often associated with behavioral disturbances. In the mild stages, patients are often independent and suffer only from memory problems and perhaps some mild attention difficulties. In the moderate stages, they become dependent on others for assistance with instrumental (more complex) activities of daily living, and a broader pattern of intellectual impairment develops. In the severe stages, dependence is even greater and the patients may lose the ability to perform even basic activities of daily living, including personal hygiene. In profound stages, patients may be mute and completely dependent on others for care. AD is said to be a terminal disease; life expectancy is reduced, although death usually occurs through infection, secondary to immobility (pneumonia, for example).

Although these features are typical of AD, they are not specifically exclusive to AD. AD is often considered a diagnosis of exclusion, meaning that the diagnostic assessment discloses no other explanation for the cognitive impairment. However, depression and normal aging are also not accompanied by any alterations in biological tests to allow clear differentiation from AD. Thus, the clinician is often left with a diagnostic dilemma in mild cases as to whether a person has normal age-related cognitive changes, depression, or AD. Depression can also co-exist with a neurological cause of dementia. Delirium (acute confusional state) is also commonly associated with AD. An abrupt change in mental status in AD should prompt a search for a metabolic or infectious cause of the decline. No biological test has been approved to diagnose AD, although hundreds of claims for the utility of various approaches have been made.

Treatment

The treatment of any dementia involves both biological and psychosocial interventions, or, to put it another way, drugs and non-pharmacological approaches. All dementias demand attention to the therapeutic goals of patients and families and to the resources of the family and community to provide such services. These interventions should be tailored to individual preferences as well as to the different stages of the disease. Maintaining or even enhancing quality of life of the patient and caregivers should be an overarching goal.

Drugs for Improving Cognitive Symptoms

Five drugs have been approved for the treatment of cognitive symptoms in AD. Four of them are cholinesterase inhibitors that act on the deficiency in the neurotransmitter acetylcholine associated with the loss of cells in the cholinergic basal forebrain. The first approved was tacrine, but this drug is not used today because it needs to be administered four times a day and causes reversible liver toxicity. Donepezil, the most commonly used drug, can be administered once a day and is not associated with liver toxicity. It shares with all the cholinesterase inhibitors the tendency to cause some degree of gastrointestinal upset such as nausea, vomiting, diarrhea, and/or

abdominal cramps. Moreover, muscle cramps and sleep disturbances can also occur. The latest cholinesterase inhibitor approved, galantamine, now can be given once a day. Rivastigmine is not as widely used as the other two because it causes more severe gastrointestinal side effects and is required to display a black box FDA warning concerning weight loss. All of the cholinesterase inhibitors have a similar efficacy profile, and decisions about which to use have more to do with side effects (claims that they have other properties that may be advantageous and differentiate them from each other are of unclear clinical relevance). The cognitive benefit of these drugs is very modest and the impact on activities of daily living rather minimal. Their effects are rarely of sufficient magnitude to improve or even maintain quality of life, although little data exist to support or challenge this assertion.

The last drug approved for the treatment of cognitive impairment in AD is memantine, which acts through a different mechanism, glutamate receptor antagonism. Its efficacy is comparable to the cholinesterase inhibitors, but its side effect profile is different. It occasionally causes constipation, dizziness, and rarely confusion. This drug is also thought to possibly have an effect on any excitatory amino acid overactivity that may occur in AD. However, this mechanism is speculative, and no drug has been approved by the US Food and Drug Administration as a disease-modifying agent. Similarly, the pharmacoeconomic benefits of these drugs (i.e., whether they save health-care dollars by, for example, delaying nursing home placement) have yet to be adequately demonstrated.

Drugs for Modifying the Course of Disease

As mentioned previously, the manufacturers of cholinesterase inhibitors and memantine have claimed that they may have mechanisms of action that may modify the biology of the disease, but these claims have not been demonstrated in clinical studies. As mentioned in the section on etiology, a variety of mechanisms of neuronal damage have been proposed in AD. Associated with each of these theories are potential drug approaches, such as the use of antioxidants, anti-inflammatory agents, or estrogen replacement therapy. Although case control epidemiological studies have supported the idea that the use of these medications may protect from AD, randomized control studies have not supported these claims. Vitamin E (an antioxidant) was widely recommended in the United States for AD, but recent studies questioning its efficacy and raising concerns about safety are curtailing its use. A variety of complementary and alternative medicine approaches have also been suggested to either treat or to prevent the progression of the disease. However, none of these claims has been adequately justified. Ginkgo biloba is widely used around the world, and studies are under way to determine whether it has benefit in memory-impaired patients.

Drugs for Behavioral Symptoms

Patients with AD, particularly later in the illness, develop depression, agitation, and frank psychosis. Though the evidence is not strong, clinicians often use drugs that have been approved for other psychiatric conditions to treat these symptoms. Hence, the antidepressants and the antipsychotics are commonly used. New-generation agents in both classes may have advantages in terms of causing fewer side effects than the tricyclic antidepressants and typical neuroleptics. However, there are dangers associated with the use of all psychiatric drugs in patients with dementia, and non-pharmacological approaches should be emphasized. Avoiding situations that provoke the behavioral symptoms, trying to understand the situation from the patient's perspective, and redirecting attention away from the provocative situation are helpful approaches.

The Future of AD

The most critical issue facing our efforts to better understand what we now call AD is the relationship between AD and normal aging. AD is a heterogeneous class of diseases that is currently subsumed under one single eponym. Numerous genes can cause AD, and many likely await discovery. Neuroimaging studies as well as studies of clinical phenomenology suggest considerable overlap between AD and disorders such as Parkinson's disease, vascular dementia, and frontal lobe dementia. Thus, it is likely that a variety of biological processes affect the brains of older people, and we have only a very rudimentary understanding of how those processes could best be classified diagnostically.

Much effort is being applied to finding a specific diagnostic test, particularly using neuroimaging. Compounds to image amyloid in the brain using functional neuroimaging such as positron emission tomography (PET) are the most interesting. However, they face the same challenge of all biological markers – amyloid is found in varying degrees in most people as they age. AD will likely remain a sociomarker (a label applied clinically). Tremendous energy is being applied to the development of more effective drugs. Most of this attention is focused on

agents that may be able to modify the biological progression of the disease. Most effort has been placed on the hypothesis that agents that would eliminate or remove amyloid from the brain can be developed. Excessive expectations have been raised by approaches such as the use of vaccines or stem cells. The development of effective therapies to reverse or arrest the biologies of AD remains a distant prospect.

In the immediate future, however, there are significant issues with regard to health-care costs associated with AD. As mentioned, pharmacoeconomic studies do not demonstrate convincingly that current drugs provide a significant impact on quality of life and health-care costs. The costs of long-term care are increasing as the population of most countries ages.

Thus, there needs to be considerable energy applied to the development of better psychosocial and educational approaches for patients with AD and their families. Again, recognizing that AD may be a form of brain aging, all of these approaches are relevant to older individuals with memory problems of any cause. Although we focus extensively on the power of biotechnology, we should recognize that information technology allows the opportunity to assist people with memory problems. Computers better educate us, offer opportunities to integrate our lives, and can help us adapt to changes in our cognitive abilities as we age. They could also allow us to monitor and improve the quality of life for people with AD. Regardless of the diagnostic label, older individuals should remain engaged in the community. The advice to continue to keep mentally and physically active should be given to all patients. New opportunities should be created that are adapted to people with memory problems. In Cleveland, for example, the Intergenerational School offers learning opportunities for patients with so-called mild cognitive impairment and AD. This provides not only the opportunity to keep mentally active by reading and interacting with children, but by doing so, it also creates a sense of engagement in community and purpose in life.

For those individuals that eventually become dependent on others for basic activities of daily living, change in residence from home to long-term care facilities will often be required. There are ongoing rapid changes in the provision of residential care for people with dementia. Assisted living programs have been developed for people with milder symptoms. Once the symptoms are apparent, so-called special care units have been developed within the context of nursing homes. However, there are many cultural changes necessary in the long-term care industry. For example, the Eden Alternative emphasizes a resident-focused care that is more harmonious with the natural environment. In long-term care, relabeling AD special care units as memory support units is one example of how to de-emphasize the labeling process and focus on providing functional support. Timeslips is a narrative therapy intervention that encourages creative storytelling even in people with moderate and severe dementia, emphasizing the importance of keeping cognitively vital regardless of diagnosis.

End-of-life care for people with dementia also needs considerable improvement. In general, palliative care is being introduced too slowly into medicine, even for those with more classic terminal illnesses such as cancer. However, many hospices are now developing programs specifically for patients dying with cognitive impairment. Empirical studies suggest that some of the interventions we use, such as feeding tubes and antibiotics, actually do not improve either quantity or quality of life. The critical issue for the future will be how much effort we can apply to feeding individuals with severe dementia. These questions will grow as the numbers of affected people increase and resources for long-term care of older demented people become fewer as other health-care priorities emerge, such as care of children.

Finally, the ethical issues raised by the challenges of dementia will continue to increase. These issues range from prediagnostic assessment of genetic risk to the end-of-life issues just discussed. The future world of medicine is said by some to depend upon molecular biology and genetics. Yet, it is unclear whether individuals at risk for AD can use the complex genetic information that we are now able to provide them. As mentioned, the diagnostic confusion about mild cognitive impairment and AD challenges us to think more deeply about diagnostic disclosure. What are we saying to people when we apply the label AD with all its complexities and heterogeneity?

In the research environment, many ethical issues challenge us, such as finding the appropriate means for gaining informed consent from someone who has lost the capacity to understand a research protocol. Now that we have a few, albeit rather modestly effective, agents, under what circumstances is it appropriate to use placebos in controlled studies?

Finally, there are major ethical issues concerning the relationship between the pharmaceutical industry and the medical profession pertaining to conflict of interest. We must encourage more open reporting of clinical trial results and limit the financial relationships between physicians and industry.

Unfortunately, the field of bioethics has not adequately risen to the challenge of providing society input about these difficult decisions. There is little challenge from bioethicists to the dominance of

genetic rather than environmental medicine and public health. Moreover, bioethicists themselves are facing issues of conflict of interest through their own involvement with pharmaceutical companies. Bioethics tends to support the goals of medicine and physicians rather than challenge them and guide patients and society as a whole.

Conclusion

AD is an important bellwether for the future of medicine and, in fact, the health of our planet. Chronic diseases are proving to be a major challenge to our simplistic biological models of disease. Medicine has not adequately dealt with the boundaries between enhancing normal function and the concept of disease. Finally, the dominance of medical models of care using drugs has replaced broader concerns about the impact of diseases such as AD on individuals and populations. Considering these complex issues in AD may lead to improvements in our values and processes in health care more generally.

Demography

G C Myers, Duke University, Durham, NC, USA
M L Eggers, Economic Commission for Europe, Geneva, Switzerland

Glossary

Demographic Transition – The historical process of change in national populations from high levels to low levels of fertility and mortality.

Demography of the Aged – Examination of the changing social, behavioral, economic, demographic, health, and epidemiologic status of older persons, the factors responsible for these changes, and their consequences.

Demography of Population Aging – Examination of the causes, mechanisms, and societal consequences of age structural changes in the total population.

Population Aging – Changes in the age structure of a population that can be measured by increases in the proportion of total population at older ages and increasing mean or median age of the population. Sometimes also used to reflect the increasing numbers of older persons and high annual rates of growth.

Stable Population – A virtually unchanging population age structure that would result inevitably from the application of given constant schedules of age-specific fertility and mortality.

Introduction

There is growing interest in demographic research directed to various aspects of the field of aging. The term demography of aging has come increasingly to be used to identify studies that adopt demographic perspectives to study aging processes and the

changing characteristics of older populations. In general, demographers focus on the examination of the size, composition, and spatial distribution of populations and the four main determinants of changes in these population characteristics namely, fertility, mortality, migration, and changes in status. In addition, demographers are concerned with the measurement, modeling, and policy implications of past, current, and projected levels and age patterns of these determinants. Age, therefore, is a central focus of attention for demographers and provides a natural rationale for examining many gerontological issues.

Demography as a field is noted for several distinctive features. Demographers address societal issues of major policy importance, such as rapid population growth associated with high fertility, the effects of large-scale population movements, and more recently changes in population structures marked by global population aging. The conceptual models that they bring to bear include not only the interrelationships among the main demographic factors, but also the social, economic, and behavioral determinants and the consequences of major population trends. This broad perspective involves the description and analysis of major population shifts, with the main goal being to measure and untangle the forces that brought them about historically and how they may shape the future. This entails the construction and specification of mathematical and statistical models – life table approaches, stable population models, hazard models, and structural equation models – to provide an understanding of causal relationships, a necessary condition for forecasting future trends. It is acknowledged that demographers have made important contributions in designing and improving the accuracy of major data-collection efforts, such as censuses, vital registration systems, and broad-based population surveys. In recent years, longitudinal surveys have been undertaken increasingly to provide a means for examining important transitions and behavioral changes that affect individuals and their families over the life course. Thus, demography has developed into an interdisciplinary scientific field with distinctive methodological approaches for the empirical study of comparative population structures and changes over time.

The demography of aging actually comprises two distinct subfields: the demography of population aging and the demography of the aged. Each of these subfields has a distinct substantive and methodological orientation. The demography of population aging is primarily concerned with the causes, mechanisms, and societal consequences of age structural changes in the total population, whereas the demography of the aged is concerned with the evolving social, economic, demographic, health, and epidemiological status of older persons who exceed some arbitrarily defined age, most frequently ages 60 and 65. Like the major field of demography, the subfields are interdisciplinary in nature, which has precipitated several new areas of concentrated research interest. Two of these, family demography and biodemography, are examined in a later section.

Demography of Population Aging

Historical Development

The emergence of concern with population aging initially arose from two distinct developments. First, the recognition in the late nineteenth century that an impressive shift in the age structure was occurring in certain national populations and, second, the subsequent uncovering of several analytical relationships that provided significant insights into the forces and processes of population aging.

Early recognition of population aging occurred in France and Sweden in the late nineteenth century, at a time in which the proportions of the population aged 65 and over in both countries were approaching 8%. In 1900, Gustav Sundbärg, a Swedish researcher, conducted the first rudimentary comparative analyses of the age profiles of national populations. He calculated the proportions of population in three age groups – under age 15, 15 though 49, and 50 and over for several countries. In comparing the results, he found that most European countries had nearly 50% of their population in the age group 15–49, but differed markedly in the proportions at young and old ages. He speculated that countries would retain the same levels at adult ages, but would shift over time from having high proportions of young persons to high proportions of older persons.

This remarkable insight then led him to characterize national populations as gradually shifting from progressive (younger) to stationary and eventually to regressive (older) age structures. Moreover, he indicated that these shifts in the age structure of a population were due primarily to changes in fertility and mortality. Sundbärg can thus be credited with being the first person to conduct quantitative cross-national comparisons of changing levels of vital events and their effects on population structures that would lead inevitably to population aging. Moreover, by stipulating the roles of declining fertility and mortality, he anticipated the notion that came to be known later as the demographic transition.

Although some attention to the possibilities of population aging and accompanying fears of

depopulation was manifested in the recession period of the 1930s, especially in France and Great Britain, concerted research into the analytical aspects of the issue only began in the post-World War II period. In the early 1950s, several relationships and mathematical equations of fundamental importance to the demographic dynamics of population aging were introduced by demographers at the Population Division of the United Nations and Princeton University, most notably Jean Bourgeois-Pichat, Frank Lorimer, and Ansley Coale. The discovery of these equations, which unveil precise relationships among several elementary population parameters, put the demography of aging on a sound analytical footing.

Models of Population Dynamics

Using stable population equations first expressed by Lotka and co-workers in the early part of the twentieth century, these demographers began with an initial stable age structure, varied the fertility rates while holding mortality constant, and then compared the resulting stable age structures. With this comparative statics approach, they were able to isolate the effects of fertility declines on population age structures. Similar procedures were applied to examine the effects of changing mortality rates while holding fertility schedules constant. Three key findings relevant for the field emerged from these exercises.

One, Coale's research, in particular, showed that changes in fertility (e.g., in the birthrate) cause the entire age distribution to pivot about the mean age of childbearing. The mean age of childbearing is approximately equal to the mean length of generation, which is between ages 25 and 30 for most countries in the world. The pivoting of the age structure about the mean age of childbearing connotes that an increase in the birthrate, *ceteris paribus*, results in an increase in the proportion of the total population below that age and a decrease in the birthrate on the proportion above it. Thus, declines in the fertility rate, which have been observed in most of the world's populations in the past 30 years, lead to population aging.

A second major finding relates to the effects of changing mortality on age structure. Demographers have demonstrated that a mortality change with respect to age (measured by a log linear transformation that expresses the mortality rate decreasing by the same relative amount throughout the age range) has little or no effect on the age structure. Thus, mortality levels can change, albeit in a restricted form, and have no effect on the age distribution. In this specific case, the entire effect of the change is felt equally among all age groups resulting in no structural adjustment. The population growth rate may change, but not the age structure. Observed mortality declines in real populations, however, do not occur in such a simple pattern with respect to age. Instead, they are concentrated either between birth and early childhood or at ages 50 or 60 and above. Concentration of a mortality decline between birth and early childhood results in a younger age distribution; the effect of more infants surviving is analogous to an increase in the birthrate. Concentration of a mortality decline at later ages results in an older age distribution. The point at which a mortality improvement leads to an older, rather than a younger, population is marked by a life expectancy at birth of between 60 and 65 years.

A third finding was that fertility changes have far more influence on initial population aging than do mortality changes, a somewhat counterintuitive result now well known to demographers. Fertility changes have more initial impact because they are introduced into the age structure at a single point – age zero. In contrast, age-specific patterns of mortality improvement that are spread throughout the age range have offsetting effects with respect to age structure adjustment. As major declines in mortality levels shift from younger to older ages, as has been historically the case, mortality comes to play a major role in the population aging process. The effects of these transitions on age structure lie at the heart of what has been described as the shift from aging from the base (of the age distribution) to aging at the apex.

Formal demographic investigations carried out by Preston and associates in the mid-1980s on the relationship between intrinsic and actual population growth rates revealed further analytical insights into population aging. They showed that when the fertility rate drops to replacement level in a population closed to migration and remains there indefinitely, a condition corresponding to a total fertility rate slightly over two children per woman and an intrinsic growth rate of zero, the growth rate of the population below the mean age of childbearing is zero. This is an important insight into the forces of population aging because it implies, and in fact necessitates, that all future population growth beyond the time at which fertility achieves replacement level takes place in age groups above the mean age of childbearing.

Thus, after the fertility rate falls to replacement level, all subsequent growth is the result of growth momentum built into the age structure, and it occurs because already-born, large cohorts replace the smaller cohorts above the mean age of childbearing. The inevitable result of this growth of the middle and upper age population segments is rapid population aging. Moreover, in populations experiencing low and falling mortality (life expectancy exceeding 60 years),

the growth of upper age segments is enhanced because mortality reductions occur at ever more advanced ages. This results in steady gains in life expectancy and the growth of the oldest old population (85 years and over). The picture is much the same for both sexes, except that the relative survival of women is much greater than that of men, and as a group they usually experience more advanced population aging.

Population Aging Trends

World The world's population is aging rapidly and will continue to do so well into the twenty-first century. **Table 1** shows that the world's number of older persons 65 years of age and over more than doubled between 1950 and 1990 and is projected to reach over 809 million by the year 2025. The annual growth rate for the total population decreased slightly from 1.8% just after World War II to 1.7% in 1985–90, but is projected to fall to 1.0% by 2020–25. In contrast, the growth rate of the aged population moves in an opposite direction; it increases from 2.0% in 1950–55 to 2.4% in 1985–90, and continues to accelerate to a level of 3.0% annually in 2020–25. In terms of the two summary measures of population aging reported in the table (the percentage of the population age 65 and over and the median age) both show only a modest rise in the earlier period, but marked increases from 1990 onward. Within the aged population itself, the numbers of the oldest old, 80 years of age and over, have increased greatly. However, in the period ahead they will only increase marginally as a proportion of the total aged population. This reflects the large influx of the Baby Boom cohorts into the older ages in the second and third decades of the twenty-first century.

Table 1 Dynamics of world population aging, 1950–2025[a]

	1950	*1990*	*2025*
Numbers (1000s)			
Total aged	144 380	325 747	809 339
80+	15 853	53 692	135 923
80+ of total aged (%)	11.0	16.5	16.8
Indicators			
Percent 65+	5.1	6.2	9.7
Median age	23.4	24.2	31.0
Rates of growth			
Total	1.8	1.7	1.0
65+	2.2	2.7	3.0
65+ — total	0.4	1.0	2.0
Growth factors			
Total fertility rate	5.0	3.4	2.4
Life expectancy at birth	46.4	63.3	72.5
Infant mortality	155.0	68.0	31.0

[a] From *World Population Reports: The 1992 Revision*. New York: United Nations, 1993.

Population aging, as noted earlier, is the result of dynamic changes that have taken place in fertility and mortality levels. The total fertility rate, life expectancy at birth, and the infant mortality rate are commonly used by demographers to measure these levels. The total fertility rate decreased from five children per woman on average in 1950–55 to 3.4 in 1985–90, and is expected to decline further to 2.4 in 2020–25, according to these United Nations projections. World mortality rates also have improved markedly during most of the twentieth century, in spite of some countertrends in certain geographic regions (e.g., Central and Eastern Europe, and the former Soviet Union). The average life expectancy at birth increased between 1950–55 and 1985–90 by nearly 17 years to reach 63.3, and it is projected to reach 72.5 years by 2020–25. Declines in infant mortality accounted for most of the increase in life expectancy in the earlier period. In accordance with theoretical expectations, the proportion of aged persons was moderated in the period up to 1990 by large reductions in infant mortality, in spite of substantial declines in fertility. However, in the 1990–2025 period the sustained fertility reductions, even at lower levels, acting in concert with mortality reductions concentrated at later ages, will bring about major changes in the median age and percentage of older persons in the world's population.

Major Regions These observations for the world as a whole serve to illustrate the main dimensions of population aging, but they do not capture the major differences that exist between the world's major regions and the countries that they comprise. The demographic transition in vital rates from high levels of fertility and mortality to low levels has already progressed significantly in the more developed countries. The median age of the aggregated, more developed region was 33.6 years in 1990 and is expected to reach 39.8 by 2025. The percentage of population 65 years and over is slightly over 12% currently and will rise to 18.3% by the end of projection period. The current rate of growth of the older population in the more developed region will remain fairly stable at about 1.9% annually.

In contrast, population aging in the less developed region is far less advanced, with a median age of 22.0 years in 1990 and 4.5% of the population aged. These levels will increase to 29.6 years and 8.0%, respectively in 2025. The rate of growth of the older population will continue to accelerate from 4.5% currently to 8.0% annually in the period 2020–25. A majority of the world's aged already live in less developed countries (56.2%), and by 2025 nearly 70% of the 809 million older persons will live in this

region. This reflects the enormous population momentum that is built into the age structures and the changing vital rates for the less economically advanced countries. Truly, it is fair to say that population aging has become a worldwide demographic phenomenon.

Policy Implications

Demographers and other social scientists increasingly have been called upon to examine the consequences of the broad shifts in overall population structure brought about by population aging. Because of the seemingly irreversible nature of these developments, some observers have referred to them as a gerontologic revolution that brings about enduring societal changes in economic, social, and political structures. Forecasts inform us that the effects of population aging are expected to be particularly significant in the second and third decades of the twenty-first century, but it is important to emphasize that important changes already have occurred to alter the composition and age structure of the older population.

In the economic realm, attention has been given to the effects of population aging on rates of economic growth, aggregate savings, investments, consumption patterns, and labor supply. There is growing concern over the future capacity of state economies to maintain social security, health, and other entitlement programs at existing levels. Moreover, the labor force in many developed societies is continuing to age, therefore raising questions about potential labor scarcity, productivity, and appropriate retirement ages. These macroeconomic issues arising from population aging require demographic projections and integrated models to examine current trends and future scenarios (*see* Economics: Society).

There also are social and political implications of major importance. Many of these relate to changes in kin and family structures and intergenerational relations, a topic considered in a later section. Population aging affects roles, role transitions, and behaviors across the life course, as well as the expectations that individuals hold regarding their future lifetimes. The progressive aging of the voting age population in many countries, along with prevailing patterns of voting behavior, has raised concerns over the extent to which older persons may gain increasing influence in political spheres and the possibility of intergenerational conflict.

Demography of the Aged

The second major subfield directs attention primarily to the composition of the older population, how it changes over time, and the major dynamic factors that bring these changes about. The aged can be viewed as a particular subpopulation that has its own age, sex, and other defining characteristics. Like the total population, it is subject to change resulting from entrants (persons reaching the qualifying ages or moving geographically into the population); exits (persons dying or moving out of the population); and changes in the characteristics of the population through either volitional (e.g., persons marrying) or non-volitional shifts (e.g., becoming widowed).

If is often noted that turnover in the older subpopulation is usually greater than in the younger population because of the frequency of events that take place at these ages. For example, over three-quarters of the deaths occurring in more developed countries occur at ages 65 and above. Similarly, change is common in terms of working behavior, social relationships, onset of multiple chronic diseases, disability, living arrangements, and not infrequently in the economic conditions of later life. Thus, studying the dynamic changes in the composition of the older population and transitions occurring in the lives of older persons presents some challenging conceptual and methodological issues.

Population aging, as noted earlier, brings about increased numbers of older persons and generally increases the proportion they represent of total population. The momentum for the numerical growth emanates from the size of earlier birth cohorts and the survival that they have experienced. Thus, the great surge in the growth of the older population that can be expected in the second and third decades of the twenty-first century reflects the succession of large Baby Boom cohorts from the post-World War II period. Analyses of cohort succession, the dominant characteristics of these cohorts, and their likely effects on the composition of future older populations has been a very fertile field of recent demographic research.

Considerable attention has been given to the increasing demographic diversity found in this subpopulation. Among characteristic features that have been most often noted are the rapid growth of the oldest-old segments of the older population, the declining ratios of older males to females, and the increasing ethnic and racial makeup of the older population. These changes reflect not only cohort succession, but important changes that have occurred in levels of survival for subgroups in the older population. Mortality reductions continue to be experienced at the older ages, thereby raising life expectancies at even the most advanced ages. The trends in survival have been largely responsible for the growth of the oldest-old population, the most rapidly

increasing age group in most countries. An increasing number of research studies focus on this segment of the older population, for they are often the most in need of social supports and long-term care.

Finally, it should be noted that demographic studies of the geographic mobility of older persons continue to receive considerable research attention. Although levels of mobility among older persons are substantially below those of the younger population, the nature of the moves and their implications for older persons can be significant. Among the main types of mobility that have been examined are retirement moves, geographic relocations made to be closer to other family members, and moves into institutions and family households necessitated by health and other circumstances. These various types of moves have often proved difficult to measure, and concerted data collection efforts are currently being developed to assess their importance.

New Directions

Family Demography

A flourishing area of demographic research focuses on how population aging affects changing family structures and functions. The more generic term family is used to identify this subfield in order to encompass broad family features such as kinship structures and extended family relations, as well as the structure of households and dynamic aspects of intrafamily interactions. Demographers have been concerned with examining major trends and determinants in these dimensions across time and in different societal settings. The determinants of these trends that have been studied include not only demographic factors, such as changes in fertility, mortality, and geographic mobility, but also related social changes in family formation and marital patterns, labor supply, and preferences as they are shaped by cultural values and norms.

The family, as a major social institution, plays a central role in socialization, accumulation and allocation of resources, and provision of support and care for family members. The latter dimensions are particularly important in the case of families that contain older members in need of assistance. These functions are strongly influenced by structural features of the extended and nuclear family, household living arrangements, and interactions among family members.

Kinship Structures Formal demographic analyses, along the lines presented in the earlier discussion, have yielded some important observations about the effect of the main demographic changes on family structures. Declines in fertility naturally bring about smaller families and less extensive lateral kinship ties with siblings, cousins, and eventually with aunts and uncles. Lower mortality, especially concentrated at younger ages as it is initially, may counteract some of these tendencies. However, as mortality declines extend into the older ages, they increase the number of surviving parents for an adult child. Thus, there is greater vertical kinship. The result of changes in these two demographic parameters is the creation of what has been referred to as the 'beanpole' family, with greater numbers of generations made up of smaller-sized nuclear families.

A corollary of these developments reflects on the numbers, types, and durations spent in various roles over the life course. Because of less time spent in child rearing for a parent, greater durations of one's adult lifetime are spent with parents, and interestingly, a greater number of family membership roles will be experienced in a lifetime. Depending on the generation in question, older persons will have less younger relations, but younger persons will have more older relations. It is this paradoxical situation that contributes to the concern over the future burdens of caring for older persons if mortality continues to decline at advanced ages and fertility remains low or declines further.

These kin structures may differ significantly between rural and urban areas within countries; reflecting variations in the timing of changing vital rates and internal migration. They are also affected by sex differentials in mortality that lead to sex imbalances that favor female over male kin. However, in some Asian societies, such as China and Korea, sex selectivity in fertility favoring males through selective abortion may serve to counteract these imbalances over time.

Household Structures Household composition, which greatly influences the level of emotional, physical, and material support available to elderly persons, is formed from a constellation of kin and unrelated individuals. A trend reported for most countries in the world has been toward smaller household sizes. Lower fertility accounts for some of this decline, but it also can be attributed to shifting living arrangements away from coresidence of older persons with their adult children.

For many elderly persons, living arrangements are the single most important social structure governing their everyday lives. The term living arrangements is interpreted broadly and includes the full set of within-household social relationships, as well as the features and conditions of the dwelling units in

which households reside. However, demographers have devoted greater attention to the former considerations.

The most dominant trend in living arrangements among the elderly has been the steady increase in the proportions of older persons living with spouses and those who live alone, especially among widows, and declines in those living with children or other relatives. Trends in independent living by older intact husband–wife families are greatly affected by the improved joint survival of married persons up to and continuing into the later stages of life. For both intact nuclear families that contain older persons and for older unmarried persons, factors that have been found to be related to independent living are improved economic circumstances, better health and disability status, and declines in available kin, most notably children. Underlying these factors has been the implied desire for greater independence and privacy on the part of both older parents and their children. Recent econometric analyses suggest, however, that a downturn in the proportion of young-old widows (ages 65–74) living alone has occurred in the 1980s in the United States, mainly due to greater numbers of baby boom children who are themselves unmarried and in need of assistance in living accommodations. This suggests that trends in such arrangements as living alone are not unilinear, but are sensitive to cohort fluctuations in the number and demands of children, as well as the conditions of older parents (*see* Housing).

Coresidence is only one reflection of the ties that parents can have with their children. Indeed, it is often noted for developed societies that coresidence is much less common than in developing countries, but that close spatial residence may exist and communications and assistance and social support between kin may be very strong. Another feature of living arrangements that has been receiving increased research attention is the role that geographic mobility can play in altering the propinquity of kin. One way that this can be assessed is by the amount of travel time that it takes for a parent to visit a nearest child or vice versa. Recent examination of changes in these travel time differences among older persons indicate that they tend to decline over time (attributable mainly to geographic shifts) and that increased functional disability is associated with the probability and size of spatial convergence, especially for lower-income and ethnic groups.

Family Dynamics These basic analyses of kin and household structure have provided the groundwork for extensive research that has been undertaken on intergenerational flows of resources on both macro and micro levels. An important feature of recent demographic research in this area has been to examine intergenerational transfers and the decision-making processes underlying the use of resources.

The family plays a major role in the societal allocation of resources through such mechanisms as the creation of human capital, family labor supply, direct *in vivo* financial transfers, and bequests. But not all of these transfers are monetary or in goods, many are social support services, such as caregiving (either instrumental or expressive). Considerable research is underway that attempts to assess the amount of these transfers among household family members and across generations. Moreover, attention also is being given to larger societal accounting for all transfers including governmental transfers. Formal demographic analyses provide macroparameters for estimating the demand side of these equations.

On the micro level, there is considerable attention being given to intrafamily decision-making regarding transfers of various types. These social demographic studies are focusing on expectations that individuals have regarding future transfers, especially those relating to potential sources of care and other forms of support. Moreover, attention is being given to the likelihood of future survival, economic conditions, and possible future changes in living arrangements, such as movement into a nursing home. These research efforts directed to expectational data are not unlike those of earlier studies of expectations regarding fertility outcomes (e.g., ideal and expected family size) that demographers have developed. Surveys also have increasingly sought to obtain data from multiple individuals in a household, including spouses and other caregivers, that make it possible to examine the dynamics of the family interactions and decision-making. Moreover, many recent surveys involve longitudinal designs that make it possible to assess transitions in important dimensions of the lives of older persons.

Biodemography of Aging

A new direction of research that seeks to integrate more fully demography and the biological sciences has been termed the biodemography of aging. The fields of comparative population biology, population genetics, and epidemiology have long shared common perspectives and methodological approaches with the field of demography. For example, the stable population model discussed earlier has been widely used for studies of not only human populations, but those of other species as well. In turn, demographers have examined biological and genetic factors as possible explanations for fertility and mortality trends

and differentials (e.g., the effects of fecundity on fertility levels and genetic factors on sex mortality differentials).

Although the term biodemography was first introduced in 1949, the emphasis on the aging process accounts for much of the recent interest in this interdisciplinary perspective. The great gains in life expectancy that have been made in the last half of the twentieth century have raised important questions about the possible biological limits to human longevity, the factors that are involved in the observed deceleration of mortality rates at advanced ages, and how these changes affect the incidence and prevalence of chronic diseases and disabilities, especially among persons at older ages. To probe such questions requires deeper understanding of the complex, interrelated factors that underlie the disease, disability, and death processes.

A focus on aging and the aged population calls attention to a number of distinctive features of current developments: one, a majority of deaths occur at the older ages, with half of the female and one-third of the male deaths occurring at age 80 and above in developed countries. These deaths at older ages are mainly attributable to non-communicable chronic diseases with extended lifetime trajectories. Two, older persons are more likely to experience comorbidities, sensory deficits, and functional limitations that limit their capacity to fulfill the basic activities of daily life. Three, a broad range of factors can be identified that influence age-related changes in health and functioning, such as senescence, genetic predispositions, physiological states, nutritional status, physical and cognitive functioning, health behaviors, and medical care and other interventions. Thus, there is a rich set of conceptual issues that challenge interdisciplinary researchers in this subfield.

A broad range of data sources is being developed that will enable studies to be undertaken to address these issues. The first, surveys of older persons, including the oldest-old, are increasingly being designed to examine multidimensional aspects of the aging process. This includes clinical assessments of anthropometry, physical performance, cognitive status, blood chemistry, and genetic markers. Many of these surveys are longitudinal in design, which enable researchers to identify important transitions in physiological and psychosocial states and, thereby, examine causal relationships more precisely. Data from surveys are being linked to other sources of data (e.g., administrative records, death certificates) that make it possible to enrich analyses of outcomes and intergenerational patterns with more reliable data. Finally, many surveys are now national in scope and include samples of important subgroups in the population, such as minorities, women, and cohorts of persons at important transition points in the later life course (e.g., preretirement and retirement periods, the advanced ages of life).

Second, studies of twins are being expanded to provide natural experiments for examining the inheritability of longevity, frailty, and patterns of dementia across the life course and especially at older ages. These studies enable researchers to investigate the relative roles of genetic and environmental factors for measurable outcomes in the aging process. Multigenerational twin registers are being created in a number of countries, which will enable important comparative analyses to be undertaken (*see* Behavioral Genetics).

Third, animal colonies of mammalian and nonmammalian species already exist to study issues relating to aging, but there is a new emphasis on conducting research to examine age-related mortality, cause of death, and even disability processes using animal models. Understanding the demographic structures and dynamics of non-human species may offer important insights into aging processes in humans. There have been renewed calls for a more comparative emphasis in aging research to emphasize the place of humans in a larger mammalian demographic perspective. Animal models also offer the advantages of experimental designs for studying various interventions. An example of the latter is the large-scale programs to examine diet restriction and its effects on life extension (*see* Models of Aging: Vertebrates). Evidence suggests a deceleration in the rate of increase in mortality at the oldest ages for insect and human populations, perhaps due to heterogeneity at the cohort level, allowing only the heartiest to survive to the most advanced ages. Thus, Gompertz curves, which imply exponentially increasing rates of mortality with age, do not fit actual age mortality patterns at advanced ages for several species.

Demographers and other social scientists have been involved in a broad range of activities relating to the biodemography subfield. An important aspect of this effort involves the use of demographic analytic models for examining population structures and their dynamics. These include stable population models; actuarial procedures, such as the life table, multistate models, and hazard models; and multivariate statistical applications. Many of these tools are now being used to make forecasts of mortality, disease, and disability trends on a national level. Thus, the implications of population aging are being examined not only in terms of compositional changes, but also many dimensions of direct importance in determining appropriate societal responses

to the relative health and well-being of older persons. Simulation approaches also are used for examining the potential impact of various interventions on levels of these dimensions and their economic and social implications.

Glossary

Abrasion – Physical wear of the teeth brought about by contact with objects other than food or other teeth.

Attrition – Repetitive tooth to tooth contact results in the loss of tooth tissue at the contacting surfaces.

Caries – A disease process where plaque has been allowed to develop for a period of time. Carbohydrates in food and drink are fermented by the microorganisms in plaque, which produce acid, resulting in the demineralization of teeth.

Dentures – Removable prosthetic appliances.

Erosion – Loss of enamel and dentine arising from chemical attack from sources other than chemicals produced intraorally by bacteria.

Periodontal Disease – A progressive, chronic inflammatory disease of the supporting tissues of teeth. Bacterial placque results in gingivitis or periodontitis.

Introduction

A functioning mouth is essential for the enjoyment of life in old age. The oral tissues undergo a number of changes with age. Dental disease is common in the elderly, although largely preventable. Replacing lost teeth is possible but is becoming increasingly technically demanding as patients' expectations increase. Diseases of the oral soft tissues are often found, and oral carcinoma is a major problem.

There is little doubt that the past two decades have seen an increasing amount of attention paid to the oral health of the elderly. This has come about because of the increase in the numbers and proportions of elderly persons, but also because of changes in disease patterns, patient expectations, and improvements in dental technology. Some older patients have perfectly functioning dentitions and to an

extent can be treated as perfectly normal patients, particularly if they are biologically young. However, many older patients have extensive dental disease, the treatment of which is complicated by oral age changes and systemic disease. Older dental patients may also suffer from cognitive deteriorations that may influence dental treatment. In some cases older adults may be accompanied by relatives or other caregivers who may act as patients' advocates to help explain procedures and treatment choices.

Total tooth loss (edentulism) is a significant finding in elderly patients throughout the world (**Table 1**). Edentulism is influenced not just by patterns and prevalence of dental disease but also by socioeconomic factors. In the more economically developed nations, the past few decades have seen a dramatic decline in edentulism. It is certainly true that denture wearing is much less socially acceptable and is no longer seen as an inevitable consequence of growing older. A number of pathologies are associated with denture wearing; these are discussed later in this article.

Periodontal disease is predominantly a progressive chronic inflammatory disease of the supporting tissues of teeth. It is initiated by the presence of bacterial plaque, which, in susceptible patients, may result in the development of gingivitis or periodontitis. Severe periodontitis may cause marked loss of the alveolar bone, which supports the teeth and, in some cases, may ultimately cause tooth loss. The prevalence of advanced periodontal disease in elderly patients varies from 5 to 70%. The risk factors and treatment modalities are discussed later.

Dental caries is the most prevalent disease in the world and is of significant economic consequence. Caries is a disease associated with sugar; it is much less prevalent in the developing world, where there is less intake of refined food. In elderly patients the incidence of caries varies widely and is associated with diet, socioeconomic status, and, most importantly, fluoridation of the water supply. A particular type of caries (root caries) is associated with elderly patients and is found at the gingival margins of teeth. It is associated with gingival recession, which is common in elderly patients. It is thought that the bacteria that are associated with this type of lesion are different from those causing caries on other tooth surfaces.

Most dental diseases are preventable, and strategies that minimize risk of disease should be universally employed.

There is some speculation about the effect of oral infection on cardiovascular disease. In particular, it is thought that periodontal disease may be a risk factor for the development of a number of conditions, including coronary heart disease, cerebrovascular disease, and diabetes. The results of these studies need to be treated with some caution; a causal link has yet to be proved but a linking pathogenesis has been proposed. This involves the presence of hyperinflammatory monocytes in susceptible individuals that react to the challenge of oral bacteria and that locally cause periodontal destruction and more distantly in the body cause changes that result in the aforementioned related pathologies.

Table 1 Prevalence of edentulousness of elderly in selected countries

The Aging Mouth

The normal functioning of the oral cavity involves a complex interaction of a number of different systems. In order to chew, taste, speak, and swallow, all of the components of the oral cavity must work efficiently. To a considerable extent, facial aesthetics depends on a healthy dentition and its supporting structures. As we age, many of the components of the oral cavity undergo age changes. Some changes are caused by disease rather than by aging, and often it is difficult to make a distinction between the two. The teeth undergo a number of important changes in older individuals. Most changes, however, are related to physical-chemical processes and are not therefore true age changes. Tooth enamel undergoes changes in terms of its mineral content, and both fluoride and nitrogen content increase with age. This can be modified, however, in the presence of tooth wear or dental caries. One clinically important change is a gradual reduction in the size of the pulp chamber and an increase in secondary dentine. Another change in dentine involves a gradual obturation of the dentinal tubules leading to dentinal sclerosis. Cementum, which covers the roots of teeth, shows a gradual increase with age. Taken together, these changes are used in forensic dentistry to age unidentified

individuals. Oral mucosal thickness is reduced with age and in the tongue by about one-third from 20 to 80 years of age. This thinning of the oral mucosa (**Figure 1**) leads to underlying structures being more prominent; this is particularly true in the case of underlying vascular tissues and sebaceous glands. Sublingual varicosities are almost universally present in those over the age of 70 but are clinically unimportant except in terms of their recognition. In general terms, the microscopic appearance of the oral mucosa shows a simplification in structure with age, and the rete pegs/ridges are less well developed. The age changes in the oral mucosa may well make it more susceptible to noxious agents such as tobacco and alcohol and lead to the age-associated increase in oral cancer and precancer. It is often very difficult to differentiate the effects of disease and age in the oral mucosa. Many vitamin deficiencies are known to affect the oral mucosa, and these are more common in older age groups. It is often stated in medical and even dental texts that an inevitability of growing old is a reduction in salivary flow. This is erroneous – there is little evidence to suggest that in healthy elderly individuals saliva production from the major salivary glands is reduced. Certainly, structural changes with age are noted in the glands (**Figure 2**), including a reduction in secretory tissue, but this seems to have a minimal effect on actual salivary

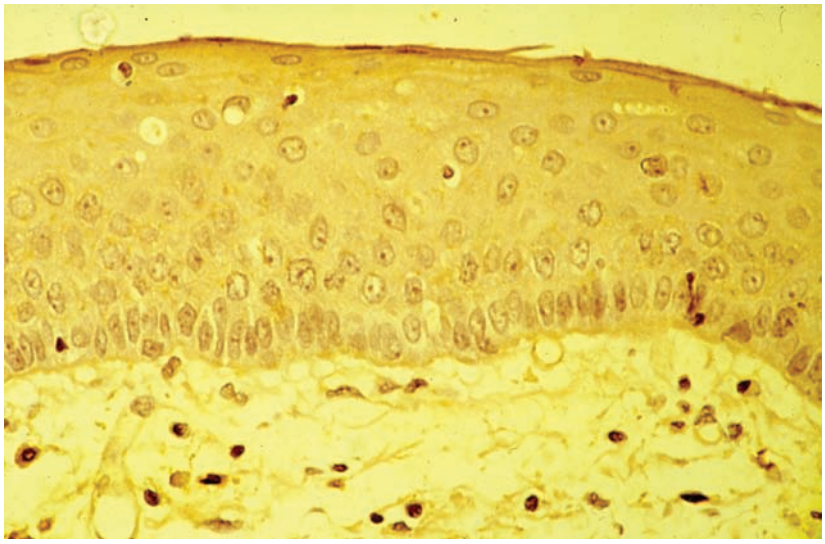

Figure 1 Thinning of the oral mucosa.

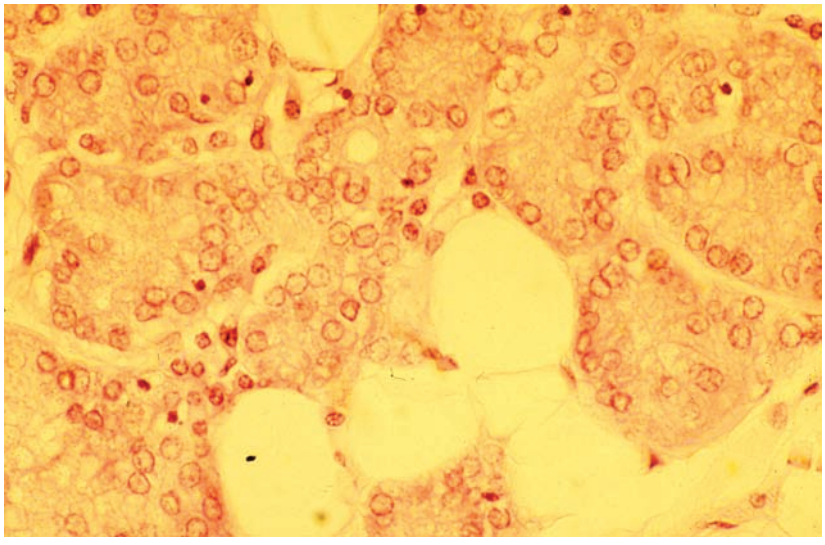

Figure 2 Structural changes with age in the major salivary glands.

production in healthy older individuals. It is thought that this is one example of a change with age that is compensated for by an increased efficiency of the remaining tissue, and the concept of a secretory reserve in salivary glands has been postulated. It is certainly true that many older patients have a reduction in salivary flow, but this is commonly caused by prescribed medication (see **Table 2**) that is common in this age group or the result of connective tissue disorders such as Sjögren's syndrome. Another cause may be therapeutic radiation therapy, although the more targeted treatment and better screening now available has reduced this problem. A reduction in salivary flow has a profound effect on oral health and will result in a dramatic increase in dental caries if aggressive preventative measures are not in place. Other problems associated with xerostoia are shown in **Table 3**. Oral/facial muscles are also affected by the aging process, and it has been shown that the bulk of the masticatory muscles reduce by up to one-third over an 80-year period. The retention of natural teeth and a normal diet throughout life almost certainly will mitigate against this in exactly the same way that exercise provides protection against aging in skeletal muscles. Electrophysiological studies show that there is a prolongation of the muscle contraction in older individuals. This combined with the loss in masticatory muscle bulk leads to a loss of precision of jaw movements, which is particularly relevant in denture wearers. Mandibular and maxillary bone shows variable osteoporotic changes with age, with mandibular bone density decreasing by 20% from 45 to 90 years of age. This change is not related to tooth loss and has been shown to progress independently.

Table 2 Main classes of drugs reducing salivary flow

Anticholinergic drugs, e.g., diuretics, antihistamines, antidepressants
Sympathomimetic drugs, e.g., bronchodilators, antihypertensives, antidepressants
Skeletal muscle relaxants
Antimigraine agents
Cytotoxic drugs
Opioids and hypnotics
Retinoids
Cytokines

Table 3 Problems associated with xerostomia

Increase in dental caries
Increased risk of periodontal disease
Oral mucosa more susceptible to injury
Difficulty with mastication
Speech problems
Dentures poorly retained

However, an important factor in the preservation of alveolar bone in the jaws is the retention of teeth and the absence of periodontal disease. In the absence of natural teeth there is a steady loss of supporting alveolar bone, which can make the successful wearing of dentures difficult. There is little evidence that the incidence of temporomandibular joint problems is independently associated with age. Masseteric muscle pain is commonly found in denture wearers where there is an excessively vertical jaw position.

Carious and Non-carious Tooth Tissue Loss

Teeth are both subject to the cyclic forces of mastication and exposed to a wide variety of chemical challenges during life. These ultimately result in the loss of enamel and dentine from the following processes:

- Attrition, in which repetitive tooth-to-tooth contact results in the loss of tooth tissue at the contacting surfaces from chemical attack from sources other than chemicals produced intraorally by bacteria (**Figure 3**).
- Abrasion, in which physical wear of the tooth is brought about by contact with objects other than a tooth, such as when using the teeth to open packaging or to hold objects such as nails, hair grips, or pen tops.
- Erosion, in which the loss of enamel and dentine arises from chemical attack from sources other than chemicals produced intraorally by bacteria. This distinguishes the erosive process from dental caries. The acid sources may be either intrinsic or extrinsic.

Any condition or behavior that results in acid from the gastrointestinal tract coming into contact with the teeth constitutes an intrinsic factor. This may be as a result of the following:

- Vomiting: When this is frequent, an organic or psychosomatic disorder may be the cause.
- Regurgitation and reflux: These are generally associated with increased gastric volume and pressure and could be a sign of an incompetent cardiac sphincter.

Three principal sources of extrinsic acid are identifiable:

- Diet: Principally acidic foods and beverages that are consumed frequently and in excess. These include carbonated beverages, citric fruit juices, sports drinks, certain herbal teas, fruits and berries, salad dressings, and vinegar conserves.

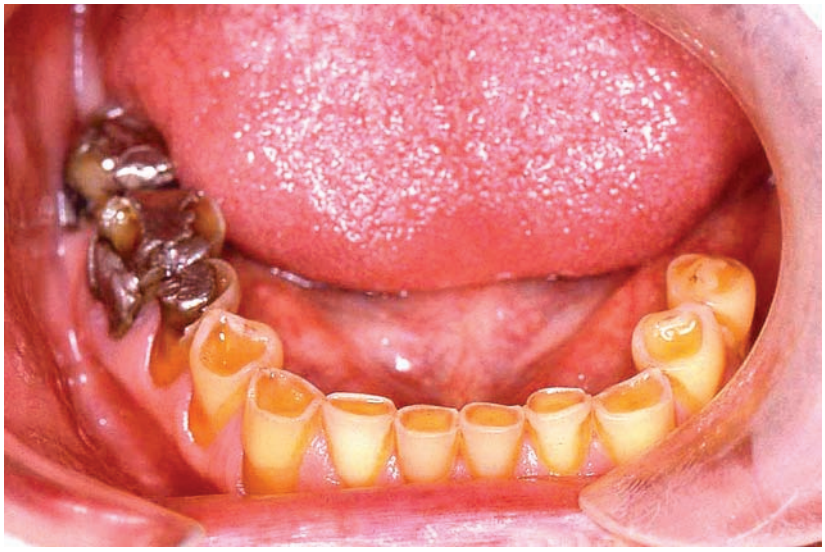

Figure 3 Loss of tooth tissue due to attrition and erosion.

- Medication: Any medicament that has a low pH that comes into contact with the teeth. Examples include chewable aspirin, iron tonics, and vitamin C.
- Environment: Principally exposure of the teeth to acid in the working environment. This includes workers in the printing, fertilizer, battery, and munitions industries as well as professional wine tasters.
- Dental caries: A disease process that can occur on any part of a tooth in the oral cavity where dental plaque has been allowed to develop for a period of time. Carbohydrates in food and drinks are fermented by the microorganisms of dental plaque. These produce acid as a by-product, and this, on coming into contact with tooth substance, brings about the demineralization of the surrounding tooth substance, thus initiating the carious process. A pH of less than 5.5 is required for demineralization of enamel to occur. In the case of dentine and cementum, the tissues attacked by root surface caries, the required pH is less acidic (6.2–6.7). Remineralization occurs when the pH is restored to neutrality as a result of the actions of the buffering capacity of the saliva and the availability of calcium and phosphorous ions at the tooth surface. Caries progresses when the equilibrium between demineralization and remineralization favors demineralization. This results in extensive tooth destruction (cavities) in which the dental pulp may become involved with loss of vitality and abscess formation of potential sequelae. Factors that favor demineralization are excessive and frequent intake of sugar, poor oral hygiene, and low salivary flow rate. A particular problem in elderly patients is root surface caries (**Figure 4**). Although the caries process on root surfaces is similar to that on the crown of the tooth, initiation and progression occur more rapidly. A prerequisite for this to develop is exposure of the root surface to the oral environment. This arises from the gingival recession that occurs with age, attachment loss, or exposure of the root to the oral environment from periodontal pocketing. Major factors determining susceptibility are a reduced salivary flow rate (such as a side effect of medication for a medical condition), poor oral hygiene, and a cariogenic diet. The institution of good oral hygiene and application of fluoride to the lesion may arrest the active lesion and obviate the need for restoration. An active root caries lesion usually spreads laterally and eventually, if left untreated, can encircle the tooth, culminating in tooth fracture. Restoration is possible in some cases but is problematic mainly due to impaired visibility and difficult access. These factors compromise the final restoration.

Modern dentistry seeks to prevent the loss of tooth substance from such processes before it occurs. Advising patients on the major causative factors and offering appropriate preventive advice is core to this goal. This should also involve liaison with other health-care professionals if appropriate. Dietary analysis and advice is a common preventive measure in the management of both dental caries (improve oral hygiene, reduce level and frequency of sugar intake) and dental erosion (reduce level and frequency of acidic food or beverage intake). In the case of attrition, it may be that wearing a hard splint at night, when grinding of the teeth is thought to occur, will prevent further tooth substance loss, as will the identification and elimination of a habit

Figure 4 Root surface caries.

(such as gripping nails with the teeth) when abrasion is suspected. When prevention fails and loss of tooth substance continues, restoration is indicated. The extent to which this is viable depends upon the residual quantity and quality of tooth tissue.

Active caries should be eliminated by conventional cavity preparation and restoration with an appropriate restorative material. The advent and application of adhesive restorative materials, such as resin composites and glass ionomer cements, have challenged the use of traditional restorative materials (such as amalgam and gold) in specialized circumstances. They can enable more tooth tissue to be preserved than older materials such as dental amalgam and gold. Glass ionomer cement is thought by many to be the material of choice for treating root caries, for it both bonds to tooth substance and has a caries inhibitory effect by virtue of its fluoride-releasing properties. Furthermore, research has shown that bacterial colonies fail to thrive on its surface, and, as a result, there is a high level of tolerance to this material displayed in the surrounding soft tissues. When the level of tooth destruction is greater, however, crowns may be necessary to restore both appearance and function. In all cases it should be borne in mind that the dental pulp may be diseased and root treatment may be necessary prior to the restoration of the tooth. Sometimes due to the inherent self-repair mechanisms of the tooth, namely, the laying down of secondary and tertiary dentine within the pulpal space, it is not possible to root treat the tooth, as access to the residual pulp has been obliterated.

Once provided, restorations have a finite life span and will ultimately fail, necessitating replacement or repair. The ability of the patient to maintain a satisfactory level of oral hygiene may decline with age and circumstance. The maintenance of good oral hygiene demands a high level of manual dexterity, which is even greater when complex cleaning regimes are required around crowns and bridges.

The ever-changing needs of elderly patients present a challenge to the restorative dentist.

The Periodontal Problem

Periodontal diseases are a group of multifactorial disorders that affect the supporting structures of the teeth. Inflammatory gingivitis and periodontal diseases are initiated by dental plaque, but the incidence, prevalence, and severity seen within both populations and individuals are not necessarily directly related to quantitative measures of deposits. This occurs because individuals have differing disease susceptibilities, with more severely affected individuals usually displaying one or more risk factors for the conditions.

Investigation of the role of age as a risk factor is not simple, as differentiating the effects of intrinsic aging and the effects of cumulative environmental challenge over many years is difficult. Study of the epidemiology of periodontal diseases is complex, and interpretation of it has been contentious. There is no doubt that age brings many changes to both the periodontium and the host responses to bacterial challenge, but the modern consensus is that age *per se* is unlikely to increase susceptibility to periodontal diseases. The problem, however, is that around 75% of persons aged over 65 years suffer from chronic disease, and affected patients are often

treated with multiple prescribed medications. These factors may result in deficits in general dexterity, coordination and mobility, and reduced mental capacity, which in turn may have direct and indirect negative effects on the periodontium. Undesirable effects from medications include xerostomia, increased bleeding tendency, and gingival overgrowth, and clinicians must have an understanding of these issues if adequate treatment is to be provided.

The Scale of the Problem

Edentulism is declining and life expectancy is increasing, and these facts combine to lead to increased demand for periodontal treatment in the elderly. Fortunately, if an elderly patient has retained teeth into old age, this implies that the individual is not highly susceptible to periodontal disease, which improves periodontal prognosis. Periodontal therapy can and should be provided for elderly patients whenever possible.

Periodontal Management

Clearly all necessary dental management must be provided, but this section concentrates upon the periodontal aspects only.

It is essential that periodontal therapy is tailored to the individual needs of the older patient. Dentists are trained to try to achieve periodontal health, defined by lack of bleeding on probing and manageable probing depths, as the treatment outcome. This is the laudable ideal, and where possible should be the goal of treatment. However, in some circumstances, for example, when an individual patient cannot maintain plaque levels below his or her individual disease threshold, achieving periodontal health is not an attainable objective. From the patient's perspective, having a comfortable, functional, and aesthetically acceptable dentition may be the desired treatment outcome. Therapy that meets these requirements, even if not achieving periodontal stability, should not be regarded as inadequate and in some circumstances is entirely appropriate.

Detailed medical, dental, family, and social histories should be recorded and regularly updated. Patients who are confused or who have poor memory may be unreliable historians, but it is essential that the dentist has access to all relevant information if safe and effective treatment is to be planned and instituted. Clarification of the facts may have to be sought from other health-care professionals and family, though consent must be given for such approaches to be made. A periodontal diagnosis should then be produced, followed by an individually designed treatment plan. At this stage it may be clear whether attaining periodontal stability is an attainable treatment goal.

Minimizing bacterial load through a combination of both thorough mechanical therapy and improving plaque control is usual, and a non-surgical approach is commonly adopted. Some elderly patients may require extra support, including provision of additional or modification of existing hygiene aids, but advancing age *per se* does not necessarily result in reduced self-care capacity. Powered toothbrushes may be helpful, though heavy or bulky models are not advised. Chemical plaque control using twice daily 0.2% chlorhexidine gluconate mouthwash may be appropriate for a very small number of patients who are incapable of achieving adequate physical plaque control, though this should be a very carefully considered last option, as the disadvantageous side effects usually outweigh the advantages. Root surface instrumentation should ideally be restricted to removal of plaque and calculus so that removal of the fluoride-rich outer root surface is not removed. This precaution is advised because of the increased prevalence of root caries with age. Application of fluoride to treated surfaces and provision of dietary advice are useful preventive measures.

Reevaluation following completion of cause-related therapy is essential. Three main outcomes are then possible:

1. If the therapy has resulted in stability, an individually designed maintenance program is required, as the patient has not been cured. Many elderly patients respond very well to simple nonsurgical therapy as can be seen in **Figures 5** and **6**.
2. If disease is still present, a careful appraisal of the cause of treatment failure is mandatory. If the cause is not identified and rectified (the most common being inadequate plaque control), any subsequent treatment is likely to fail. If elimination of the cause of failure is possible and is in accordance with the wishes of the patient, cause-related therapy may be performed again with a reasonable chance of success. Periodontal surgery, if indicated by the clinical examination, may be undertaken with a good chance of success, provided that there are no medical contraindications and the plaque control is adequate. Pocket elimination surgery is best avoided in favor of flap surgery to reduce root exposure due to the root caries risk. Stabilization is followed by maintenance.
3. Treatment failure due to causes that cannot or will not be rectified requires a pragmatic approach. The patient's wishes are very important. Research suggests that on average, teeth require bone support covering at least one-third of the root length to preserve adequate function. If it is judged, given the

Figure 5 Patient before beginning a course of non-surgical therapy.

Figure 6 Patient from **Figure 5** after a course of non-surgical therapy.

average life expectancy, that there is sufficient remaining periodontal support, palliative periodontal care, comprising regular professional scaling and polishing, may be instituted, though if adverse signs or symptoms subsequently appear, extraction of the affected teeth may be the only option. If it is judged that there is insufficient remaining periodontal tooth support, extraction and possible tooth replacement must be considered.

Treatment Options for Missing Teeth

It is common knowledge that people do not always retain all of their natural teeth into old age. When some or all of the natural teeth have been lost, elderly people may wish to explore the options for their replacement. Replacement options are considered separately for the partially dentate (people who have some natural teeth remaining) and for the edentulous (people who have no natural teeth remaining).

The Partially Dentate Person

In an elderly person who retains some of their own teeth, the loss of others may impact on either their appearance or function. The loss of anterior teeth will usually cause the elderly person to seek treatment because of unacceptable aesthetics. In contrast, they may be unconcerned about the loss of some of the posterior teeth unless they perceive their masticatory ability to be compromised. There are a

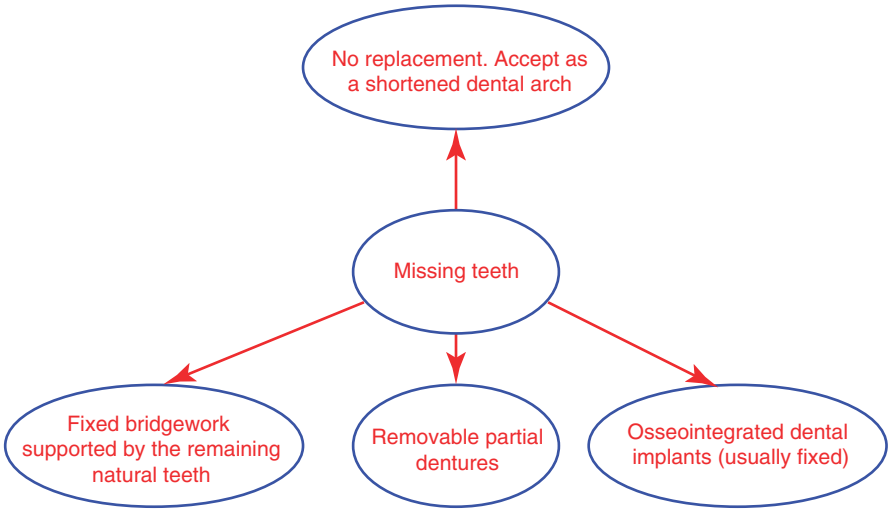

Figure 7 The main options for the replacement of missing teeth in partially dentate people.

number of possibilities for replacement (**Figure 7**). These are not mutually exclusive options, and in some situations a combination of approaches may be needed.

Fixed Restorations Many people will seek replacement of their missing teeth by dental restorations that are fixed to structures in their mouth. The main advantage of this approach is that it can permit function with the replacement teeth similar to when the natural teeth were present. There are two ways in which the missing teeth can be replaced. The first approach is to use fixed bridgework, in which the replacement teeth attach to the natural teeth adjacent to the missing teeth. Since this approach uses the adjacent teeth as abutments, it is more commonly used when there are only a small number of missing units and the spaces between the natural teeth are not too large. Traditionally this type of treatment has been carried out by removing part of the structure of the adjacent abutment teeth so that the restorations incorporating the replacement missing teeth can be cemented to these. There are a number of materials that can be used to construct bridgework, but all need to have sufficient strength to withstand the high forces that are applied during mastication. This type of approach may be contraindicated if the abutment teeth are heavily restored because of previous dental disease, because there may no longer be sufficient tooth structure to support the masticatory loading that would be directed onto the fixed bridgework.

A particular disadvantage of the traditional fixed bridgework approach for the replacement of missing teeth is the need to remove significant amounts of enamel and dentine from the abutments. For this reason, techniques have evolved that have allowed a much less invasive approach. It is possible to bond bridgework to the abutment teeth using adhesive materials without needing to remove more than very minimal amounts of tooth tissue. However, this approach is usually not possible when the teeth adjacent to a space have been damaged by dental caries that has resulted in the replacement of a large part of their structure with dental restorations.

The second approach to replacing the missing teeth is the use of osseointegrated dental implants, which are surgically placed into the bone of the mandible or maxilla in the region where the teeth are missing. Replacement crowns can then be subsequently constructed and attached to the implants (or in some cases removable dentures can be constructed that are attached to them; see later). This technique is becoming increasingly used as a first-line treatment modality for people who have a small number of missing teeth, provided that the remaining dentition is in good condition. There are some anatomical factors that may restrict the location of where the implants can be placed. The success rates of this approach are generally high, but factors such as smoking may compromise this.

Partial Dentures This treatment modality involves the construction of removable prosthetic appliances. This may be the only realistic treatment modality for people with very few remaining natural teeth. The advantage of using removable prostheses is that this line of treatment is non-invasive to the remaining tissues of the mouth. However, they are generally more obtrusive than fixed restorations, as they usually have to cover a much broader area of the oral tissues (**Figure 8**). Partial dentures can be particularly useful when the long-term prognosis of some of the

Figure 8 A removable partial denture.

remaining teeth is unclear, as they can be planned so that they can be modified if circumstances change. However, some groups of elderly people, such as those with dementia or other neurological conditions, may have particular difficulties in wearing partial dentures. Such an approach may therefore be contraindicated for these groups of people.

Non-replacement of Missing Teeth It may be a perfectly acceptable option not to replace the missing teeth. This concept is sometimes referred to as the shortened dental arch. It is unlikely to be acceptable to elderly people if anterior teeth are missing, due to concerns about appearance, but may be quite appropriate if only posterior teeth are absent. It is apparent that many people with lost and unreplaced posterior teeth are able to adapt their chewing and function with the teeth that remain. People with such reduced dentitions may still have more than adequate masticatory ability.

Maintenance One major issue concerning the replacement of missing teeth in the elderly is that of keeping the remaining teeth and oral tissues healthy. A high standard of oral hygiene is required to ensure that plaque is adequately removed around fixed restorations. If this is not carried out effectively, it may result in failure of the restorations and loss of further teeth. Even though assistive devices or professional support may be available, the ability to maintain an adequate standard of oral hygiene can become more difficult in the elderly, who may have problems such as poor vision or reduced manual dexterity (e.g., due to arthritis). Furthermore, some medical conditions and the use of certain therapeutic agents can affect salivary flow, which may result in the remaining dentition becoming very susceptible to further plaque-induced disease. For this reason, very careful deliberation is required when considering even the use of removable partial dentures, as well as the more advanced treatment options such as bridgework or implants. There is a need for meticulous hygiene around any type of bridgework or implant-supported restorations. It can be very difficult to maintain a high standard of oral hygiene if elderly people have compromised vision or because of loss of manual dexterity due to tremors or other neurological conditions. Care workers might be able to assist such people, but they must be effectively trained to do so.

The Edentulous Person

Improvements in oral health may mean that a significant proportion of people will be able to retain at least some of their teeth for all of their life. However, some people may be rendered edentulous because of the effects of oral disease (**Figure 9**). Most edentulous people will wish to have their teeth replaced, and this is usually carried out by the provision of removable complete dentures. The ability of patients to wear complete dentures successfully may depend on a number of factors, including the anatomical form of the maxillary and mandibular alveolar ridges, the general health, the salivary flow, and the motor skills required to control the dentures during oral function. It can be difficult for some elderly people to adapt to complete dentures if they are introduced to them at a very advanced stage of their lives. Nevertheless, many patients do manage to acquire the skills

Figure 9 An edentulous maxillary ridge.

Figure 10 Osseointegrated implants in the mandible.

necessary to function with complete dentures successfully. When difficulties arise, they appear to be much more common with mandibular dentures that replace the missing lower teeth.

There are some groups of elderly people who may experience major difficulties wearing complete dentures. Neurological conditions such as Parkinson's disease or strokes may severely compromise motor skills, which may result in the individual having great difficulty in functioning effectively with complete dentures.

The use of osseointegrated implants to stabilize complete dentures (**Figure 10**) has been a major advance in improving oral function in edentulous elderly people. The most common treatment modality is the placement of two implants, one on each side of the mandible, to which a lower complete denture can be attached. The prosthesis is removable, which means that it is more straightforward to keep the implants clean than it is with fixed prostheses.

It may be simple for care workers supporting elderly edentulous people to help maintain their tissue health by means of good oral and denture hygiene. However, it should be emphasized again that care workers should be effectively trained in such procedures, particularly when removable complete dentures are worn over osseointegrated implants.

Oral Surgery for Elderly Patients

Oral surgery for elderly patients may be straightforward or more complicated. A number of local oral factors may complicate matters, but the medical health of patient is a vital factor. Elderly patients are often taking multiple drug regimes, which, along with the presence of the common diseases of old age,

may complicate surgery. Older patients surprisingly often require the removal of retained teeth, commonly the wisdom teeth (third molars),which may cause a problem at any age. Even those who appear to be edentulous may in older age have wisdom teeth erupting. Often retained wisdom teeth may be incidental radiographic findings and if symptomless and showing no cystic change or causing damage to adjacent teeth may be left untreated. In some elderly patients, erupting wisdom teeth may present with acute or chronic infection, and a surgical removal of the tooth is required. Other teeth less commonly retained in elderly patients include lower premolars and upper canines. These are often symptomless, and surgical intervention is only required in the minority of patients. Retained roots may cause no symptoms or may require surgical removal if infected or causing pain. A very common surgical problem in older patients is denture-induced hyperplasia. This is usually the result of damage to the oral soft tissues caused by patients wearing ill-fitting dentures that should have been replaced many years previously. Commonly hyperplastic tissue is found in the vestibular areas of both jaws and in the palate (**Figure 11**). It is often sensible to radically adjust the denture prior to surgery to reduce the size of the lesion. Pre-prosthetic surgical procedures including ridge augmentation and implants may significantly improve the prognosis for elderly denture wearers. Facial fractures in elderly patients who are involved in trauma are common because of osteoporosis of the facial bones. The reduction and fixation of these fractures may be complicated by the increased risk of infection and decreased facial blood supply.

Health of the Oral Soft Tissues

It is vital that health-care professionals are able to recognize normal oral mucosa. This is particularly

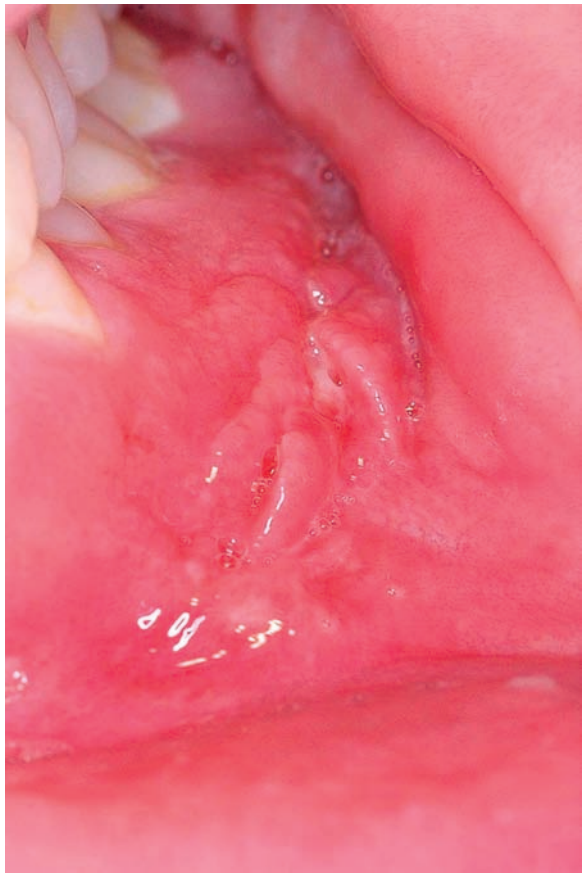

Figure 11 Hyperplastic fibrous tissue in the buccal sulcus.

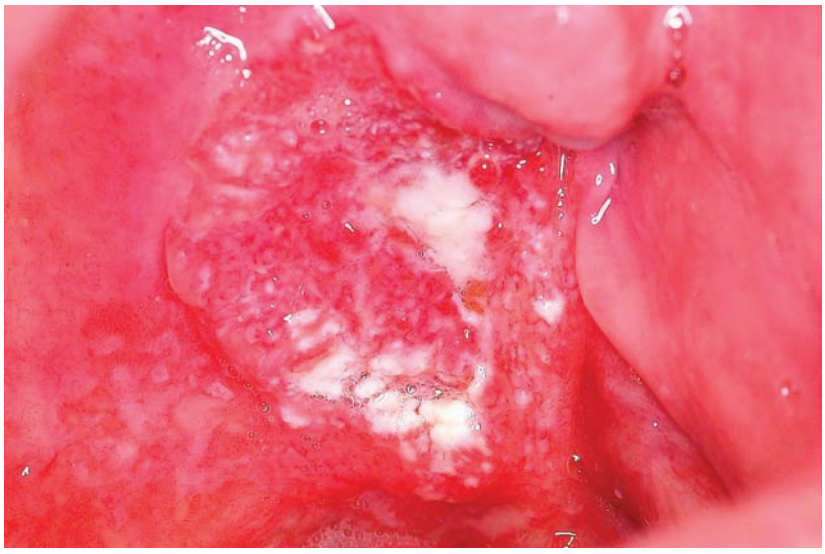

Figure 12 Oral carcinoma.

Table 4 Diseases of the oral cavity seen in older patients

Infections
Chronic atrophic candidosis
Chronic hyperplastic candidosis
Acute pseudomembraneous candidosis
Acute atrophic candidosis
Herpes zoster (shingles)
Oral manifestations of dermatological diseases
Lichen planus
Mucous membrane pemphigoid
Pemphigus
Oral mucosal malignancy/premalignancy
Leukoplakia
Erythroplakia
Submucosal fibrosis (rare except in Asia)
Oral carcinoma
Malignant melanoma (rare)
Pleomorphic adenoma (major and minor salivary glands)
Adenoid cystic carcinoma (more common in minor salivary glands)
Lymphoma (rare in mouth but more common in parotid gland)
Miscellaneous conditions
Black hairy tongue
Geographic tongue
Traumatic ulceration
Denture-induced hyperplasia
Aphthous ulceration
Lingual varicosities
Traumatic keratosis
Amalgam tattoo
Burning mouth syndrome
Trigeminal neuralgia
Oral manifestations of Paget's disease
TMJ pain/syndrome
Mucocele (of minor salivary glands)

important in older individuals, in whom certain normal anatomical features, including prominent sebaceous glands, lingual varicosities, and lingual papillae, may be mistaken for disease. By far the most important of the non-dental diseases affecting the oral soft tissues is squamous cell carcinoma. There is a steady increase in the incidence of oral carcinoma (**Figure 12**) after midlife, and the disease is predominantly found in males. Survival rates remain modest and the 5-year survival rate, although site dependent, can be as low as 50% even after aggressive surgical, chemotherapeutic, and radiological treatment. There is evidence that survival rates are relatively age independent and that staging, site of tumor, therapeutic regime used, and general health are much more important determinants of outcome. There are a number of distressing consequences of the treatment of oral cancer, including xerostomia, trismus, loss of hard and soft oral tissues, aesthetic problems, and mucositis. The aesthetic and functional replacement of soft tissues may be challenging for both patient and practitioner. Risk factors include smoking and alcohol consumption. In some parts of the world (e.g., India), oral squamous cell carcinoma is particularly common because of betel nut chewing and reverse smoking habits. Premalignant lesions of the oral mucosa are also found in older patients; these may require monitoring over a number of years with periodic histological assessment. Oral lichen planus can be seen in older patients, particularly on the tongue and buccal mucosa. It is controversial to suggest that oral lichen planus is associated with transformation to oral cancer. There is little evidence to suggest that, in the absence of other risk factors, oral lichen planus leads to oral cancer but it should be routinely monitored. Other oral diseases that may be seen in elderly patients are summarized in **Table 4**.

Depression

P A Parmelee, Emory University School of Medicine and Atlanta Veterans Affairs Medical Center, Atlanta, GA, USA

Glossary

Anhedonia – Loss of interest or pleasure in daily life.

Bereavement (also called Uncomplicated Grief) – Response to the loss of a loved one or valued possession such as one's home.

Bipolar Disorder (also called Manic Depressive Disorder) – Depression cycles with periods of excessive optimism, elation, and activity.

Depression – Disorder of mood characterized by cognitive, affective, and somatic or vegetative physical symptoms. Key characteristics are an overwhelming sense of despondency or discouragement, and/or lack of interest in or enjoyment of everyday life.

Dysthymia – Defined by the presence of one of the two defining symptoms plus at least two other symptoms of depression continuously for at least 2 years.

Introduction

Depression is the single most common emotional disorder in all age groups: as many as 14% of US citizens will experience major depression at some point in the life cycle. Although some forms of depression are no less prevalent among older than among younger adults, the disorder has more profound implications for the elderly by virtue of its strong links with physical illness and impaired function, cognitive decline, impaired overall quality of life, and even mortality. As recently as 30 years ago, little was known about the prevalence or manifestations of late-life depression. There is now, however, a substantial research literature on depression among the elderly, describing its epidemiology, its diagnostic differentiation from other physical and emotional comorbidities, and its sometimes unique presentations and outcomes in older as compared with younger adults.

This article provides an overview of current knowledge of depression in late life, beginning with a brief review of the epidemiology of depression, in terms of its population prevalence both overall and with specific respect to older adults. Key diagnostic issues that complicate identification, classification, and treatment are then discussed, followed by an overview of risk factors for depressive disorders in late life. Current trends in pharmacological and non-pharmacological treatment are then highlighted, with special emphasis on so-called second-generation treatment problems that typically emerge in primary care settings.

Epidemiology and Significance

Depression is a disorder of mood characterized by cognitive, affective (emotional), and somatic or vegetative (physical) symptoms. Its key characteristics are an overwhelming sense of despondency or discouragement and/or lack of interest in or enjoyment of everyday life. Persons with diagnosable depression may experience sadness, tearfulness, feeling of worthlessness or guilt, difficulty concentrating and making decisions, changes in appetite and energy levels, physical restlessness or retardation, and sleep problems. Unlike the normal day-to-day fluctuations of moods we all experience, clinical depression is persistent and pervasive, lasting weeks, months, or even years.

It is now well established that major depressive disorder (MDD), as defined by the *Diagnostic and Statistical Manual*, 4th edition (DSM-IV; see next section for more information), is no more prevalent in the elderly than in persons under the age of 65. In fact, major depression is most common in adolescence and early adulthood and declines thereafter, yielding a point prevalence of 3–5% across the adult life span. Prevalence among older adults living independently in the community is, if anything, slightly lower than this. However, rates of MDD climb sharply as one moves from the general population of older persons to those with acute or chronic illness. It is quite common among older persons in acute hospitals and postacute rehabilitation settings, and even more so among those receiving long-term residential care. As many as one-quarter of cognitively intact nursing home residents suffer from a MDD. Furthermore, less severe depressive syndromes are quite common among older adults, affecting about 25% of individuals regardless of their health status or living arrangements. Hence, depression at some level affects a broad spectrum of older adults, particularly those who are ill or disabled.

These figures are chilling because of the implications of depression for health and well-being in late life. Ill health and functional disability are clearly risk factors for depression, but depression also increases the risk of incident health problems and functional decline. Depression intensifies illness symptoms and exacerbates suffering. It impairs cognitive function and may in fact place persons at risk of dementia. Although mechanisms are unclear, depression is also clearly associated with increased risk of mortality among older adults. In short, depression is a significant problem that compromises quality of life for older adults and may hasten physical decline and death.

There is reason to believe that rates of late-life depression will rise as the current cohort of middle-aged adults – the Baby Boomers – move into their later years. Compared with that group, the current generation of elderly, who came of age during the Great Depression and World War II, has displayed consistently lower rates of depression and other psychiatric disorders across their adult years. A number of reasons for this have been offered, including greater resilience of the 'great generation' and lowered inhibitions against reporting and seeking treatment for emotional distress among younger cohorts. Whatever the cause, it is probable that the prevalence of late-life depression will increase in coming years and that record numbers of older adults will seek treatment for depression during the coming decades.

Diagnostic Issues

Depression is not a monolithic disorder. Rather, it presents in a variety of syndromes that may vary in severity, length, and association of depression with other symptoms. A number of ongoing controversies attend identification and differential diagnosis of depression in late life. This section considers three such issues: common clinical syndromes and diagnoses, major versus minor depressive syndromes, and the question of whether late-life depression is qualitatively different from depressive syndromes at younger ages.

Diagnosing Depression: Common Clinical Syndromes

A constellation of mood disorders, many of them involving depression, are identified by DSM-IV. The key symptoms that are used to diagnose various depressive disorders appear in **Table 1**. In brief, *major depression* is characterized by presence of at least five of these symptoms, including one of the defining symptoms (depressed mood, loss of interest/pleasure), at least all or most of the time for 2 weeks or more. Major depression is most often observed as a single episode or as a series of such episodes; the latter is termed *recurrent* MDD. However, major depressive symptoms may also be present in at least two other disorders. First, in *bipolar disorder* (formerly manic-depressive disorder), depression cycles with periods of excessive optimism, elation, and activity. Bipolar disorder appears to be far less common in older than in younger adults, but it is unclear whether this reflects a true difference in lifetime prevalence across cohorts or simply a change in how the illness manifests in later life. Second, when major depression is accompanied by delusions and/or hallucinations, it is termed *psychotic depression*. Older adults with MDD are far more likely than younger persons to present with psychotic symptoms, particularly delusions. It is nonetheless a relatively rare manifestation, affecting only about 0.1% of elderly community residents.

Even when depressive symptoms are severe, the older individual may not actually be suffering from MDD. Grief reactions are a good example. *Normal bereavement*, also referred to as *uncomplicated grief*, is a response to loss of a loved one or even a valued possession such as one's home. Symptoms of depression are normal and understandable reactions to such losses, but usually resolve within about

Table 1 Symptoms of depression

Defining symptoms

1. Depressed mood: most of the day, nearly every day. May be established by self-report or by observation made by others (e.g., crying, tearful).
2. Loss of interest or pleasure (anhedonia): markedly diminished interest or pleasure in all or almost all activities most of the day, nearly every day. May be established by self-report or by observation made by others.

Additional symptoms

3. Significant weight loss or weight gain: change of 5% or more in body weight in 1 month or decrease or increase in appetite every day or almost every day.
4. Insomnia or hypersomnia nearly every day.
5. Psychomotor agitation or retardation: every day or almost every day. Must be observable by others, not just subjective feelings of restlessness or slowing down.
6. Fatigue or loss of energy every day or nearly every day.
7. Feelings of worthlessness or guilt: every day or nearly every day. Guilt must be excessive or inappropriate, not merely self-reproach.
8. Diminished ability to concentrate or indecisiveness every day or nearly every day. May be established by self-report or observation.
9. Recurrent suicidal ideation: recurrent thoughts of death or wish to die without a plan, or a suicide attempt or specific. Not just fear of death.

Adapted from *Diagnostic and Statistical Manual,* 4th edition. American Psychiatric Association, 1994.

6 months. In a very different vein, depression may also be caused directly by physiological effects of a medical condition unrelated to emotional processes or functions. Such syndromes, termed by DSM-IV as *depression due to a general medical condition*, are characterized by the same symptoms as, and hence may be difficult to differentiate from, MDD or other depressive disorders. There is some reason to believe that these syndromes are more common among the elderly, if for no other reason than the higher prevalence of many depressogenic diseases in later life.

Major versus Minor Depression

As noted earlier, the majority of older adults who suffer from depression experience lower-level symptoms that do not meet diagnostic criteria for MDD. The DSM recognizes several well-defined disorders that are considered minor depressive states. *Dysthymia* is defined as presence of one of the two defining symptoms plus at least two other symptoms of depression continuously for a period of at least 2 years. This chronic, low-level depression typically manifests relatively early in life and is in fact less prevalent in older than in younger persons. However, in a significant number of elderly adults with dysthymic disorder, the syndrome first occurs in middle or late adulthood. This form of dysthymia is less frequently preceded by a major depressive episode and is less likely to be associated with a comorbid personality disorder. In fact, some experts maintain that late-life dysthymia is a disorder qualitatively different from that seen in younger people. Lower-level depressive syndromes may also be a maladaptive response to emotionally distressing circumstances, as in *adjustment disorder with depressed mood*. These reactive depressive symptoms may or may not meet diagnostic criteria for MDD but usually resolve as the individual copes with or adapts to the precipitating event.

These clearly diagnosable disorders cannot account for the majority of non-major depressive syndromes that affect older adults. In fact, the majority of older persons with clinically significant depression may *not* meet diagnostic criteria for MDD, dysthymia, or other DSM-defined disorders just reviewed. These individuals nonetheless have significantly compromised quality of life because of their depressed mood. The prevalence of these less severe forms of depression has generated a great deal of interest in describing and defining *subsyndromal* depression among older and younger persons alike. Although some early research suggested that non-major depressive syndromes may be qualitatively different from MDD, the general consensus at present is that they simply represent one point along a continuum of depressive symptomatology. From this perspective, both minor depressive disorders and subsyndromal depressive symptoms are simply a lower-level manifestation of the same basic cognitive, affective, and physiological processes that underlie MDD, psychotic depression, and other more severe unipolar depressions.

This view of depression as a continuum of symptoms and severity is upheld by a number of lines of evidence. For example, both diagnosable and subsyndromal minor depressions are clear risk factors for development of MDD. They have neuroanatomical characteristics similar to major depressive syndromes and generally respond favorably to the same treatment regimens. Development of a major depressive episode is gradual and may present as a minor or subsyndromal depression in its early stages. Similarly, some apparently lower-level depressive syndromes may represent partial remission or the process of recovery from a more severe depression.

At this point, there is no consensus about how to define subsyndromal depression, and no clear distinction of subsyndromal depression from diagnosable minor depressive illnesses. Nor can researchers or clinicians reliably determine whether subsyndromal symptoms are prodromal to a full-blown major depressive episode. What is agreed upon is the fact that these lower-level depressive symptoms, previously believed to lack the clinical significance to merit diagnosis and treatment, in fact seriously impair quality of life among older adults. Reflecting this realization, the DSM now recognizes subsyndromal depression as a potential diagnosis under the 'not otherwise specified' rubric, and there is some impetus to add it as a distinct syndrome when the manual is next revised.

Is Late-Life Depression Different from Early or Midlife Syndromes?

It was previously noted that various depressive syndromes may be more or less common and may manifest somewhat differently in the elderly as compared with younger adults. This raises the more general question of whether depression in late life is qualitatively different from earlier-onset disorders. Three lines of evidence have fueled discussion of this issue. One concerns the unique presentation of depression among some older adults, in terms of the complex of symptoms characteristic of the disorder. A second has to do with the association between depression and cognitive impairment. The third, perhaps best

summarized in terms of early versus late-onset depression, draws from studies of the neuroanatomical characteristics of late-life depression.

Depressive Symptomatology in Late Life Although many older adults may present with the classic defining symptoms of depression, others may experience significant symptomatology in the *absence* of the sadness and discouragement that are considered central to identifying depression in younger adults. Depression without sadness is now a recognized syndrome among older adults, in whom hopelessness, helplessness, and anhedonia (loss of interest or pleasure in daily life) may be more common than outright despondency. Alternatively, some older adults may, like children and adolescents, display anger or irritability in lieu of sad mood.

Anxiety often co-occurs with depression across the life span, and differential diagnosis of depressive versus anxiety disorders can be challenging. This is particularly true among older persons, in whom symptoms are often so intertwined as to confound attempts to differentiate anxiety from depression. Although depressed older adults may display generalized anxiety, their worries frequently center on common problems of aging – to wit, physical health and cognitive function. Some older people may be reluctant to disclose feelings of depression to providers, instead presenting with somatic complaints that substitute for or mask depression. This is not to imply that the physical health complaints of depressed older persons are not real. Rather, depression may foment preoccupation with existing, very real health problems and accentuate the suffering that accompanies them. Alternatively, particularly in the primary care provider's office, older adults may focus on vegetative symptoms of depression, describing them in lieu of emotional distress. The picture is further complicated by the fact that many diseases may themselves trigger depressive symptoms (see next section), as may medications used to treat common disorders of aging. Hence, it can be difficult to distinguish physical from psychological processes. This clearly complicates diagnosis of depression in this age group; careful probing and analysis are recommended when the elderly person presents with multiple physical complaints.

Depression and Cognitive Function Complaints of memory problems are also associated with depression in complex ways. There is some natural confounding of depression and cognitive functioning, inasmuch as difficulty concentrating and making decisions are among the symptoms used to diagnose depression in any age group. Furthermore, depression itself may produce some cognitive slowing, particularly when the task involves executive function – that is, planning and coordination of complex activities. This is also true throughout the life span. But for older persons, this co-occurrence of mood and cognitive disturbances presents unique diagnostic difficulties, as it is possible that cognitive symptoms stem not from depression but from real memory disorders. Alternatively, the cognitive slowing common in depressive disorders may be misinterpreted as indicating a true dementing disorder in the phenomenon known as pseudodementia. The key characteristic of a true pseudodementia is its reversibility: When the depression remits, the cognitive problems also resolve. But there is also a clear association between depression and real (irreversible) cognitive deficits ranging from mild cognitive impairment to profound dementia. This association is not a straightforward one, however. It is manifested in a number of different ways and involves several independent dynamics.

First and most generally, depression is far more prevalent among persons with Alzheimer's disease or other dementias than in cognitively intact elders. In Alzheimer's disease, which is characterized by gradual and insidious onset, depression may be prodromal to incident cognitive impairment, occurring in the early stages of the disease and reflecting the individual's awareness of and emotional reaction to early signs of memory loss. As the disease progresses, and particularly as the individual loses the ability to express him- or herself verbally, it becomes more difficult to assess depression and differentiate it from the apathy and flatness of affect that typify dementing illness itself. However, depressive symptoms are generally most predominant in the early and middle stages of the disease and lessen as the individual's self-awareness wanes.

There is also some evidence that one or more episodes of major depression may increase risk of cognitive impairment later in life. Data on this point are just beginning to accrue, but it currently appears that some cognitive symptoms accompanying a major depressive episode may not resolve when the depression remits. Even when cognitive symptoms do remit in tandem with the depression, persons who suffered MDD with comorbid cognitive impairment are at increased risk of developing dementia over the next 5–10 years. In fact, incidence of diagnosable dementia is significantly greater in persons with a lifetime history of MDD, regardless of age at onset or of presence of cognitive symptoms. It thus appears that depression per se may place people at increased risk of developing dementing illness in late life. At

this point, however, the mechanisms of this effect are unknown.

Early- versus Late-Onset Depression Thus far, our differentiation of depression in late life from syndromes seen in younger persons has concentrated on symptomatology. However, this focus on overt manifestations begs the question of whether late-life depression is in fact the same disorder as that seen in non-elderly individuals. For the most part, attempts to link late-onset depression (first episode occurring at age 60 or later) with unique syndromes or histories have yielded little more than the broad descriptions just reviewed. However, a growing body of research using neuroimaging techniques suggests that at least some late-onset depressions have a unique neuroanatomical etiology that may be specific to old age. Specifically, these studies have identified a relatively consistent set of alterations in brain structure that accompany late-onset MDD and have linked these structural changes to some of the distinct patterns of symptomatology reviewed earlier.

Magnetic resonance imaging (MRI) studies indicate that this unique late-onset syndrome is characterized by numerous small hyperintensities – areas of brightness on the scan – that are thought to represent effects of ischemic vascular disease in subcortical structures of the brain and their frontal lobe projections. Although these lesions are not sufficient to cause the kind of functional changes associated with more dramatic vascular breakdowns such as stroke, they are closely linked with a unique syndrome that has come to be termed *vascular depression*. Vascular depression is characterized clinically by apathy (also termed lassitude in this context), psychomotor retardation, and particularly the executive dysfunction syndrome described earlier; vegetative symptoms are less common than in other depressive disorders. Persons with vascular depression tend to be functionally more impaired than elders with a recurrent early-onset depressive disorder and are at greater risk of further functional decline. They also respond less well to pharmacological treatment.

The body of work on functional neuroimaging in late-life depression is less well developed. However, if one borrows from age-non-specific studies, a coherent picture begins to emerge that bolsters clinical and structural support for the vascular depression hypothesis. There is good evidence that late-life depression is accompanied by decreased global cerebral blood flow and poorer activation in response to cognitive stimuli. As with younger adults, this is particularly evident in the prefrontal cortex. Global suppression of glucose metabolism is another common finding, specifically with respect to dorsal neocortical structures. In contrast, and perhaps reflecting a reciprocal relationship, ventral limbic structures associated with emotional function are hypermetabolic among depressed individuals.

Research on vascular depression is in its early stages. The literature cannot yet speak definitively to causal relationships among risk factors, neuroanatomical changes, and observed affective, cognitive, and behavioral symptoms identified thus far. However, it is clear that this syndrome is both unique to late life and qualitatively different from early-onset depressive disorders.

Risk Factors for Depression in Late Life

Biological Risk Factors

Depression in late life is closely linked with senescence at a very basic level. Before discussing medical illness and disease processes, however, it will be helpful to review some more basic processes that may trigger, or at the very least exacerbate, depression through biochemical or neuroanatomical mechanisms. A noticeable omission in the following discussion is the role of genetic factors in late-life depression. Although evidence is scant, there does seem to be a familial risk for late-onset depression. However, genetic risk factors appear to play a lesser role here than in early-onset disease and probably act through their association with other disease processes.

Cerebrovascular Factors As previous discussion of vascular depression implies, changes in brain structure and function related to vascular pathologies are a strong risk factor for incident depression. Interestingly, there is little empirical support for a direct link of late-onset depression with general vascular risk factors such as hypertension. This may, however, be due to the very small number of tightly controlled research studies examining this phenomenon. There is nonetheless strong evidence that subcortical hyperintensities are strongly linked with late-onset MDD and that depressive symptoms are well predicted by the site and size of observed lesions. A number of structures and processes related to frontal lobe function appear to be involved in vascular depression. In addition to white matter hyperintensities, identified structural markers include decreased volume of limbic and basal ganglia structures, including the hippocampus, amygdala, anterior cingulate gyrus, caudate, and the putamen; increased metabolism in areas of the limbic system; and decreased

metabolic activity in dorsal neocortical areas and the basal ganglia.

Whereas the lesions responsible for vascular depression tend to be relatively small and diffuse, other, more specific neurological dysfunctions may produce depression as well. Perhaps the most obvious and most heavily studied is *stroke*. Of persons in acute hospitals or in-patient rehabilitation for stroke, almost 20% meet criteria for MDD and an equal number experience minor depressive symptoms. Although functional deficits contribute to depression among stroke patients, there is now good evidence that structural damage to the brain is a causal factor, particularly in the months immediately preceding the stroke itself. Studies seeking to identify specific sites that are most closely associated with poststroke depression have yielded mixed findings, but the bulk of evidence implicates left anterior cortical and basal ganglial lesions. Poststroke depression is especially insidious because, unless aggressively treated, it impairs both the pace and final outcome of rehabilitation.

Endocrine Function It is well documented that depression is associated with abnormalities of hypothalamic–pituitary–adrenal (HPA) axis activity across the life span. This is most easily observed in high rates of hypercortisolemia, reflecting hypersecretion of corticotrophin releasing factor (CRF), among depressed individuals. Although research directly linking HPA axis function with depression in older adults is limited, they may be especially vulnerable to this dynamic because of increased sensitivity of adrenocorticotropin to the effects of CRF. Levels of dehydroepiandrosterone (DHEA) are lower in older than in younger adults; this pattern is associated with depressive symptomatology as well. Normal age changes in sleep patterns and sex hormones are also linked with HPA axis activity and may dispose some older adults to depression. There has as yet been little integration of these kinds of findings into a comprehensive model of stress response in late-life depression. However, this is a promising avenue for future study.

Medical and Clinical Risk Factors

It is well substantiated that ill health is a strong risk factor for both incidence and persistence of depression in late life (and, for that matter, across the life span). However, there remains some controversy about mechanisms underlying this association. At issue are two primary questions. First, is the correlation between depression and ill health driven by specific disease processes or by overall medical burden? Stated otherwise, do depression and medical conditions share common biological mechanisms, or does depression stem from cognitive and emotional reactions to overt illness symptoms, their effects on functional ability and/or implications for longevity? A second, orthogonal question is that of causal associations between depression and ill health. It was long assumed that the association of physical and mental health problems was driven by the former – that is, that people were depressed because they were sick. An emergent literature suggests, though, that the reverse is often equally true. These two questions form the basis for the following review of patterns of comorbidity of depression with other medical illnesses and of the role of functional disability and other illness symptoms in fomenting those patterns.

The Relationship of Specific Medical Conditions with Depression The list of specific disease processes that are known to be associated with depression is quite long, but for only a few has the link been definitively shown to derive from basic biological dysfunctions. Even for those conditions that have been identified as having an independent association with depressive symptomatology (i.e., net of other health conditions), dynamics of the relationship are not yet clear.

Cardiac disease provides an excellent example of the dilemma facing those who would parse the association of depression with ill health in late life. Depression is a frequent concomitant of heart disease, including acute conditions such as myocardial infarction (MI) as well as congestive heart failure (CHF) and other chronic heart problems. Persons who are not depressed at the time of an acute episode are at high risk of developing depression over the coming year. Those who are depressed at illness onset tend to remain depressed, to experience greater (cardiac) disease-related morbidity, and to be at greater risk of mortality due to the illness. A variety of shared biological mechanisms may account for these effects, including dysfunctions of the neuroendocrine and sympathetic nervous systems, immune dysfunction and consequent susceptibility to inflammation, poor adherence to medical regimens, and, of course, the cerebrovascular dysfunctions described earlier. In some cases, depression may represent a response to the stress engendered by an MI and its implications for mortality. However, there is now ample evidence that the association between depression and cardiac disease is bidirectional. That is, depression is equally as much a risk factor for subsequent heart disease as vice versa.

A handful of other health problems has been shown similarly to bear a mutually influential relationship with depression, such that depression either

predisposes individuals to incident disease or causes exacerbations and poorer prognosis of existing disease. The best documented examples are *diabetes, cancer, stroke, primary sleep disorders*, and *Parkinson's disease*, although the bidirectionality of the latter association is just beginning to be explored.

It is also important to note that many treatments for physical health problems may cause depression as well. A number of medications commonly used by older adults have been shown to cause depressive symptoms. These include (but are not limited to) selected anticonvulsants, flouroquinolone antibiotics, antihypertensives, anti-Parkinsons medications, barbiturates, benzodiazepines, beta-blockers, calcium channel blockers, narcotics, some non-steroidal anti-inflammatory agents, and steroids.

Overall Medical Burden and Depression Beyond this handful of disorders, there has been very little attempt to trace associations between medical disease process and depression systematically. There have, however, been a number of epidemiological surveys linking a range of disorders to depression. Interestingly, results have fairly consistently indicated that it is the number or severity of comorbid health problems, rather than the presence of any specific disorder, that predicts depression. Older adults with a greater number of health problems, or whose medical conditions are relatively more serious, are at substantially greater risk of depressive symptomatology regardless of the specific medical illnesses in question. Several phenomena may account for this effect.

Most obvious is the increased risk of functional disability that attends multiple medical comorbidities. Of all risk factors for late-life depression, impairment of basic and instrumental activities of daily living is the strongest and most consistent predictor. Large epidemiological surveys nearly universally have shown that the association of depressive symptoms with any given health problem, or with overall burden of illness (number and severity of comorbidities), can be wholly explained by the functional impairment associated with physical health problems. But as with the specific disorders just discussed, the relationship in question is a complex one. Disability can obviously cause emotional distress due to limitation of one's ability independently to conduct necessary daily activities. However, it is equally true that depression causes disability not only cross-sectionally, in the form of so-called *excess disability* due to lack of motivation or interest in activities, but also over time. Even controlling for medical status, depressed older adults are at much higher risk of incident functional disability than their non-depressed peers. It is as yet unknown whether this effect of depression upon subsequent functional status is caused by atrophy of functional abilities due to disuse or by effects of depression upon neuroendocrine and immune systems. Both paths likely play a part.

Disability is perhaps the most common, but certainly not the only, illness effect associated with late-life depression. In fact, any symptom that compromises continued daily function may predispose individuals to depression. Perhaps the most common symptom, after disability, is pain. A substantial proportion of older adults suffer to some extent from persistent pain due to osteoarthritis and other chronic illnesses. Over the past two decades, evidence has accrued documenting the strong association between chronic pain and depression in older adults. Causal associations among pain, depression, and disability remain a matter of dispute and likely vary with specific illness dynamics. Nonetheless, there is solid evidence that, as with other health processes, the relationship between pain and depression is mutual. Pain causes persons to become depressed, and depression both exacerbates the suffering attending physical pain and disposes individuals to increased pain and pain-related disability over time. The latter is a particular concern because older persons' pain, whether acute or chronic, is often underdetected and undertreated. Failure to control this very common illness symptom may thus place older adults at risk of a downward spiral of pain, depression, and disability.

Psychosocial Risk Factors

Psychosocial risk factors include external events and conditions, as well as behavioral, cognitive, and emotional responses to them, that make people vulnerable to emotional distress. Perhaps the largest broadly defined category of psychosocial risks for depression are factors that produce stress: enduring or transitory situations whose demands on the individual exceed his or her perceived ability to manage them. Those demands may in turn arise from characteristics of the situation itself, the individual coping with it, or other people or circumstances relevant to the situation. More pragmatically, primary psychosocial risk factors for depression include major and minor stressors, inadequate cognitive and behavioral coping skills, and lack of social resources for managing the situation.

Only a few of these types of risk factors are unique to late life. However, a number of stressors are more common among the elderly simply because they are normative for that stage of the life course. For example, many major life stressors are more common

in later life, e.g., death of a spouse or other loved one, one's own or a family member's severe illness, and retirement. Similarly, chronic illness and functional impairment, again more common in late life, often produce chronic stressors such as transportation problems for persons who do not drive or the high cost of prescription medications for chronic health problems. Coping resources may also be curtailed in late life. Social support – presence of one or more individuals who offer direct help or emotional nurturance – is an extremely important resource for coping with stress and for emotional well-being in general. Social isolation and loneliness are strong, consistent predictors of depression across the life span. Yet here again, many older adults may have lost or find it difficult to maintain contact with supportive friends and family members. In short, although the dynamics are much the same as earlier in life, the fact of aging itself may put older adults at increased risk of depression due to psychosocial circumstances.

Cognitive and behavioral strategies for coping with stress also differ among older as compared to younger adults. In particular, strategies for maintaining a sense of personal control over life circumstances – and hence, for interpreting them as benign or challenging rather than as inherently stressful – tend to shift in later life toward less direct, more self-focused efforts to manage one's response to events rather than the events themselves. This shift from primary to secondary control strategies – that is, from direct attempts to change the situation to self-management to control its effects – can be adaptive if coping attempts fit the circumstances. In particular, as objective opportunities for exerting direct control over life circumstances dwindle, it may be most beneficial to compensate by adapting one's own expectations of or responses to the situation. This sort of cognitive, behavioral, and affective flexibility is a crucial means of warding off the feelings of helplessness that predispose people to depression. In contrast, failure to make the shift to secondary control tactics or appropriately to evaluate the demands of the situation for direct versus indirect coping efforts can exacerbate stress and its effects.

Treatment of Late-Life Depression

It is now almost axiomatic that late-life depression is underdetected, underdiagnosed, and undertreated. Although this basic fact has not changed, there has been tremendous progress over the past 10 years in ensuring that older adults with depressive disorders are in fact appropriately assessed, triaged, and provided adequate treatment for their symptoms.

Pharmacological Treatment

As recently as 20 years ago, drug treatment of late-life depression was a somewhat risky business. Tricyclic antidepressants (TCAs), though effective in alleviating symptoms, often produced undesirable and even dangerous side effects due to their marked anticholinergic effects. However, with emergence of the selective serotonin reuptake inhibitors (SSRIs; e.g., citalopram, paroxetine), serotonin-norepinephrine reuptake inhibitors (SNRIs, e.g., venlafaxine), and other new-generation medications (e.g., bupropion), pharmacological treatment of depression in the elderly has become a less daunting enterprise.

Rigorously controlled studies of the effectiveness of antidepressants for treating late-life depression are surprisingly few, owing both to underrepresentation of older people in clinical trials and to ethical constraints against using a placebo condition. The efficacy of TCAs is nonetheless fairly well established, and a handful of studies have compared those medications with SSRIs as well. Serotonin system agents have generally proven no more effective than proven TCAs such as nortriptyline. However, their more benign side effect profile has made SSRIs the drugs of choice in first-line treatment of late-life depression. A number of different SSRIs have been proven effective in treating late-life depression. There is at present no strong evidence in favor of any one of the SSRIs for use with older adults. Similarly, although evidence is sparse, there is nothing to suggest that either TCAs or SSRIs are more or less effective than the newer selective norepinephrine reuptake inhibitors or combined serotonin–norepinephrine system agents.

Perhaps the more important choice in treating late-life depression is not selection of a specific medication, but structuring of the overall treatment regimen to improve chances of remission and prevent relapse. Because much pharmacological treatment occurs in the primary care context, depressed elders may not receive state-of-the-art treatment for their symptoms. In fact, it has been estimated that 40–45% of elderly antidepressant users may be on a suboptimal treatment regimen. For example, the 'start low, go slow' adage is always recommended when initiating pharmacological treatment of older persons, but existing evidence recommends titrating up to standard adult therapeutic dosage for optimal response. In practice, however, many older persons receive subtherapeutic dosages for the duration of treatment. Follow-up of elderly primary care outpatients may also be fragmented in terms of monitoring not only response but also compliance. In particular, many patients may discontinue medications when

symptoms begin to remit, placing themselves at high risk of relapse or recurrence. At present it is recommended that maintenance therapy continue for at least 6 months to ensure that symptoms do not recur.

When prescribing and monitoring meet best practice standards, about 60% of older adults with MDD respond to initial pharmacological therapy. This is comparable to rates among younger individuals. However, older persons may take longer to show improvement in symptoms and are more prone to relapse if and when treatment is discontinued. Overall, etiology of depression does not appear to be a strong factor in treatment response. The one exception to this rule is vascular dementia, which is more refractory than other syndromes and may require more prolonged treatment to achieve gains in quality of life. It nonetheless does respond to antidepressant medications, as does depression accompanying stroke, Parkinson's disease, and Alzheimer's disease and other dementias. Minor and subsyndromal depressive symptoms also respond well to pharmacological treatment. Just as depression is associated with incident cognitive and function impairment, as well as mortality, drug treatment has been shown to ameliorate health and functional consequences of depressive illness in older adults. Hence, particularly when symptoms are severe, aggressive pharmacological treatment, coupled with careful monitoring and follow-up, is essential.

Other Treatment Modalities

Although carefully controlled trials are relatively few, various forms of psychotherapy have proven useful in treating late-life depression. Perhaps the most heavily studied is cognitive-behavioral therapy (CBT), which has been proven to relieve depressive symptomatology in several studies with relatively healthy community-dwelling elderly. Although CBT and interpersonal therapy (IPT) are the most heavily studied forms of talk therapy for older adults, several other approaches have also yielded positive outcomes, including problem-solving therapy, psychodynamic therapy, and life review or reminiscence therapy. Although evidence is quite limited, group approaches appear to be as effective as one-on-one psychotherapy for cognitively intact elderly.

Psychotherapy appears to be equally effective for treating depression among cognitively intact older persons as among middle-aged adults and is generally recommended for use in similar ways. Specifically, for persons with severe depression, psychotherapy alone is not recommended; medication is usually needed to achieve marked remission of symptoms. However, talk therapy can be effective as an adjuvant treatment and may be central to maintaining treatment gains and preventing relapse in MDD. In contrast, for non-major disorders, psychotherapy may be all that is needed to achieve remission of symptoms.

Electroconvulsive therapy (ECT, or shock therapy) fell into popular disrepute for a number of years. With refinement of therapeutic methods and indications, however, ECT has become a very useful approach for treating severe or refractory depression. At present, older persons are disproportionately referred for ECT. Factors contributing to this include the greater prevalence of psychotic symptoms among elderly as compared with younger depressives, inability of some older persons to tolerate side effects of antidepressant medications, and vulnerability to health complications of depressive symptoms such as inactivity or self-neglect. As with other aspects of depression treatment, carefully controlled trials of the safety and efficacy of ECT for older adults are few. However, existing evidence shows good results in terms of remission of symptoms following ECT and few lasting side effects. In particular, there appears to be little grounds for concern about incident or exacerbated cognitive symptoms following ECT. Hence, for elders who are unable to profit from other forms of treatment, ECT may be a reasonable alternative.

Summary

In summary, as many as 40% of adults may suffer some form of depression during their later years. Although many of the risk factors for late-life depression parallel those for young-adult manifestations of the disorder, older persons may be at higher risk simply because of the circumstances of aging: increased risk of health and functional problems, greater exposure to some stressors, and shrinking resources. On the other hand, some older persons are at risk of late-onset depressive disorders due to aging of the brain. Regardless of etiology, late-life depression is a serious medical condition that demands treatment to avoid not only prolonged distress but also incident disability and further health problems. With appropriate treatment and monitoring, however, depressed elders can safely be restored to good mental health and prolonged quality of life.

Published 2007 by Elsevier Inc.

Glossary

Metabolic Syndrome – Involves markers of inflammation associated with diabetes, hypertension, and stroke.

Noninsullin-Dependent Diabetes Mellitus (also called Type 2 Diabetes or Adult Onset Diabetes) – A chronic disease of insulin resistance and glucose intolerance contributing to vascular aging.

Introduction

Diabetes is a common disorder. The earliest known record of diabetes is mentioned on third dynasty Egyptian papyrus in 1552 BC. Polyuria was recognized as a symptom. In the first century BC, the Roman philosopher Arateus called diabetes "the melting down of flesh and limbs into urine." Galen labeled diabetes a kidney disorder. By the sixteenth century, Paracelsus had recognized diabetes as a serious general disorder.

The French physician Bouchardat recognized 135 years ago that cases of glycosuria were resolved during the siege of Paris in the Franco-Prussian War. The nineteenth-century Italian diabetelogist Catoni locked up patients to enforce dietary compliance. New approaches are being developed, but treatment problems continue and treatment outcomes are unclear for elderly diabetics.

Non-insulin-dependent diabetes mellitus (NIDDM), type 2 diabetes, also known as adult-onset diabetes, is a generally incurable chronic disease causing multisystem failure. NIDDM is part of the larger picture of insulin resistance and glucose intolerance contributing to vascular aging. Mechanisms for this association are being elucidated. Just as glycemia can be treated by diet, so can the vascular issues. For example, Biosphere 2 was a 3.15-acre ecosystem of energy and fuel production with recycled air, water, and organic material. When a shortfall occurred with replenishing atmospheric gases, participants were forced into extended caloric restriction. As a result, the blood pressure, cholesterol, and body weight of the participants significantly improved. These are all risk factors for vascular aging. The biosphere study suggests that caloric restriction may prevent vascular aging and reverse the metabolic syndrome, but lifestyle changes of this magnitude are rarely sustained and recent studies question what diet is best.

One reason the general public continues not to understand the pathogenesis of NIDDM relates to the fact that diabetes was first recognized as an acute process of fluid loss, not chronic degeneration. The first insulin preparations were developed in 1922. However, it was not until 1959 that a distinction was made between type 1 diabetes and NIDDM. NIDDM affects 90% of diabetics, causes most age-related pathology, and usually progresses insidiously. As the population ages, NIDDM prevalence will increase. In addition, diabetes prevalence is increasing worldwide, and repercussions for older adults have yet to be evaluated.

Epidemiology and Mortality

Mortality

Of the four most common causes of death, three relate to diabetes because insulin resistance contributes to diabetes and to death from heart disease and stroke. Diabetes, by itself, is the fourth leading cause of death for people aged 64 to 74 and for those aged 75 to 84. Diabetes is the sixth leading cause of deaths after age 85. Cardiovascular disease, usually congestive heart failure, causes death in 60 to 80% of diabetics. Diabetes increases mortality from acute myocardial infarction, acute stroke, and peripheral vascular disease. Other risk factors, including smoking and dyslipidemia, amplify diabetes mortality rates.

Epidemiology

Currently, 18.2 million Americans have known diabetes, 4 million are undiagnosed, and 60 million have the metabolic syndrome. Diabetes is a disease of the elderly; prevalence increases with aging. In the Framingham cohort, 30–40% of those over age 65 were glucose intolerant. The Honolulu Health Study found that high prevalence of diabetes and impaired glucose tolerance continue beyond age 75. Up to 20% of those over age 80 are diabetic, but studies on non-White groups such as African Americans, Hispanics, and American Indians, who appear to have higher prevalence, are limited. Public health implications are great, since a few years ago there were more people alive at age 80 than in all of history. Among those admitted to nursing homes, 26.2% had diabetes.

Diabetes and obesity have reached epidemic levels in Western and developing countries. There are 1.8 million diabetics in Britain – an increase of 400 000 since 1996. Worldwide, the number of people with diabetes is expected to rise from 171 million in 2000 to 366 million in 2030. In countries such as China, where the prevalence of diabetes was 0.6% in 1980, starvation has been resolved. Now 200 million Chinese are overweight, and diabetes prevalence has ballooned. On the South Pacific island Nauru, the inhabitants historically ate bananas, yams, and coconuts and were totally free from diabetes. When the population became wealthy from phosphate deposits, the islanders switched to a diet of refined flour, sugar, and processed vegetable oils. Up to one-half of the urbanized Nauru are now diabetic. In the United States, the overwhelming majority of diabetic children had type 1 disease; only 1 to 2% had NIDDM. Recently, however, 8 to 45% of newly diagnosed children have NIDDM.

In 1962, J. V. Neel proposed a thrifty gene that preserves extra dietary calories as fat during times of relative plenty to better survive times of famine. The full import of such a gene for aging is still unclear. Such genes become more common by natural selection. In the face of current plentiful foods, people with this gene are prone to obesity and diabetes. Natural selection against a thrifty gene is weak because detrimental effects do not occur until late in reproductive life.

Risk Factors

Insulin Resistance Glucose clearance by peripheral tissues is slowed for up to one to two decades before NIDDM develops in older people.

Family History Prospective studies show that insulin resistance predicts onset of diabetes, particularly in patients with family history.

Aging Insulin resistance has been related progressively to aging, but not all studies relate causation to age alone.

Hypertension Up to 60% of people with essential hypertension have insulin resistance and the metabolic syndrome. A prospective cohort study found that NIDDM was 2.5 times more likely in those with hypertension than in normotensives, possibly due to an intrinsic defect in vasodilatation that decreases efficiency of muscle glucose uptake. Vasodilatory agents such as angiotensin-converting enzyme inhibitors may improve glucose uptake and prevent diabetes.

Inactivity and Obesity Overeating and high-fat diet are the major causes of insulin resistance causing glucose intolerance, the metabolic syndrome, and subsequently overt diabetes. One study using glucose clamps found that obesity may have greater influence

on insulin action than diabetes itself but did not focus on age changes per se. Visceral adipose tissue correlates to insulin resistance in elderly women. A number of large epidemiological studies showed that risk for NIDDM, and presumably insulin resistance, rises as body fat increases from very lean to very obese. This implies that the absolute amount of body fat has an effect on insulin sensitivity across a broad range. Recent studies relate loss of lean body mass to insulin resistance and such changes are common as older people develop frailty and impaired appetite. Increased percent adiposity also contributes.

Human obesity typically arises from increased food intake and decreased expenditure of energy. The surplus energy is stored as fat in adipose tissues. The system controlling fat accumulation involves many different cellular processes, including energy expenditure, digestion, absorption, transport, and storage of nutrient fuels. A complex system of hormonal signaling pathways is coordinated by neural circuits that regulate fat formation. Several hormones produced by adipose tissue play a critical role in the regulation of energy intake, energy expenditure, and lipid and carbohydrate metabolism. For example, leptin is produced exclusively in fat cells and the placenta, and blood-borne leptin signals the brain regarding quantities of stored fat. Leptin receptors in the hypothalamus regulate the neural appetite and satiety centers that control body weight. Although leptin deficiency from a single gene mutation is associated with overweight in homozygous or hemizygous humans, mutations of leptin or its receptor are clinically rare. Rather, it appears that age-related obesity is caused by a spectrum of leptin resistance with hyperleptinemia (analogous to insulin resistance). At present, we are just beginning to unravel the physiology of the complex system that regulates body weight.

Medications Glucocorticoids increase the likelihood of diabetes in susceptible patients. Psychotropic agents, including certain atypical antipsychotics, selective serotonin reuptake inhibitors, and mood stabilizers, have metabolic sequelae, such as obesity, dyslipidemia, glucose dysregulation, and the metabolic syndrome. Case reports, observational studies, retrospective database analyses, and controlled experimental studies suggest that treatment with antipsychotic medications is associated with insulin resistance and weight gain. Persons with schizophrenia and affective disorders also have a high prevalence of risk factors for ischemic cardiovascular disease including diabetes and obesity, that is, 1.5 to 2.0 times higher than in the general population.

Minerals Altered mineral metabolism is prevalent with aging and may affect glucose. Low zinc levels are reported with aging, but for most old people plasma zinc levels are generally normal. However, reliable indicators of tissue zinc nutriture are still being developed, and functional tests suggest that impaired tissue zinc metabolism is widespread and muscle zinc accumulation is altered with aging. Impaired zinc metabolism affects production of essential proteins that may contribute to impaired glucose metabolism. Numerous studies on tissue utilization of zinc have indicated that unusable 'junk' zinc accumulates in aged tissue. Unusable or spent zinc may be bound or chelated to junk proteins in aged cellular tissue. Such junk zinc leads to apparently normal levels despite deficits of useful zinc.

Pathophysiology

Metabolic features of diabetes include impaired carbohydrate metabolism and impaired lipid metabolism. How these change with advanced age is modified by adiposity as well as by declining body weight, which, for men, tends to occur after age 60. Although total body weight may be lower, percent adiposity increases, with a decline in lean mass. While there is a survival advantage to maintaining body weight into advanced age, as indicated by U-shaped survival curves, the implications of the epidemic of obesity-related diabetes will presumably be reflected in accelerated mortality and earlier functional impairment in a subset of the population. New research has strongly suggested that inflammation through activation of the NF kappa beta cascade may be a primary cause of development of age-related diabetes as well as complications including cardiovascular disease.

Carbohydrate Metabolism

Insulin initiates glucose transporter synthesis by binding to the α subunit of the insulin receptor, which phosphorylates the β subunit and activates its tyrosine kinase. Activated kinase signals genes to produce and translocate the insulin-sensitive glucose transporters from an intracellular pool to plasma membranes. Glucose transport and activation of the receptor kinase is impaired with age. Production and translocation of preformed glucose transporters to plasma membranes are also reduced with aging. This leads to impaired glucose transport and accelerated muscle glycogenolysis with age. The common toxic disorder of insulin resistance accelerates aging and may deteriorate to glucose intolerance and diabetes. Skeletal muscle is quantitatively the major site of

age-related impairments responsible for 80–90% of muscle, the tissue responsible for the disposal of 80–90% of an ingested glucose load.

Insulin resistance is manifested by impaired suppression of hepatic glucose output and decreased insulin-stimulated glucose transport and metabolism in adipocytes and skeletal muscle. Hyperglycemia itself by virtue of glucotoxicity can cause insulin resistance, and fasting hyperglycemia is the primary determinant of insulin sensitivity in skeletal muscle.

Impaired insulin secretion increases with age and abnormal first phase insulin release precedes overt diabetes. Some elderly patients develop brittle diabetes with marked insulin deficiency. Recent studies have found that the inflammatory cascade also explains development of age-related insulin deficiency through damage to beta cell function but there remains sufficient insulin that type I diabetic ketoacidosis does not occur.

Lipid Metabolism

Lipids relate to glucose metabolism. Insulin decreases free fatty acids by suppressing lipolysis. Free fatty acids increase hepatic glucose production by stimulating gluconeogenesis. When reduction in free fatty acids during hyperinsulinemic clamp was prevented, insulin-mediated suppression of hepatic glucose output was dampened.

Dyslipidemia with hypertriglyceridemia, low plasma HDL, and small, dense LDL particle concentrations leads to coronary artery disease with insulin resistance and NIDDM. When diabetic control is poor, total cholesterol, LDL, VLDL cholesterol, and triglycerides can be very high and HDL decreased. For men, diabetics do not have rates of abnormal cholesterol different from those of non-diabetics. However, for women, diabetics have nearly double the rate of hypercholesterolemia, and other lipid parameters are worse, increasing cardiovascular risk. The abnormal lipid profile results when insulin augments liver overproduction of VLDL particles with apolipoprotein-B. Insulin and fatty acids mediate transfer of lipids to apolipoprotein-B, thus decreasing apolipoprotein-B degradation. Exchange of VLDL triglyceride for LDL cholesterol esters and subsequent triglyceride hydrolysis yields small dense LDL particles.

Complications

Depression is more common in diabetics than in non-diabetics, and this has been shown to increase the risk of hospitalization.

Macrovascular

NIDDM in the elderly is associated with increased risk of vascular disease. Risk for myocardial infarction is five times higher, and insulin resistance increases death from heart disease. Hypertension and smoking double the risk of cardiovascular disease. Many studies have found an independent association in men and women of increased risk of heart attack and stroke risk that continues into advanced age. For any level of blood pressure, diabetic persons have twice the risk of stroke, myocardial infarction, and peripheral vascular disease. Hypertension and overt diabetes double the risk of cardiovascular disease. In addition, affected individuals have a greater likelihood of having dyslipidemia, hypertension, and obesity. Relative risk for ischemic stroke is 1.8; that for stroke of all types is 3.0. Risk relates to degree of glycemic control, but prognostic association and the magnitude of the effect are less clear in the elderly. Increased risk for hemorrhagic stroke in older diabetic patients is still unsubstantiated but may relate to cardiovascular risk. Silent myocardial infarction increased in men with diabetes, with unrecognized myocardial infarctions three times more common in diabetic than in non-diabetic men; this risk may be greater in older diabetics.

The Framingham Study found that the relative risk for coronary artery disease in diabetic men and women up to age 74 was 2.4 and 5.1 times greater, respectively, than for age-matched non-diabetic men and women. Risk of cardiovascular disease was twice as high for men with diabetes and threefold higher for women, which eliminates the female advantage over men for all outcomes except stroke. In the Islington Diabetes Survey, the prevalence of serious coronary disease increased from 9% in subjects with normal glucose tolerance to 17% in those with impaired glucose tolerance and 20% in those with diabetes.

Macrovascular disease is increased before glucose levels surpass the threshold to diagnose diabetes; 25% of newly diagnosed diabetics have overt cardiovascular disease. Risk of macrovascular disease is increased before glucose levels surpass the threshold at which diabetes is diagnosed. This is reflected by the fact that 25% of newly diagnosed people with diabetes already have overt cardiovascular disease. Women are particularly vulnerable to cardiovascular effects from NIDDM related to menopausal changes.

The Metabolic Syndrome Macrovascular disease is markedly increased by insulin resistance, glucose intolerance, and diabetes. Reactive oxygen species are generated, creating oxidative stress, which exerts major effects on signaling pathways, further affecting

cellular metabolism and triggering low-grade inflammatory reaction. Macrovascular pathophysiology derives from the metabolic syndrome, which leads to a clustering of atherogenic factors. Defects in vasodilatation and alterations in blood flow may provide a link to hypertension in insulin-resistant subjects. The normal vasodilatation response of insulin is disrupted in obese, insulin-resistant, and diabetic individuals, perhaps through inability of insulin to increase endothelial cell nitric oxide. Men with the metabolic syndrome were 2.9–4.2 times more likely to die of coronary disease after adjusting for usual risk factors.

The metabolic syndrome is associated with insulin resistance, but it is not just a consequence of insulin resistance, nor of lack of insulin action. The interface with advanced age has yet to be deciphered. While the metabolic syndrome has become very popular, some suggest that it is time for a re-appraisal because the pathogenesis and clear markers have yet to be defined and some have cast doubt on the value of the metabolic syndrome as a risk marker for cardiovascular disease. New research has suggested that inflammatory markers may explain this process but only limited studies have been performed to date. Insulin resistance alone is not the cause, since patients with insulin receptor mutations or autoimmune insulin receptor antibodies with hundred-fold higher insulin levels are not obese or hypertensive. Some abnormalities of the syndrome actually contribute to insulin resistance, hypertension, dyslipidemia, coronary arteriosclerosis, and stroke. This cluster also causes much of the dysfunction that occurs with usual versus successful aging in the United States.

The metabolic syndrome involves the following markers of inflammation that are closely associated with diabetes, hypertension, and stroke, which may decrease after weight loss:

- Elevated interleukin-6
- Elevated tumor necrosis factor-α
- Impaired fibrinolytic activity
- Easily oxidized, small LDL particles
- Heightened blood-clotting activity
- Increased adipocyte-derived plasminogen activator inhibitor 1
- Increased clotting factors
- Increased fibrinogen
- Increased factor VII
- Increased platelet adhesiveness.

Microvascular

Microvascular complications have been most feared by lay people; this reflects the fact that diabetes is the most common cause of blindness and renal failure in the non-geriatric population. Prevalence of retinopathy was 85% in older diabetic patients, but nonproliferative retinopathy was considerably more common than proliferative. Aging also increases prevalence of renal insufficiency, and correspondingly there is an increased age-related occurrence of diabetes-related renal failure.

Diabetes causes impaired white blood cell function that impedes healing and also prevents wound healing through vascular impairment. Wounds take longer to heal in part due to the immune compromise that is caused by diabetes, notably interference with white blood cell chemotaxis and leukocyte killing capacity.

Neurodegenerative

It has long been recognized that older patients with diabetes develop some cognitive impairment, but recent studies have found that incidence of Alzheimer's disease is higher in those with diabetes. There is growing evidence that the spectrum of insulin resistance and NIDDM glucose intolerance plays a major role in common neurodegenerative disease. Incidence of dementia will increase 400% in the next 20 years. Neurodegenerative disease is predicted to replace heart disease as the largest cause of death and disability among elderly people during the first century of this third millennium. Impaired glucose metabolism may contribute to the two major causes of dementing illness, multi-infarct dementia and Alzheimer's disease, which make up 80% of all dementia. Weight loss from decreased appetite may occur during the subclinical phase or initial onset of dementia, which explains lack of association with weight changes near the time of diagnosing dementia. In a retrospective study of 10 276 men and women in their 40s, compared with those of normal weight, those with body mass index greater than 30 had 74% higher risk of dementia, while those with body mass index greater than 25 had 35% greater risk. A prospective study found obesity in elderly woman increased the risk of dementia.

NIDDM prevalence is significantly higher among those with Alzheimer's disease. Increased CNS amyloid relates directly to development and progression of Alzheimer's disease, and insulin-degrading enzyme has a role in degrading amyloid β-protein. Lower levels of this enzyme relate to degree of insulin resistance. Deficient insulin signaling with decreased PI-3 kinase correlates with reduced insulin-degrading enzyme in Alzheimer's brains. No prognostic studies have investigated potential therapy. Cardiovascular disease and diabetes also increase dementia associated with interleukin 6 and C-reactive protein.

Atypical presentation in elderly diabetics includes the following:

- hyperosmolar non-ketotic coma
- malignant external otitis
- emphysematous cholecystitis
- neuropathic cachexic, especially in older men.

Treatment and Prevention

Diabetes in all adults, particularly in older adults, is altogether a patient's illness since compliance has the largest impact on the course of the disease. What appears more relevant is that diabetes, or at least the bulk of the cases that are diagnosed in adults, is entirely preventable by lifestyle modifications. Compliance for such recommendations is no easier now than it was for Catoni. Very few behavioral therapists and some lifestyle-oriented workshops or clinics are successful in getting patients to comply. Those patients most interested in making lifestyle changes are often those who recognize the impact of their behavior on their sexual function. A broader solution for this epidemic awaits societal shifts, health conscious motivation, or more effective medication.

What seems particularly compelling about this clinical predicament is that arteriosclerotic disease may well be preventable and possibly reversible by simple non-toxic maneuvers. Such conceptions were broached by the paradigms of usual aging as opposed to successful aging developed in the 1980s. Certainly in terms of diabetes and the metabolic syndrome, lifestyle choices affect much of the resultant age-related disease, and clinicians have been less motivated to encourage changes. These simple issues become increasingly relevant with the shift in prevalence of diabetes across the world. Some patients are sufficiently insulin deficient that diet and exercise are not as helpful even though insulin deficiency promotes development of insulin resitance.

Diet

Caloric restriction improves whole body glucose homeostasis, increasing insulin sensitivity even though obesity is not controlled, and is advocated as a first-line therapy. Caloric restriction studies show slowing in many aspects of age-related deterioration in rodents, including glucose tolerance, despite finding very high levels of stress hormones, including glucocorticoids. Thus, caloric restriction sufficient to maintain a negative energy balance with or without exercise is highly desirable for diabetes control by reducing hepatic glucose production, fasting hyperinsulinemia, lipid profile, glucose tolerance, and blood pressure, and can possibly prevent diabetes. People at risk of NIDDM decreased that risk by more than half by exercising moderately only 30 min/day, losing only 5–10% of their body weight. During one study of people over 60, risk was cut by 71%. One possible mechanism for improvements in insulin sensitivity through weight loss may be effects on the pattern of muscle fatty acid metabolism and the accumulation of lipid within muscle. Response to such dietary therapy for diabetics of advanced age may reflect differences in pathophysiology because of age-related decrease in appetite and body weight. Controlled diet therapy studies have yet to be completed for the oldest-old and for nursing home patients since some suspect that this will not be helpful, as such patients have lost enough weight with advanced age.

Specific food types impact glycemia. The amount of fiber eaten affects glycemic response to meals. There are large differences in different starch-containing foods. Cooking starch-containing food increases glucose by half. Raw starch ingestion led to 44% less glucose response and 35–65% less insulin response compared to eating glucose or sucrose. Foods such as rice and potatoes release more glucose in relation to time of cooking, but uncooked legumes, which have more indigestible starch, are ideal foods to control diabetes. Patients who ate whole grains in a long-term cohort study had less risk of NIDDM compared to controls who ate white rice. Such studies suggest that eating a raw vegetable calorie-restricted diet would decrease incidence and delay development of diabetes. A previous study also found that compared with a diet of 45% fat, 40% carbohydrate, 1 and 15% protein, a higher carbohydrate diet of 30% fat, 55% carbohydrate, and 15% protein increased fasting triglycerides by 41%. Postprandial triglyceride, glucose, and insulin levels were also higher on the higher carbohydrate diet, and triglycerides relate to cardiac risk for diabetics. Another study of a 60% carbohydrate diet compared to a diet with less carbohydrate but more fat found for patients on the 60% carbohydrate diet glucose and insulin concentrations significantly elevated throughout the day, doubled 24-h urinary glucose excretion, and 30% higher total and VLDL triglyceride with lower HDL. Fatty foods may be more likely to induce obesity. When converting ingested fat to fatty acids and then esterifying these to triglyceride for fuel storage in adipocytes, only 3% of the net fuel consumed as food is lost, but for ingested carbohydrates, 10 to 15% of the energy is lost. Hence, eating fatty food may increase the amount of weight gained.

Exercise

Glucose utilization for healthy elderly relates closely to fitness as measured by maximal aerobic capacity, but evidence varies as to whether exercise improves diabetic control in older diabetics. Four months of aerobic exercise can improve muscle oxidative capacity similarly in young and old, but insulin sensitivity is less likely to improve in older people and benefits take longer and require more frequent training. Others found that exercise may reverse the metabolic syndrome for some elderly hypertensives, improves insulin resistance without weight change, reduces cardiovascular disease, and may decrease total mortality as much as 44%. However, it appears that benefits from exercise are transient and may disappear shortly after stopping. Effects of exercise on insulin sensitivity have been proposed to be due to number of glucose transporters, changes in capillary density, and increases in the number of red glycolytic fibers. Age effects are unclear. Increasing lean body mass by resistance exercise may also improve glycemia especially among frail diabetics.

Glycemic Agents

Copper, magnesium, and chromium were implicated with some benefits, but supplementation does not improve glucose tolerance in old people. Lithium and vanadium help, but toxicity occurs near therapeutic doses. However, toxicities of zinc appear to be the least, and zinc has broadest involvement in normal metabolic processes, with more than 300 known zinc-requiring proteins and enzymes. Zinc activates insulin receptor β subunit autophosphorylation to stimulate glucose uptake in insulin-requiring cells at sites that deteriorate with age. Glucose intolerance and insulin resistance occur with zinc deficiency. Supplementary zinc may help impaired glucose tolerance, but results have not been consistently replicated. In contrast, zinc added to prostate extract, to the prostaglandin precursor arachadonic acid, or to the pancreatic peptide cyclo-histidine-proline, did improve glycemia in multiple experiments. Discrepancies may derive from inadequate tissue zinc utilization. Experiments have indicated that pancreatic cyclo-histidine-proline acts like an oral form of insulin and enhanced muscle zinc utilization. This peptide also reverses insulin resistance in aged rodents as documented by euglycemic clamp studies. At higher doses the peptide appears to decrease leptin resistance, with food intake decreasing up to 45% in aged obese rats. Sustained 10% weight loss has been observed. There was no significant change in food intake when young non-obese rats were given the same treatment, and no toxicities have been observed.

Analogous results with metformin include less improvement acting predominantly by decreased appetite and hepatic glucose production not enhanced by muscle glucose utilization. Metformin was recently used in a trial to prevent development of NIDDM in glucose-intolerant patients, but that study was not geared toward old people. Troglitazone improves muscle insulin action, but fatalities occurred and the drug was taken off the market. The safety and utility of rosyglitazone are not yet confirmed for the aged. The same therapeutic dearth pertains to glucose intolerance due to age or obesity. There is concern with using metformin and glitazones because of potential age, renal, and cardiac-related toxicities. Insulin-augmenting agents such as repaglinide, designed to normalize postprandial glucose excursions, increase early and late phases of insulin responses in hyperglycemic patients without markedly enhancing insulin secretion in euglycemics and are less hypoglycemia-prone than sulfonylureas and have limited indications.

Vascular Treatment

Increased risk of heart disease in patients with diabetes has prompted the recommendation that individuals with diabetes be treated for their dyslipidemia as aggressively as individuals who have had a previous myocardial infarction. In addition, individuals with the metabolic syndrome are in a higher risk category and should also be aggressively treated to lower lipids. LDL level is not as valuable as the LDL/HDL ratio. Most coronary prevention measures, including weight control, exercise, avoidance of cigarettes, and improvement of glucose tolerance, also increase HDL.

Intensive Glycemic Control

The UK Prospective Diabetes Study evaluated tight insulin control for NIDDM. After 10 years, glycemia significantly improved, with 25% reduced retinopathy and nephropathy. Intensive therapy decreased development and slowed progression of diabetic neuropathy. Four weeks of intensive glycemic therapy improved glycemic nerve conduction velocities, increased strength-duration time constant, and decreased rheobase. The lack of focused outcome studies for the elderly suggests that the benefit of tight glycemic control to prevent or treat neuropathy, nephropathy, and retinopathy is unclear in elderly diabetics. This may in part relate to the duration of disease and the time course of benefits in relation to survival of older patients.

Potential Reasons for Tight Control in Older Diabetics

Clinical trials have demonstrated lower risk of developing or progressing retinopathy, nephropathy, or neuropathy. Follow-up studies have shown that previous degree and duration of glycemia are important risk determinants for microvascular complications. This prevents and improves retinopathy, but such issues are not well studied in certain elderly groups even though a very high percentage of older diabetics (>80%) have background retinopathy. Progressively lower risk to develop acute myocardial infarction is seen with improved glycemia. Data on macrovascular risk benefit for elderly is inconclusive, but a study of 229 65- to 75-year-old subjects found linear association of glycemic control with 3.5 year coronary mortality. A few years of good glycemic control may reduce the risk for cardiovascular events a few years later, but the role of tight glycemic control in reducing the risk of stroke is still uncertain. Previous studies extrapolated such results to older patients, but no evidence-based studies of tight control have focused on elderly patients.

Reasons why improved glycemic control may be beneficial for older diabetics include the following:

- Improved urinary incontinence
- Better glycosuria with improved inanition, better fluid balance
- Improved energy level, fatigue; possibly better mood
- Improved white cell chemotaxis; possibly improved wound healing
- Improved nerve conduction; possibly better neuropathic symptoms
- 50% better mortality for ICU patients, acute myocardial infarction, and acute stroke
- Improved glucotoxicity, better insulin release, better insulin action, not studied in elderly.

Potential reasons why tight control may not be a good idea for older diabetics include the following:

- Limited evidence-based trials on prevention and treatment of microvascular complications in specified elderly populations; especially understudied in nursing home patients
- More patients have visual problems interfering with complex treatments or insulin adjustments
- Less neuronal reserve should patients suffer hypoglycemia
- Cardiac impact of hypoglycemia is more likely in older diabetics and may worsen angina
- Elderly are more likely to have renal impairment and decreased drug clearance
- Impaired dawn phenomenon with aging; less capacity for counter-regulatory response
- Diminished tissue sensitivity to β-adrenergic signals
- Less likely to get warning symptoms if glucose falls and have impaired vasoreceptor response
- Older men are prone to more severe cognitive impairment during hypoglycemia
- Toxicities are more likely for metformin and are unclear for glitazones
- Tight control is poorly studied in the oldest-old, notably nursing home patients
- Altered renal, hepatic function, polypharmacy, complex regimens increase toxic risk
- Decreased clearance of insulin
- More liable to develop hypoglycemia; decreased clearance of oral medication, notably sulfonylureas with potential for protracted hypoglycemia.

It appears that optimal therapy for older patients with diabetes is best guided by two considerations, the likely duration of survival in terms of time to worsened complications and likelihood that hypoglycemic risks may outweigh potential benefits. In one study of patients older than 65, many hypoglycemic events occurred and more than one-third of these were severe. Patients of advanced age have large interindividual differences. Some are particularly frail while others may be relatively active, and as a result life expectancy varies tremendously for the oldest-old or nursing home patients. It is difficult to manage risk of hypoglycemia in frail patients. Studies in ICU patients may be a model for the frail elderly, but this is not yet clear. Non-glycemic therapy may be most germane. Short-term trials do show benefit for retinopathy and nephropathy from blood pressure control. For any level of blood pressure, diabetic persons have a doubled risk of coronary disease, stroke, or peripheral arterial disease.
