Glossary

Anorexia – A lack of appetite leading to low food intake.

Body Mass Index (BMI = kg/m^2) – A ratio of weight (kg) over height (m) that is commonly used as a measure of overweight.

Endogenous Opioid – A naturally occurring peptide with effects similar to morphine.

Preload – A fixed amount of food given before a meal in order to test how well people adjust or compensate for the calories or nutrients in the preload.

Primary Aging – Changes in physiological or metabolic functioning that are due primarily to age.

Satiety – The reduction of hunger and the termination of eating that mark the end of a meal.

Secondary Aging – Effects due to acute and chronic disease and medication use.

Sensory-Specific Satiety – As a food is eaten it is judged as less pleasant, whereas the pleasantness of other foods is unchanged.

Introduction

Aging is accompanied by a variety of physiological, behavioral, and socioeconomic changes that may have a negative impact on diet and nutritional status. Energy needs and energy intake decline with age, as do body weight and lean body mass. Poor health, the use of medications, and sedentary lifestyle may all contribute to age-related anorexia and inadequate dietary intakes. Nutrition studies conducted in clinical and in community settings have pointed to an increased risk of nutrient deficiencies among the elderly. Diets of the elderly have also been described as monotonous and bland, and are said to be marked by sharply reduced consumption of nutrient-dense foods.

Although the prevalence of malnutrition among the elderly in the United States is reported as low, aging does place individuals at greater nutritional risk. There are many ways in which the aging process can influence diet and nutrition (see **Table 1**). First, primary aging has been associated with altered sensations of hunger, thirst, and satiety and with imperfect compensation for day-to-day variations in the diet. Low fluid intake, for example, is not compensated for by increased thirst. Sensory-specific satiety, which may serve as a variety-seeking mechanism, is also reported to be reduced. Age-related deficits in smell, and possibly taste, may lead to a lowered enjoyment of foods. These age-related physiological changes may account, in part, for the reported poor quality of the diet in older individuals.

Secondary aging is defined as including some of the age-associated chronic disease states, notably

Table 1 Influences on the nutritional status of the elderly

Primary aging
Changes in the regulation of thirst and fluid intake
Changes in the regulation of hunger and food intake
Poor compensation for the energy content of foods
Changes in satiety possibly related to hormones, neurotransmitters, or gastrointestinal tract
Decreased energy output
Lowered physical activity
Slowed metabolic rate
Alterations in ability to taste or smell
Alterations in sensory-specific satiety
Secondary aging
Chronic disease states
Cardiovascular (e.g., hypertension, atherosclerosis)
Endocrine (e.g., hyperlipidemia, diabetes)
Cancer
Infections
Gastrointestinal (e.g., constipation, diarrhea, nausea, malabsorption)
Swallowing problems
Pulmonary
Muscular and neurological (e.g., stroke, immobility)
Psychiatric (e.g., depression, dementia, anorexia nervosa)
Medications
Medically prescribed diets
Poor oral health and dentures
Socioeconomic influences
Lower economic status
Retirement
Failing health
Fixed income
Death of spouse
Social isolation and loneliness
Bereavement

hypertension, hyperlipidemia, atherosclerosis, and diabetes. The presence of chronic disease together with the use of medications and medically prescribed diets is likely to have an impact on energy intake and on diet choices. Impaired mobility, inability to feed oneself, poor oral health, or the use of dentures can also affect the amount and types of foods consumed. In addition, nutrient malabsorption can be caused by altered gastric acid secretion or by interaction with medications.

Finally, social and economic factors play a vitally important role. Old age has been associated with lower economic status that may stem from retirement, failing health, living on fixed income, or death of a spouse. Social isolation has been associated with depression and loneliness, which in turn can be linked to significant changes in eating patterns. These factors can influence the type and quality of food consumed. Marital status, for example, has a major impact on the diets of elderly men, and it is generally accepted that socialization at meals can increase energy intakes.

Primary aging, disease states, and social factors can all affect diet and nutrition in the elderly. Describing their respective contributions is the primary focus of this article.

The Population at Risk

The elderly are the fastest growing segment in the US population. Over 25 million Americans are over the age of 65. By the year 2030, 57 million people are expected to be 65 years or older. Yet the elderly are not a homogeneous population with uniform nutritional needs. Although some subgroups may be at greater risk for anorexia and associated nutritional deficiencies, others, especially women, are more likely to be overweight and obese. In general, body weight increases until late middle age, then plateaus and decreases for older persons.

Nutritional surveys of the US population have shown poor correlations between reported dietary intake of nutrients and clinical and biochemical measures of nutritional status. For example, data showing inadequate intake of energy and protein among the elderly are difficult to reconcile with increased prevalence of obesity and increased percentage of body fat. However, many measures of dietary and nutritional assessment may not be applicable to older people. Most of the nutritional standards that have been used were generated from data on young individuals and were then extrapolated to the elderly. Awareness of the problems this can cause is leading to collection of more data on intake patterns of the elderly. However, the assessment of dietary intake in large-scale epidemiological studies is often based on self-administered food frequency questionnaires or diet records. Such procedures place demands on memory and cognition and their accuracy may be compromised by forgetfulness, fatigue, or dementia. Dietary intake assessments that are shorter and interview based may be more appropriate for use with the elderly populations. The accuracy of body composition measures also changes as a function of age. Although body fat in young people is stored largely in subcutaneous depots and can be easily measured by skinfold thickness, much of the body fat in older people is stored in the trunk, which is harder to measure using readily accessible techniques such as skinfold thickness. These various assessment problems make it difficult to draw firm conclusions about the nutritional status of the elderly, especially because they are a heterogeneous group. One thing is clear: there is a need for two sets of age-specific nutritional status standards for older people, one set for the free-living

population and one for those who are chronically or acutely ill.

With these problems in mind, we will briefly examine what existing nutritional surveys indicate about changes in body weight (BW) and nutritional status with age. The National Health and Nutrition Examination Survey II (NHANES II, 1976–80) shows that the prevalence of overweight increased with age. As shown in **Figure 1**, older people weigh more and many are fatter than are young people. Body mass index (BMI), the principal measure of overweight for adults, is correlated reasonably well with body fatness.

In contrast to BMI, energy intakes decline as a function of age. Based on a single 24-h diet recall, a more recent NHANES III study (NHANES III phase 1; 1988–91) (see **Figure 2**) shows that median energy intakes for adults aged 70–79 years are 1797 kcal for men and 1382 kcal for women. The reported macronutrient composition of energy in their diet is approximately 50% carbohydrate, 16% protein, and 34% fat. These data are similar to the results reported for the population as a whole. However, the finding that intake of some vitamins and minerals is low has given rise to concerns that some elderly individuals may consume inadequate levels of nutrient-dense foods. For example, low consumption of calcium and vitamin D has been attributed to low intake of dairy products by the elderly.

Anorexia, or low food intake, is a problem in the elderly because it increases the risk of nutrition-related illness. Though nutritional surveys have shown a low-to-moderate prevalence of nutrient deficiencies in free-living populations, elderly persons

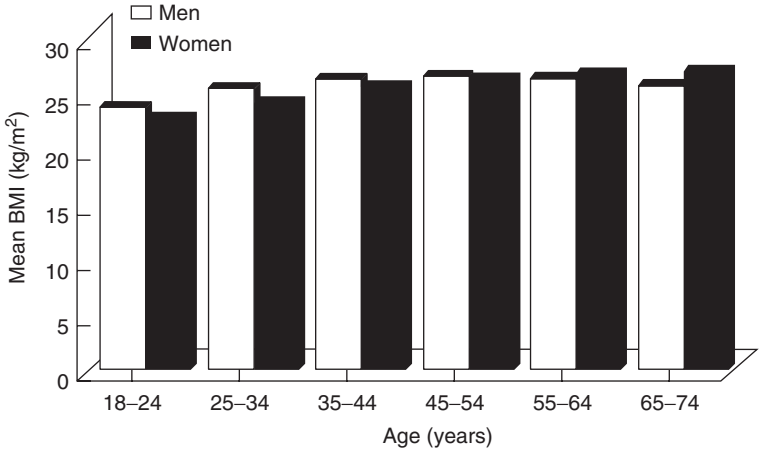

Figure 1 Body mass indices (BMI) for US men and women by age from the National Health and Nutrition Examination Survey II, 1976–1980 (NHANES II).

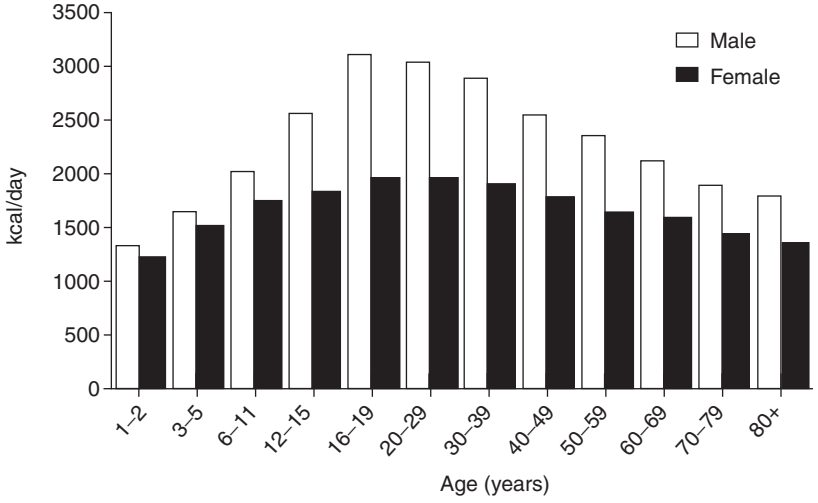

Figure 2 Energy intakes (kcal) for men and women by age from the National Health and Nutrition Examination Survey III, 1988–1991 (NHANES III).

living in institutional settings may be at greater risk for malnutrition. Although estimates vary, between 30 and 60% of long-term care older institutionalized individuals have some degree of malnutrition. Studies show that poor nutrition and low BW are not simply a result of disease states, but often precede and predispose elderly individuals to disease and death.

Loss of appetite can be caused by age-related psychological and physical factors. Eating patterns can be influenced by mental factors, such as depression or dementia, and physical factors, including immobility, inability to feed oneself, and poor dentition or ill-fitting dentures. Many elderly individuals have problems with their oral cavity. For example, 42% of the geriatric population in the United States have no natural teeth. Of those with their teeth, 60% have tooth decay and 90% have gum disease, which impair their ability to chew. Tooth loss also affects chewing ability, and this is not completely restored by dentures. Impaired chewing can cause changes in food selection, such as decreasing the variety in the diet, which could contribute to nutritional problems.

Decreased physical activity and a slower metabolic rate are part of the explanation for lowered food intake in the elderly. However, decreased energy demands cannot be the explanation for why nutritional problems related to low food intake develop.

Thirst and Fluid Intake

Studies on the regulation of fluid intake demonstrate the difficulty experienced by many elderly persons in adjusting to environmental changes and in maintaining their internal state. Salt and water imbalances can lead to illness and death. These difficulties are partly caused by age-associated changes in regulatory systems. Maintenance of sodium and water homeostasis depends on a balance between intake, controlled by thirst and sodium appetite, and output, controlled by the kidneys. Thirst and water intake play a vital role in maintaining fluid and electrolyte balance, because it is only through these intakes that water deficits can be replenished. Conservation of water by the kidneys can only minimize further losses.

Although dehydration is a common cause of fluid and electrolyte disturbance in the elderly, it is a common clinical observation that the elderly do not seem to get thirsty despite obvious physiological need. Clinical studies have examined the effects of dehydration on thirst in both healthy young and healthy active elderly men. The men were dehydrated by depriving them of water and were asked to consume a dry diet. After 24 h without fluids, the elderly men had a reduced ability to experience the sensation of thirst, and they did not drink adequate amounts of water to restore fluid balance. Additional studies have shown that the elderly do not restore fluid losses induced either by exercise or thermal dehydration. The impaired thirst in elderly individuals is due, in part, to changes in the receptors in the central nervous system (CNS) that detect changes in the level of sodium in blood (*see* Thirst and Hydration).

The Regulation of Food Intake

Several recent investigations have tested the hypothesis that, analogous to the situation for the regulation of fluid intake, aging is associated with a decline in the regulatory mechanisms that influence hunger, appetite, and food intake.

One study demonstrated that elderly men do not adjust their food intake following periods of over- or underfeeding. During a period of *ad libitum* intake following 21 days of overfeeding, younger men (mean age 24) lost the excess weight gained during overfeeding, whereas the older men (mean age 70) did not. A similar indication of impaired regulatory ability was seen following 21 days of underfeeding in that younger men (mean age 22) regained lost weight and older men (mean age 66) did not. Measurements showed that energy expenditure was unaffected by aging, whereas food intake was not adjusted appropriately to compensate for the over- or underfeeding. Although this study shows that the ability to adjust food intake in relation to BW is impaired in older men, it does not touch on whether aging is associated with changes in hunger and satiety or whether the elderly can adjust appropriately to changes in the energy content of foods.

The preloading method has been shown to be a sensitive test of the regulatory capabilities of young study participants. When fixed amounts of a food (preloads) varying in energy content are given 30 min before lunch, the degree to which intake at lunch is adjusted for the energy in the preloads indicates how well food intake regulatory mechanisms are functioning. Thus, healthy elderly (ages 60–84) and young (ages 18–35) men were given either yogurt preloads that varied in energy content or no yogurt followed by lunch. The elderly males consumed significantly less energy at lunch than the young males in the baseline (no yogurt) condition. Lower intake was concordant with subjective sensations of satiety; ratings of subjective sensations indicated that the older men were less hungry and more full at the start of lunch. This could be part of the explanation for lower intake. The elderly men also showed an impairment in energy intake regulation. Compensation for energy in the

preloads was less precise in the elderly than in young males; older men did not appropriately reduce intake at lunch to compensate for the calories in the yogurt.

There are changes in a number of physiological and metabolic systems with age, but the link between these and changes in the regulation of food intake has not been established in humans. Animal studies point to physiological changes that could be involved in changes in food intake regulation with age. For example, it has been shown in young animals that some naturally occurring peptides such as endogenous opioids may be involved in determining the palatability of food and in initiating and terminating eating. Studies indicate that older rats show diminished responses to blockade or stimulation of opioid peptides compared to young rats. Also, older rats have a lower concentration of endogenous opioid peptides in some areas of the brain.

Changes in the gastrointestinal tract with age may affect food intake. The presence of food in the stomach and gut can affect food intake through receptors that detect stretch, or the concentration of nutrients or electrolytes such as sodium. The early onset of satiety sometimes experienced by the elderly could be due to alterations in the hormonal responses that normally accompany eating. For example, cholecystokinin (CCK), a hormone released by the gut in response to eating, has been shown to decrease food intake. Studies in mice show that CCK decreases food intake more in older than in younger animals. CCK also has a prolonged action in older mice. CCK levels have been found to be elevated in older humans. This, combined with an increased sensitivity to CCK, could lead to early satiety in the elderly. Another factor that could affect satiety is the rate at which foods and drinks empty from the stomach. The emptying of solid and liquid foods has been found to be significantly slower in older subjects. Although the difference in stomach emptying is small, it is possible that retaining food in the stomach could affect hunger and satiety and the pattern of meals; that is, the interval between meals might be expected to be longer. This needs to be assessed experimentally by recording food intake (*see* Gastrointestinal System: Function and Dysfunction).

A number of other possibilities have been suggested to explain the anorexia of the elderly, such as changes in various neurotransmitters and hormones. However, there is no direct evidence to support such speculation. Indeed none of the physiological changes associated with aging have been directly linked to changes in food intake regulation in elderly humans. Clearly, more studies are required to understand changes in physiological systems that impact on the nutritional status of the elderly.

Deficits of Taste and Smell

It is commonly believed that age-related deficits in taste and smell are directly responsible for some of the nutritional problems in old age. However, there is very little direct evidence to link diminished sensory functioning with inadequate nutrition and ill health. While there is general agreement that many elderly people suffer from deficits in smell, and possibly taste, the impact of such impairments on nutrition and diet has not always been clear. No study has demonstrated a causal relationship between sensory deficits and altered food choices in the elderly, and there is little evidence to link chemosensory deficits with nutritional status.

There is no doubt that sensory impairments do occur. Studies on taste sensitivity have observed some decline of taste acuity with age, especially after the age of 70 years. Taste sensitivity to water solutions of sweet, sour, salty, and bitter compounds was measured using detection and recognition thresholds. The detection threshold was the minimum concentration of a solution that was perceived as distinct from distilled water, whereas the recognition threshold was the level at which the solution was perceived as salty or sweet. Taste sensitivity was also assessed at solution concentrations above threshold. Studies showed an increase in detection and recognition threshold levels among the elderly and, in some cases, impaired perception of more intense solutions, notably those with bitter and sour tastes.

Although the loss of taste sensitivity with increasing age was initially attributed to degeneration and loss of taste buds, it now appears that the taste system is relatively robust, and that whole-mouth tasting is stable even in late old age. On the other hand, localized taste losses do occur in some elderly subjects, although sometimes they go unnoticed. Taste losses that have been observed among the elderly may be the result of cumulative pathology, including poor oral health, rather than the inevitable outcome of primary or normal aging.

Despite reports of diminished taste acuity for dilute solutions, the perception of sweet, sour, salty, and bitter tastes in foods appears to be resistant to age. Sensory evaluation studies have failed to observe age-related deficits in ratings of saltiness in tomato juice, or a decline in the perception of saltiness in potatoes or broth, or sourness in apple drink. There was no age-related deficit in the intensity ratings for salt and sugar in salted or sweetened dairy products. Only one study reported an age-associated decline in the perception of protein taste in soup.

However, conventional studies on taste acuity do not give an indication of how aging may affect taste

preferences. Arguably, not taste perceptions but taste preferences are likely to affect food preferences or food dislikes. Taste preferences have been measured by asking subjects to rate the perceived pleasantness of a stimulus, or through direct ratings of like and dislike. However, hedonic ratings can be influenced by the type of the stimulus, or by the subjects' own concerns with health and dieting. As a result, studies on taste preferences of older subjects have produced no consistent pattern of results. Whereas one early study reported that older subjects preferred less sweet samples of pineapple juice, some later studies showed that the elderly, on the contrary, preferred sweeter and saltier stimuli than did younger subjects. One study reported an increase in liking for higher concentrations of salt with age, but only for water solution and not for chicken soup. Other studies reported no difference in hedonic preferences for sweet solutions between children, young adults, and the oldest adults.

Only one study showed a clear increase in preferences for more intense solutions of sodium chloride, sucrose, and citric acid as a function of age. Four concentrations of each stimulus were presented either in water or in vegetable juice or lemonade. In general, the subjects judged beverages as more pleasant than water solutions. Older subjects preferred higher concentrations of sugar and salt in both water and beverages than did younger subjects. This shift in hedonic preferences toward higher levels of sugar and salt was again thought to be caused by age-related impairments in sensory function.

Though it is generally believed that elevated preferences for salt taste are associated with increased sodium intakes, no study so far has managed to link sensory preferences for salt to dietary sodium intakes at any age. Measures of salt taste preference in the elderly have not been linked to estimated salt intakes. Similarly, no study has linked altered preferences for sweet taste with changes in sugar consumption in the same subject population.

The taste impairments observed in several studies might be the consequence of poor health, including poor oral health, or medication use, and not a direct consequence of normal aging. Whatever the reason, no study has shown a causal link between such impairments and altered patterns of food intake or inadequate nutrition. Research attention has therefore focused on aging and the sense of smell.

The perception and identification of odors is clearly impaired in the elderly. The University of Pennsylvania Smell Identification Test (UPSIT), composed of 40 odors on paper strips, has been used to assess smell functioning in a large number of people including the elderly. In one study, the subjects were 1955 men and women aged 5 to 99 years, including university students and employees, residents of homes for the elderly, and primary and secondary grade school students. Odor identification data (**Figure 3**) showed that women were better than

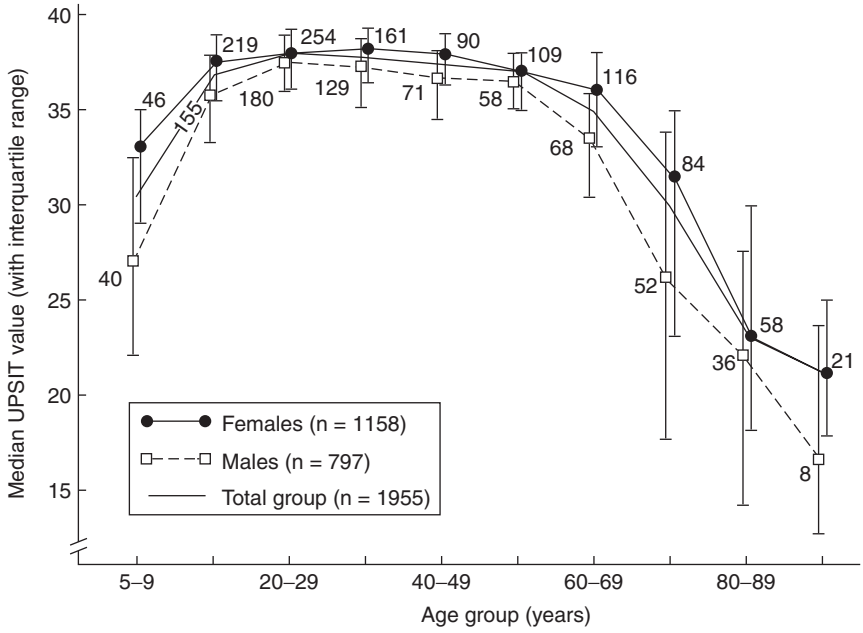

Figure 3 University of Pennsylvania Smell Identification Test (UPSIT) median scores as a function of age and gender. Reproduced with permission from Doty RL, Shaman P, Applebaum SL, Giberson R, Siksorski L, and Rosenberg L (1984) Smell identification ability: changes with age. *Science* 226: 1441–1443. Copyright 1984 American Association for the Advancement of Science.

men and non-smokers were better than smokers. Peak performance was seen among subjects aged 20–40 years, with a sharp decline observed after age 60 years. More than half of the people aged 65–80 years had a major olfactory impairment, while three-quarters showed olfactory impairments after the age of 80 years.

Arguably, the selection of real-life foods involves smell rather than taste. Identifying and distinguishing between foods depends on the perception of taste, flavor, and texture. Studies on sensory identification of foods by the elderly showed that food recognition diminished with age. In a pioneering study, young college students (ages 18–22) and elderly residents of a retirement home (ages 67–93) were presented with 24 different foods to taste and smell. Fresh fruits, vegetables, meats, fish, nuts, grains, and dairy products were steamed, blended and strained, or pureed. Water was added to minimize texture differences. Blindfolded subjects were first presented with a container of food to smell, and then they tasted a teaspoon of the food sample.

The results showed that elderly subjects were sometimes unable to identify blended foods by taste and smell. Out of 24 foods, 21 were more frequently identified by young people than by the elderly. More elderly subjects than younger ones commented on the weakness of taste and smell for the unseasoned, blended foods.

Impaired food identification by the elderly is therefore more likely to involve smell rather than taste deficits. In another study, young (ages 18–26) and older people (ages 65 years and over) attempted to identify pureed foods while blindfolded, using only taste and odor cues. The freshly prepared, steamed, and blended foods were potato, tomato, carrot, broccoli, celery, lemon, pear, banana, beef, coffee, sugar, and salt. Younger people identified more foods on the first attempt than did older subjects. Repeating the task with nostrils pinched to eliminate olfactory input removed the age-related differences, suggesting that the foods were identified largely by smell. The key question is whether impairments of smell in the elderly have a measurable impact on food selection.

There is evidence that sensory factors related to the sense of smell play an important role in diet choice. The elderly rated taste, or specifically flavor perception, as a strong influence on their food choices. In a recent survey, 30 elderly individuals ranked the factors that affected their food purchase decisions in three different eating situations (celebration, eating with a friend or spouse, or eating alone). Familiarity and prior experience with foods and the sensory properties were significantly more important than other factors in all three situations, except when eating alone, when ease of preparation was the most important. Apparently the elderly were often unaware of their sensory loss and reported no decrease in their appreciation of foods or in their ability to smell. It may be that when sensory losses occur gradually over a period of years, the importance of smell in promoting appetite also gradually declines and cognitive compensatory mechanisms take over. In a recent study, smell deficits were observed in a large proportion of elderly women. However, their impact on food consumption patterns and nutritional status appeared minimal.

Still some scientists believe that sensory impairments are the direct cause of reduced pleasure response to foods that may result in a consumption of a monotonous and nutritionally inadequate diet. One intervention approach has been to restore the missing sensation by adding synthetic flavorants to food. These studies reported that flavor amplification increases the intake of nutrient-dense foods in the elderly and may result in improved nutritional as well as immune status (*see* Smell and Taste).

Dietary Variety and Food Selection

Age-related sensory impairments are said to result in the consumption of a more monotonous diet. Some studies have reported a decline in dietary variety with age. Analysis of the self-reported dietary intakes of elderly participants in the 1977–78 National Food Consumption Survey (NFCS) showed that the oldest participants consumed the least varied diets. These data were based on a sample of adults more than 54 years old ($n = 4983$) drawn from among more than 30 000 people interviewed in the NFCS study. Food consumption data were based on one 24-h food recall and 2-day food records.

Consumption patterns were analyzed using two separate measures of dietary variety. The first measure, the variety index, was calculated by counting the number of different foods in each of 18 previously defined food groups that were eaten by each individual over 3 days. The elderly respondents ate approximately 35 different foods over 3 days, with men reporting more different foods than did women. The variety index declined slightly from the youngest (age 55–64 years) to the oldest group (>75 years).

The second measure, that of core foods, was based on a straight frequency tally of foods consumed over the 3-day period. Foods consumed on at least one of the 3 days by approximately 50% of the elderly respondents were whole milk, coffee, white bread, potatoes (other than fried), margarine, and sugar. The authors noted that these items were relatively

inexpensive, simple to chew, and easy to prepare. They also noted that a higher proportion of the sample population 75 years and above lived alone and had lower income and educational levels.

An analysis of the most frequently consumed foods in the NHANES II database shows that coffee, white bread, and margarine are the core foods of the American diet. These foods were consumed by more than 50% of the respondents on any given day. The most frequently consumed foods were coffee and tea, white bread, margarine, whole milk, doughnuts, cookies and cake, and sugar. The core foods of the elderly and the core foods of the general public are in fact very similar. Moreover, nutritional trends among the elderly have followed those of the American public. A comparison of 1977–78 NFCS data with the 1985 Continuing Survey of Food Intakes by Individuals showed that American women ages 19–50 years reduced the consumption of red meat and full-fat milk, but consumed more low-fat milk and low-calorie soft drinks. A similar analysis of intake trends for the elderly showed that they too reduced the consumption of meat, and increased the consumption of low-fat milk, low-calorie beverages, and take-out foods.

The moderate trend toward consumption of a less varied diet seen in community-dwelling elderly individuals is much more pronounced in long-term care facilities. A survey of 303 institutionalized persons over 65 found that almost two-thirds had changed their diets within the past 5 years. Many of these changes resulted in subjects eating less or restricting their food choices. The effect of limited food choice on the health and nutritional status of the elderly can be serious because consumption of a varied diet is considered the most effective way to assure adequate nutrient intake.

One possible explanation for reduced dietary variety involves altered pleasure responses to food. Normally, as foods are consumed they become less pleasant. This decline, called sensory-specific satiety, is associated with a shift to other food choices during the meal. As a result, people eat more foods when offered a variety of choices than when a single food item is available. Sensory-specific satiety can therefore promote the intake of a more varied and nutritionally balanced diet.

Because sensory-specific satiety encourages consumption of a varied diet and because the elderly have relatively monotonous diets, a reasonable hypothesis is that the elderly have diminished sensory-specific satiety. The effects of age on sensory-specific satiety were investigated in adolescents (ages 12–15), young adults (ages 22–35), older adults (ages 45–60), and the elderly (ages 65–82). Subjects rated the pleasantness of the sensory properties and their desire to eat five foods and then ate either a fixed amount or as much as they wanted of one of the foods (yogurt). They rerated the foods immediately after they finished eating the yogurt. The results showed that sensory-specific satiety differs across age groups (see **Figure 4**). Subjects over the age of 65 did not show a greater decrease in the rating of the pleasantness of the taste of the food they had consumed compared with ratings of the uneaten foods, that is, they did not show sensory-specific satiety for the taste of the food they had eaten.

It is not clear why the elderly did not show sensory-specific satiety, but it did not appear to be related simply to a loss of sensory function. At the start of the tests, before eating the yogurt, the elderly subjects rated the sensory properties of the test foods as pleasant, as did the other groups. Although the elderly subjects showed the typical decline with age in

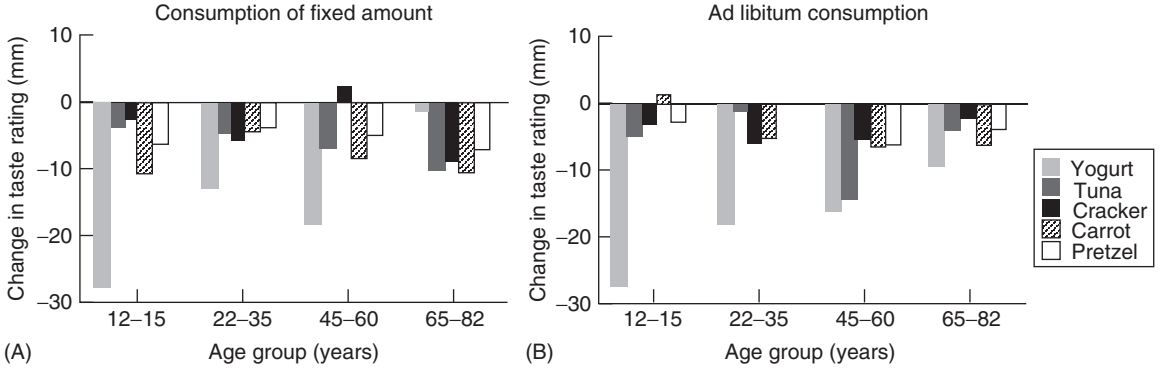

Figure 4 Mean changes in ratings for each of the foods sampled of the pleasantness of the taste of that food from just before to just after eating either 300 g (A) or ad libitum (B) amounts of yogurt by different age groups. This shows that sensory-specific satiety, or the change in pleasantness of the food consumed (yogurt) compared with those not consumed, declines with increasing age. Reproduced with permission from Rolls BJ, and McDermott TM (1991) Effects of age on sensory-specific satiety. *American Journal of Clinical Nutrition* 54: 988–996, 1991. Copyright American Society for Clinical Nutrition.

the ability to identify odors, this did not correlate with sensory-specific satiety for either taste or odor. This was surprising because it seemed likely that changes in the pleasantness of the taste or odor of a food would depend to some extent upon olfactory function. Further studies relating sensory impairments to the changing hedonic response to foods will be of interest because the mechanisms underlying sensory-specific satiety are not well understood. It is likely that in addition to a sensory component, there is a cognitive component related to the knowledge that a food has just been consumed. It is not clear why the elderly would differ in this respect, but it may be related to a decreased desire for change of all types.

An impairment in sensory-specific satiety would be expected to be associated both with consumption of monotonous diets and with a failure to increase the amount consumed in response to variety in the diet. A recent study showed that the elderly are insensitive to the stimulatory effect of variety on fluid intake. Elderly subjects drank similar amounts following 24 h of dehydration when they were offered just one beverage (water) and when they were offered four beverages (water, mineral water, cola, orange juice). Although a young control group was not tested, a previous study in young people showed that more fluid was consumed with a variety of drinks than with just one drink. Also, young subjects ate more when a variety of foods was available than when offered just one food, and this increase in intake was related to sensory-specific satiety. Thus, a failure to experience sensory-specific satiety would be expected to be associated not only with a monotonous diet, but also with a lower caloric intake in a varied meal. More studies are needed to examine how age-related changes in sensory-specific satiety influence variety in the diet and food intake, both in experimental situations and in the natural environment. Variety in the diet has been found to be associated with better health in the elderly, and further studies could suggest strategies for increasing the variety in the diets of elderly individuals and in improving their nutritional status.

Socioeconomic Issues

Low food intake in the elderly can be accounted for by multiple factors, ranging from primary aging to changed social and economic circumstances. In several studies of the elderly, a majority indicated a recent change in food habits for reasons of health, changes in living status, health beliefs, or simply because of a change in finances. Living arrangements, social isolation, and no socialization at meals may play a role. The living arrangements of older individuals can affect their diet quality. More men living alone consumed a poor-quality diet than did men living with a spouse, particularly those 75 years of age or older. The main effect of living alone was to decrease the amount of energy consumed rather than the types of foods chosen. Bereavement was found to be associated with negative effects on nutrient intakes by changing the social environment and altering the social meaning of eating (*see* Bereavement and Loss).

Education and other socioeconomic issues appear to play a major role. In a recent study of 152 women aged 85–94 years, old age did not have an adverse effect on food or nutrient intakes. The oldest women reported eating a similar or greater number of weekly servings of fruits, vegetables, dairy products, meats, and sweets as did women aged 64–85 years. On the other hand, education level did have a major impact on nutrient intakes. Women with education beyond high school reported higher intakes of selected vitamins and minerals than did less educated women.

Some of the nutritional problems can be remedied to some extent by providing home-delivered meals and groceries and convenience foods of high nutrient density. Increasing socialization at meals could also have a significant impact, although this has not been investigated experimentally in the elderly. Studies in young men and women showed that they ate up to 50% more when eating dinner with three friends than when they ate the same meal alone. The nutrient composition of the diet was not affected. Of interest was the finding that eating with strangers did not increase intake at dinner compared to eating alone. Thus, although socialization at meals could increase intake of the elderly, this may depend on the type of social interactions that take place.

Diet-related attitudes and beliefs may also influence food habits. Some studies have identified taste, health beliefs, familiarity, price, convenience, and prestige as being among the key social determinants of food selection. Older people are generally more concerned with health issues, notably energy and fat consumption, and with food costs. Saving time is not a major issue. Single elderly women are most concerned about food costs.

Pathological concern with BW and dieting has also been observed among elderly women. There have been concerns that age-related anorexia among the elderly resembles the psychiatric syndrome of anorexia nervosa, more commonly reported among young women. Anorexia nervosa is characterized by refusal to maintain a minimum BW, disturbance of body image, morbid fear of fatness, and a preoccupation with food and eating. Endocrine abnormalities

are also seen, the most frequent of which is amenorrhea, or cessation of menstruation. A survey of elderly individuals who were below 90% of average BW indicated that pathological responses on a questionnaire used to assess eating-related attitudes were seen in 9% of those tested. Abnormal attitudes included a display of self-control around food, avoiding eating when hungry, enjoying having an empty stomach, engaging in dieting behavior, and being terrified about being overweight. Case reports of anorexia nervosa among elderly women have been described in the literature. The patients were described as having all of the features of the diagnosis except for the amenorrhea. Typically anorexia nervosa is associated with other conditions, particularly depression. Depression in the elderly could exacerbate their anorexia.

Intervention Strategies

Ideally, diets designed for the elderly should provide nutrient-dense foods. Although energy needs are reduced in old age, dietary requirements for protein, vitamins, and minerals are increased. For example, studies of elderly women in nursing homes reported that calcium intakes were at best marginal in that age group. Women living at home consumed even less calcium than those in nursing homes. As a result, dietary strategies have focused on the consumption of fortified or nutrient-dense foods.

The impaired regulation of food intake seen with aging could influence responses to high-energy nutritional supplements. The elderly are less likely than younger individuals to compensate for the energy in supplements by reducing intake of other foods. This was confirmed in the study in which healthy elderly men did not reduce intake at lunch following high-energy yogurt consumed 30 min earlier. The older men had significantly lower baseline lunch intakes than the younger men, but by preceding the meal with a high-energy supplement the total intake for the meal was increased significantly and to a level comparable to that of the younger men. Thus, dietary supplementation may be an important approach to enhancing the energy intake of the elderly. However, not all of the available data indicate that supplementation is beneficial. In a recent study of frail elderly men and women (mean age 87), daily evening supplementation for 10 weeks with a high-energy multinutrient liquid increased total daily energy intake only when combined with exercise. Participants not exercising decreased intake to compensate for the energy in the supplement. This result differs from that of findings from other laboratories. For example, in one study when elderly patients with poor appetites were given two different nutritionally complete liquid diets to consume freely for 10 days, energy intake was increased significantly. It appeared that there was little compensation for the energy from the supplements. In another study of elderly participants at risk of malnutrition, dietary supplementation was found to increase daily energy intake and weight gain over a 12-week period. Thus, most studies indicate that nutrient-dense supplements can increase energy intake and improve the nutritional status of the elderly. Future studies should systematically determine the critical parameters (type, amount, or energy density of the supplement) associated with supplementation that influence energy intake.

There are a number of other possible strategies for optimizing the diets of the elderly. One strategy involves sensory supplementation. Flavor amplification and flavor enhancement have been mentioned as ways of increasing food palatability to counteract sensory deficits. However, there is little evidence that moderate sensory deficits as opposed to sensory distortions affect nutritional status. Rather, studies indicate that the sensory system in healthy older people is relatively robust and that sensory deficits are not always linked to poor nutrition and weight loss. Although age-related sensory losses undoubtedly detract from the quality of life, no evidence so far has linked them to impaired nutritional status and ill health.

Such narrowing of dietary choices as has been observed may have been due to a deliberate restriction of calories, fat, sugar, and salt. People over the age of 60 are concerned with coronary heart disease, hypertension, and diabetes, and many follow medically prescribed diets that are low in fat, sugar, and salt. Foods containing intense sweeteners and fat substitutes might fulfill a special need. At present, low-calorie foods are used chiefly by people wishing to lose weight. This allows dieters to reduce energy intakes, without narrowing food choices and compromising the hedonic value of food. For elderly individuals who have health problems associated with obesity, such foods can be of benefit. However, many elderly people have energy intakes that are too low to meet energy requirements. Clearly, choosing reduced-calorie products could exacerbate problems of anorexia and low-energy intake in these individuals, especially because they are less likely to compensate for changes in the energy content of foods. Given the growing size of the elderly population, the market for such foods is increasing. A survey by the Calorie Control Council in 1991 indicated that consumers age 60 and over showed the most dramatic increase in the use of low-calorie, sugar-free foods

and beverages. Because the elderly are heterogeneous in terms of their BW and nutritional requirements, they must be appropriately informed about how energy-modified foods fit into their diets. Regardless of their BW, if they consume reduced-calorie foods these should be of high nutrient density.

A number of strategies for increasing daily energy intakes involve addressing social and economic problems and changing dietary behaviors. Community nutrition programs aimed at the elderly provide subsidized meals both in the home and at congregate sites. Such programs help to overcome some of the problems associated with nutritional difficulties stemming from low income, impaired mobility, loneliness, and lack of socialization at meals. Other strategies involve managing dental and medical problems that affect food intake and encouraging consumption of foods that are readily chewed and digested. Many elderly individuals have swallowing problems that require individualized diets that provide foods of textures that promote consumption. Some elderly individuals, because of low appetite and impaired thirst, must be prompted to eat and drink. Clearly management of the nutritional problems associated with aging requires sensitivity to a wide range of physical, psychological, and environmental influences on food and fluid intake. Future interven tion studies should focus on optimal intervention strategies for improving the nutritional status of both community-dwelling and institutionalized elderly individuals.

Glossary

Disability – An individual's physical, cognitive, or psychological incapacity to function within a given social and environmental context.

Functional Limitations – Limitations in performance at the level of the whole organism or person.

Impairment – A loss or abnormality at the tissue, organ, and body system level.

Introduction

Older age is characterized by increased susceptibility to disease, functional decline, and cognitive impairment, and, therefore, older persons have multiple comorbidities and disabilities and are often high consumers of health-care resources, particularly at the end of life. Thus, measuring and understanding disability are essential in developing and implementing preventive, therapeutic, and rehabilitative strategies that are urgently needed to improve the quality of life of millions of suffering individuals and to reduce, at least in part, the physical, psychological, and financial burden of caring for the disabled that currently rests on the shoulders of informal caregivers and the health-care system.

Identifying people with disability and measuring disability across a wide spectrum of severity are challenging tasks. Disability refers to an individual's capacity to function within a given social and

environmental context. Thus, disability is not an attribute of an individual; rather, it exists when an individual's physical, cognitive, or psychological capacity does not fit the demands of a given task within a specific environment. An individual's assessment of the difficulty in performing a task may be affected both by self-perception and by adaptations made to compensate for, or minimize, a decline in function. Therefore, self-perception of difficulty provides information on impending disability that is not detected as the need for help of another person because it is already compensated for. For example, an individual who has installed rails in the bath, when questioned, reports no difficulty when bathing. Thus, information on personal and environmental adaptations to disability, and the perception of making an effort while performing activities of daily living, can provide more accurate information than asking about difficulty alone. It is important to point out that even in very old individuals, disability is not a static condition: many people recover from a disease or injury (for example, after a fall or a stroke), while others experience wide fluctuations in their physical and cognitive function. As a consequence, measuring disability has no unique gold standard.

The subsequent sections of this article deal with why and how disability is measured. It begins by delineating how the paradigm that maps the different components of the pathway from disease to disability has evolved from the initial World Health Organization (WHO) model, its customized version proposed by Nagi and the Institute of Medicine, and, more recently, the International Classification of Functioning, Disability, and Health (ICF). Then, it lists selected well-established instruments that operationalize the elements of these paradigms in measurement tools used in real life. The final section of the article addresses some of the special problems that may be encountered using disability measures in geriatric research, with particular attention paid to clinical trials.

Why Measure Disability in Older Persons?

Without pretense of exhaustiveness, a list of the main reasons for measuring disability in older persons is presented in **Table 1**.

First and foremost, measures of disability in older persons provide information on health status that is independent and superior to any other measures from more traditional, medical, disease-oriented approaches. There is consistent evidence that a large percentage of disability in older persons is the direct consequence of chronic morbidity and, especially, comorbidity. A stroke, a massive myocardial infarction, pneumonia, and a hip fracture are catastrophic events that often cause substantial disability. Conversely, in the year when they develop severe disability, less than one-fourth of older individuals have an acute diagnosis that requires hospital admission, while in the others no specific precipitating disease can be identified. Perhaps even more surprising, older persons affected by comorbidity are more likely to report disability than age-matched individuals free of these diseases, and the risk gradually increases with the number of coexisting diagnoses. Thus, disability summarizes the balance between the negative impact of multiple medical conditions of varying severity and the overall health and vitality of the individual. Capturing the same information by traditional measures of health status is almost impossible because coexisting diseases may occur in an almost infinite number of combinations, relative severity, and synergistic and compensatory patterns.

Targeting the medical condition as the priority for treatment is most likely to have an effect on the patient's present and future functional status. In older individuals, the transition from the active to the disabled portion of their life marks a critical point in their everyday experience. Active life expectancy is generally considered a major indicator of health status at a population level and the gold standard outcome of any intervention aimed at improving the health and quality of life of older individuals.

Table 1 Main reasons for measuring disability in the older population

1. Assessing disability provides information on global health status of older individuals, which is independent of other disease-oriented measures of health
2. Assessing disability provides important prognostic information on multiple negative health-related outcomes
3. Assessing disability helps to estimate the type and amount of care needed currently and/or in the immediate future
4. Assessing disability may be important for legal purposes and to establish priorities in the allocation of support services
5. Assessing disability informs decisions regarding the current and future health-care needs of older persons. From an epidemiological perspective, measuring disability is also essential for studying predisposing risk factors and subsequent precipitants
6. A measure of disability should be considered the gold standard in any clinical trial that, indirectly or directly, is aimed at improving quality of life in the older population

Measures of functional status provide important prognostic information on multiple negative health outcomes, including risk of disability progression, health-care utilization, nursing home admission, and death. Performing a simple test of the lower extremity provides information on the risk of developing disability in basic activities of daily living (BADLs) superior to any known biomedical and clinical marker of risk. Medical oncologists realized this concept long ago. The Karnofsky performance status scale was originally designed to measure the level of patients' activity and requirement for assistance but was soon introduced as an important effect modifier in most prognostic indexes created for different types of cancers and for the stratification of cancer patients enrolled in clinical trials. The performance status is still widely used for prognostic purposes in oncology, although recently more refined measures of functional status specifically tailored to cancer patients have been introduced.

Assessing disability provides unique information on the type and amount of care needed, currently and in the immediate future, for older disabled individuals. Measuring disability helps to develop and optimize a detailed care plan, track the clinical progression of the patient, and, especially in rehabilitation, understand whether the patient is still improving or has plateaued. In community-dwelling older individuals, the assessment of care needs is essential to establish the allocation of adequate services. For example, eligibility for nursing home admission or home care is often based on the level of disability and autonomy. In addition, level of disability determines the optimal balance between formal and informal care, in terms of providing the best care for the disabled person while minimizing stress on the caregiver and reducing the risk of institutionalization.

Assessing disability is important for legal purposes such as insurance, medical reimbursement, driving eligibility, and others.

Measures of disability collected at the population level are often used to inform decisions regarding the current and future health-care needs of older persons and to forecast the likely demand for long-term care and support services. From an epidemiological perspective, measuring disability is essential in identifying predisposing risk factors and subsequent precipitants for accelerated functional decline. In general, rates of disability increase with age and across age groups, and women tend to have higher rates and severity of disability than men. Unfortunately, very little data exist on the fraction of disability that is attributable to different causes, and the different risks of disability between men and women are also not well understood.

From a research perspective, measuring disability in epidemiological and observational studies is important for identifying risk factors for disability that can be targeted for preventive interventions. A comprehensive list of major risk factors for old age disability is still in the stage of development. In particular, risk factors for transient and short-term disability and risk factors for disability in specific tasks are the focus of studies now in the field.

Finally, measures of disability should be considered the gold standard in any clinical trial that, indirectly or directly, aims to improve quality of life in the older population. There is consensus that functional status, particularly level of disability in ADLs, is the most important condition affecting perceived quality of life in the adult and older population.

Operational Paradigms of the Causal Pathway to Disability in Older Persons

In the past two decades, many tools for measuring disability have been developed and validated, including self-report batteries as well as objective, standardized tests of performance. The availability of many different instruments contrasts with the lack of a consistent framework for organizing and categorizing types of measure. A basic approach is to classify measures that track different stages along the disablement process according to whether they identify impairments, functional limitations, or disability.

The WHO model of Impairment, Disability and Handicap (WHO ICIDH) was perhaps the first serious and systematic attempt to classify factors that lead to the condition of illness, defined as the subjective and functional experience of disease (**Figure 1**). At the foundation of the pathway is pathology, which

Figure 1 Theoretical pathway from disease to disability traditionally used in geriatric medicine and research. Top, WHO (1980); bottom, Nagi (1965) and Institute of Medicine (1991).

is defined as any abnormality of macroscopic, microscopic, or biochemical structure or function affecting an organ or organ system. The second step of the pathway is impairment, defined as any abnormality of structure or function at the whole organism level, independent of any specific environment, symptom, or sign. At the third step is disability, which derives from the interaction between the organism and the environment and is defined as any change or restriction in an individual's goal-directed behavior or behavioral repertoire, usually manifested as dependence. Finally, handicap is defined as any alteration in a person's status (position) in society, including alterations in roles. Each level of the pathway should be considered as independent and may or may not be determined by the previous level and/or cause the successive level. For example, coronary heart disease pathology may not be followed by any impairment, disability, or handicap.

The categories of the ICIHD model are appealing because they create a taxonomy of functional measures. However, translating this theory into practice has proven to be difficult. Measuring the impact of single or multiple impairments on entire body function is almost impossible when the effect of the environment needs to be considered. For example, in patients enrolled in a hospital rehabilitation program, progression of physical function improvement should be evaluated with performance-based measures referenced to a standardized environment and then again after the patient returns to his or her home, with measures that capture the effect of the environment. The discrepancy between these two measures provides information on the potential gain that can be gathered by reducing environmental challenges. The value of using the concept of handicap has always been hampered by its difficult practical applicability to the elderly, the tendency to consider an almost exclusive environmental approach to handicap in health-care services, and the different (somewhat negative) notion attached to the word handicap in different contexts.

Some of these limitations were overcome by the active pathology, impairment, functional limitations, and disability model proposed in the early 1960s by the sociologist Saad Nagi and further refined in 1991 by the Institute of Medicine. According to Nagi, functional limitations are defined as limitations in performance at the level of the whole organism or person. In contrast, disability is defined as limitation in performance of socially defined roles and tasks within a socio-cultural and physical environment. Thus, Nagi views the concept of disability as representing the gap between a person's capabilities and the demands created by the social and physical environments and is therefore consistent with the traditional approach to rehabilitation (**Figures 1 and 2**).

For Nagi, active pathology involves the interruption of normal cellular processes and the simultaneous homeostatic efforts of the organism to regain a normal state, a concept that is extraordinarily compatible with the current view on the pathogenesis of age-related frailty. Impairment refers to a loss or abnormality at the tissue, organ, and body system level. To describe the distinct consequences of pathology at the level of the individual, Nagi uses the term functional limitations to represent restrictions in basic performance. Verbrugge and Jette attempted to operationalize Nagi's disablement model to attainable measures. A further elaboration of Nagi's conceptual view of disability is contained in the Institute of Medicine report *Disability in America*. An important advantage of utilizing different definitions for functional limitations and disabilities, as proposed by

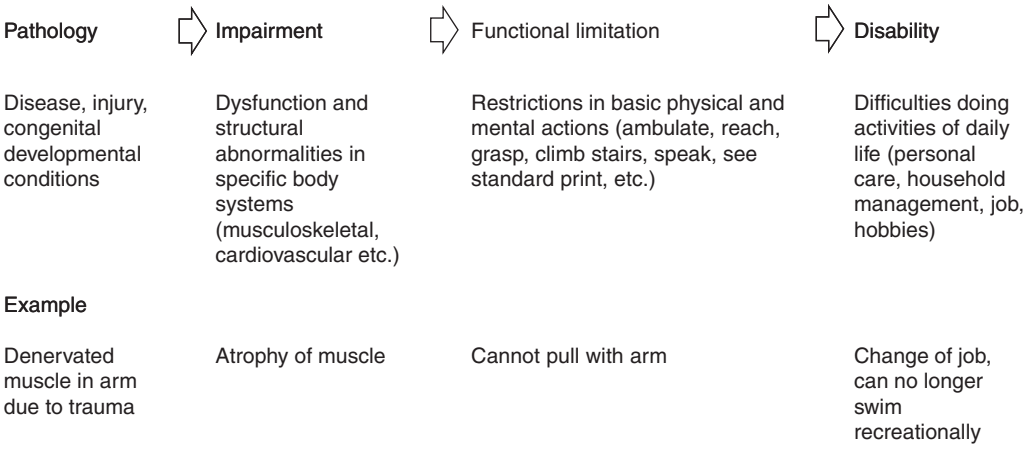

Figure 2 Theoretical pathway from disease to disability proposed by Nagi (1965), with operational definitions by Verbrugge and Jette (1994) and an example proposed in the Institute of Medicine report *Disability in America* (1991).

Nagi, is that they can be considered as sequential steps on the pathway from disease to disability. The validity of this theoretical pathway is supported by a large body of literature, and it is becoming evident that by utilizing this pathway we can address practical issues of care and prevention that can have a real impact on health outcomes.

In response to criticisms of the ICIDH classification system, in 2001 the WHO released a largely revised version under a new name, the International Classification of Functioning, Disability and Health (ICF) (**Figure 3**). The ICF is a clear shift in the paradigm of measuring disability: from describing disability, impairment, and handicap in terms of diminishments to describing body structure, functioning, activities, and participation in an objective way. In the ICF, the term functioning refers to all body functions, activities, and participation, while the term disability deals with the interaction between impairments and externally imposed activity limitations or participation restrictions (**Figure 3**). Furthermore, disability and functioning are considered outcomes of interactions between health conditions and contextual factors such as social attitudes, architectural characteristics, gender, age, and coping styles. Four main levels of human functioning are categorized by the ICF: the body or body part level, the whole person level, the person in the environment level, and the whole person in a social context level. The organ (pathology) level is similar to medical assessment of disease and disease severity, which is an expansion of the ICD classification. The whole personal level corresponds to the impairment approach, which consists of collecting information on the direct consequences of disease, disorders, and injuries and establishes the need for medical and rehabilitative services. The impairment approach ignores the fact that levels of disability cannot be inferred from the presence of an impairment, which leads to a tendency to underreport. The person in the environment approach is meant to directly acquire information about the day-to-day life of persons with disabilities in order to evaluate the need for social and support services. The need to develop an exhaustive list of important daily life activities and the tendency to consider disability as unidimensional (level of disability in different activities can be aggregated in a single score) are the main limits of this approach. A further limitation, which is addressed in the subsequent, hierarchical ICF environmental factor approach, is the lack of consideration for facilitators and barriers that may profoundly impact on the person's functional status. For the ICF, the interaction between the personal, physical, and social components results in a unique combination of factors that has a specific effect on the well-being of the individual (**Figure 3**). Since the ICF is still in a stage of development, this article uses a classification of functional status measures according to the Nagi model, therefore extending the approach already attempted by Verbrugge and Jette.

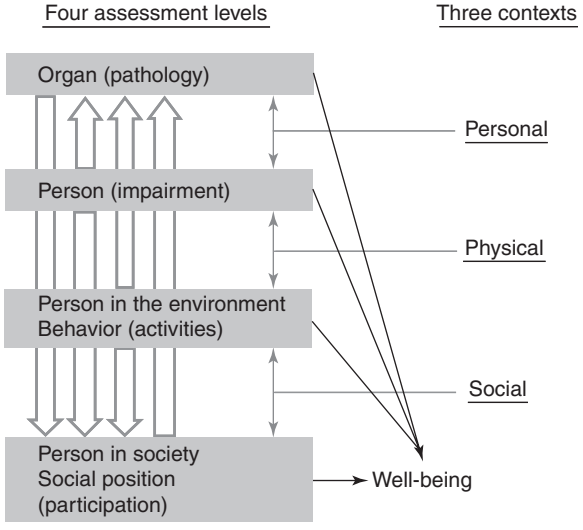

Figure 3 The International Classification of Functioning, Disability, and Health (ICF) model of illness (see text)

How is Disability Measured in Older Persons?

The following description of measuring disability is limited to selected tools that are most likely to be useful in clinical practice and in research projects in frail older persons. For each instrument, a brief description and some notes are reported. Instruments for measuring functional limitations and instruments for measuring disability are described separately. As a rough generalization, measures of functional limitation tend to be objective and performance based, while measures of disability tend to be self-reported. Common measures of functional limitation are listed in **Table 2**, and measures of disability are listed in **Table 3**.

Index of Independence in Activities of Daily Living (ADLs)

The index of independence in ADLs is a question-and-answer instrument. A dichotomous rating (dependent or independent) of six ADL functions (in order of decreasing dependency), bathing, dressing, going to the toilet, transferring from bed to chair, continence, and feeding, are rated on a three-point scale of independence and with reference to the past 2 weeks. This tool has been used for so long and in so

Table 2 Examples of tools used to assess functional limitations[a]

Assessment tool	*Assessment method*
Upper extermity	
Purdue Pegboard (Purdue Research Foundation)	Objective
Performance test aimed at assessing the coordination of gross movement of hands, fingers, arms, and find fingertips dexterity	
Timed Manual Performance (TMP)	Objective
Used in evaluation of manual dexterity and/or cognitive function of older persons, which is a strong predictor of dependency, need for increased care, and institutionalization	
Disabilities of the Arm, Shoulder and Hand (DASH) Scale	Self-report
A 30-item questionnaire that was developed to evaluate symptoms and upper extremity functional status	
Upper Extremity Physical Performance Battery (UEPPB)	Objective
Combines three standard measures (William's hand test, hand signature, functional reach) and provides a composite score	
Multidimensional	
Physical Performance Test (PPT)	Objective
Commonly used measure of overall functional ability of older adults that predicts mortality, nursing home placement, and risk of falls	
Nagi Activities	Self-report
Includes nine basic activities to be used for reference in measuring functional limitations, which is strongly predictive of health-care utilization	
Rosow Breslau Activities	Self-report
Evaluates the relative difficulty of performing daily living tasks for persons with a high-level of physical function	
Physical Disability Index (PDI)	Objective
Mostly used in a clinical setting, by trained professionals, with assessment of the passive range of motion and strength in several joints and muscle groups of the upper and lower extremities	
SF-36 Physical Function	Self-report
A short-form health survey that is particularly useful for comparing general and specific populations rather than individuals	
Physical Capacity Evaluation (PCE)	Objective
Averages performance scores on 13 tasks chosen to represent musculoskeletal activities necessary to perform instrumental activities of daily living. Poor performance is associated with difficulty in performing ADLs	
Continuous-Scale Physical Functional Performance	Objective
Assesses maximal performance in tests mimicking ordinary ADLs in standard conditions and in a continuous sequence and is a good choice in outcome measures of interventional trials aimed at increasing endurance	
Lower extremity (including balance)	
EPESE Short Physical Performance Battery (SPPB)	Objective
A composite performance-based test that is strongly predictive of negative health-related outcomes, including disability, nursing home admission, mortality, hospitalization, and utilization of health-care resources	
Tinetti Gait and Balance Scale Test	Objective
Assesses balance and gait, with a poor score indicating high risk of falls	
Avlund Mobility Scale (AMS)	Self-report
Incorporates two subscales, Mob-T and Mob-H, in which a high score describes better functioning	
Timed Up and Go (TUG)	Objective
Provides a measure of motor skills essential for independent living, which has mostly been used in the hospital setting, especially in the evaluation of patients with neurological motor disorders	
Berg Balance Scale (BBS)	Objective
A commonly used measure of postural control and stability that evaluates performance on 14 tasks, with evidence of responsiveness following rehabilitation intervention for frail elders as well as individuals with neuromuscular impairment	
Functional Reach	Objective
Measures dynamic balance and is strongly associated with measurements of center of pressure excursion evaluated on a force platform. Studies have demonstrated that a reach of less than or equal to 6 inches indicates a high risk of falling	
Fitness/endurance	
Six-minute walk	Objective
Assesses exercise tolerance in adults with cardiac and respiratory conditions and exercise capacity in older adults, which predicts hospitalization and mortality in patients with left ventricular dysfunction and advanced lung disease	
Health ABC Long Corridor Walk	Objective
Measures cardiorespiratory fitness longitudinally in well-functioning older individuals, which additionally provides a valid estimate of peak VO_2 in older adults, therefore providing a safe assessment of fitness in clinical and research settings	

Table 2 (*Continued*)

Assessment tool	*Assessment method*
Functional Fitness Test Measures parameters associated with functional ability in daily life and evaluates the risk for future accelerated decline of physical function and helps to identify older adults at risk for mobility loss	Objective

[a] Note that both self-report and performance-based instruments are reported and that the list is limited to tolls that are not specific for functional limitations due to specific diseases.

The WHO Eleven-Country Study Disability Scale
Disability Adjusted Life Years (DALY)

many studies and care settings that it is generally considered the gold standard to which any other measure of disability should be compared. The index of ADLs has strong predictive validity for a number of negative health outcomes.

The Nottingham Extended Activity of Daily Living (ADL) Index

The Nottingham extended ADL index was established as a postal questionnaire to monitor the level of ADL disability in patients discharged into the community after rehabilitation, in particular after an acute stroke. The tool assesses 21 activities within four categories: mobility (e.g., do you walk over uneven ground?), kitchen activities (e.g., do you do the washing up?), domestic activities (e.g., do you do a full clothes wash?), and leisure activities (e.g., do you go out socially?). It is a simple, self-administered questionnaire that can be completed by the patient in approximately 10 min; it provides an extended ADL score that is highly correlated with more complex, self-reported interviewer-administered measures of disability.

The Barthel Index

The Barthel index is an ordinal scale that measures functional independence in the domains of personal care and mobility in patients with chronic, disabling conditions, especially in the rehabilitation settings. Two main versions exist: the original 10-item form and expanded 15-item version. The 10-item version is the most used; it includes evaluation of independency in feeding, moving from wheelchair to bed and return, grooming, transferring to and from a toilet, bathing, walking on a level surface, going up and down stairs, dressing, and continence of bowels and bladder. The Barthel index is used to assess disability and to monitor changes in disability over time. The scoring method takes into account whether the person evaluated receives help while doing each task. The scores for each of the items are summed to create a total score, with higher scores indicating higher levels of independency.

The Functional Independence Measure (FIM)

The FIM is an 18-item instrument measuring a person's level of disability in terms of burden of care. The FIM should be rated by the consensus opinion of a multidisciplinary team, but the evaluation is often performed by a single professional. Each item is rated from 1 (requiring total assistance) to 7 (completely independent). Three independent FIM scores can be generated by summing item scores: a total score (FIM total: 18 items), a motor score (FIM motor: eating, grooming, bathing, dressing – upper body, dressing – lower body, toileting, bladder management, bowel management, and transfers bed/chair/wheelchair, toilet, tub/shower, walk, stairs), and a cognitive score (FIM cognitive: auditory comprehension, verbal expression, social interaction, problem solving, and memory). Multiple studies support the reliability and validity of FIM scales in the older population.

The Instrumental Activities of Daily Living (IADLs)

Lawton and Brody introduced the concept of IADLs in 1969. IADLs were defined as abilities in activities physically and cognitively more complex but still important for independent life. The Lawton and Brody IADL scale includes seven activities: use of the telephone, traveling via car or public transportation, food or clothes shopping, meal preparation, housework, medication use, and management of money. Each criterion is graded as independent, assistance needed, or dependent.

The Karnofsky Performance Status

The Karnofsky score is a simple and rapid method to assess patients' performance in ADLs, which has been mostly used in medical oncology. The score has proven useful not only for following the course of the illness, but also for obtaining prognostic information. Patients with the highest (best) Karnofsky scores at the time of tumor diagnosis have the best survival and quality of life over the course of their illness. The scoring is subjectively assigned by a health professional based on the following hierarchical scale: 100 = normal, no evidence of disease; 90 = able to perform normal activity with only minor symptoms; 80 = normal activity with effort, some symptoms; 70 = able to care for self but unable to do normal activities; 60 = requires occasional assistance, care for most needs; 50 = requires considerable assistance; 40 = disabled, requires special assistance; 30 = severely disabled; 20 = very sick, requires active supportive treatment; 10 = moribund. Intermediate or even decimal scores can be assigned. The tool is named after David A. Karnofsky, who described the scale in 1949.

The Minimum Data Set (MDS) Disability Scale

The MDS is a standardized, primary screening and assessment tool of health status that measures physical, medical, psychological, and social functioning of nursing home residents. The general categories of data and health status items in the MDS include demographics and patient history, cognitive, communication/hearing, vision, mood/behavior patterns, psychosocial well-being, physical functioning, continence, disease diagnoses, health conditions, medications, nutritional and dental status, skin conditions, activity patterns, special treatments and procedures, and discharge potential. The disability subscale has a hierarchical structure and provides information that is highly correlated with other self-reported ADL assessment instruments. The MDS is administered regularly to all nursing home resident in the United States.

The Office of Population Census and Surveys (OPCS) Disability Scale

The OPCS disability scale was developed by the Office of Population Censuses and Surveys in England and derived from the WHO Classification of Impairments, Disabilities and Handicaps. This disability scale is perhaps the most comprehensive tool yet devised. However, it is mostly used in epidemiological research rather than for the evaluation of single patients. The scale evaluates 25 activities distributed among the following domains: behavior, locomotion, continence, intellectual functioning, dexterity, personal care, consciousness, communication, reaching and stretching, hearing, seeing, disfigurement, eating, and digestion.

The Nottingham Health Profile (NHP) Disability Scale

The NHP is a well-established health status measurement instrument. The NHP is a self-administered questionnaire developed in the United Kingdom in the late 1970s. The 45 items of this two-part questionnaire were selected from an original pool of more than 2000 statements about the impact of illness obtained from more than 700 patients. The instrument is widely used in many countries. The physical mobility subscale, which includes questions about disability in eight activities, is valid, reproducible, and responsive to changes.

The Sickness Impact Profile (SIP)

The SIP is a multidimensional measure of health status and the impact of sickness that has been extensively used in older individuals to describe and monitor health status. The scale consists of 136 items in 12 different categories: sleep and rest, emotional behavior, mobility, body care and movement, eating, ambulation, recreation and pastimes, social behavior, communication, alertness behavior, home management, and work. Questions in the mobility and ambulation categories have been used in many studies and provide information on both functional limitations and disability. Total, category-, and dimension-specific scores can be calculated, with higher scores representing greater dysfunction. In a landmark study, changes in functional status identified using the SIP appeared to be valid representations of true changes in health-related functional status.

The Health Assessment Questionnaire (HAQ) Disability Scale

The HAQ is a functional status developed by Fries *et al*. in 1980 and is mostly used in rheumatology, especially in clinical trials and observational outcome studies. The HAQ score is accepted by the US Food and Drug Administration for evaluation of the prevention of disability in chronically ill patients. A large portion of the HAQ concerns the evaluation of disability in ADLs and 14 questions relating to the use of aids and devices. It has been suggested that the HAQ score is best used to evaluate disability in patients who are severely ill.

The WHO Eleven-Country Study Disability Scale

This assessment instrument was derived by combining questions on disability in six basic and nine instrumental ADLs that were used to assess disability in the WHO Eleven-Country Study. A particular scoring algorithm was developed that classifies responses to the 15 questions into four domains of disability that are hierarchical in severity and are characterized by specific underlying physical impairments. The cross-cultural reliability of this model was verified in seven population-based samples of older persons living in five European countries.

Disability-Adjusted Life Years (DALY)

Disability-adjusted life years (DALY) have been proposed by the World Bank and the WHO as a measure of the global impact of disease on individual illness status. DALY combines information about morbidity and mortality and is expressed in terms of numbers of healthy years lost. In the DALY approach, each state of health is assigned a disability weighting on a scale from 0 (perfect health) to 1 (death), based on expertise and available data. To calculate the burden of a certain disease, the disability weighting is multiplied by the number of years lived in that health state and is added to the number of years lost due to that disease. The evaluation of DALY is only used at the level of large populations, mostly for addressing issues of international health policy. In spite of its wide use, the conceptual and technical basis for DALY's estimation has been seriously questioned.

Caveats Concerning the Use of Disability Measures in Older Persons

Although the introduction of measures of functional limitation has substantially improved the chances of studying and understanding the disablement process, several aspects of the complex relationships among aging, diseases, functional limitations, and disability are still unclear. For example, while a specific intervention may improve walking speed, the minimal degree of improvement needed to have a positive effect on the level of autonomy in ADLs is still unknown. Therefore, in spite of their objectivity, performance-based measures of physical function are still not used as primary outcomes in clinical trials. As experience with these tests accumulates, set points that define poor levels of functioning would have to be developed. For example, a gait speed of $\leqslant 0.4$ m/s is now recognized as representing a very substantial functional limitation with associated high risk of poor outcomes.

Although ascertainment of disability appears simple, a number of pitfalls may threaten reliability or validity of traditional self-reported measures. The threshold of physical ability below which older individuals perceive difficulty can be influenced by factors that change over time, such as social environment, economic status, cognition, and depression. Disability is dynamic and amenable to recovery and fluctuation. For some frail persons, the response to disability questions more accurately reflects what caregivers allow them to do than their actual capacity (perceived ability vs. actual performance in daily life). To avoid these problems, disability questions should be standardized and made applicable in the context of day-to-day life. Whether the question addresses potential capability or current behaviors should be specified. Whether disability is defined as perceived difficulty or as need for help should be determined, because only a small percentage of older persons who perceive difficulty in performing ADLs actually receive help in executing those tasks.

Objective, performance-based measures of functional limitation should be collected in parallel with self-reported measures of disability. However, it should be acknowledged that objective measures of functional limitation and self-reported measures of disability serve different purposes and, therefore, are complementary and not alternative assessments. In fact, performance at the time of assessment may underestimate (e.g., due to stress from testing) or overestimate (e.g., due to patients trying harder than usual) usual performance in normal daily life.

Further work is required to improve standardization and measurement of functional limitations. Although several functions, such as gait speed and time to complete a set number of chair rises, are commonly assessed, the technical aspects of doing these tests have not been standardized, making it difficult to directly compare function across studies. For example, gait speed may be tested at different distances. In some assessments, the participant is already walking when the starting line is reached, while in others, the test starts with both feet planted on the starting line, and different criteria are used for deciding when the participant actually crosses the finish line, as well. It would also be valuable if the instructions, motivational cues, and feedback after completion of the test were standardized.

The final challenge in moving forward with the use of disability measures is to reach a consensus on a standard core battery of assessment tools that should be used in specific clinical settings, residential accommodations, and research projects. The challenge is to support the validity of this battery with research

and to make it practical and easily interpretable by the clinician so that it can become a clinical vital sign of function that is routinely measured in practice.

Conclusions

The need for mapping specific measures of the different steps of the disablement process is well established both in geriatric medicine and in geriatric rehabilitation. Measurement tools for administrative and organizational purposes are also available for different types of settings. A number of projects that explore factors affecting the pathway from disease to disability in older persons are now in the field. This wide range of tools should be extensively utilized to guide interventions aimed at improving the quality of life of the older population, especially the segment that bears the burden of multiple morbidities, frailty, and disability. Research in this area is desperately needed.

DNA and Gene Expression

J Vijg, University of Texas Health Science Center, San Antonio, TX, USA

Glossary

CpG Islands – Stretches of DNA, about 1–2 kb long, with an average GC content of about 60%, compared to 40% for the genome overall. CpG islands often surround the promoters of constitutively expressed genes.

DNA Damage – Changes in the DNA chemical structure induced by a variety of different chemical, physical, and biological agents.

DNA Repair – The complex of enzymatic systems to remove DNA damage and to restore the original situation.

DNA Replication – The process of copying the entire complement of genetic information.

DNA Transcription – The process of copying the genetic information encoded in a gene into mRNA.

Gene – The segment of DNA encoding a polypeptide chain; it includes regions immediately preceding and following the coding sequence as well as intervening sequences (introns) between individual coding sequences.

Genome – The coordinated ensemble of DNA and protein in the cell, carrying out all its genetic transactions. The human genome consists of approximately 6 billion base pairs of DNA distributed among 46 DNA–protein complexes termed chromosomes.

Intron – A transcribed but non-coding part of a gene, separating one exon (coding part) from another. Introns are removed from the transcript by splicing together the exons on either side of them.

Mutation – Change in the sequence of DNA in a genome that can involve a single base pair position (point mutation) or a rearrangement (deletions,

insertions, recombinations). The *in vivo* mutant frequency is defined as the frequency at which a mutated variant of the gene is found among unmutated copies.

PCR Amplification – An *in vitro* process used as a laboratory tool for copying DNA fragments in an amount sufficient for their analysis.

Promoter – The portion of a gene to which RNA polymerase must bind before transcription of the gene can begin.

Protein Translation – The process of producing a protein based on the mRNA code.

Repetitive DNA – A collective term for all the DNA sequences that occur more than once in the genome of an organism. Minisatellites are tandem repeats of a short unit occurring all over the genome (clustered at the telomeres). At a given minisatellite locus, the copy number can be highly variable and differ between 5 and 50 copies among different chromosomes.

Transcriptome – The complete set of mRNAs of a given cell or cell type.

Introduction

Genes are the units of inheritance. They reside in the genome as sequences of deoxyribonucleic acid (DNA), carrying the information representing a particular polypeptide. The DNA sequence of the human genome, as well as that of many other species, including mouse and rat, has been completely decoded. The human genome contains between 20 000 and 25 000 genes. In mammalian genomes, genes are clustered densely into small islands in desert-like expanses containing few or no genes. The information encoded in the genes is expressed, first by generating a single-stranded messenger RNA (mRNA) identical in sequence to one of the strands of the duplex DNA (RNA transcription), and then by converting the nucleotide sequence of the RNA into the sequence of amino acids comprising a protein (protein translation). While the protein-coding sequences of genes occupy only about 1% of the entire DNA sequence, their interruption by introns allows them to be spread over huge distances. Introns, which comprise 24% of the genomic sequence, are non-coding stretches of DNA that are transcribed, but eventually excised from the mRNA, thereby fusing the remaining parts, termed 'exons,' by a process called splicing, into the final protein-coding mRNA.

Genes are perpetuated (as in cell division or the generation of gametes) by a duplication process of the double-stranded DNA to give identical copies (DNA replication). A gene is a stable entity, but can suffer changes in its chemical structure or in its sequence. Sequence changes are called mutations, and may occur as a result of replication errors or mistakes made during the repair of chemical damage. The phenotypic results of mutations range from undetectable to lethal. Patterns of gene expression can undergo changes with time, either in a random fashion, for example, through genomic alterations, or in a programmed manner, as exemplified by the switching on and off of individual genes during development and differentiation. Aging is a process of change with time that is associated with increased loss of function, increased pathology, and increased susceptibility to disease. Although aging never fails to result in the death of the organism, the information encoded in its genes is perpetuated in the form of an immortal germline. A multitude of physiological, cellular, and molecular changes have been found to occur in aging individuals of various species. The relevance of many of these changes, with respect to possible causal relationships with age-related pathology and/or functional decline, is unclear at present. This is the case for most age-related changes in DNA and gene expression, which have been considered, alternatively, as the basic cause of aging or merely background noise against a predominantly pathophysiological process occurring at a higher level of organization. The question to be addressed in molecular gerontology is whether aging can be reduced to a finite number of molecular processes based on stochastic damage and/or genetically programmed events.

Underlying Theory

Background

Changes in genome organization and expression have long been considered as possible explanations for the general breakdown of structure and function during aging. Stochastic damage to DNA, the ultimate template, could lead to qualitative and/or quantitative changes in gene expression, resulting in random phenotypic alterations in individual cells with a loss of tissue function and multiple forms of pathology as potential consequences. Alternatively, age-related changes in gene expression could occur in a programmed fashion, resulting in phenotypic changes that are similar from cell to cell. In testing these two scenarios, which are not mutually exclusive, the following questions regarding aging-related changes need to be addressed: (1) what kind of alterations in the somatic genome and its translation into phenotypic information need to be considered; (2) do such

changes actually occur and can they be causally related to the aging phenotype; (3) what are the mechanisms by which these changes arise; and (4) what are the defense systems minimizing their effects?

Evolutionary Basis

While the mechanisms underlying age-related degeneration and death in various species still need to be uncovered, a consensus as to why and how we age has begun to emerge. It is now generally accepted that the time-dependent decrease in fitness in most multicellular organisms is non-adaptive; that is, it is not controlled by a purposeful genetic program similar to the control of development. Aging provides no specific advantage and most researchers now accept that age-related degeneration and death is ultimately due to the greater relative weight placed by natural selection on early survival or reproduction than on maintaining vigor at later ages. This is due to the scarcity of older individuals in natural populations owing to mortality caused by extrinsic hazards, which essentially prevents the manifestation of late age effects of genes. Consequently, such late effects of genes, whether positive or negative, will be ignored by natural selection.

Life span is often considered as the result of a trade-off between growth and reproduction on the one hand and somatic maintenance on the other. High extrinsic mortality would favor investment of scarce resources in early reproduction rather than somatic maintenance. Indeed, the so-called disposable soma optimizes rather than maximizes maintenance and repair activities to meet the requirements of the life time strategy of the organism. This suggests that organisms age as a result of the accumulation of unrepaired somatic damage due to their continuous exposure to damaging agents, such as free radicals, the toxic by-products of normal metabolism. Shifts in resource utilization towards increased investments in somatic maintenance would then lead to increased life span. This may have occurred over evolutionary time and could explain the emergence of long-lived mammalian species, such as humans. However, it could also happen more quickly by down-regulating growth and reproduction, for example, by caloric restriction. Caloric restriction is a very effective intervention that has been shown to increase life span in multiple species, including mammals. Other examples are laboratory strains of evolutionary distant organisms such as nematodes, fruit flies, and mice, in which life span can be increased causing a down-regulation of growth and reproduction. Examples are mutations that downregulate insulin signaling, growth hormone levels, and nutrient sensing. It is assumed that such downregulation facilitates a shift in resource allocation to longevity assurance processes, which occurs naturally in many species under adverse conditions when reproduction needs to be postponed. Indeed, life span is highly plastic and can be manipulated, as a function of different circumstances, by metabolic switches that can affect the levels of spontaneous somatic damage or the proportional effort that is devoted to somatic maintenance.

Not surprisingly, cells and the various macromolecular complexes that serve to provide for their function are generally considered as the main target of somatic damage accumulation in aging. Which of the major biomolecules –DNA, RNA, protein, lipids, and carbohydrates – would be the most important cellular targets? Some would argue for DNA in view of its unique role in transferring genetic information from cell to cell and from generation to generation. Others, however, would say that changes at the protein level can potentially influence all other macromolecular structures in the cell, including the DNA. Changes have been found at all levels, and the various pathways involved in the cell's macromolecular machinery and its maintenance and repair are so intertwined that no single molecule, system, or structure can be considered on its own (**Figure 1**). Nevertheless, there are some very good arguments for assigning a primary or predominant role to changes in DNA and gene expression.

First, a strong, logical argument for considering the DNA of the genome as the Achilles heel of an aging organism is the irreversibility of unwanted sequence changes in view of the lack of a back-up template. This is in contrast to RNA or proteins, which, at least in principle, can be easily replaced with the corresponding gene as a template. Indeed,

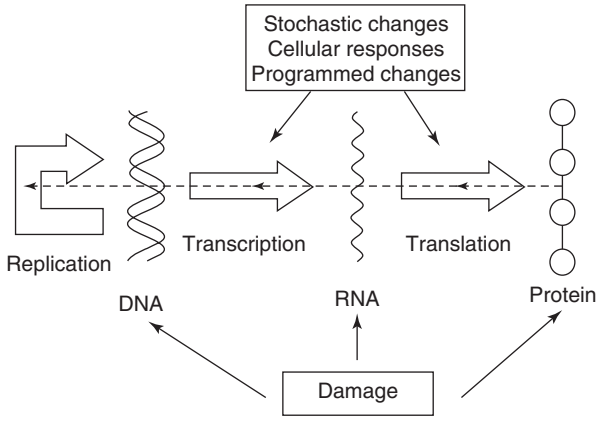

Figure 1 Flow of cellular information from DNA to protein (large arrows). The dotted reversed arrow indicates the influence proteins exert at all stages of the information flow. Thin solid arrows indicate the changes that can occur in the different molecules and their transactions.

the maintenance of genomic DNA is of crucial importance to survival because its alteration by mutation is essentially irreversible and has the potential to affect all downstream processes.

A second, powerful body of evidence for considering changes in DNA as critically important in driving the aging process involves the demonstrated association between heritable DNA repair defects in humans and premature aging. Such genetic disorders are termed segmental progeroid syndromes because they accelerate some but not all of the signs of normal aging (**Table 1**). While these disorders have been known for over a century and were from the beginning recognized as being associated with premature aging, it has only been recently discovered that in virtually all cases the cause is a heritable mutation in a gene that is involved in genome maintenance, i.e., the network of processes that maintain the integrity of the genome over chronological time and during cell division. This highlights the importance of DNA transactions (such as replication, repair, transcription, and recombination) for somatic maintenance during aging. The segmental progeroid syndrome that is most similar to normal aging is Werner syndrome (WS), caused by a defect in the WS gene (WRN), one of several highly conserved RecQ helicase genes that help to maintain genome stability. WS individuals prematurely develop characteristics of old age, such as atrophic skin, thin gray hair, osteoporosis, type II diabetes, cataracts, arteriosclerosis, and cancer.

Interestingly, mice harboring engineered genetic defects in genome maintenance often display multiple symptoms of premature aging. Indeed, genetic defects in few, if any, other systems than DNA repair and genome maintenance have been associated with premature aging.

What are the types of aging-related changes that can occur in biological macromolecules along the axis of the central dogma, i.e., DNA → RNA → protein? First of all, as realized early on, spontaneous errors may occur during the processes of replication, transcription, and translation. Chemical damage to all major biomolecules, from such sources as reactive oxygen species and various environmental agents, has been demonstrated to occur and may lead to loss of function. Random damage to DNA may affect transcription and can result in mutations as a consequence of errors during replication or repair. Mutations have the potential to result in permanent gene expression changes that are different from cell to cell.

Damage to DNA and other macromolecules in the cell can elicit powerful programmatic responses, such as DNA repair, apoptosis, cellular senescence, and other stress responses. The gene expression changes associated with these responses would be very similar from cell to cell. This may explain many of the consistent alterations in gene expression that have been observed in organs and tissues of animals during aging. Other consistent gene expression changes at old age could include delayed pleiotropic effects of developmental processes or rare postdevelopmental, programmatic changes in the elderly, selected during evolution when they influence the reproductive success of their kin.

It follows from the above that both stochastic and programmatic changes in DNA and gene expression can be expected to occur during aging. Age-related changes in DNA can be expected to be predominantly stochastic. That is, each specific alteration occurs as a relatively rare event, which essentially transforms each organ or tissue into a mosaic of cells. Each cell would have its unique set of 'genomic scars' that distinguishes it from all other cells. By contrast, age-related changes in gene expression can represent both programmatic and stochastic events. That is, while each aged cell can have its own unique set of

Table 1 Some of the best-known human segmental progeroid syndromes

Syndrome	*Incidence (per live birth)*	*Inheritance*	*Age of onset (years)*[a]	*Mean life span (years)*	*Genes*	*Defect*
Hutchinson-Gilford	$<$1/1 000 000	*De novo*	2	13	Lamin A	Nuclear stability, transcription?

up- and downregulated genes, consistent changes occurring in each cell of a tissue or organ should also be taken into consideration.

Changes in DNA

DNA Damage

Cellular DNA is continuously damaged by a variety of exogenous and endogenous physical, chemical, and biological agents (**Table 2**). Such damage includes breaks in the sugar-phosphate backbone of the DNA, both single-strand breaks and the highly toxic double-strand breaks, base loss, base adducts, methylation, deamination and inter- and intra-chromosomal cross-links. The main sources of endogenous DNA damage, which is now considered more important than exogenous damage, include hydrolysis and oxidation. Especially oxidation through reactive oxygen species (ROS), the by-product of oxidative phosphorylation and other normal, physiological processes, can induce a variety of chemical damage into cellular DNA. It has been estimated on the basis of urinary excretion of DNA adducts that oxidative damage to DNA alone occurs at a rate of 10^4 hits per cell per day in humans; in rodents the rate may be an order of magnitude higher. Exogenous damage can be a result of exposure to ultraviolet light, background ionizing radiation or environmental chemicals, such as polycyclic aromatic hydrocarbons.

As indicated by the occurrence of DNA adducts in the urine, most of the damage is repaired. However, repair is imperfect, which may lead to an increased steady state level of DNA damage. Evidence has been obtained that the steady state levels of several forms of DNA damage (e.g., breaks, oxidative damage) increase with age in both humans and rodents. Increases of a factor of approximately two to three in the rat liver have been reported for nuclear and mitochondrial DNA (mtDNA). The mitochondrial genome is much more susceptible to oxidative damage than the overall nuclear genome. mtDNA from the rat liver has more than 10 times the level of oxidative DNA damage than nuclear DNA from the same tissue. This may be explained by such factors as a less efficient DNA repair system to protect mtDNA, the close vicinity of the main source of ROS, or the lack of histone proteins to protect mtDNA. However, it is entirely possible that certain areas of the nuclear DNA also accumulate DNA damage much faster than the genome overall. Indeed, DNA repair efficiencies vary considerably between different types of DNA sequences, with actively transcribed genes being repaired best.

Table 2 Major causes of DNA damage

Endogenous
Hydrolysis
Reactive oxygen species
Nonenzymatic glycosylation
S-adenosyl-L-methionine (alkylation)
Steroid hormones, excitatory amino acids
Exogenous
Dietary factors (e.g., benzo[a]pyrene)
Lifestyle (e.g., smoking)
Environmental exposures (e.g., UV, ionizing radiation)

Thus, higher levels of DNA (oxidative) damage, especially in mtDNA, appear to be present in at least some organs of older humans and rodents. The question is whether this kind of chemical damage can by itself explain some of the age-dependent functional declines that have been reported, for example, by interfering with transcription. While DNA damage can certainly interfere with transcription, such direct interference is unlikely to have a major functional impact. First, after taking extensive precautions against artificially induced damage – a notorious problem in such studies – results from various investigators indicate very low amounts of oxidative DNA damage. For example, the most frequent oxidative lesion, 8-oxoguanine, appears to be present in tissues from old animals as one lesion per 10^6 undamaged guanines. It is unlikely that such low levels of altered DNA bases could exert an important effect. While in mtDNA the levels at old age are much higher, the many mtDNA copies provide ample opportunity to compensate for the loss.

Second, it is not always realized that instead of a genuine accumulation of DNA damage, it is the difference between induced and repaired DNA lesions that has been measured, that is, steady state levels of DNA damage. It is not possible to know whether a particular lesion detected today will still be present tomorrow. Hence, the possibility should be considered that any increase in DNA damage, unless it completely overwhelms all defense systems (which at the levels reported is extremely unlikely under normal conditions), has no functional consequences.

DNA chemical damage becomes highly relevant when a lesion is fixed in the form of a mutation, that is, when a chemical alteration in DNA structure, recognizable by DNA damage processing systems, is turned into an erroneous base sequence as a permanent part of the genetic heritage. Such DNA sequence changes are discussed in the next section.

DNA Sequence Changes

In contrast to DNA damage, DNA mutations are changes in a DNA sequence that can be transmitted to daughter cells. Hence, mutations are not altering

the DNA chemical structure, but merely its sequence organization. They can affect a gene, gene regulatory region, or some other non-coding part of the genome. Mutations are usually introduced as a consequence of errors made during replication or repair of a damaged DNA template. Mutations can vary from point mutations, involving single or very few base pairs, to large deletions, insertions (for example, due to the activity of mobile genetic elements), duplications, and inversions. In organisms with multiple chromosomes, DNA from one chromosome can be joined to another, and the actual chromosome number can be affected. Because mutations are rare and do not affect DNA chemical structure, they are not easy to detect and the total number of mutations in individual cells of an aged tissue cannot be quantified. Hence, while we know that DNA damage induces a variety of cellular responses, the possible impact on the aging process of its stochastic endpoint, i.e., the spectrum of DNA mutations, is unknown.

It is difficult to reliably quantify and characterize spontaneous mutations, but a variety of methods have emerged, including methods that can be applied to the *in vivo* situation, which allow some conclusions to be drawn. Both cytogenetic tests and the HPRT assay, which is based on the selectable inactivation of this X-linked gene, have indicated the accumulation of mutations with age in lymphocytes from both humans and mice. Using transgenic mouse models harboring reporter genes that can be analyzed in *Escherichia coli,* it has been demonstrated that mutations accumulate with age in most organs and tissues at rates that are tissue specific. A substantial fraction of those mutations, depending upon the tissue, appeared to be genome rearrangements, i.e., deletions, inversions, or translocations. Some of such mutations appeared to be very large, i.e., involving millions of base pairs of DNA, even in postmitotic tissues such as heart. Some areas of the genome, such as those areas containing repetitive DNA (e.g., telomeres), appeared to be especially vulnerable to sequence alterations. Notably, apart from the nuclear genome, the mitochondrial genome is also subject to a variety of DNA sequence changes. Indeed, similar to DNA damage, the mitochondrial genome accumulates mutations much more rapidly than the nuclear genome. Since there are many copies of mtDNA in each cell, prevention of mutation accumulation may be less urgent in this case. Similar arguments apply to the various repeat element families.

An important question involves the functional impact of the observed mutation load and its increase with age. For most organs the magnitude of the age-related increase was small, i.e., about twofold on average. However, the functional properties of an aging organ can become compromised, even if most of the cells still function optimally. We will see later how a relatively small number of stochastic events can lead to adverse effects on the transcriptome, i.e., the complete set of mRNAs in a given cell type.

Epigenetic Changes

The genome is the carrier not only of genetic information, encoded in the DNA, but also of epigenetic information, including differential methylation of DNA on cytosines and histone protein modifications. Epigenetic changes alter gene activity without modifying the DNA sequence and are essential to normal development. However, similar to DNA damage and mutations, random alterations in the epigenetic code can cause problems, for example, when they disable genes that suppress tumorigenesis. A well-characterized mechanism for the heritable propagation of epigenetic information is methylation of cytosine residues at carbon 5 of the pyrimidine ring, primarily at CpG sequences. Methylation can silence a nearby gene in the context of histone protein modification patterns. Histone modification, the 'histone code,' comprises a pattern of posttranslational modifications including acetylation, methylation, phosphorylation, and ubiquitination. Histones are the proteins responsible for higher-order DNA structure. At the lowest level of organization, the DNA of the genome is wrapped around an octamer of core histone proteins. This structure can be condensed into the tightly packaged solenoid structure or 30-nm fiber, which can be further arranged into loops. Such higher-order structure of the DNA of the genome appears to be under control of DNA methylation patterns and the histone code, faithful maintenance of which is important since ultimately they determine the accessibility to the gene promoter sequence of various transcription factors. In general, DNA methylation and histone deacetylation is associated with transcriptional silencing, while demethylation and histone hyperacetylation on lysines make the DNA more accessible for transcription and are therefore associated with active genes. Unmethylated CpG sequences are specifically found in the GC-rich sequences in promoter regions of housekeeping genes, i.e., genes that are constitutively expressed in all tissues. Such areas are called CpG islands.

Very little research on aging has been devoted to the higher-order structure of the genome and alterations therein. The results of such research have varied, but overall the level of methylation tends to decrease with aging in most vertebrate tissue. This appears to coincide with observed increases in

nucleosome spacing and a lower sensitivity to nucleases, pointing toward a general relaxation of DNA higher-order structure. These changes could be caused by DNA damage, which can alter histone–DNA binding, or mutations, which can alter the sequence environment in which the methylation and histone codes have to act. Age-related changes have also been reported in covalent modifications of histones and non-histone proteins in mammalian tissues, for example, phosphorylation, acetylation, and methylation. More recently a number of age-related changes in methylation, both hypermethylation and demethylation, have been observed in specific gene sequences.

Cellular Defense against DNA Changes

To summarize the preceding, there is abundant evidence for alterations in the DNA of the genome during aging. The frequency and spectrum of such events may vary from genomic region to genomic region and are also different between tissues. The mitochondrial genome and repeat elements, such as those at telomeres, especially seem to undergo mutations at a high rate. There are some isolated reports of high-frequency mutations in protein-coding genes. Defense against the time-dependent loss of DNA functional template takes place at various levels (**Table 3**). First, damage can be prevented at an early stage, for example, by the activity of antioxidant enzymes if ROS are the primary cause of the damage. Then, damage can be repaired through the complex system of genome maintenance pathways, restoring the original situation as far as possible. This includes the restoration of methylation patterns and the histone code, which also need to be faithfully propagated during cell division, similar to the DNA primary sequence. Finally, when all other defense systems threaten to be overwhelmed, the cell itself can either shut down its replicational machinery, termed replicative senescence, or be entirely eliminated by programmed cell death or apoptosis. In this sense apoptosis is the ultimate mechanism for the maintenance of phenotypic fidelity in multicellular organisms.

Table 3 Molecular and cellular defense systems

- Antioxidant defense
- DNA repair and genome maintenance
- The P450 superfamily of detoxifying systems
- Tumor-suppressor genes
- Heat shock and other stress proteins
- Regulatory cytokines (e.g., interferon, tumor necrosis factor, interleukins, other growth and regulatory factors)
- The immunoglobulin superfamily
- Apoptosis
- Cellular senescence

Naturally, cellular defense systems function well enough at early age. However, as predicted by the evolutionary theory of aging, there is no reason to assume that the preservation of the genetic material in the somatic tissues until long after the reproductive period has a high priority. The previously described aging-related DNA alterations are, therefore, not surprising. Moreover, although there is no evidence that repair activities are overwhelmed at old age, moderate declines in, for example, the rate of DNA repair have been reported. It should also be noted that cellular defense systems against DNA damage and other stresses can turn from anti-aging into pro-aging systems. For example, apoptosis and cellular senescence help to suppress cancer at early age, but possibly at the cost of promoting aging at later ages by exhausting progenitor or stem cell reservoirs. Likewise, a powerful response to infection undoubtedly has a high survival value, but may at later age contribute to inflammation.

The combination of suboptimal cellular defense systems and increased age can be expected to give rise to three major cellular endpoints: neoplastic transformation, cell death, and cellular senescence. The exponential increase in cancer during aging has been well documented and could be explained at least in part by increased DNA mutations and/or methylation. Cell death can be observed as atrophy in a variety of tissue systems in aging organisms and could be due to increased levels of DNA damage, inducing apoptosis. Cell transformation and cell death are not sufficient to explain age-related degeneration of an organism and its ultimate demise, however. Indeed, most manifestations of normal aging at the cellular level are probably due to an increasing fraction of senescent cells. While such cells could in part result from replicative senescence, i.e., the irreversible cessation of cell proliferative activity in response to genomic stress, senescence is defined here as a general loss of function. It would be important to know if such seemingly unaffected cells, which form the majority of tissue mass in old animals, are in reality irreversibly damaged cells with seriously dysfunctional patterns of gene expression.

It is too early at this stage to generate a definitive 'damage report' for the aging higher animal genome in terms of the total amount of information loss due to random DNA alterations of various kinds. For this purpose more quantitative data are needed on the occurrence of some well-defined genomic lesions in various cell types of humans or animals over their lifetime. On the basis of such data it should be possible to calculate the average amount of functional

DNA template that is lost with age. Then it should also be possible to predict whether the genomic scars of aging are sufficient to seriously influence patterns of gene expression to significantly affect cell and tissue functioning.

Changes in Gene Expression

General

Some general characteristics of changes in gene expression with age are listed in **Table 4** and are briefly discussed here. A general age-related decline in transcription, that is, overall RNA synthesis as measured by the incorporation of radiolabeled precursors into RNA, has been observed to occur in a wide variety of organisms. Because the total RNA content does not seem to change, a decline in RNA turnover has been proposed. A comparable decline has been found for protein translation, and because the levels of most proteins also seem to remain constant, a decline in protein turnover was suggested and subsequently found. The primary cause of such general declines in macromolecular synthesis and their ultimate consequence for the individual to cope with environmental stresses are unknown.

Most attention has been paid to the expression of individual genes with age. Although gene expression can also be controlled posttranscriptionally and posttranslationally, the relative concentrations of individual mRNAs primarily determine the cellular phenotype, and it would be important to gain insight into the kinds of changes occurring at this level. Different kinds of changes can be envisaged. Genes can become over- or underexpressed during aging, previously silent genes can become activated, and previously active genes can be silenced. One can also envisage qualitative changes, such as in RNA editing (i.e., sequence changes).

It is important to distinguish non-consistent from consistent changes in gene expression. Consistent changes are changes that are the same in every cell of a given type or group. They are usually under the control of a genetic program, for example, late pleiotropic effects of differentiation and development, long-term environmental influences (e.g., viruses), and/or responses to environmental damage. Plus, genuine programmed alterations, even at late age, cannot be ruled out. Non-consistent or stochastic changes in gene expression would be unique to each cell and can occur as a consequence of random events, such as DNA alterations or errors during RNA transcription.

Table 4 Observed changes in gene expression with age: general characteristics

- Decline of total transcriptional and translational activity
- Decrease in total RNA and protein turnover
- Changes in constitutive levels of many individual mRNAs and proteins
- Decrease in inducibility of various mRNAs and proteins (e.g., immediate early genes, acute phase proteins, P450, c-myc)

Consistent Changes in Gene Expression

Most of the interest in gene expression and aging has been devoted to consistent changes, that is, changes in the expression of a gene in the tissue overall. This is undoubtedly due to the difficulty in accurately analyzing individual cells for molecular alterations. While in the past a number of well-described consistent changes in the expression of individual genes have been reported, such as the hormonally regulated $\alpha 2\mu$ globulin gene and several acute phase protein genes in the rat and mouse liver, the field is now completely dominated by the use of microarrays. Microarrays of up to tens of thousands of cDNAs or oligonucleotides, specific for parts of individual mRNAs, attached to a glass slide can be hybridized with labeled probes, obtained from reverse transcribed RNA from tissues or cells of interest. Such relatively simple experiments permit the analysis of changes in expression of a large number of genes simultaneously. This technology has the ability to reveal common patterns of gene expression across different samples. For this purpose, genes have to be grouped in an approach called cluster analysis into genes with similar profiles of activity. Such genes may have related functions or may be regulated by common mechanisms. The structured gene functional categorization database, Gene Ontology (GO), provides the opportunity to partition genes into functional classes.

A number of studies in which transcriptomes of aged tissue were compared with those of young tissue have now been performed, mostly with aging rodents, but also with other model organisms, such as nematodes and fruit flies. While definite conclusions must wait for improvements to the design of microarray experiments and for ways to optimally interpret results of such global analysis tools, some general conclusions can be drawn. First, it is clear that a wealth of genes undergo aging-related alterations in mRNA level, both up- and downregulation. Then, it appears that many rodent tissues as well as nematodes and flies are characterized by increases in expression of genes involved in stress responses at old age. For example, the results of a meta-analysis of microarray gene expression data obtained from *Caenorhabditis elegans* and *Drosophila melanogaster*

appeared to confirm that while most aging-related changes in gene expression are species specific, there is a shared adult-onset expression program of genes involved in mitochondrial metabolism, DNA repair, catabolism, peptidolysis, and cellular transport. There may also be tissue specificities. For example, in mouse liver and heart, genes involved in lipid metabolism were downregulated, but this is not the case for skeletal muscle, in which predominantly genes involved in biosynthesis and protein turnover were found to be downregulated. Since some of the results published were deficient with respect to their design, and the interpretation of such comprehensive gene expressional alterations is still in its infancy, it is impossible to draw more detailed conclusions at this point in time.

Consistent changes in gene expression could have a number of possible causes. First, the possibility cannot be excluded that they do result from stochastic damage to DNA and/or proteins interfering with proper gene regulation. For example, genes in mutational hot spot regions could undergo downregulation at a high frequency, which would eventually affect all cells in the tissue. Second, many expressional changes could be the result of stress induction, for example, by DNA or protein oxidative damage. Gene expressional changes occurring at old age may be responses to processes (e.g., hormonal secretion) already determined during development. Such cascades are apparently initiated because they offer some advantage at young age. At later ages they could cause problems and actually be responsible for a number of age-related disorders (e.g., loss of androgen sensitivity due to a decrease in the androgen receptor gene or heart failure due to hemodynamic stress as a consequence of a downregulation of proto-oncogene expression). Finally, some consistent changes in gene expression at old age may actually be programmed as part of the normal life history strategy. A speculative example in humans, explaining their long postreproductive life span, involves age-related gene expressional changes that help improve the capacity to transfer information to the younger generation.

Non-consistent Changes in Gene Expression

Non-consistent changes in gene expression during aging include the possibility of random gene activation or inactivation as a direct effect of stochastic gene mutations. Dominant (in proto-oncogenes) and recessive (in tumor suppressor genes) mutations play an important role in cancer initiation and progression, and in that sense they are also indirectly relevant to aging. There is some doubt with respect to the importance of such recessive and dominant gene mutations in aging. Assuming a spontaneous mutant frequency of 1×10^{-4} in old cells on average (as mentioned earlier, there are large differences from locus to locus), one cell in 10 000 will have lost a particular gene. Such defects by themselves are unlikely to influence any given cellular function. In reality, most cellular functions are based on several genes rather than just one, which would increase the DNA functional target size. However, the effects of random gene inactivation are likely to be buffered by complementation of function between different enzymatic pathways, metabolic cooperation between cells and redundancy at the cellular and tissue level. Hence, is it possible that genomic alterations cause cancer but do not directly influence organ and tissue functions? To address this question we need to know more about how our genome is organized and how the activities of our genes are controlled.

In pondering the possible effects of stochastic genome alterations on the cellular transcriptome it is important to realize that the DNA sequences comprising the protein coding segments of a gene are not the only regions in the genome with relevance to function. A simple organism such as *E. coli* has about 4000 protein-coding genes, comprising almost 90% of its total sequence. Humans and mice have realized their increased structural and functional complexity not by dramatically increasing the number of their protein-coding genes, but merely by increasing the size and diversity of their transcriptomes. In humans and mice, almost half of the genome is transcribed. It is assumed that this non-coding transcribed part of the genome has a regulatory role, which is greatly facilitated by the unique single-stranded nature of RNA. Therefore, while only few spontaneous DNA alterations are likely to hit protein-coding regions, many more would be expected to affect gene regulatory regions. Large genome rearrangements are especially likely to adversely affect normal gene expression, for example, as a result of a gene dose effect (partial haploidization), or position effects due to reshuffling of long-distance gene regulatory interactions. Hence, rather than drastic gene expression alterations, which are likely to be rare, one would expect a multitude of slight changes in the expression levels of many genes that will slowly lead to increased heterogeneity of the transcriptome in aging cell populations.

Any functional effect of a random DNA alteration would be enormously enhanced through epistatic effects. For example, it has been demonstrated that haploinsufficiency of genes encoding transcription factors increases the probability of stochastic activation or inactivation of its target genes, varying from

relative insensitivity to gene dosage to complete loss of expression. The functional impact of such random alterations is likely to be cell type and tissue dependent, in the context of individual genetic make-up and environmental conditions. Each tissue or cell type has a unique set of active functional modules (groups of proteins that work together to execute a function), the activity of which is primarily determined by transcriptional regulation of the genes involved, with individual genetic, environmental, and lifestyle factors as modifiers. Random DNA alterations are likely to be tissue specific, possibly as a consequence of tissue function and the tissue-specific utilization of genome maintenance systems. While there is a chronic lack of quantitative data on well-defined genetic lesions in different organs and tissues with age, it is conceivable that the stochastic accumulation of DNA alterations by itself is sufficient to cause aging. A conceivable scenario is that the gradual accumulation of DNA alterations in an aging tissue, affecting patterns of gene regulation in a stochastic manner, eventually results in a mosaic of cells, varying from cells that escaped significant damage to cells with severe dysfunctions, neoplastically transformed cells, and cells that are dying. Indeed, using immunohistochemical analysis methods (which are not quantitative), random loss of gene activities has been reported. For example, an age-related increase of cardiomyocytes without cytochrome *c* oxidase in the human heart has been reported and was suggested to be caused by mutation accumulation in mtDNA. An age-related increase in hepatocytes, which had reactivated the gene ornithine transcarbamoylase on the inactive X chromosome, has been observed in mouse liver and was ascribed to an age-related reduction in DNA methylation. Finally, in mouse brain, a random loss of cells expressing estrogen receptor-α was reported at old age. Such findings suggest age-related defects in DNA and gene expression that are stochastic in nature and may well reflect a broad loss of genome integrity with age.

Another type of stochastic alteration in gene expression involves errors made during RNA transcription or protein translation. In 1963, not long after the discovery of the fundamental mechanism of protein biosynthesis, Leslie E. Orgel proposed that cellular aging may well involve the accumulation of defective enzymes as a result of an inherent inaccuracy of the translational machinery. This is generally known as the 'error catastrophe theory of aging and longevity', based on Orgel's realization that the faulty RNA and DNA polymerases, also resulting from translational errors, would lead to an exponential increase of defects in protein, RNA, and DNA, causing the collapse of the cellular machinery for information transfer. This idea is not supported by experimental evidence, but it can be argued that errors are random, with each cell acquiring a unique set of errors. Since current technology is geared towards analyzing mixtures of cells rather than individual cells, we may simply be unable to detect error catastrophes.

Transcriptional errors could result from defective RNA editing, which involves the alteration of the sequence of nucleotides in the RNA after it has been transcribed from DNA but before it is translated into protein. This is a normal process, which – like alternative splicing – is a mechanism to increase the number of different proteins available without the need to increase the number of genes in the genome. However, it is conceivable that aging-related defects in this process could lead to gene expressional alterations. (The same would apply to alternative splicing.) However, there is no evidence for RNA editing of genes participating in information transfer. There is evidence for an age accumulation of aberrant transcripts due to dinucleotide loss during or after transcription of several genes, including the vasopressin gene, the β-amyloid precursor protein gene, and the ubiquitin B gene. In view of the role of ubiquitin in tagging proteins destined for proteasomal degradation, its inactivation would suggest that abnormal proteins accumulate with age, which is in keeping with the Orgel hypothesis.

Finally, there is now a tendency to develop and apply methods for the comprehensive analysis of transcriptomes and proteomes in single cells, either isolated from their tissue of origin or *in situ*. This is important to address the issues raised earlier, which typically involve different sets of aging-related alterations in different cells. However, it is of more general importance to abandon the concept of an average cell, which is not a good reflection of reality. Indeed, tissue samples are invariably composed of different cells and cell types. Since the cellular composition of tissues may greatly change with age, it is important to adapt current analysis methods to the reality of the single cell.

Changes in Genome Organization and Expression: A Synthesis

Aging has been considered both as a programmed series of events and a stochastic process of damage accumulation. The evolutionary theory of aging is a logical explanation of senescent deterioration and death and excludes a genetic program that actively causes aging as a purposeful process. Nevertheless, it cannot be denied that aging has programmatic

aspects, as indicated by the many observed consistent and reproducible changes in gene expression. It seems important to reconcile the stochastic with the programmatic aspect of aging.

Such a reconciliation has been done before, namely, for cancer. Indeed, stochastic somatic mutations are the ultimate cause of a series of events in which the cancer phenotype becomes increasingly more malignant and eventually shows a number of consistent alterations when compared with normal tissue. Many possible pathways that lead from the actual mutational event to the progressed tumor have been unraveled. Thus far, this has not been the case for aging. The reason is that an aged individual, much more than a progressed cancer, is essentially a mosaic of cells; each individual cell in a tissue bears a different pattern of 'scars.' It is more difficult to explain this in terms of consistent patterns of phenotypic changes observed in a typical aged individual, but it is nevertheless possible.

Based on the data presently available, it is possible to see the contours of the aging genotype as a prelude to the aging phenotype. Rather than a catalog of useful genes interspersed with functionless DNA, each chromosome is now viewed as a complex information organelle with sophisticated maintenance and control systems. In this concept of a genome, each part has a function, even its non-protein-coding parts. Such a holistic view of the genome would assign a variety of functions to non-coding DNA (e.g., structural maintenance, gene regulation).

Having extended the target for age-related changes to the whole genome rather than to a number of individual genes, it is also necessary to address the question of what kind of genetic changes are likely to play a role in determining the aging phenotype. In this context it is important to realize the single most striking characteristic of mammalian genomes: redundancy of genetic information. The simplest form of redundancy is copy number. With many gene copies present, the effect of some loss has no immediate adverse effects. This could explain, for example, the increased accumulation of DNA damage and mutations in mtDNA, which has ample redundancy to compensate for such loss of undamaged DNA template. Other forms of redundancy include the fact that more than one gene may specify a given cellular function. Finally, the existence of metabolic and other cellular networks allows the cell to accomplish similar endpoints through multiple overlapping pathways.

On the basis of these insights it is unrealistic to interpret the occurrence of changes in DNA and gene expression in the context of unique genes with unique effects. Instead, as pointed out by the late Bernard Strehler, a more useful background for understanding aging would be in terms of a gradual loss of functional informational redundancy. Rather than the inactivation of unique genes with unique functions, one should think of an initially tolerable loss of genome structural integrity, which would become manifest as a loss of phenotypic flexibility. Indeed, rather than some form of massive loss of essential genes, it is more likely that aging is accompanied by a slow but inexorable loss of genetic redundancy. This would undoubtedly lead to subtle scattered changes in gene expression and in the efficiency of gene regulation. Although primarily a stochastic process, this would rapidly take on some programmatic characteristics. The continuous randomization of the genome, by alterations in genes or in regions important in their regulation, unequivocally triggers the cell to respond. This response is programmatic and consists of species-specific stress and repair systems.

It would be premature to consider errors in genetic transactions, i.e., replication, repair, transcription, and translation, possibly driven by chemical damage to informational macromolecules, as the major cause of aging in all multicellular organisms. As a model, it does no more than account for some of the observations that have been made. Nevertheless, DNA damage as the original driver of a universal process of aging has some inherent logic. After all, damage to nucleic acids is the most ancient example of damage accumulation in the living world. Ever since the first replicators, genetic damage posed both a fundamental problem and an opportunity for living systems. A problem, because genetic damage essentially prevents the perpetuation of life, since it interferes with replication (and transcription); an opportunity, because it allows the generation of genetic variation through errors in replicating a damaged template, thereby facilitating evolutionary change. As we have seen, genetic stability in somatic cells of metazoa has become part of the trade-off between the allocation of scarce resources to either reproduction or somatic maintenance and is not expected to be maximized. While the concept of DNA damage as a main driver of aging is intuitively attractive, evolutionary logic dictates that other causes of aging would emerge over evolutionary time. Indeed, it is likely that age-related deterioration and functional decline is synchronized across different organismal functions. This would imply that given a molecular machinery of limited endurance, all bodily functions would adapt, and under such conditions a variety of harmful physiological late-life effects can be expected to develop.

Driving Behavior

J C Stutts, University of North Carolina, Chapel Hill, NC, USA

Glossary

Certified Driving Rehabilitation Specialist (CDRS) – A certified specialist, most often an occupational therapist, physical therapist, or driver education instructor, trained to provide driver assessment and rehabilitation services to persons with disabilities or functional impairments that may affect their ability to safely operate a motor vehicle.

Mobility – The ability to get from one place to another, whether inside the home (in-home mobility) or outside the home (out-of-home mobility).

National Household Travel Survey (formerly Nationwide Personal Transportation Survey) – A national survey of a representative sample of US households to collect data on the frequency, purpose, and mode of personal transportation, as well as other information on users of the transportation system. The survey is conducted by the US Department of Transportation Federal Highway Administration approximately every 5–7 years.

Transit/Public Transportation – Transportation by bus, rail, or other conveyance, either publicly or privately owned, providing general or special service to the general public on a regular and continuing basis. Excludes school buses or charter or sightseeing service.

Introduction

Driving, and the ability to travel outside the home, is an important component of independent daily living. More so than in any other developed nation, Americans are highly dependent on personal automobiles for getting places. This is as true for older adults as it is for young and middle-aged adults. Compared to the overall US population, the population of licensed drivers is aging at an even faster rate, especially with respect to women. While older adults are generally safe drivers based on crash rates per licensed driver, they have higher crash rates per mile traveled, and they are much more likely to die in their crashes. Declines in vision, cognition, and physical function can make older adults less safe drivers, and many older adults will outlive their ability to drive. Improvements to the driver, the roadway, and the

vehicle can all help to keep older adults driving safely longer. When stopping driving is inevitable, improved transportation options can enable older adults to retain mobility and independence and remain engaged in their communities.

Importance of Driving

People today are highly dependent on personal automobiles for travel outside their home. The National Household Travel Survey shows that nine out of ten trips people make are in cars. Most of the remaining are walking trips, while less than 2% involve the use of public transportation.

Older adults are as dependent on personal automobiles as younger age cohorts. With increasing age, however, they are less likely to be drivers and more likely to be passengers in vehicles (see **Figure 1**). Still, persons age 65 or older drive themselves for two-thirds of the trips they take, and even those 85 or older are drivers for over half of their trips.

Like the US population as a whole, older adults tend to live in places where distances to needed services and destinations are great and where alternative means of transportation are not available. In the United States, half of all older adults live in the suburbs, and over a fourth live in rural areas outside of suburbs. In such locations, driving is often the only option for getting to the grocery store, going to see a doctor, or visiting friends. Driving also allows older adults the option of continuing to work or participate in volunteer activities. The preference of most older adults to age in place has contributed to a rapid graying of the suburban population over the past decade and reinforces the importance of retaining a driver's license for as long as possible.

Driving has both practical and symbolic importance to older adults. Even when alternative transportation is available, most older adults are reluctant to surrender their license to drive. This is true even if a spouse is available for driving. For many older adults who have grown up with the automobile, the ability to drive, and having a driver's license in their billfold or purse, is closely tied to their sense of independence and autonomy. Driving is also the most convenient, flexible, and accessible means of meeting one's transportation needs. Studies have shown that compared to drivers, non-drivers make significantly fewer trips and are less likely to engage in activities outside the home.

According to the most recent National Household Travel Survey estimates, men, on average, drive just under 10 200 miles per year, while women drive 4800 miles per year. Both numbers have increased over the past two decades, but the increase has been greatest for men.

Changing Driver Demographics

The US population is aging, but the population of licensed drivers has been aging at an even faster pace. This is primarily because more women drive today than in the past. During the early and mid-1900s, it was quite common for women not to drive, so that today's cohort of older drivers excludes many women who never learned to drive and who never obtained a driver's license. In contrast, driving is almost universal among women today, so that future cohorts of older drivers are likely to include many more women. Adults age 65 or older currently constitute just under 13% of the overall US population and a slightly higher proportion of its licensed drivers. Over the

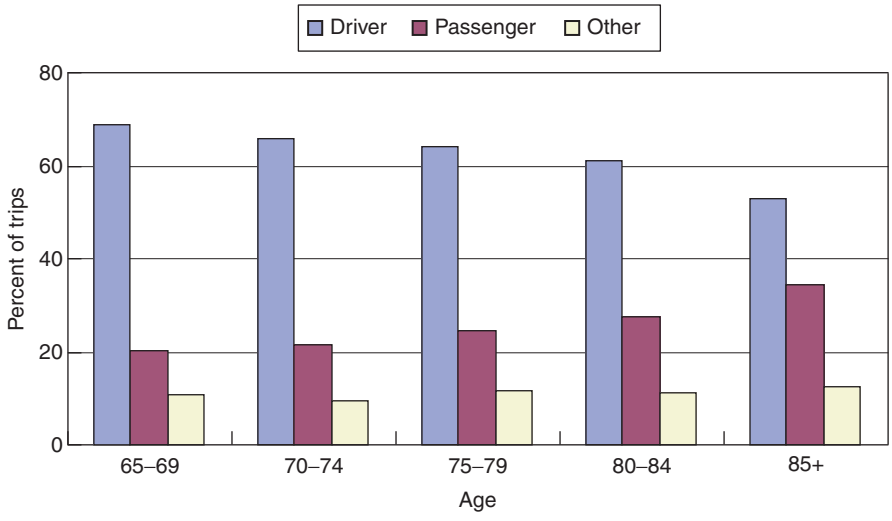

Figure 1 Travel mode of adults ages 65 and older. (From 2001 National Household Travel Survey data.)

next two decades, the proportion of licensed drivers aged 65+ is projected to swell to one in five.

Even though older women outnumber older men by a ratio of 3:2, women's and men's representation in the current licensed driver population is almost equal, due to the fact that women are more likely than men to stop driving. Although this may be less true of future cohorts of older women drivers, it is unlikely that the difference will be erased. **Figure 2** shows the percentage of men and women licensed within different age groups.

Older adults are less diverse racially and ethnically than the overall population, and licensed older adults are even less diverse. As minority populations age, it is anticipated that their share of the overall population over age 65 will grow, increasing from roughly 16% today to an estimated 27% by 2030. Just how this trend will manifest itself in the population of licensed older drivers is uncertain. Hispanic and Asian women, for example, are less likely than non-Hispanic White women to have a driver's license, a countertrend to the increase in licensure rates among older women. In addition, both minority men and women may have very different travel patterns and needs than the current cohort of predominantly non-Hispanic White older drivers.

Safety of Older Drivers

Motor vehicle crashes are the leading cause of injury death for persons ages 1–64; for adults age 65 or older, they are the second leading cause of injury death, behind falls. Based on number of crashes per licensed driver, older adults are among the safest drivers on the roadway. This is primarily because they drive many fewer miles than other drivers, and also because they tend to drive under safer conditions, e.g., during daylight hours and when traffic is less congested.

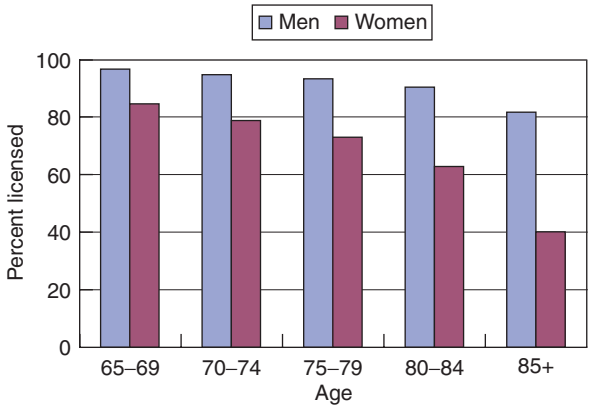

Figure 2 Percent of population licensed, by age and gender. (From US Department of Transportation, Federal Highway Administration, Traffic Statistics 2003, Table DL-20.)

When based upon number of miles driven, older drivers do exhibit higher crash rates, especially after age 75. This increase is largely attributed to age-related declines in functional capabilities important for safe driving. However, lower annual mileages and the fact that much of this mileage is accumulated on urban and suburban roadways are both likely to contribute to higher per mile crash rates.

The greatest concern, however, arises when one examines fatalities associated with involvement in a crash. Due to increased fragility that accompanies aging, older adults are much more likely to die as a result of a crash. This increased risk of dying in crashes of similar magnitude is apparent in crash data in adults as young as age 60 and increases steeply with age. As a result, both fatal crash involvements per licensed driver and fatal crashes per mile traveled are significantly higher for older drivers, especially those past the age of 75.

Figure 3 shows population-based motor vehicle crash deaths, differentiated by age and gender. Despite the fact that older adults are less likely than others to be involved in a crash, they are more likely to die from a crash. Population-based fatality rates are higher for men than for women, primarily because of the higher licensure rate among men, coupled with their higher annual mileages. The latter is especially true for the older adult population.

Along with their greater risk of dying in crashes, older drivers are also more likely to require admission to a hospital, to have longer hospital stays, and to experience more long-term disability, compared to younger drivers in crashes. However, older drivers are less likely than younger drivers to injure others in their crashes, including pedestrians. When older drivers crash, it is most often themselves who are injured.

The types of crashes in which older drivers are involved differ from those of younger drivers. Older drivers are more likely to crash at intersection locations and are especially overrepresented in crashes at signalized intersections when making a left-hand turn. They are also more likely than younger drivers to crash when entering or crossing a roadway at a stop sign location. Whereas younger drivers are more likely to be cited for speeding and following too closely, older drivers are more likely to be cited for failure to yield and disobeying a traffic signal.

Driving exposure likely plays a role in determining the crash patterns of older drivers. That is, because older adults accumulate a greater proportion of their driving time and miles in in-town and residential locations, one would expect a higher proportion of

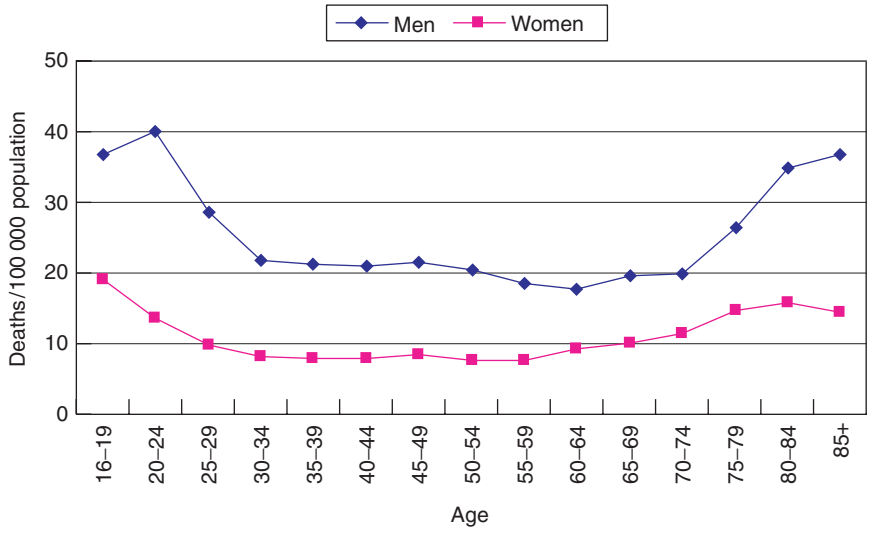

Figure 3 Motor vehicle crash deaths per 100 000 people by age and gender. (From Insurance Institute for Highway Safety, 2004.)

intersection collisions. However, declining functional abilities also increase older adults' risk of crashing. Problems in distinguishing target vehicles from surrounding clutter, judging closing speeds of approaching vehicles, attending to multiple events simultaneously, and quickly accelerating into traffic can all contribute to an increase in crash risk, especially when negotiating intersections.

In 2004, 15% of all persons killed in traffic crashes were age 65 or older. Taking into account projected increases in the older population, in the percentage of older adults (especially women) who are licensed, and in number of miles driven by both men and women, it has been estimated that by the year 2030 as many as one in four traffic fatalities will involve an older adult.

Age-Related Changes Affecting Driver Performance

Driving is a complex task, requiring the integration of a broad range of sensory, cognitive, and motor abilities. As people age, they are more likely to experience a variety of functional declines that can affect their ability to operate a motor vehicle safely. They are also more likely to have medical conditions and to take medications that can adversely affect driving performance. These changes contribute to their higher crash risks, as well as to a greater likelihood that they will be at fault in their crash.

Age-related changes in vision that can adversely affect driving performance include reduced visual acuity (both static and dynamic), decreased contrast sensitivity, reduced peripheral vision or other visual field losses, increased sensitivity to and poorer recovery from glare, decreased depth perception, and poor scotopic visual acuity or ability to see at night. Cataracts, macular degeneration, glaucoma, and diabetic retinopathy contribute to vision loss, and all are more prevalent in older populations.

Age-related changes in perception and cognition that have been linked to driving safety include attentional deficits (especially the ability to divide attention between two or more competing tasks), slower information processing and decision making, longer reaction times, poorer visuospatial skills, memory loss, and reduced judgment and decision-making abilities. For example, a person with impaired divided attention capabilities may be unable to attend to oncoming traffic, a pedestrian in the crosswalk, and the traffic signal when trying to negotiate a left turn at an intersection. Someone with poor visual search capabilities may not scan the driving environment to recognize potential driving hazards in time to react. Drivers must have knowledge of the rules of the road (e.g., which side of the road to drive on) and remember how to get to their destinations.

Alzheimer's disease and other progressive dementias are a particular concern for the older driver, since they inevitably imply a need to stop driving. Even in its early stages, dementia has been associated with an increase in crash risk. The question then becomes one of how much increased risk is too much. Since the patient's judgment is compromised, this decision often must be made by family members and other caregivers.

A final category of age-related changes that can affect driving safety relates to motor ability. Included in this category are muscle strength (e.g., the ability to apply brakes sharply and to grasp the steering

wheel), joint flexibility (e.g., the ability to turn the neck and look over the shoulder to check for oncoming traffic when merging into traffic), and general mobility (e.g., the ability to enter and exit the car). Arthritis can significantly compromise motor ability, as can Parkinson's disease and other neuromuscular disorders.

Driving ability can also be compromised by the medications used to treat conditions. Although this is true for persons of any age, it is especially important when considering the older driver, since older adults take many more medications, on average, than the rest of the population. Common medications that can raise red flags for older drivers include antidepressants, antihistamines, antihypertensives, antiparkinsonians, antipsychotics, benzodiazepines and other sedatives/anxiolytics, muscle relaxants, narcotic analgesics, and stimulants, including alcohol. Research has shown that the first few weeks of taking a newly prescribed medication can be an especially high-risk period for driving.

When evaluating an individual's fitness to drive, it is important that emphasis be placed on that person's actual functional abilities and likely prognosis, rather than on age or disease diagnosis per se. In driving, as with other areas of function, older adults exhibit tremendous individual variation.

Improving Safety for Older Drivers

Older drivers voluntarily engage in many practices that improve their driver performance and safety. They drive fewer miles, refrain from driving at nighttime or in heavy traffic, and drive in familiar areas and on familiar roadways. They also are less likely than others on the road to speed or to drive after consuming alcohol or drugs (except for prescribed medications). Older adults have the highest rates of seat belt usage, and they are less likely to engage in potentially distracting activities such as talking on cell phones or eating and drinking while driving. All of these practices help older adults remain safe behind the wheel.

In recent years, a variety of programs and initiatives have been undertaken to further assist older adults in continuing to drive as long as they safely can. For example, the American Medical Association collaborated with the National Highway Traffic Safety Administration to develop a guide to assist physicians in assessing a patient's fitness to drive and providing guidance for addressing identified problems. Some state driver licensing agencies have implemented increased driver screening at license renewals or have changed their driver license renewal policies pertaining to older adults. For example, states may require more frequent renewals for drivers past a certain age, require older adults to renew their licenses in person, or require that they pass certain vision tests or take a behind-the-wheel driving test.

For drivers facing medical problems and/or functional losses that can impair driving performance, certified driving rehabilitation specialists or other specially trained professionals can work with them to maximize their safe driving potential. This would typically involve a thorough clinical evaluation to identify the extent of functional loss, followed by a behind-the-wheel driving assessment. When warranted, driver rehabilitation services may be offered to help remediate or compensate for identified losses. For example, the driving rehabilitation specialist may recommend adaptive vehicle equipment or may work with the driver to improve certain driving techniques or skills. Interactive driving simulators are another option for helping older adults develop safe driving practices.

Improving driver performance is one way to help older adults remain safe on the road. However, it is just one part of a comprehensive approach to enhancing older driver safety and mobility. Equally important is improving the roadway and driving environment to better accommodate the special needs of older adults. Roadway improvements have the added benefit of increasing safety for all drivers, including those whose alertness may be temporarily impaired by drowsiness, distraction, or the consumption of medications, alcohol, or other drugs.

During the time that many of our nation's roadways were being built and standards were being set for everything from pavement markings to road signage to street lighting, there were very few older drivers, so that the 'design driver' was someone much younger. Today, however, it is becoming increasingly important to design our streets and highways with a much older population in mind. New standards and guidelines have been published specifically to address the needs of an aging population. Wider and brighter lane lines, more overhead street lighting, advance street name signs, larger and brighter signs, and protected left turn signals (left turn arrows) are just a few examples of roadway changes that can make it easier and safer for older adults to continue driving. In addition to benefiting older drivers, these changes should improve safety for all drivers, including drivers of any age with functional limitations as well as those who may be temporarily impaired by drowsiness, alcohol, or even the distraction of a cell phone conversation.

A final area of focus for improving safety for older drivers is the vehicle itself. Due to their increased fragility, older adults are particularly likely to benefit

from design changes to improve vehicle crashworthiness. Safety belts and front and side airbags help to protect older adults from injury and death when involved in a crash – even more so than for younger drivers. In the future, cars are likely to have safety belts with mechanical force limiters that keep the belt force from exceeding a predetermined threshold, thus avoiding some of the chest injuries encountered by some older drivers involved in crashes. There may also be smarter air bags that automatically adjust to inflate with less force for smaller and more fragile bodies.

Technologies such as in-vehicle communication systems can automatically notify emergency services in the event of a crash or other medical emergency, getting needed medical attention to the scene more quickly. Future cars may also come equipped with collision avoidance systems that will automatically sound an alarm or stop the car if approaching another vehicle too closely or quickly.

Many adults are already benefiting from adaptive equipment installed in their vehicles. Some examples include a knob attached to the steering wheel to make gripping and turning the wheel easier, pedal extensions so that a shorter person does not have to sit so close to the steering wheel, and seats that swivel to make it easier for someone to enter and exit the vehicle. Although these are all relatively simple interventions, they can make driving safer, easier, and more enjoyable for some older adults.

In summary, improving safety for older road users is best accomplished through a comprehensive program that simultaneously addresses the driver, the roadway, and the vehicle. Although significant progress has been made in all three areas, much remains to be accomplished.

Driving Cessation

Given the important role that personal automobiles continue to play in meeting transportation needs as people age, it is not surprising that stopping driving and surrendering one's license can have significant negative consequences. These consequences primarily affect older adults themselves, but can also extend to family members and other caregivers, as well as to the larger society. There are many factors affecting both the decision to stop driving and the consequences of stopping. In addition, stopping driving is not always an all or nothing situation: for many older adults, it is a gradual process, and for some it can involve intermixed periods of driving and non-driving. All of this makes driving cessation a difficult topic to study.

Age and gender are both significantly associated with stopping driving: as people age, they are less likely to drive, and older women are much more likely to stop driving than older men. These results were reflected in **Figure 1**, showing trip mode by driver age and gender. Declining health has also been linked to driving cessation. However, while certain medical conditions such as arthritis, Parkinson's, and stroke or heart attack may cause some older adults to give up driving, many others continue to drive, and poor health can sometimes even encourage driving if it makes it more difficult for people to walk or to access alternative forms of transportation.

In general, problems with vision (cataract, macular degeneration) and neurological disorders are most strongly linked to driving cessation. Women are more likely than men to stop driving for non-health reasons, including a general lack of confidence in their driving and a greater willingness to rely on others (including husbands) for getting places. For both men and women, socioeconomic factors can also play an important role, as can a ready access to alternative forms of transportation.

For many older adults, driving cessation is a gradual process, brought about at least in part by a reduced need or desire to go places. However, reduced trips outside the home are also an important consequence of driving cessation. Studies have consistently shown that non-drivers are much less likely than drivers to travel outside the home, especially for non-essential trips such as visiting friends, attending religious services, or participating in volunteer activities. Often it is difficult to distinguish those who have reduced driving because they have less need or desire to go places from those who go fewer places because they are unable or unwilling to drive.

This blurring of cause and effect is also true for other adverse outcomes linked to driving cessation. A very important question that many have tried to answer is whether driving cessation contributes, either directly or indirectly, to a decline in functional status and health. For some older adults, giving up driving leads to social isolation and increased depression symptoms. Former drivers may experience a loss of independence, a drop in self-esteem, and decreased life satisfaction. This is true even if alternative transportation (e.g., a spouse still drives) is available, and regardless of the reason for stopping driving. The end result can be a downward spiral of negative events that ultimately leaves the individual in a poorer state of health.

Fortunately, most individuals do adjust to giving up the keys, even if they are not entirely happy with their situation. Much depends on the extent to which they remain in control and are able to continue to

meet their transportation needs, whether this be through rides from family members or friends, use of public transit and/or paratransit, or, depending upon their health, walking or bicycling.

Driving Alternatives

An estimated one in five American adults age 65 or older does not drive. This number includes many former drivers who have outlived their ability to drive. Women are especially likely to outlive their ability to drive, since they both live longer and stop driving earlier than men. For men and women, the need to travel does not stop when they stop driving; they still need to go to the grocery store, to the pharmacy, and to their doctor, and they still enjoy visiting with friends and participating in a variety of activities outside their homes. A growing number also hold jobs and require transportation to continue working or volunteering.

To meet their travel needs, older non-driving adults most often rely on family members and friends to drive them places. However, a range of transportation options is needed to ensure that all older adults are able to access the goods and services they require and can continue to live full and active lives. In addition to traditional fixed route buses, older adults benefit from flexible route buses, paratransit services, public dial-a-ride systems, taxis, and specialized medical and other transportation services for seniors. These options vary in the level of support services they provide, e.g., whether the individual is picked up at a bus stop, in front of the home, or escorted from the home. They also vary greatly in terms of cost, both to the individual and to the provider. Because older adults differ in their functional capabilities, their living situations, and their experiences and preferences, there is no one-size-fits-all transportation solution.

A growing number of communities offer supplemental transportation programs for older and disabled adults. These programs are intended to complement existing public transit and paratransit services, serving older and/or disabled adults who are no longer able to walk to a bus stop, need help getting into or out of a van, cannot afford taxis, or simply want to go places they cannot get to on a bus. Most of these programs are run by non-profit organizations (churches, hospitals, senior centers, agencies on aging, volunteer groups, etc.), and many target rural and suburban areas not normally serviced by transit. Typically, they are funded by a combination of grants and fees or donations from riders, and often they are able to provide rides at no cost or for a small flat rate fee. Perhaps most importantly, they are able to provide senior-friendly service, escorting seniors to and from their homes, transporting them in vans or autos that are often driven by senior volunteers themselves, and generally mimicking the comfort, convenience, and flexibility of traveling in one's own car.

Currently less than 2% of all trips taken by older adults involve public transit, in part because bus and other transit services typically are not available in the suburbs and rural areas where older people live, but also because transit does not adequately serve the special needs of older persons. Bus service in particular could be made more attractive to seniors if it provided some of the amenities of private transportation programs such as more flexible routing, drivers trained in assisting older adults, and service to destinations frequented by seniors. Buses themselves can be made more accessible to seniors, for example, by having wider and lower entries.

Next to riding in cars, the greatest number of trips taken by older adults are shorter trips made on foot. Walking, however, can be a dangerous activity for older adults: although they comprise 13% of the population, over 20% of pedestrian fatalities in 2003 were adults age 65 or older. Wider sidewalks, improved street lighting, pedestrian signals that accommodate an older person's slower walking speed, and benches that allow for stopping and resting are just a few of the amenities that contribute to a safer and more attractive walking environment for older adults.

Beyond safe and attractive places for walking, it is also important that destinations (shops, grocery stores, churches, etc.) be located close to residential areas where older people live. This, in turn, requires that communities adopt mixed-use zoning and other planning practices conducive to shorter trip distances. It also requires that people plan ahead for the possibility of not driving, choosing to live in places where they will be able to remain mobile even if they can no longer drive. Doing so greatly facilitates an older person's ability to age in place.

Both transportation choices and walkable communities are vital components of a recent movement to create more livable communities. Such environments allow older adults to remain independent and engaged in their community while aging in place. However, their benefits extend to community residents of all ages.

Future Directions

Given the projected increase in the number of older drivers and the importance of driving for maintaining mobility and quality of life, future research and

programmatic efforts should focus on improving safety for older road users as well as on providing viable alternatives to driving for meeting everyday transportation needs. A comprehensive approach to improving safety that addresses the driver, the roadway, and the vehicle is required. With respect to the driver, further research is needed to identify functional abilities important for the safe operation of motor vehicles, ways to assess these abilities in the broader population, and approaches for assisting drivers in compensating for identified losses. When remediation is not an option, as may be the case with dementia and other cognitive disorders, research is needed on how best to assist older adults in transitioning from driving to alternative forms of transportation.

With respect to the roadway, much work has already been done in identifying improvements that should benefit older road users. The main challenge here lies in evaluating the effectiveness of the recommended changes and encouraging state and local transportation departments to incorporate the changes into their highway maintenance and traffic operation programs.

As is the case with roadways, vehicle design has only fairly recently begun to take into account the special needs of older drivers. As new designs and technologies are considered, it will be important to include older adults in the development process. In addition, older adults should be educated about those vehicle features that are most important to their safety as drivers and car occupants.

Continued research is also needed to elucidate the importance of driving to the health and well-being of older adults, actions older adults can take to extend their safe driving years, and ways to minimize the negative consequences of driving cessation. An important area of research and program development is how to provide an alternative to driving that is acceptable to older adults but that does not unduly burden society. It is likely that a combination of alternatives will be needed with support from both the public and private sectors.

The preceding represent only some of the areas in which continued research and programmatic activities are needed to enable older adults to continue to drive as late in life as possible and to access alternative transportation when driving is no longer an option. Given the importance of driving to older adults and the increased risks faced by older drivers, there is obviously considerable work to be accomplished in preparation for a rapidly aging driving population.

Glossary

Snitching a Sandwich – Restructuring institutions or incentives to make the system work more smoothly than it did before.

Mandatory Spending – Spending not directly controlled through the annual appropriations process.

Discretionary Spending – Spending resulting from annual congressional acts of appropriation.

Entitlement Programs – Federal programs providing benefits to individuals, businesses or units of government that apply for payments and meet eligibility requirements established by law.

Introduction

The expansion and contraction of social programs for older people and for the population in general occur historically. Changes in direction have often been ascribed to political and ideological movements, but the powerful role of economics in creating, expanding, or contracting social programs must also be considered.

When the direction of public policies changes, it is often ascribed to changes in ideology or politics. Of course, ideology and politics do play a part, but frequently lost in this consideration is the powerful role of economics in creating, expanding, or contracting social programs. The primary insight that economics has to offer is often summed up in the phrase 'there is no such thing as a free lunch.' This insight, often presented as a law of economics, permeates all policy issues; it is a law that individuals and societies do their best to hide from or at least to avoid facing. But they cannot.

Luckily, the law has an ancillary that lessens the force of the law and allows public policy to work: 'once in a while you can snitch a sandwich.' It may be said that this ancillary is the foundation of public policy, and good public policy essentially means snitching sandwiches.

'Snitching a sandwich' involves restructuring institutions or incentives to make the system work more smoothly than it did before. For example, paying tolls only one way on bridges where the majority of people return over a connected toll bridge makes traffic flow better. Integrating road pricing for certain highly congested roads, as was done in London, yields a similar net gain. Instituting tradable permits for pollution reduction, as in the Kyoto Accord, is another example. The list goes on. All of these programs offer some gains and some costs, but by almost all observers' accounts, the gains exceed the costs.

Unfortunately, government programs are not often sold as sandwich snatching, but instead are sold as free lunches, which promises too much. Social programs are often presented or justified by hiding the costs and/or overselling the benefits. Some would argue that this has been the case with the United States government's role in providing economic security for the elderly. This policy is indeed an example of a snitched sandwich, but because it was presented as a free lunch, it will pose serious problems for the government in coming decades.

The reason for the problem is the interaction of economic growth and entitlement provision. When an economy is growing quickly, future entitlements can be provided out of that growth. When the economy is growing more slowly, it is more difficult to provide for those entitlements; demand outruns supply, which aggravates the problem of scarcity.

Scarcity, with all of its social, political, and economic consequences and implications, is such a persuasive concept in the social sciences and social philosophy that it has been frequently taken for granted or treated as an assumption. Although the competition for, and distribution of, material and human resources obviously influence human behavior and public policies, the notion of scarcity as such is often ignored during discussions of public policy

changes. Frequently, suggestions about policies have been branded as 'political.'

While the political and legal forces in society do indeed influence the types of human behavior and the directions of public policies, over the coming decades economic factors will likely predominate due to pressure placed on the fiscal capacity of the government. Politics may be the vehicle for change in policies, but the underlying fiscal capacity of government drives politics and policies, dictating whether legislators support a program's expansion or its contraction. In short, political moves and changes in public policies in one direction or another are heavily influenced by economic consideration and are tempered by social and political philosophies.

Social Programs to Help the Elderly

It is difficult to see someone suffer when others have plenty. Civilized societies deplore that scenario and establish programs to lessen that suffering. That is the underlying basis of many government programs that provide economic security for the elderly; it makes good policy sense, which is why the Social Security program is strongly supported by a large majority of the population. Most social programs have been positive additions to society by most people's standards; they are examples of snitching sandwiches, which is what good public policy is all about. But they are not free lunches. Because they are presented as free lunches, without cost, the snitched sandwich they actually provide is much smaller than it could be. The problem is that the programs have been oversold on the benefits, and costs have been hidden or pushed aside, to be faced later, which leads to decisions about programs being made without the appropriate balancing of revenues and outlays.

The central problem with government programs for the elderly is that entitlements have been emphasized but costs have been downplayed and pushed aside. Initially, when these programs were established, many people were paying in but there were few recipients, resulting in the government appearing more generous than it would have had the costs been faced directly. The programs were sold to society by creating a sense of future entitlements among the population without fully accounting for the costs of those entitlements.

The created entitlements were both implicit and explicit. The explicit entitlements sometimes, but not always, showed up on the government budget; the implicit ones did not show up on the budget, but they were entitlements just the same. The problem is a 'real' problem, not a 'financial' one. Trust funds, or individual investment accounts, will not solve the problem unless they either include a way to get a larger percentage of real resources from workers in the future or reduce the benefits that are promised for the future. Most political discourse shies away from discussing the degree to which the entitlements will have to be cut, or how greater resources will have to be gathered to meet promised entitlements. Ideally, these programs would have been structured as 'steady state sustainable' – that is, structured so that steady state expenditures and revenues would be neutral in response to changing economic and demographic conditions over time. Steady state sustainability should be a central consideration of policies, and embedding that consideration in the design of the system will lead to a better balancing of obligations to pay the entitlements and the ability to pay them.

Because social programs have been designed without many, if any, built-in adjustment mechanisms, the programs have been expanded too much in good times and will have to be cut in bad times. Political considerations will push aside facing these problems until they are at crisis levels and must be faced. For example, in the mid-1990s there was a move to face these problems; at that time both the Republican-dominated Congress and the Democratic President advocated cuts in Medicare and Medicaid due to the slowing economy and the declining fiscal capacity of government. However, in the late 1990s economic growth increased, and the willingness of either side to consider the issues started to wane.

In 2001 economic growth slowed, but by then the political will was lost. Instead of facing up to the difficult issues, both sides essentially pushed them aside, and jointly expanded the Medicare program to include prescription drug benefits, enacted in 2003, even as the forecasted trillions of dollars of surplus metamorphosed into large projected budget deficits, making it even more difficult to deal with the future imbalance between expected entitlements and expected responsibilities to pay for those entitlements, responsibilities captured in the concept of fiscal capacity of the government.

Fiscal Capacity of the Government

Fiscal Capacity in the 1960s

During the 25 years between 1940 and 1965, both the young-age and old-age dependency ratios were rising. Whereas the young-age dependency ratio increased from 0.582 (i.e., 582 persons under the age of 20 per 1000 persons between the ages of 20 and 64) in 1940, to 0.764 in 1965, the old-age dependency ratio rose from 0.116 (i.e., 116 persons age 65 or over per 1000 persons between the ages of 20 and 64) in 1940 to 0.182 in 1965. As a consequence, the

total dependency ratios increased from 0.698 in 1940 to 0.946 in 1965 (see Appendix A).

The concurrent increase in old-age and young-age dependency ratios implied substantial need for social programs for both young and old dependants. In the 1960s, when the demand for resources for social programs was rising, the fiscal capacity of the federal government was able to accommodate the needs. By the time the recession of 1960–61 ended in early 1961, there was an unprecedented, continuous expansion of the economy through the end of 1969. Therefore, it was no accident that the Great Society programs, such as antipoverty measures, Medicare, and Medicaid, came into existence by the mid-1960s.

Fiscal Capacity since the 1970s

The federal budget has been in continual deficit in all the years since 1969, except 1998 through 2001. In the 1970s, budget deficits averaged some $35 billion per year. In the 1980s, the average annual budget deficit reached a much higher level of approximately $150 billion. From 1990 through 1997, the average annual budget deficit was higher yet, at $190 billion (see **Table 1**). Under these fiscally restrictive circumstances, not only were new social programs virtually precluded from being enacted, but also existing programs were faced with cutbacks.

In the late 1990s, reversing the trend of some 30 years, budget deficits were replaced by surpluses as a result of tax and spending policies conducive to economic growth. Thus, from 1998 through 2001, budget surpluses averaged nearly $160 billion per year (see **Table 1**). This development was, however, short lived. Tax cuts, spending increases, and slower growth soon eliminated the surpluses and returned the government to large deficits, averaging some $315 billion a year from 2002 to 2004. These deficits are expected to continue into the foreseeable future. Short-term projections indicate that the estimated deficits for 2005 and 2006 will be more than $400 billion per year (see **Table 1**).

Table 1 Budget deficit or surplus, 1970–2006 (in billions of U.S. dollars)

Year	*Annual deficit*	*Year*	*Annual deficit*
1970	−2.8	1989	−152.5
1971	−23.0	1990	−221.4
1972	−23.4	1991	−269.2
1973	−14.9	1992	−290.4
1974	−6.1	1993	−255.1
1975	−53.2	1994	−203.2

Balancing the Budget

Public opinion polls show that, in the abstract, 80% of Americans favor balancing the budget. However, that percentage falls precipitously if budget balancing means cuts in Social Security or Medicare, or increases in taxes.

Strong economic arguments can be made for moving toward a balanced budget. A major reason to lower the deficit is to increase national savings, which in turn increases national investment in physical and human capital, which in turn increases productivity growth and raises the standard of living. A second reason is for the government to retain significant borrowing capacity for emergencies. But the real issue is not balancing the budget, but rather balancing entitlements, including implicit ones, with responsibilities to pay for them. Budgets do not necessarily capture this larger sense of balance (and are often designed or manipulated to hide that larger sense of balance) and thus can be misleading.

Although balancing entitlements may be a wise course, specifying how it should be done is another matter. In the political climate of the early twenty-first century, military expenditures cannot be cut and taxes cannot be raised. This puts almost all the pressure of entitlement reductions on Medicare and Medicaid because as of 2005, they comprise one-third of the spending of the 10 largest entitlement programs and are projected to assume greater importance in future years. However, the need to balance entitlements comes at a time when health-care programs for the economic security of older people are becoming ever more important (see Appendix B).

Entitlement Programs and the Budget

Federal outlays may be divided into two categories: mandatory and discretionary. Mandatory spending refers to spending not directly controlled through the annual appropriations process. Discretionary spending, on the other hand, results from annual congressional acts of appropriation.

The bulk of mandatory spending consists of entitlement programs – federal programs providing

Table 2 The 10 largest entitlement programs in the United States, 2002

Program	*Entitlement spending (%)*
Social Security	37.8
Medicare	21.2
Medicaid (federal share)	12.3
Federal civilian retirement and disability	4.7
Unemployment compensation	4.2
Military retirement	2.9
Earned income and child tax credit	2.7
Supplemental Security Income (SSI)	2.6
Family support payments (federal share)	2.1
Veteran's benefits	2.1
Total	**92.7**

benefits to individuals, businesses, or units of government that apply for payments and meet the eligibility requirements established by law. Nonentitlement forms of mandatory spending include net interest on the national debt and deposit insurance.

The federal budget contains over 400 entitlements and other mandatory spending accounts. The largest 10 programs, listed in **Table 2**, accounted for nearly 93% of entitlement spending in fiscal year 2002.

Federal entitlement spending has been rising significantly faster than the overall economy. Some believe that explosive growth in entitlement programs is a very recent phenomenon, but entitlement growth was actually most pronounced from 1967 to 1976, when Medicare and Medicaid began and grew, the food stamp program became a national program, the Supplemental Security Income (SSI) program was established, and major increases in Social Security benefits (the most prominent of which was the cost-of-living adjustment) went into effect.

Social Security, Medicare, and Medicaid account for more than 70% of the 10 largest entitlement programs listed in **Table 2**. From 1993 to 2003, the annual rates of growth in Social Security outlays averaged 4.5% of the gross domestic product (GDP), according to the Congressional Budget Office (2005). This rate is projected to rise to 5.6% per year during 2005 through 2015. In contrast, Medicare and Medicaid will become greater financial issues. While the annual growth rates averaged 6.7% for Medicare from 1993 to 2003, the program is projected to grow at 9% a year from 2005 to 2015. For Medicaid, the average annual rate of growth was 7.8% during the years from 1993 to 2003, and the same rate of annual growth is projected for this program from 2005 to 2015.

By comparison, the consumer price index (CPI) grew at an annual rate of 2.5% from 1993 to 2003, and it is projected to rise only 2.2% annually from 2005 to 2015. So all three entitlement programs have been growing and are projected to grow at rates much faster than general inflation.

Furthermore, the annual average rate of growth in the GDP from 1993 to 2003 was 5.1%, and this rate is projected to rise at a lower rate of 4.9% per year for the period 2005 to 2015. So, again, all three entitlement programs have been growing and are projected to grow at rates much higher than the rates at which the economy has grown and is expected to grow in the next decade.

These trends imply increasingly larger claims on the federal budget to meet the obligatory payments under these programs, which, in turn, implies greater influence of economic consideration on policy decision making.

Economics and Social Programs

The 'no free lunch' law is essentially an expression of the phenomenon of scarcity, the fundamental issue with which economics is wrestling. Economists start from the basic notion that our ability to satisfy human wants is limited. At any one time, an economy has only a limited command over the human and material resources with which to produce goods and services. On the other hand, human wants for goods and services seem limitless. Therefore, one of the central issues is how best to satisfy unlimited human wants with limited available resources.

Scarcity, as the basic fact of economic life, pervades all societies, regardless of their political orientation or levels of economic development. Societies simply do not have all the resources needed to produce all the goods and services their members want. This fundamental constraint is as true in a rich country as it is in a poor one; this same constraint exists in countries with different ideologies. Although scarcity always imposes the ultimate constraint, the condition is more acute in poor countries than in rich ones.

Because society does not have all the material and non-material resources with which to produce all the goods and services wanted, choices must be made. Economic reasoning leads one to recognize the trade-off: if one wants more of one thing, one must be prepared to have less of another thing, or a little less of everything. What one must give up in order to get something else is known as the opportunity-cost concept of cost.

The opportunity-cost concept applies to all aspects of life. It embodies economic forces, the forces of scarcity, as noted earlier. In order to allocate scarce resources and scarce commodities, some socially agreed-upon criteria must be established.

When a society allows economic forces to work through the market relatively freely, they are called

market forces. Market forces deal with scarcity of goods and services by means of their relative prices. Market forces have been captured in the symbolism of the 'invisible hand,' which is the price mechanism in which the rise and fall of prices guide people's decisions in buying and selling.

Societies cannot choose to allow economic forces to operate, because they are always operating. Societies can choose only whether to allow market forces to predominate. Other forces play a major role in deciding whether market forces will operate. Social and historical forces can prevent the invisible hand from working in an unfettered manner, and the way in which entitlements and the responsibilities to fund them play out will depend on how these social and historical forces interact with economic forces.

The Policy Challenge Ahead

Although most policy discussion in 2005 has focused on the Social Security program, Medicare and Medicaid programs will be under greater budgetary scrutiny over the coming decades. With advances in health care and growth in the older population, especially among the oldest-old (generally defined as those 85 or older), the medical needs of the elderly will be growing almost exponentially, in terms of both medicines and hospital care. Furthermore, long-term care for many of the elderly population needs to be provided. Will the needed resources be made available? Economics and the fiscal capacity of the government will be central in the debate. Society must decide whether it should increase the percentage of real resources it gets from workers or decrease the real resources it provides to the elderly, or some combination of these choices. Somehow, society must balance these choices by facing up to the 'no free lunch' law. Doing so will not be easy, but it is a policy challenge that society must face.

We suspect the options chosen will be some combination of tax increases and benefits decreases, and possibly some borrowing (which will solve the current problem, by pushing the responsibility issue off to the future). Economics does not dictate which of these solutions is the best; it simply says that some combination of them must be implemented. Our hope is that, in doing so, government snitches as many sandwiches as it can.

Appendix A: Dependency Ratios and Dependency Costs

Because the future financing of entitlement programs (relying on taxes from workers, typically younger persons, to pay benefits to recipients, typically older persons) depends considerably on the number of workers in relation to retirees, dependency ratios serve as useful approximate indices of costs. This section provides a discussion of dependency ratios and dependency costs. **Table 3** shows dependency ratios in the United States in selected years from 1940 through 2080.

The old-age dependency ratio is projected to rise in the future. Assuming a fertility rate of 1.9 (referring to the average number of children a woman gives birth to in her lifetime), this ratio will increase from

Table 3 Dependency ratios in the United States in selected years from 1940 to 2080

Year	*Old-age dependency ratio*[a]	*Young-age dependency ratio*[b]	*Total dependency ratio*[c]
1940[d]	0.116	0.582	0.698
1945[d]	0.124	0.557	0.681
1950	0.138	0.587	0.725
1955	0.157	0.657	0.814
1960	0.173	0.732	0.905
1965	0.182	0.765	0.947
1970	0.185	0.713	0.898
1975	0.190	0.638	0.828
1980	0.195	0.555	0.750
1985	0.201	0.505	0.706
1990	0.209	0.489	0.698
1995	0.213	0.495	0.708
2000	0.208	0.485	0.693
2005	0.203	0.464	0.667
2010	0.210	0.446	0.656
2015	0.235	0.437	0.672
2020	0.271	0.436	0.707
2025	0.313	0.439	0.752
2030	0.350	0.443	0.793
2035	0.368	0.441	0.809
2040	0.373	0.435	0.808
2045	0.376	0.430	0.806
2050	0.381	0.430	0.811
2055	0.389	0.430	0.819
2060	0.401	0.431	0.832
2065	0.409	0.430	0.839
2070	0.419	0.429	0.848
2075	0.425	0.428	0.853
2080	0.431	0.428	0.859

[b] The number of persons under age 20 divided by the number of those aged 20–64.

[c] The sum of the number of persons aged 65 and over and the number of those under age 20, divided by the number of those aged 20–64.

[d] From special tabulations by the Office of the Actuary, courtesy of Felicite Bell and Stephen C. Goss, January 15, 1992.

0.214 in 1995 to 0.394 in 2060, or an 84% increase for the 75-year period. Such an increase implies an immense rise in the tax burden on the working population in order to finance public expenditures for the old.

However, in addition to increasing the old-age dependency ratio, low fertility rates will result in fewer young persons and thus in a declining young-age dependency ratio. This ratio is projected to decrease from 0.494 in 1995 to 0.417 in 2055, a decline of about 15.6%.

Because workers are called on to support both old and young dependants, the total dependency ratio suggests the total support burden on the working population. The total dependency ratio is projected to rise from 0.708 in 1995 to 0.811 in 2060, a 14.5% increase over the 75-year period. A rise or decline in the total dependency ratio tends to increase or decrease the total tax burden, but the extent of change depends on the relative costs of supporting the old versus the young and on the degree to which the old-age and young-age dependency ratios change. Moreover, the ability and willingness of the working population to bear such a burden are also important considerations.

The relative costs of supporting the old versus supporting the young are crucial factors in determining what effect the changing dependency ratios will have on society's support burden. The average cost of the old dependant is believed by some to be approximately three times that of the young dependant based on a study from the mid-1970s. It was estimated that $3701 was spent for each aged person under government programs compared to an estimated $1215 per young dependant. This three-to-one cost figure was arrived at for the old-age dependants by dividing the population over 64 into the estimated total government program expenditures for the old; for the young dependants, by dividing the population under 18 into the estimated total government program expenditures for this population.

That procedure for arriving at the average cost per dependant produces what should properly be called the 'per-assumed-dependant cost' in contrast to the 'per-actual-recipient cost.' The per-assumed-dependant cost is a definitional one, because all persons in a given age category are included in the figure that is divided into the program expenditures in the numerator. By contrast, the alternate method – per-actual-recipient cost – is a more appropriate measure, because it counts only those in the dependant age group who actually receive program expenditures. The assumed-dependant cost approach conceptually underestimates the support cost for the young who receive benefits under government programs, because relatively more young persons than old persons do not receive benefits, yet in the calculation all persons are included as if they were recipients. Moreover, the three-to-one cost relationship was based on estimates that define young dependants as being under age 18; they thus leave out most of the expenditures for higher education.

However, the per-actual-recipient cost is difficult to obtain for several reasons. Many government programs do not have published (or in some cases, even unpublished) data on age and other characteristics of recipients. Also, calculations of per recipient cost are more difficult because a number of persons are recipients of several government programs. In addition, in-kind programs such as public housing are not easy to measure. A lack of time-series data on recipient characteristics under various government programs poses yet another impediment to analyzing the historical development in dependency ratios and dependency costs.

As mentioned previously, the change in the tax burden resulting from the change in the total dependency ratio also depends upon the degree to which the old and young dependency ratios change. In the preceding discussion of the per-assumed-dependant cost as opposed to the per-actual-recipient cost, the old dependants were defined as the population over 64 and the young dependants as the population under 18. Obviously, if the old group is defined to begin at age 62 or 68, or the young category at age 20 or 22, the dependency ratios and the associated dependency costs will change.

As also mentioned, the ability and willingness of the working population to bear the support cost are important considerations. The ability of the working population to support dependants is influenced by such factors as the level of earnings, the labor force participation rates, and the unemployment rate, and these factors are in turn influenced by the level of productivity, the rate of economic growth, the state of demand, and the like. Furthermore, the overall financial ability of the working population to bear the support cost will be affected by private as well as public expenditures on behalf of the old and the young dependants.

Finally, the total support cost for all dependants would have to include dependants in the middle-age group in addition to the old and young dependants. Expenditures for middle-aged dependants include a number of government programs covering unemployment, disability, medical care, public assistance, and housing subsidies.

Appendix B: A Supply-and-Demand View of Economic Security

Economic well-being is generally discussed in reference to several different criteria, such as income, wealth, and consumption. Over the years, the gap has narrowed between the elderly and non-elderly insofar as income is concerned. Some conclude that the elderly have reached the same level of economic security as the non-elderly. However, even if the elderly have gained income parity with the non-elderly in terms of poverty rates, one may not thereby infer that their economic security levels are the same.

Economic security is a broader concept than income security. A person is concerned not only with the acquisition of income and assets, but also with their retention and disposal. It is well known, for example, that the elderly, when compared to the non-elderly, are at greater risk and must budget more for medical and personal care services despite Medicare and Medicaid. But potentially significant expenditures for health care are not generally given explicit consideration in assessments of the economic status of the elderly versus the non-elderly. A more accurate assessment of economic security, therefore, requires that current income, accumulated wealth, and consumption expenditures be considered from the standpoint of supply and demand. In that light, income and wealth represent the supply of resources, and consumption represents the demand on those resources.

Before arriving at the demand-and-supply view of economic security, we briefly discuss each of the three criteria, income, wealth, and consumption, that have been commonly used to assess economic well-being.

Income

The income status of the elderly has substantially improved in the last several decades, but income status often is discussed by reference to the incidence of poverty. In 1967, for example, the poverty rate among the elderly (age 65 +) was 30%, whereas the poverty rate among those aged 18–64 was 10%. Since then, those rates have converged; they stood at 10.2% for those 65 and over versus 10.8% among those 18 to 64 in 2003. In terms of per capita income, statistics show that the elderly have reached the relative standing of the non-elderly over several decades.

Wealth

Another criterion is ownership of accumulated wealth, or more precisely, net worth, which is the value of assets minus the value of liabilities. In terms of wealth, the elderly also fare well. Wealth holdings by persons 65 and older is the highest among all age groups except those between 55 and 64 years old. Some conclude, therefore, that the elderly are better off than the non-elderly, but a good deal of their net worth is in traditionally illiquid forms. Combining illiquid and liquid assets in order to measure economic capacity implies converting illiquid assets into readily spendable income. Home equity, for example, represents a significant part of net worth, but how meaningful is it to impute income from home equity?

Some see the increasing use of home equity lines of credit among middle-aged homeowners as a harbinger of their future comfort with reverse mortgages. But encumbered home equity in middle age is likely to reduce the equity that may be needed for retirement income. This is an important issue, because home equity can be a resource with which to finance consumption in old age. It is especially significant because home equity is increasingly seen as a viable resource to help finance future long-term care.

Consumption

The third criterion uses consumption expenditures to infer economic well-being. Neither income nor wealth is a good measure, some argue. They propose that consumption is a superior measure of economic well-being. For example, in 1986, the ratio of income between the affluent and the poor was 16 to 1. That is, a vast difference existed between the poor and the affluent: if a poor person had $1.00, the affluent person had $16.00. But in terms of per-consumer-unit spending, they would infer that life at the bottom of the American money-income distribution was only moderately less attractive than at the middle, and about half as attractive as at the top. According to per-consumer-unit spending, for every $1.00 spent by the poor, the middle class spent $1.29 and the affluent spent $2.31. Seen in terms of consumption, therefore, the difference between rich and poor was much narrower than in terms of income.

The difference between poor and rich was even smaller when considering consumer expenditures on the four essential necessities, food, shelter, apparel, and medical care. For every $1.00 spent by the poor on these necessities, the middle class spent $1.14 and the affluent spent $1.82. This view must not be taken lightly.

Of the five income distribution quintiles, only the top two showed an excess of incomes over expenditures. All three lower quintiles showed expenditures

over income; not all of the members of these quintiles may be expected to be dissavers (i.e., those disposing of accumulated savings). Perhaps the humorist Artemus Ward anticipated the consumption measure when he said, "Let us all be happy and live within our means, even if we have to borrow the money to do so." (Mardy Grothe (2004) *Oxymoronica: Paradoxical Wit and Wisdom from History's Greatest Wordsmiths*, p. 33. New York: Harper Collins). Consumption as a measure of economic well-being can be misleading.

How well-off are the elderly under this measure? The same data source, the Consumer Expenditures Survey for 1986 conducted by the Bureau of Labor Statistics, provided information for seven age groups. Per person spending on the four basics by the oldest two age groups (65–74 and 75+) was higher than that by all five younger groups. Were the elderly enjoying a higher measure of economic welfare than the non-elderly?

Per person spending on food, shelter, and apparel, with minor exceptions, was remarkably similar among all age groups. Health care, however, accounted for about 18% of the four basics for the 65–74 age group and more than 25% of the four basics for the 75+ group, compared with 9% for the 45–54 age group and less than 7% for all the younger age groups. That the elderly group spends more of its total budget on health care is not surprising. But the inference from using consumption as a measure is that if the elderly spend less on health care, their economic well-being would be lower. Conversely, the younger age groups can improve their economic well-being by spending more on health care. The irony is apparent.

Supply of and Demand for Resources

In summary, income, wealth, and consumption may be viewed from the standpoint of supply and demand. As stated earlier, income and wealth represent the supply of resources, and consumption represents demand on those resources. In order to measure economic well-being, therefore, income, wealth, and consumption should be included. Even if the elderly have achieved income and wealth levels on par with the non-elderly, it does not follow that their economic security is the same as younger groups, because older people are faced with an actual or potential higher demand on resources for health care, including long-term care.

Health-care expenditures represent what could be called a first claim on income. When the income and net worth of the elderly and non-elderly are equal, then the supply of resources is the same for both groups. After the first claim is deducted from these resources, however, an obvious disparity in resources results between the elderly and non-elderly groups.

It is difficult to exaggerate the importance of health care to older Americans. A Greek physician, Herophilus 335–280 B.C., (who is called the Father of Anatomy) said it well, "To lose one's health renders science null, art inglorious, strength effortless, wealth useless and eloquence powerless" (Massengill, 1943, p. 28).

Education and Aging

R J Manheimer, University of North Carolina, Asheville, NC, USA

Glossary

Formal Learning – Education sponsored by the state or private institutions with parallel interests and goals directly related to societal needs, usually terminating in a degree or credential.

Informal Learning – The lifelong process by which individuals accumulate knowledge, skills, attitudes, and insights from daily experience and exposure to the environment.

Non-formal Learning – Organized systematic, educational activity carried on outside the framework of the formal system, such as adult literacy or occupational training.

Introduction

Adult education includes the trilogy of formal, non-formal, and informal learning arrangements. The first, usually terminating in a degree or credential, is typically provided by an education and training system sponsored by the state or private institutions with parallel interests and goals directly related to societal needs. The second, non-formal, is usually defined as organized, systematic, educational activity carried on outside the framework of the formal system; examples include agricultural extension, adult literacy, and occupational training. The third, informal education, is an all-inclusive term referring to the lifelong process by which individuals accumulate knowledge, skills, attitudes, and insights from daily experience and exposure to the environment. The modifier adult emphasizes personal agency and signifies educational activities voluntarily chosen by people who have attained a stage of maturity and self-responsibility that makes them important decision makers in what and how they choose to learn.

Older adult education, a field within adult education that emerged during the middle of the twentieth century, is generally of the non-formal type. Conditions that have encouraged older adult education to flower include the lengthening of the life course, improved health and economic status among retirement-aged adults, higher rates of prior education among those reaching later life, the rising popularity of the notion of lifelong learning (whether formal or non-formal) as both a personal and public good, developmental and neurological theories advancing the appropriateness and the benefits of continued learning, and greater opportunities for learning and teaching in mid- and later life through such diverse organizations as colleges and universities, churches, synagogues and mosques, senior centers, public libraries, day health centers, hospitals, unions, and residential housing groups. Purposes of education for midlife and older adults cover a spectrum from life enrichment (often liberal arts focused) to skills enhancement and job retraining.

In a global perspective, education for midlife and older adults varies from country to country depending on economic and social conditions, traditional roles played by educational institutions, and prospects for innovation. In the UK, lifelong learning is also known as recurrent education, and on the Continent and within the United Nations Educational, Scientific and Cultural Organization (UNESCO), the term permanent education is frequently used. The phrase older adults' learning is sometimes favored by UK researchers who want to include independent learners and those who learn through voluntary service activities. Educational gerontology is both the study of how, where, and why mature adults learn and the study of how gerontologists themselves are educated.

Historical Perspectives

Adult Education Precedents

The roots of adult education programs as we know them today have precedents in both formal and informal arrangement that can be traced back several centuries. For example, American inventor and Constitutional founding father Benjamin Franklin established a weekly study group of 12 people who met to discuss community and social issues. With its origins in 1727, Junto (Latin for meeting) combined intellectual and social aims (members held annual dinner parties) and required its members to pose questions and periodically prepare and read an essay of their own making. Junto continued for 30 years and inspired numerous spin-off groups, including the first subscription library in the United States and the American Philosophical Society. Today, we would call Franklin's Junto a study circle. Though not directly derived from Junto, many lifelong learning programs in the United States, Canada, and Europe have chosen this method that combines the self-responsibility of

learners helping to educate one another in a socially conducive atmosphere as key elements of the educational experience.

Almost 100 years later, in 1826, a lecture series, the Lyceum (in ancient tradition, an association providing public lectures, concerts, and entertainment), was established to introduce adult citizens residing in small American towns and rural areas to scholarly knowledge. These lectures were an attempt to raise the educational levels of citizens who had not completed an elementary-level education. Approximately 50 years later, the Methodist Episcopal Church established a residential learning retreat or village on the shores of Lake Chautauqua in New York State to provide training for Sunday school teachers, enlightenment for church members, and the basis for a national series of tent performances that took place over several decades. Fairly nondenominational in character, the Chautauqua movement helped to introduce religious studies, liberal arts education, and the performing arts to residents in small towns across the country.

In England, adult education has even earlier roots in religious education but became secular and more widespread as industrialization fed the demand for popular democracy. Landmarks include the development of the Mechanics' Institutes in the early nineteenth century and the Workers' Educational Association and local adult education in the early twentieth century.

The idea that universities should play a major role in diffusing knowledge throughout society led in 1880s to the concept of university extension, an idea borrowed from England. At first offered through public libraries and at Chautauqua, the idea took root more successfully on college campuses to which the educated public was invited. Eventually, university extension would include correspondence teaching, lecture services, summer and evening school classes, and conferences, institutes, short-course activities, and even broadcasting services.

Adult education programs flourished in many other countries in the early decades of the nineteenth century, with the residential people's colleges (Danish *folkhjskoler*) and evening schools (*aftenskole*) gaining popularity throughout Scandinavia, particularly in promotion of civic literacy for participation in the new democracies and knowledge of discoveries arising in science and technology, and to foster a stronger sense of national identity through study and appreciation of the myths and sagas of the northern lands.

Though not residential, community colleges in the United States began almost 100 years ago when they were known as junior colleges. The establishment of hundreds of new community colleges throughout the United States in the 1960s further opened access to continued learning for adults of all ages; they covered topics ranging from mechanical and industrial skills to the acquisition of foreign languages and computer literacy.

The British Open University, an early form of distance learning using televised courses, went public in 1970, providing access to students of all ages who might formerly have been deemed unqualified. Over 200 000 people had graduated from the OU by 1998. Many other UK countries have also established OU type programs. Now the Internet has largely supplanted television as the medium of instruction and communication.

Since the middle of the twentieth century, workplace- and corporate-sponsored education has grown at an enormous rate, with participation rates surpassing even those of colleges and universities. With the advent of the Internet, distance education has spawned limitless access to adult education of all types, ranging from degree programs to online courses for personal enrichment. The Internet has supplemented the public library in giving the independent learner a powerful tool for self-directed, individual learning.

Mid-twentieth Century Emergence of Education for Midlife and Older Adults

The idea that midlife and older adults might benefit from and enjoy opportunities to initiate or renew their learning experiences built on these early innovations, though in many cases existing models were independently rediscovered. Critical additional factors can be traced to three sources: emerging theories in developmental psychology that traced personal growth well into later life, theoretical and ideological shifts in the field of gerontology, and related attitudinal shifts in the growing field of adult education.

Foremost among developmental psychologists who had a profound impact on theories of aging and later life was Eric Erikson, whose 1950 publication, *Childhood and Society*, contained what became the famous eight epigenetic stages of the life course, each stage holding the promise of a resolution to an inherent crisis of development formed by opposing tendencies. Erikson's midlife and older adult stages, generativity (nurturing that which outlives the self) and integrity or wisdom (seeing the larger patterns of life and accepting one's finitude), supported the value of continued learning. Combining this heightened appreciation for ongoing adult development with geriatrician Robert Butler's hypothesis of a universal life review process characterized by the tendency to reminisce in

later life, we see the implied rationale for learning opportunities that would promote what Abraham Maslow called (following Aristotle) self-actualization. In fact, reminiscence groups became highly popular educational activities among seniors in the 1960s and 1970s, and these in turn led to autobiographical writing and living history drama groups and other personal narrative-based forms of creative expression and performance. If midlife adults were to stay generative and older adults to find wisdom, opportunities for continued education could enhance these goals.

In the field of gerontology, the early 1960s saw the beginning of the pendulum swing from regarding aging mainly as a matter of irreversible decline in physical and cognitive functioning (the so-called failure model of aging) to a more optimistic emphasis on the strengths gained through aging. The Kansas City Study of Adult Life, one of the first large-scale demographic surveys of the aging population, culminated in the disengagement theory of aging, articulated in the 1961 publication *Growing Old*. The authors, Elaine Cumming and William E. Henry, found that as people withdrew from the workforce in retirement, they began a process of pulling back from social encounters and activities as society itself showed diminishing expectations and demands on older people. The study and theory were met with a sharp critique from scholars and researchers who argued that disengagement was not a natural process but was socially constructed and based on ignorance, stereotypes, negative self-esteem, and policies that pushed older people to the periphery of society. They countered with the activity theory of aging, which promoted the view that if older people were adequately stimulated and encouraged to stay physically and mentally active, they would show renewed vitality and contributive value. Education would certainly qualify, they argued, as one way for mature adults to remain active and productive citizens.

The field of adult education also began to stir as early as 1949 when a Committee on Education for Aging was established under the Department of Adult Education of the National Education Association (NEA). In 1951, this committee became part of the Adult Education Association of the United States. For the first time in U.S. history, this committee developed a descriptive book on educational programming for older adult learners, *Education for Later Maturity: A Handbook*.

The 1960s and early 1970s saw adult education further influenced by developments in gerontology and public policy on aging driven by various senior advocacy organizations. For example, as an outgrowth of the 1971 White House Conference on Aging, the Administration on Aging awarded a 2-year grant to the American Association of Community and Junior Colleges to explore ways for community colleges to highlight the needs of older persons and contribute to their quality of life. In addition, several community college systems tapped new funds made available through Title I of the Higher Education Act of 1965 and Title III of the Older Americans Act of 1965 to hire coordinators or part-time program directors to design and implement courses for seniors.

Still, the burgeoning lifelong learning movement should not be viewed as linear in development. The prevailing thinking in this period tended to regard the role of seniors' education as providing knowledge and skills to cope successfully with the problematic aspects of growing older. According to David A. Peterson, (1983: 219) "educational programs emphasized the crisis of adjustment to retirement and the need for outside assistance to overcome the trauma of role change." This approach corresponds to what Harry R. Moody characterized as the social service model of older adult education. As such, aging was still regarded as a problem that education could help to ameliorate. The pendulum might have been swinging, but it quivered in its arcing.

During the 1950s and 1960s, only a few educational administrators considered offering educational programs for older adults. The few programs in operation were experimental in nature, with no research base. In the early 1960s, gerontological researchers devoted considerable energy to examining links between aging, intelligence, and memory. The combined emphasis on the youth culture and research on age-related cognitive declines continued to have a negative impact upon attitudes toward older adult educational programs.

Though the 1971 White House Conference on Aging highlighted the value of education for older adults, it produced few direct results. Independent of federal legislation, a multitude of new educational programs for seniors arose in senior centers, community colleges, universities, community schools, and churches and synagogues. These programs expanded greatly in the mid-1970s and 1980s. During this period, funding from the National Endowment for the Arts (NEA) and National Endowment for the Humanities (NEH) helped support numerous educational programs, access to programs and performances, and creative works by and about older adults.

Older Adult Education and the Concept of the Third Age

For British sociologist Peter Laslett, who focused his research on the postindustrial societies of Britain and the United States, the retirement age generation of

the late 1950s to early 1960s was the first to possess the discretionary time, good health, and sufficiency of funds to determine how its members would occupy themselves in a continuing active stage, or Third Age (with dependency typically demarcating the Fourth Age). By the 1960s, unprecedented numbers of retirement-aged individuals were able to participate in leisure activities such as domestic and international travel, cultivation of hobbies, and outdoor recreation. They also had more time to volunteer, and did so in record numbers. Rising rates of high school and college completion were also attributes of this emerging age cohort. And since prior education has been the chief determinant of demand for continued learning in the later years, a growing segment of people in the Third Age represented a significant growth area for lifelong learning.

In fact, Laslett borrowed the phrase Third Age from the French L'Université du Troisième Age (University of the Third Age, or U3A), a name first proposed by Pierre Vellas, who, in 1973, founded the first U3A at the University of Toulouse. Vellas recognized that the combined vitality and longevity of many older persons in France made ideal circumstances for French universities to promote a combination of instruction for seniors, research emphasizing the well elderly, and opportunities for personal development. U3A programs subsequently spread across Europe, Britain, Australia, Canada, and, to a lesser extent, the United States. The French model featured university affiliation and instruction performed largely by university faculty. This accorded with 1968 legislation in France that required universities to provide more community education.

When the U3A idea crossed the channel this more formal, hierarchical approach was rejected and instead a self-help orientation was chosen. Consequently, British U3As are generally not affiliated with institutions of higher education and take a more egalitarian approach to teaching through use of peer study group leaders and member governance. Laslett gave the motto to the ethos of U3As in the UK: "Those who teach shall also learn and those who learn shall also teach." This French-British divergence is one among numerous examples of how political circumstances and cultural ideology have influenced the development of older learner programs.

Laslett thought that the newfound period of relative leisure must be met with opportunities for people of all classes to deepen their sense of culture and to participate in educational programs that would enable them to appreciate art, history, philosophy, music, and other subjects that were valuable to experience simply for the sake of learning itself. Without educational engagement, the Third Age would, said Laslett (1991: 170), "turn out to be indolence indefinite."

One question challenging advocates of learning in later life was the extent to which people could learn new ideas and skills and attain further stages in moral and intellectual development.

Older Person's Capacity to Learn

Research on Cognitive and Intellectual Functioning

Parallel to the emergence of older adult education meriting the attention of adult educators and gerontologists were changes in appraisal of cognitive functioning among older people. Although focus on the decline of older persons' intellectual powers characterized early research, studies conducted since the late 1960s pointed to stability in cognitive functioning over time. While recognizing decrements in some areas, researchers also emphasized older learners' relatively undiminished capacities and highlighted significant shifts in the type of intellectual abilities that may come with aging.

For example, K. Warner Schaie questioned the assumption that older people tend to function less well intellectually than younger people. He contended that all older adults do not exhibit decline. Sociologists Matilda White Riley and John Riley undertook a series of studies on intellectual functioning that showed improvement with age under certain conditions. They found continuity in intellectual functioning when life situations continued to be stimulating and challenging and when people had opportunities to use their skills and had access to educational opportunities.

Psychologist Gisela Labouvie-Vief pointed out that the early phase of geropsychology was heavily influenced by the prevailing decrement model of aging. Research presumed that physical and mental processes manifested "primary, universal, and irreversible biological concomitants of aging." But as a developmental model began to influence the direction of research, geropsychologists began to more carefully differentiate gains and losses in cognitive functioning. Hence, psychologists applied the distinction between two forms of intelligence: crystallized (derived from experience) and fluid (more biologically determined). Although the latter may show marked signs of decline with aging, the former shows less decline and longer stability. Later, the distinction between competence and performance was used to indicate differences in intellectual functioning.

Labouvie-Vief developed a trade-off view of cognitive development as a process in which some forms of intellectual integration are dissolved while

new forms of integration occur, particularly around adaptation to pragmatic necessities.

In recent years an abundance of research has focused on the role that continued intellectual stimulation and social connections make possible. Several important studies such as those conducted by Gene Cohen have shown that education and participation in the arts may actually help to delay the onset of dementia, counteract depression and social isolation, and promote the growth of new brain cells and connectivity (dendrite growth). The popular use it or lose it hypothesis has, in some cases, turned participation in continued learning into something of a cultural imperative and, at times, a scare tactic to get seniors to sign up for educational programs. There is a danger here, pointed out by Thomas Cole in his pathfinding *The Journey of Life: A Cultural History of Aging in America*, of replacing one stereotype (the frail, disengaged elder) with another (the robust, successful elder). Suggesting such direct causality between continued learning and prevention of dementia might lead to blaming the victim, as if dementia were the result of sheer indolence.

Uniqueness of Older Learners

As mentioned earlier, the tendency to reminisce as we grow older was regarded by many gerontologists as a pathology until Robert Butler showed it could be a highly positive way of integrating experiences and coming to terms with the past. As such, life review became a method for group therapy, creative writing groups, and as a source for living history drama. Some researchers went even further. They described elements of wisdom and creativity in the life review process. Not only were older adults still capable of learning and expressing themselves, but because of their treasure house of past experience, they could also be ideal students and could make excellent teachers.

If later life is regarded as a unique developmental stage with its own special tasks and opportunities, then education in the later years may be regarded as distinct from adult education. For example, Moody has argued that, unique to old age, some older learners are capable of understanding philosophical and spiritual matters that only a lifetime of experience could make possible. Just when does a person reach that threshold of unique insight? It is not a matter of chronology (how old you are) but of maturity, argued Moody.

Other researchers such as Virginia Clayton and James Birren have focused on the search for wisdom in later life as a unique characteristic of older persons. Old age, being the last stage of the life course, may be viewed as an attempt to explore the meaning of one's experiences and to integrate an understanding of these experiences or, as Schopenhauer put it, "see life as a whole." Many gerontologists and adult educators believe that self-actualization, the full realization of one's potential, should be the ultimate goal of every older adult educational program. The wisdom quest in later life would eventually be regarded as a spiritual quest and suggests another Third Age-triggered learning disposition.

Spirituality, Aging, and Lifelong Learning

Swedish sociologist Lars Tornstam proposed a theory of gerotranscendence, the notion that with age comes a radically different life outlook reflecting a cosmological shift in perception. Tornstam argued that when activity theory eclipsed disengagement theory something of vital importance was lost. Disengagement theorists highlighted an inward reflective tendency emerging in later life that denoted a change in how older people saw the world and their places within it. The problem, said Tornstam, was that these older individuals had limited resources for cultivating the new perspective that was emerging in their lives. Activity theory, he argued, for all the good it did, tended to devalue the spiritual growth of the older person, equating religiosity with social withdrawal.

From his large-scale quantitative and qualitative research – a Scandinavian version of the Kansas City study – Tornstam also found a pronounced age-related change. His subjects accepted a more nuanced sense of right and wrong, had greater tolerance for ambiguity and paradox in moral reasoning, and were able to detach themselves from the narrower cultural views of their earlier decades. In short, these individuals experienced "a new feeling of cosmic communion with the spirit of the universe," an age-triggered self-transformation that Tornstam called gerotranscendence. The Swedish sociologist argued that this was a naturally occurring transition that would be more strikingly evident if our societies (including their religious institutions) gave older people sufficient encouragement and support to make this spiritual passage to a unique late life outlook.

It is around the same time that Tornstam's articles started appearing in American journals that the spirituality and aging movement began to grow in the United States. The New York State-based Omega Institute started organizing Conscious Aging conferences in 1992 with a host of high-profile figures such as counterculture guru and spiritual author Baba Ram Dass (who had recently discovered his own aging and written a book about it), Jewish mystic

Rabbi Zalman Schechter-Shalomi, social activist and Gray Panthers founder Maggie Kuhn, and other visionaries who championed the role of both the secularly wise, politically active senior and the spiritual elder. Though Tornstam was not part of this cast of conscious aging advocates, his research-based theory and Erikson's model of development supported the views espoused at these conclaves.

In the field of aging, concurrent with this movement, the American Society on Aging (ASA) launched a new constituent unit, the Forum on Religion, Spirituality and Aging (FORSA), which grew quickly in membership. From Rabbi Schachter-Shalomi's book, *From Age-ing to Sage-ing*, a number of Spiritual Eldering Institutes were established to do what Tornstam suggested was missing, namely, to nurture older people's capacity for reaching a new level of development so that they might play new roles in society as spiritual mentors to younger generations.

Scholars, advocates, and religious leaders did not cause people to suddenly want to become spiritual elders. This trend reflected a worldwide revival of religious interest, if not zeal, that also swept into the older population and into the field of aging. The trend has also had a profound impact on expanding mainstream older learner programs to include training in yoga, meditation, and Tai Chi and numerous courses on comparative religion, mysticism, Chinese medicine, ancient and modern mythology, and so on.

Compensation and Learning Styles

Paul Baltes and his colleagues at the Max Planck Institute for Neurological Research in Berlin further supported the value of education. They examined compensatory strategies people employ as they grow older. The Berlin group distinguished between two types of mental activity: (1) the biologically shaped hardware of the mind, which operates the speed and accuracy of memory, sensory input, ability to make distinctions and comparisons, and ability to put things into categories (also termed cognitive mechanics), and (2) the software of the mind, more a product of culture, upbringing, and environment, including reading and writing skills, self-knowledge, and coping skills (which Baltes calls cognitive pragmatics).

Baltes and his associates found that although older persons' memory capacity would increase if they participated in memory training techniques, they would still not reach the level of younger persons who received the same training. They concluded that the hardware of the mind does show a decline with age. But when it came to real-life problem-solving tests – for example, counseling a threatened suicide or advising a 15-year-old girl who wants to get married – they found no major differences among those 30–70 years of age. In fact, those above age 60 were as likely to rank among the top 20% of skilled 'wisdom performers' as younger adults.

The Berlin researchers coined the infamous phrase selective optimization with compensation, to describe how older people offset slowing down in some areas of cognitive and physical skill. He cites the example of Arthur Rubinstein, the famous pianist, who concertized well into his later years. Asked how he managed to sustain his career so successfully, Rubinstein commented that he limited his repertoire to fewer pieces (selection), practiced longer (optimization), and played slow movement slower so that faster movements sounded comparatively faster (compensation). Similar examples abound in literature and film about aging competitive athletes who learn to use brain as well as brawn. They draw on hard-earned experience to strategize and outfox their opponents, reserving their strength for exactly the right moment, rather than relying on endurance and speed. Similarly, many people develop tools and learning strategies such as mnemonics (memory techniques) to aid in their acquisition and retention of information.

Motives of Older Learners

Instrumental-Expressive Continuum

Considerable research has centered on the dichotomous pair of terms expressive and instrumental to characterize learner motives. Learning for its own sake has been classified as expressive, whereas learning directed toward some further outcome or external objective is said to be instrumental. Similarly, the term enrichment is often used to describe learning undertaken to enhance personal growth, while skill-building or skill acquisition-motivated learning suggests some practical application. Educational leaders and administrators often must determine the mix or balance of these two types of learning goals in order to satisfy their existing or potential clientele. However, the distinction is not hard and fast, since the same learner may hold both motives simultaneously, for example, signing up for a computer literacy course in order to keep up with the times (enrichment), to start a correspondence with distant grandchildren, and to make birthday cards (the latter two qualifying as skill building).

Problem of Determining Motives

The majority of surveys of older learners concur that the top-ranked motive of those enrolled in liberal

arts-focused educational programs is intellectual stimulation, a seemingly expressive or enrichment orientation. But this term may cover a wide variety of motives, ranging from the desire to increase one's appreciation of literature, philosophy, or history to the mental challenge of learning a foreign language. Intellectual stimulation may mean attending an international affairs lecture series to ensure that one is a better-informed voter. Though all these motives, both expressive and instrumental, qualify as intellectual stimulation, the term covers more than it reveals.

The scholarly literature on the motives of older learner is fraught with contradictory findings. This may be a function of the context in which the studies were conducted. For example, studies conducted at senior centers in the early 1970s were likely to yield instrumental orientations because the types of programs offered tended to deal with coping issues and hobbies. By contrast, studies of participation in the travel-learning program Elderhostel tended to produce the opposite results, as most people chose those courses for intellectual and personal enhancement. Researchers Paul Wirtz and Ivan Charner pointed out that the hypothesized instrumental-expressive continuum used in various studies may force participants to choose among artificial categories. Hence, inconsistent findings may be the result of utilizing scales that lack psychometric validity. Something as subjective as intellectual stimulation may not lend itself to quantitative research tools, the method used in most of the studies.

The National Retired Teachers Association (NRTA), then a division of AARP, took another approach to older learners' motives in 2000. The AARP Survey on Lifelong Learning was conducted via telephone and online with 1019 individuals, focusing on "how and why people over 50 learn about new things." Consequently, the findings emphasized learning behaviors such as acquiring information from newspapers, magazines, books and journals, and online resources (half the respondents responded online). Overwhelmingly (93%), respondents said they wanted to learn "to keep up with what's going on in the world," for "spiritual or personal growth" (92%), and "for the simple joy of learning something new" (91%). The study included a highly diverse population, so it was not surprising that only a small percentage (15%) strongly preferred a formal teacher–classroom situation while a majority (60%) strongly preferred an informal, hands-on approach.

Life Tasks, Needs, and Wants

Louis Lowy and Darlene O'Connor found a useful way to resolve the contradictions and ambiguities of the older learner motivations when they constructed a matrix combining instrumental and expressive orientations with need categories (e.g., coping, contributive, influencing) developed by Howard McClusky. They produced a holistic overview that would integrate a wide range and mix of learner goals and orientations.

Reviews of seniors' educational motives show that, like adult learners in general, seniors exhibit a wide diversity of needs, interests, and wants that may be conditioned by socioeconomic and educational backgrounds, the institutional setting where programs are offered, and the existence or availability of opportunities.

Empowerment and Socialization

Another motive or consequence of participation in forms of continuing education is empowerment. Older learners may find peer support, heightened self-esteem, a renewed sense of efficacy, and political solidarity through involvement with peers in educational settings. Numerous studies of creative and life history writing groups, especially those primarily involving women, reveal that finding one's voice and being able to tell one's story may have enormously liberating consequence. Validating one's life experience can be an important part of continued learning.

Many informal types of lifelong learning depend on participants playing volunteer roles as teachers, committee members, and part-time administrators. The entire enterprise may constitute a learning community so that members gain a new venue for socializing and making new friends through the valued affinity of education.

Adding to and supporting the role of education for building volunteerism among seniors, the work of gerontologists such as Sandra Cusack and Wendy Thompson in Canada has demonstrated the value of leadership development programs for older adults.

Emancipation and empowerment are major frameworks for British experts writing about older learner programs. Many of them lament the absence of the national government's role in providing resources for lifelong learning for older adults, regarding it as another example of the marginalization of mature individuals.

Older Adult Education Programs and Public Policies Since 1960

By the time of the early 1960s, the impact of longer life expectancy and steady decline in the average age of retirement in the United States and other postindustrial societies yielded noticeable growth in the

population of retired citizens. Many adult education leaders as well as gerontologist asserted that seniors needed the knowledge and skills to cope successfully with the problematic aspects of growing older. Another common and related rationale of the period was that continued mental stimulation in the context of social learning would help prevent premature institutionalization. While in many countries the rise of older learner programs was independent of government and public policy, new forms of lifelong learning reflect predominant cultural attitudes and changes in health care and social support mechanisms such as public and private pensions. A few examples help to illustrate this point.

Normalization and Tuition-free Programs

When, in the 1970s, the normalization movement in the United States brought the mass exodus of thousands of patients from mental hospitals across America, discharging them to the newly established community-based care network of mental health centers, a parallel mainstreaming attempt occurred in the realm of older adult education. Some 39 state legislatures enacted bills to allow people over age 65 (or 62, depending on the state) to enroll, tuition-free, in public colleges and universities as space permitted. Rather than segregating older people, argued advocates, society should be finding ways to integrate them with other generations. In most cases, this legislation was gratuitous since no funding was attached. Consequently, most colleges and universities did little to publicize the mandated opportunity and few of the empty seats were taken. There were, however, a few notable exceptions. Because of undergraduate enrollment shortfalls of the period, several universities such as Syracuse and Western Washington State University actually established dorm space for senior housing on the campus and (e.g., at WWSU's Fairhaven College) promoted intergenerational learning opportunities. However, these experiments were short lived. In contrast, many community college systems did find state funds available to partner up with senior centers to deliver classes on site. This innovative model lasted perhaps a decade until economic pressures and the demands of other needy groups (e.g., immigrants, Vietnam veterans, women returning to school) gradually squeezed out these programs.

Changing Attitudes Reflected in the New Nomenclature

Cross-fertilization between scholars and researchers who advocated the value of education as a catalyst promoting development in later life (the humanistic gerontology school), and innovative leaders in adult education such as Malcolm Knowles, whose adopted use of the term andragogy highlighted the uniqueness of adult learner-centered education, generated the radically new view that older learner programs could serve as engines of lifelong development and even social change. Extending traditional psychological developmental life stage theories into new, uncharted territory, these programs would reflect the claim that growth did not end with the consummation of adolescence.

The names of the new older learner programs of this period reflected the shift in assumptions by playing on the irony of substitution. So from Youth Hostel came Elderhostel, the low-cost, travel-learning program for people over age 55 that was launched in 1975. These 1-week-long summer stays in Spartan college dorms, and journeys through the halls of ivy, would eventually lead to a huge, year-round, international program in which elder hostellers would have experiences usually reserved for youth. Similar substitutions of age for youth produced senior colleges, Gray Panthers, adult day care centers, senior centers, drama groups such as the Autumn Players, and later the federal program Senior Corps. The fresh nomenclature challenged the myth of disengaged seniors and replaced it with an image of the active, if not youthful, and certainly resourceful, older person. After several decades, the names no longer conveyed the same element of surprise, which is why organizations started to discard or modify them in the 1990s (e.g., senior centers became enrichment centers).

After years of pent-up demand, the surge of older learner programs in the 1970s and 1980s was remarkable, the product of a revolutionary change in attitudes about aging and later life, of more effective senior advocacy, and, demographically, of a growing number of retirees with the time, energy, and motivation to pursue continued learning. It was as if the older person had been suddenly discovered as a capable and resourceful individual whose vast developmental potential was still intact. The fact that activity theory totally eclipsed disengagement theory is borne out by changes in social policy. Mandatory retirement was gradually eliminated via the Age Discrimination in Employment Act (ADEA), which took effect in 1979 (amendments occurred in following years). By the time of the United States Bicentennial, perception of senior citizens (to use the commonest term of the period) was shifting from that of the poor, dependent, marginalized elder to individuals perceived both as deserving and (e.g., in the popular *Foxfire* books) as rich repositories of cultural wisdom if not great moral tales of courage

and survival – especially through the period of the Great Depression.

Lifelong Learning Institutes and Universities of the Third Age

It is in this same period that college- and university-based Institutes for Learning in Retirement (ILRs, later renamed Lifelong Learning Institutes, or LLIs) arose. The prototype for subsequent LLIs was the Institute for Retired Professionals established in 1962 at the New School for Social Research (now New School University) in New York City. Only a handful of the member-led, member-taught, educational programs had appeared by the mid-1970s but by the mid-1980s there was a sharp rise in the rate of new programs started each year, until, by 2000, there were more than 400 of these programs across the United States and Canada.

LLIs were unique not only because the members were in charge but also because they were based on a financial model that required participants to help pay for the cost of their own continuing education. Today, this financing method may seem unexceptional, but at the time the idea that older learners should pay for their own education was unprecedented. Previously, older learner programs generally depended on the largesse of private and public foundations and government subsidies. That funding basis explains why these programs were so often episodic, coming and going in repetitive cycles of demonstration projects that left no infrastructure behind. Perhaps the self-financing business model of most continuing education departments influenced LLIs where, institutionally, they were most often located. This radically new idea of self-financing programs was a harbinger of the future.

Today, the network of LLIs is loosely linked through affiliation with the Elderhostel Institute Network (EIN), a consortium supported, in part, through the largesse of Elderhostel and that has an extensive website that lists member programs, posts monthly newsletters, and provides extensive material on curricula, bylaws, how to start an LLI, and so on.

A new catalyst helping to promote establishment of new LLIs and expansion of existing ones is the Bernard Osher Foundation, which, since the early 1990s, has generously funded 79 Osher Lifelong Learning Institutes (OLLIs) and aims to bring that total to 100 over the next few years.

The counterpart to LLIs in the United States and Canada are the Universities of the Third Age, which, as mentioned earlier, began in 1973 in France and subsequently spread throughout Europe, the UK, Australia, New Zealand, South America, and Eastern Europe. The growth of U3As is reflected in the 574 groups, with a total membership of 153 443 as of February 2006, in the UK alone. Some U3As use a study circle approach with all participants helping to educate one another, while others use expert-led formats. Many national U3As participate in the International Association of U3As, or AIUTA (the French acronym).

Age-Segregated Programs and Empowerment

A debate in the United States in the 1970s concerned whether age segregation or age integration was the right direction for older adult education to follow. The normalization, mainstreaming argument pointed toward a future society based less on distinction of age than on needs and interests, one in which there should be more blending of generations in educational settings. But the majority of seniors seemed to prefer learning experiences shared by and with their age peers. And certainly the various organizations that depended on state, federal, and private foundation funding sought to retain their positions as the hosting sites of such programs.

Another inner tension concerned whether emphasis in older learner programs should be placed on humanistic gerontology's Maslovian self-actualization ideal or on the emerging political advocacy emphasis of empowerment. A telling example is the National Council on Aging (NCOA) anthology series that was at first called "Self Discovery through the Humanities" and later modified in the mid-1980s to just "Discovery through the Humanities." What did this small excision signify? The discussion group participants were not only to see themselves in the mirror of literature, history, and philosophy but also to peer through a "window into the lives of others." They were not only to grapple with meaning and wisdom in their later years (the Eriksonian emphasis) but also to find their place "in the fabric of American history," and to gain a voice to assert the dignity and resourcefulness of the now more visible, socially and politically active senior adult.

Participation Rates and Implications for the Future

Participation Rates

Since the 1970s, educational participation rates for people 55 and over have climbed steadily. More recently, according to the National Household Education Surveys (NHES), during the 1990s, the percentage of people in the United States aged 66–74

who took at least one adult education class in the previous year more than doubled – from 8.4% in 1991 to 19.9% in 1999. The biggest growth in participation of individuals aged 55–74 was in community-provided, non-formal education. This includes not-for-credit courses, workshops, and seminars offered by churches, libraries, department stores, senior centers, and so on, for which the rate went from 4.6% in 1991 to 11.6% in 1999. About 5.5% took courses in a school or university in 1991, rising to 8.6% in 1999. The increase among the 'young-old' surpassed that of any other age group.

Age-related role expectations still seem to be a defining factor for workplace educational participation. Participation rates for job-related education reveal modest increases compared to younger age groups. For example, between 1991 and 1999, the rate of those ages 48–56 participating in educational programs offered by business or industry increased from 12.6 to 19.6%, while for the age group 66–74, the rate rose from 2.0 to 4.8%. This reflects a continuing trend, as business and industry prefer to invest their training dollars in the younger workforce.

Degree of prior education remains the chief predictor of educational participation for adults of all ages. But greater visibility of educational opportunities and a growing acceptance of the value of lifelong learning were also factors. In all likelihood this trend will continue as an even better educated American Baby Boom population enters the retirement period and because the average age of retirement in the US is holding fairly steady at about 63. However, another strong trend, desire to return to the workforce after formal retirement in both full- and part-time second careers, may alter this pattern. If the high percentage of today's Baby Boomers actually does seek postretirement careers, there should be a huge increased demand for instrumentally oriented continuing education classes.

Unprecedented participation rates of older adults in adult education confirm an overall pattern – the emergence of a so-called lifelong learning society. It is estimated that almost half of the entire adult population in the United States participates in organized education in a given year. With regard to older adults, the United States is in what might be called a rehearsal stage. While the United States is certainly an aging society, with a median age of 36 that will rise the 39 by the year 2010, it is the aging of the huge Baby Boomer population (those born between 1946 and 1964) that will truly challenge cultural and educational institutions. Currently, those 65 and over make up 13% of the US population and those 60 and over comprise about 16%. The United States actually saw little growth in the percentage of its 65 and older population during the 1990s because of the low birth rate for the cohort born during the era of the Great Depression of the 1930s and into the early part of the 1940s. But by the year 2020, those 65 and over will comprise 18% of the US population, and that percentage will continue to rise until the 2050s (23%). The percentage of college-educated older adults will rise from the current 12% to 20% by 2010 and will continue to rise dramatically thereafter. Moreover, this rising percentage applies to a numerically vastly larger cohort.

In the current rehearsal stage, we have seen demand for education growing as education in the later years is viewed as valuable for preparation for second or third careers, personal enrichment and psychological growth, prevention or delay in the onset of cognitive decline, and aiding in adjustment to life beyond or after work. In all likelihood, the demand for educational opportunities will overwhelm current providers in terms of both numbers and range of curricular diversity. People in every industry in the United States have been gazing into crystal balls (or hiring consultants) to predict what Baby Boomers will want in their role as consumers. And this is no less true for providers of lifelong learning opportunities. But thinking only in terms of consumers may be a big mistake. What is called for is new leadership and vision.

Organizational Leadership

Currently, organizational leadership in older adult education in the United States is fragmented and decentralized. There is no organized group lobbying Congress or state governments for increased funding to educational programs primarily serving older adults. There are, however, a number of national associations with subcommittees or affinity groups focused on older learners. For example, the American Society on Aging has its Lifetime Education and Renewal Network (LEARN), composed of about 450 individuals whose work (usually only in part) is associated with some form of older adult education. And the Association for Continuing Higher Education (ACHE) has its Division of Older Adults. The Association for Gerontology in Higher Education (AGHE) focuses primarily on professional-level teaching of gerontology and only to a slight extent on education for seniors. As mentioned earlier, a majority of the LLIs are members of the EIN, affiliated with the Elderhostel organization. EIN's main activities consist of biennial regional conferences, maintenance of an informative website, and advice on how to start new LLIs. In the UK, the National Institute of Adult Continuing Education – England, Wales (NIACE) has

an Older and Bolder Initiative section that provides an information exchange mainly for professionals involved in older adult education but also for older learners through email groups.

As mentioned, the European and UK counterparts to LLI, the U3As, have national associations in many host countries, and many of these national units send representatives to the International Association of Universities of the Third Age (AIUTA) annual conference.

Professionally speaking, older adult education has no real independent standing. As a field, it is a subject of peripheral concern to both gerontological and adult educational organizations. The field lacks monetary significance since it is not a major revenue source for institutions of higher education, and only a few nonprofit organizations, for example, Elderhostel, perhaps the most significant, derive significant income from offering services and programs to seniors. Education for seniors is seen as an important marketing tool for investment companies, banks, hospitals, and cultural organizations that regard it as a mechanism to lure in potential clients, contributors, and members. In the sphere of higher education in the United States, affiliated LLI programs have proven to be a point of access to successfully solicit major donors.

Even in the area of research, where millions of dollars are spent on the causes of and potential remedies for cognitive decline as related to aging, a scant amount of research looks at the potential impact of older adult education on sustaining cognitive functioning. And little research involves applying what has been learned in cognitive science to better ways to educate or foster older adult learning.

Prospects for the Future in Cross-cultural Perspective

In the near-term future (the next 15 years), as a correlate to these trends, lifelong learning opportunities will increasingly become a function of the marketplace. Those who are in sufficiently good health are motivated by having enjoyed prior years of education (the main predictor of participation), and can afford to enroll in LLIs, pay for travel-learning excursions, sign up for continuing education courses, register for back-to-campus alumni seminars, access Internet educational sites, and choose from among a cornucopia of other lifelong learning programs, will reap the benefits of successful aging. Educational programming for Baby Boomers (the neo-elderly) especially will be a thriving business that deans of continuing education programs and directors of for-profit travel-learning companies, among others, are (or should be) discovering. We should expect an increase in demand for vocational education for second and third careers with likely emphasis on technical, managerial, and business-related training needs. Also, retirement communities associated with colleges and universities should experience a surge in growth.

Baring a change in public policy, those who do not fare so well because of poor health, limited incomes, and lack of motivation because of more restrictive prior education (especially minority elders) will find comparatively little from which to choose in the way of intellectually challenging programs. In fact, those who do not fit the image of successful aging will be chastised as failed agers, a moral castigation of those who seem not to have seized the opportunity to age well. It does not require much reflection to see that this scenario is an extension of current trends.

While current social and role theories of aging will remain relevant for certain subgroups of future seniors, it is probably what British theorists Chris Gilleard and Paul Higgs call the cultures of aging framework that will predict an emerging trend in which one finds few vestiges of solidarity among older citizens, a shunning of age-linked labels, and attitudes leading to a self-centered consumer society in which only isolated affinity groups, such as same-church elders or people living in gated, age-qualified retirement communities, will identify with one another. The gulf between the haves and have-nots, the successful and the disenfranchised future senior, will only widen. Calls for public funding for educational programs for the underserved will mainly fall on deaf ears. The disenfranchised will have become the neo-disengaged elders.

Educational programs that hold onto the current nomenclature – self-identified as for elders, for retirees, for seniors – will either dwindle or will mainly attract a frailer, older population. This trend is already occurring at some of the most popular Elderhostel sites such as the famous music conservatory the Peabody Institute and is very much like the trend in continuing care retirement communities (CCRCs), where average entry age hovers around 80. Meanwhile, other forms of lifelong learning will continue to grow in popularity as people with higher rates of college completion reach midlife and encounter the various decision points. This is not to say that the ideological dominance of the laissez-fare economy of our consumer-oriented societies is the most desirable direction, for certainly any ideal of equal access following principles of distributive justice seems overshadowed by other criteria and social values.

Lifelong learning programs in the United States and Canada will continue to mirror the economic systems of these countries. These programs – whether

conducted through colleges, senior centers, hospitals, libraries, or religious congregations or sponsored by private sector organizations such as banks, department stores, and travel-learning agencies – will remain market driven and increasingly require full fees or some form of co-payment for enrollment. Trends in other countries may be somewhat different.

Currently, there are more than 20 000 free universities for old people in China whose purpose or rationale, their mission statements proclaim, is to enable an older citizen to carry out his or her sacred duty to society by avoiding boredom and depression, gaining knowledge of hygiene and herbal medicine, and learning ways to provide care to others. An older learner in China is responsible for trying to remain as independent as possible while helping to relieve the health-care burden shouldered by the state. Yet, as China moves toward a more free market economy, this educational policy, mainly directed toward a generation of people who sacrificed many of their life opportunities during China's tumultuous years of war and revolution, will probably change direction.

In terms of the content of curricula, many older learner programs, especially in the United States and Canada, will continue to exhibit a fair degree of independence since these programs are not tied to credentialing guidelines and are far less likely to be censured for teaching controversial subjects than public secondary and postsecondary schools. A look at any of the curriculum catalogs of LLIs in the United States reveals a wide spectrum of courses ranging from "The Human Genome Project: Hope or Hype?" to "Define Your God." LLI members teach these courses after selection by a curriculum committee of peers.

Again, to draw cross-national comparisons, the almost counterculture tableau of LLI course offerings is not found in Spain, where some 50 older learner programs are administered by universities, taught by their professors, and require older students to enroll in a 3-year curriculum with limited options for elective courses. The academic authority-based *in loco parentis* approach is a by-product of Spanish history and culture. Most of the older students did not formerly have the chance to attend college during the years of the Franco regime, and Spanish universities have not, until recently, played the role of American ones with their continuing education departments serving a wide variety of purposes ranging from postdegree professional education to personal enrichment. The Spanish universities are not about to invest their older students with the power to shape their own curricula, nor is this generation of older Spanish students of a mind to regard themselves as capable of playing such a role. Whether Spain will gradually move in the direction of the United States, liberalizing and commodifying continuing education for future seniors, remains to be seen.

In the United States, a strong push is under way to convince the emerging mature generation to consider the needs of others. The message that civic engagement advocates bring to the so-called Me Generation is that freedom should not be uncoupled from responsibility. Great concern is expressed, for example, in a 2004 report from the Harvard Center for Health Communications that Baby Boomers will not volunteer to the degree of their parents' generation and that even if they did, the infrastructure that would enable society to use them appropriately does not exist. While educational programs for older learners are not obligated to incorporate community service as an element of their mission and rationale, the combination may hold particular appeal for the socially conscious neo-elder. Perhaps this option should be part of a learning, leadership, wellness, and service quaternary for future programs.

Emotions

K L Schmidt and R Schulz, University of Pittsburgh, Pittsburgh, PA, USA

Glossary

Emotions – Brief responses involving physiological, experiential, and behavioral activity generated by either an environmental or an internal stimulus.

Introduction

Emotions are relatively brief responses involving physiological, experiential, and behavioral activity generated by either an environmental or an internal stimulus. They can be characterized as globally positive or negative in valence, or as more differentiated states (e.g., anger, fear), each with its own particular functional explanation. Emotions are part of the larger concept of affect, which refers to both short-lived emotions and longer-lasting moods and feeling states. Emotions have been characterized as human universals, with stability across different social and cultural groups. They are influenced by environmental factors as well as internal regulatory mechanisms that can significantly affect the experience, expression, and perception of emotion. Healthy adults of all ages experience, express, and regulate their emotions. Key questions to be answered in research on aging and emotion include the impact of age-related processes (e.g., memory and cognition) on the experience, expression, and perception of emotion and the role of individual differences (e.g., personality) and social structural factors as moderators of the emotional lives of older adults. Psychosocial and physiological approaches to studying emotions and aging have revealed both changes and continuity in the emotional lives of older adults. Life span developmental perspectives on emotion and aging provide an interpretive framework for current research on normative changes in emotion with aging.

How does Aging Impact Emotional Experience, Expression, and Perception?

While studies of reported emotion in young, middle-aged, and older adults have revealed interesting patterns of change over time, many important issues surrounding the experience, expression, and perception of emotion with aging remain unresolved. In what has been called the paradox of aging, it appears that a stable or even increased amount of positive affect is associated with increasing age, while negative emotion in general decreases, leading to a greater emphasis on positive emotion in older adults, despite the gradual physical and cognitive declines associated with aging.

Specific emotional strengths that have been found are a focus on positive emotions and stimuli that produce them, the tendency to downplay the experience of negative emotions, and the ability to view past and present experience with mixed emotions (poignancy). Older adults have been described as having a realistic explanatory style, an absence of dispositional pessimism, and selectivity in goal pursuit and social relations.

In self-report findings, older, compared with younger, adults reported greater overall pleasure and arousal when viewing affective images designed to evoke positive, neutral, or negative feelings. Older adults in a large community-based study reported lower levels of anger than younger adults. Experience sampling of positive and negative emotion during mutual reminiscing was compared with emotional experience during other activities in older and younger adults. Older individuals reported increased positive emotion when exchanging stories about the past with others compared with younger adults, particularly when they were remembering positive events. Finally, the impact of chronic pain, increasing with age, is not reflected in an increase in pain reports among adults after age 70.

Emotional differences between older and younger adults also extend to social contexts and personal experiences, particularly with regard to close relationships. Older adults have reported that they are less often upset by interactions with family members and that they are less likely to report responding to interpersonal tensions with actively negative strategies, such as yelling. When negative emotion categories reported in response to remembered instances of interpersonal tension were investigated (anger, sadness, and non-specific negative emotion), older adults were less likely than adolescents or young adults to report anger and intense aversive experiences in general. With aging, the amount of emotional support given and received declines, and exchanges of social support change in nature, becoming more balanced over time. Older adults, it has been argued, regulate their emotional experiences by actively focusing their attention on close relationships most likely to yield emotional rewards. Studies of older married couples have confirmed that within these relationships, they may experience increased affection and decreased negative emotions. Others have proposed that developmental processes combined with cognitive strengths throughout adulthood facilitate cognitive affective complexity and can lead to improved emotional coping in older adults. However, more work is needed on the social networks of older adults, particularly with regard to reported versus desired amounts and diversity of contact in the presence of structural and physical constraints on social activity.

In the expressive and perceptual domains, research on aging and emotion has produced a more complex picture. Emotional expression generally decreases with aging, although older adults retain the ability to produce emotional expression voluntarily at the same levels as younger adults. Although expression may be less intense, this does not mean that older adults have a more neutral appearance to others. Due to changes in aging skin and appearance that are unrelated to emotion, older adults, especially the very old, are judged negatively during neutral facial expression, because wrinkles tend to mimic patterns of negative facial expression. Neutral faces of older adults, probably for this reason, were perceived as more emotionally intense in a study of posed facial emotional expression. Additionally, the expressions of older posers were rated significantly less accurately, and with significantly less confidence, than those of younger posers. Interestingly, there were no reported differences in intensity between younger and older facial expression posers for negative or positive emotions, suggesting that the capacity for voluntary emotional facial expression in older adults is similar to that in younger adults.

While research has concentrated on reported or expressed emotion in older adults, emotion perception and responsivity is also an important facet of emotion in aging. Adaptive developmental theories of emotional change rely on the assumption that emotional abilities remain intact in healthy older adults and that changes in emotion reported by older adults represent developmental psychological change, rather than degenerative changes in emotion-processing abilities. Gauging emotion perception abilities has been one approach to explaining the role of emotion in aging and to addressing important questions regarding the source of emotion differences between young and old.

There is some evidence that emotion perception abilities such as recognizing facial expressions of emotion undergo a general decline that is distinct from other perceptual and cognitive abilities. In a study of facial perception, older participants perceived lower levels of emotional intensity in sad and happy faces in a study of the perception of faces and accompanying stories. Compared with the younger group, older adults perceived neutral faces as showing low anger levels. Older adults also rated protagonists in stories as experiencing low levels of fear and rated some aspects of emotions portrayed in facial expressions and written text as less intense, although most differences could be explained by age-related differences in anxiety, depression, and intelligence test scores. One study of the perception of facial expression showed that older adults had deficits in the perception of negative and neutral expression, but not positive expression.

When viewing emotion-inducing slides in a standard laboratory paradigm, older adults exhibited significant differences in brain activity, as well as decreased activity in the corrugator muscle of the face (associated with negative emotion) and heart rate deceleration compared with younger adults. Studies

conducted in a more naturalistic context that compared older and middle-aged married couples engaged in discussions of marital conflict showed that emotion-specific autonomic activity was similar across different age groups. Facial expressions of emotion in the older adults, however, were configured differently from those of younger adults, with the quality of emotion expression rated lower. Physiological changes were consistent with but of lower magnitude than those found in younger adults. These age differences suggest that older adults have differential reactivity to both laboratory-presented affective images and the emotional context of social relationships. They also indicate that age-related changes in emotion are not uniform across emotion response systems. Several researchers have reported that older adults show a decrease in their perception of emotions such as fear and sadness, but that perception of another negative emotion, disgust, is preserved. The relation between physiological measures of emotional response and self-reported emotion on which life span developmental theories of aging have generally been based is not clear. An increased emphasis on differentiating emotions beyond the negative–positive dichotomy may help to explain contrasting results of earlier studies.

Neurobiology of Aging and Emotion

Studies of both structural and functional changes in the brain indicate that there may be important changes, not just in the response to emotion, but also in the neural systems that respond to emotional stimuli in older adults. In general, there is less reliance on limbic areas of the brain and more reliance on the frontal and prefrontal lobes when emotion perception tasks are given. For example, when discriminating emotional facial expressions, the left frontal regions of the brain were activated in older adults and the amygdala and surrounding limbic areas were activated in younger adults. In a similar study using functional magnetic resonance imaging, older adults observing faces showed less brain activity in all regions than younger adults while viewing faces with positive, negative, or neutral expressions. These results support the general conclusion that medial temporal lobe structures associated with emotion perception (amygdala, hippocampus, and parahippocampal gyrus) are significantly affected by age. Some researchers have proposed that it may be this shift in older adults toward using the prefrontal regions to process emotional stimuli that explains the enhancement of positive memories with age. The preservation of emotions in older adults may be due in part to this shift of emotion perception emphasis from medial temporal regions of the brain to regions in the frontal lobe that remain at a high level of functioning during aging. An alternative theory of emotion, aging, and brain function proposes that the emotional deficits of older adults can be explained as a result of reduced asymmetry between the cerebral hemispheres. Results from studies of perception of emotional facial expression support, in part, the association of lowered emotional perceptual ability and reduced asymmetry in brain functioning during emotion perception tasks.

Role of Individual Differences in Emotion and Aging

Individual differences can be predictive of emotional experience, expression, and perception. The role of individual differences in the emotions of older adults is relatively unknown. While differences in personality, gender, physical and mental health, education, intelligence, and other factors may have consistent effects on emotions in both younger and older adults, it is also possible that some of the emotional characteristics of older adults can be explained in reference to these differences.

Personality is known to be a significant predictor of emotion in adults of all ages. Although changes that result from major alterations, such as the death of a spouse, can cause shifts in personality, in general the stable association of extraversion with positive affect and neuroticism with negative affect remain applicable in older adults. Individual differences in personality, combined with stressors, explain some of the differences in vulnerability to negative emotions and symptoms of mood disorder in older adults. In a study of older adults ranging in age from 70 to over 100 years old, the personality factors extraversion and neuroticism were the largest single predictors of positive and negative affect.

Gender differences in emotion in older adults also have been found; women in general appear to experience more emotion and simultaneously to regulate their emotions more strongly. Older women were more emotionally distressed and distressed for longer periods of time than men by interpersonal conflicts within their social networks. While describing aspects of their own personalities, older women were significantly less variable over time than younger women. This decrease in self-reported emotional variability has been linked to increasing emotion regulation ability with aging and with decreases in intensity of positive and negative affect. Researchers have also found a reduction in symptoms of depressed mood in women aging from late 40s–early 50s to late 50s–early 60s. Differences in menopausal

status predicted symptoms of depressed mood at an 11-year follow-up among women, suggesting a hormonal basis for emotions and aging.

Health, particularly physical health, is likely an important factor in the emotions and abilities of older adults. While the emotions of relatively healthy, community-dwelling adults may represent a preserved strength, the emotions of older adults with physical disabilities present a very different picture. Poor physical health was associated with lower levels of life satisfaction in a study of well-being in older adults. The effect of poor health on emotions may be limited to its tendency to lower positive affect, while having no effect on negative emotions. In another study of aging, emotions, and subjective well-being, however, physical decline was linked to lower positive and higher negative affect. It was not, however, associated with life satisfaction.

In contrast, individuals characterized by physical hardiness and high levels of activity were less likely to be clustered in a group of individuals characterized by high negative affect in an analysis of socioemotional patterns in older adults. Active individuals in good physical health were significantly more likely to cluster with individuals that showed a relatively calm and low negative (and low positive) affect profile. Individual differences in physical health and functioning clearly affect emotions in older adults yet have not been widely considered in analyses of normative aging.

The effects of other individual differences, such as intelligence, education, and social status, on emotional experience have not been widely researched. Intelligence has been found to predict emotion in older adults, with higher intelligence associated with higher levels of positive and negative affect. The resources of crystallized intelligence and cultural knowledge accumulated during adulthood are related to cognitive affective characteristics such as coping styles. Intact cognitive abilities clearly play a role in helping at least some older adults cope with difficulties in ways that maximize emotional well-being. Many older adults also have been shown to maintain a relatively high level of happiness. It is not known whether the results found in this particular sample contrast with those of younger adults. Most studies have generally concluded, however, that even when interactions among these variables and age have been controlled, there remains a general bias toward positive and against negative emotion in old age.

Emotion and Cognition in Older Adults

Investigating emotional and cognitive processes in older adults has the potential to resolve the question of whether emotional change is a relative strength of aging that compensates for cognitive decline or whether it is an additional area of decreasing function in older adults. Cognitive characteristics and emotional health are clearly linked, and the connection may have benefits that work in both directions. Some studies have found that an emphasis on emotions in the psychology of older adults has beneficial effects on other cognitive and emotional aspects of everyday life. For example, episodic memory has been shown to be related to positive affect in older adults but not in younger adults. In the same study, other abilities such as recognition were not affected by self-reported affect, suggesting that the effect is specific to particular aspects of cognitive performance. Memory for negative images, in contrast, showed an age-related difference in a study in which older and younger adults were tested for their recall of positive, negative, and neutral emotion-inducing images, with older adults performing more poorly for negative images only. Whether or not this difference in performance reflects a loss of the capacity to respond to negative emotional input or increasing emotion regulation is not known.

Other studies have found that emotional effects on cognitive tasks are similar in younger and older adults. Older adults showed a pattern of lexical responsivity to emotional words similar to that of younger adults in an emotion induction study. Older adults that had listened to music inducing sadness responded more quickly to sad words, and those that had listened to music inducing happiness responded more quickly to happy words. Affective priming in older adults was also found to be similar to that in younger adults, with the exception being the greater reliance on the affective prime among older adults that reported a need for structure. This can be interpreted as an indication of the utility of affective information as a compensatory mechanism for some older adults. Emotional enhancement of memory for words and faces has been found in older and younger adults, with the improved performance on positive as compared to negative stimuli slightly greater in older adults. Consistent effects of emotion on memory were found across the life span in a study of adults of varying ages, supporting the theory that emotions represent an area of strength of older adults. In some cases, however, emotional focus may have a negative effect on cognitive performance. In a study of recall based on an experimental play reading task, both older and younger adults were significantly less accurate in recalling aspects of the task when instructed to focus on affective content than those who were instructed to focus on factual content. To the extent that older adults are more likely in everyday situations to

focus on affective content, their memory performance may be negatively affected.

Theoretical Perspectives on Emotion in Older Adults

Research that derives from an explicit life span perspective of development and focuses on emotions is still relatively rare. One important exception to this general conclusion is the work on socioemotional selectivity theory (SST) by Carstensen and colleagues, which postulates that in late life, social interaction is increasingly more likely to be motivated by attempts to regulate emotion and increasingly less likely to be motivated by information-seeking goals. This in turn affects the type of social partners chosen by older people as well as the types of social interaction in which they engage. A wide array of evidence is available to support this proposition, including the fact that as social contacts decline with age, older persons are more likely to prefer familiar over unfamiliar social partners and are more likely to think about social partners in affective terms.

Another approach to considering the role of emotions in the context of development throughout the life course is articulated by Schulz and Heckhausen in their life span theory of control. They posit a motivation for primary control (i.e., having impact on the external world) as a major driving force in both survival and development. In this model, emotions serve as the fuel of a regulatory system whose major goal is to maximize the primary control potential of the organism. Both positive and negative affect generated through interactions with the environment have the potential of energizing the organism toward further primary control striving. Secondary control processes (i.e., having impact on the internal cognitive world of the individual) serve the function of protecting and enhancing primary control and are closely linked to emotions. An emotional response can instigate a secondary control process, which in turn promotes the motivational resources needed for primary control striving. Thus, the emotions system serves as a signal and as a motivational resource in shaping human behavior. This view is fundamentally different from SST in that it claims that emotions cannot be ends in themselves, although they may serve as proximal goals in specific situations. Another way of putting this is that maximizing primary control, rather than feeling good, is a major goal of human development. This view of the experience of emotions emphasizes their role as facilitators or mediators of primary control and is consistent with Nico Frijda's evolutionary perspective reflected in his statement that "the human mind (is not) made for happiness but instantiating the blind biological laws of survival" (1998: 354).

Future Directions

Because the majority of research on aging and emotions is cross-sectional, it is difficult to know whether observed differences between young and old reflect ontogenetic change or, alternatively, are primarily due to cohort or survivorship effects. Clearly, much more empirical work is needed in this area.

Psychosocial and physiological approaches indicate general patterns of normative emotional change with aging. While theoretical perspectives on the role of changes in emotions over the life span differ, the patterns of change in emotion indicate that there are significant differences in the experience, expression, and perception of emotion in late life. Clarification of the role of individual differences and age-related factors in producing emotional changes is important in determining the nature of aging of emotions. Ultimately, knowledge of emotional changes will be useful in developing interventions designed to improve the health and well-being of older adults.

Endocrine Function and Dysfunction

F V Nowak, Ohio University, Athens, OH, USA
A D Mooradian, Saint Louis University Health Science Center, St. Louis, MO, USA

Glossary

Androgens – Adrenal or gonadal hormones that enhance male sexual and reproductive function. Examples are testosterone, dihydrotestosterone, androstenedione, and dehydroepiandrosterone.

Estrogens – Gonadal hormones that enhance female sexual and reproductive function and that have widespread physiological effects in both females and males.

Glucocorticoids – Adrenal hormones, such as cortisol, with predominant effects on glucose homeostasis and cell-mediated immunity.

Insulin-like growth factor-1 (IGF-1) – A major mediator of growth hormone action.

Mineralocorticoids – Adrenal hormones with predominant effects on serum electrolyte metabolism.

Progesterone – Steroid hormone secreted by the adrenal gland and ovary.

Releasing Hormones – Hormones released by the hypothalamus to stimulate specific types of pituitary cells (e.g., TRH, CRF, GnRH, GHRH; see text for definitions).

Thyroid Hormones – Thyroxine (T_4) and triiodothyronine (T_3).

Tropic Hormones – Substances released by the pituitary gland to stimulate various target endocrine tissues. These include thyroid-stimulating hormone (TSH), adrenocorticotropic hormone (ACTH), follicle-stimulating hormone (FSH), luteinizing hormone (LH), and growth hormone (GH).

Introduction

Altered cellular metabolism and intercellular signaling occur with advancing age, resulting in widespread changes in endocrine function. Aging is associated with both anatomic and secretory changes in the endocrine glands. Cellular responses within the hormone target organs also may change, including receptor binding, intracellular signaling, and gene expression responses. Hormone clearance rates and transport binding proteins may also be altered. Awareness of these changes is essential to the diagnosis and management of endocrine dysfunction in the elderly.

Overview of Hormonal Changes with Age

Altered cellular metabolism and intracellular and intercellular signaling with advancing age result in widespread changes in endocrine function. Several mechanisms interact in most systems to bring about the observed changes. Aging is associated with anatomic changes of the endocrine glands. In addition, with age, changes in hormone secretion occur, including alterations in circadian or seasonal biorhythms, changes in pulsatile frequency or amplitude of hormone secretion, as well as absolute changes in mean serum hormonal levels. The three main hormone systems that show decline with age are the gonadal hormones (menopause and andropause), the adrenal steroids DHEA and DHEA-S (adrenopause), and the GH/IGF-1 axis (somatopause).

Other changes occur in the cellular responses of target organs. Receptor binding and intracellular signaling reflect age-related alterations in plasma membrane properties, enzyme activities, and calcium mobilization. Gene expression, including translation efficiency, transcription rates, and DNA methylation, may show marked variations with age. Finally, changes in hormone clearance rates and binding to transport proteins contribute to the overall widespread changes observed.

The mode and mechanism of change vary with the hormone studied. In addition to intrinsic age-related changes in endocrine response, age-associated diseases, increased use of medications, changes in nutritional status, physical activity, and body composition also contribute to age-related endocrine dysfunction.

General Principles of Geriatric Endocrinology

The accurate diagnosis of endocrine dysfunction in the elderly requires a high index of suspicion. Signs and symptoms of hormone deficiency or excess may be absent. When such signs and symptoms are present, coexisting malnutrition or chronic disease may often make their interpretation difficult.

Hormone measurements and provocative tests must also be interpreted with respect to age. Some

hormones, such as luteinizing hormone (LH) and follicle-stimulating hormone (FSH), have clear gender-specific age-related changes. Others such as thyroid-stimulating hormone (TSH) show more subtle and variable alterations in what is considered normal with age. Provocative tests may give a blunted or altered response. Measurements of bound hormone may be less reliable due to alterations in serum proteins and hormone binding. Clearance rates are often affected by age due to changes in renal or hepatic metabolism, peripheral utilization, and even posttranslational changes in hormone processing.

Finally, therapy needs to be adjusted for age and coexisting disease. Potential side effects of therapies such as testosterone are increased and will affect the risk-to-benefit assessment of treatment and determination of optimal dose. Essential replacement, such as with thyroid hormone, should be initiated at a low dose and gradually increased to full dosage with careful monitoring of patient response and potential adverse reactions. With these precautions in mind, every effort should be made to diagnose and treat endocrine abnormalities even in the elderly debilitated patient, as this will improve quality of life. Generalized aging is intimately coupled with widespread progressive alterations in metabolism, of which changes in endocrine function are an integral part.

Anterior Pituitary

Age-Related Changes in Pituitary Function

Morphological changes are seen in the pituitary gland and fossa with aging. Chromophobe adenomas, especially prolactin producing, increase in incidence with age. They may be more difficult to diagnose, especially in females, because loss of menstrual cyclicity is the most common complaint of young women with prolactinemia, and this index is lost after menopause. In addition, many drugs commonly prescribed for the elderly, such as antidepressants, can secondarily increase prolactin levels into the range of microadenomas.

Aging is also associated with an increased incidence of anatomic and radiographic alterations in the sella turcica, including increased size and demineralization. Often no biochemical abnormalities are associated.

The peptide hormones of the anterior pituitary also change with age. A number of pituitary hormones exhibit altered patterns of secretion with advancing age, including growth hormone (GH), LH, FSH, adrenocorticotropic hormone (ACTH), and TSH. The circadian rhythms of plasma GH, prolactin, and melatonin are flattened.

There is a decrease in sleep-induced GH secretion, in peak amplitude, and in 24 h plasma levels of GH. Pituitary GH content remains unchanged with age. However, growth hormone releasing hormone (GHRH) receptors are reduced, and pituitary sensitivity to inhibition by somatostatin is increased. Both of these findings may lead to decreased release of stored GH.

There is also a decrease in the hepatic-systemic and local synthesis of insulin-like growth factor-1 (IGF-1) proteins. However, other factors, such as increased intra-abdominal fat mass and the presence of chronic illness, have a greater negative impact than advancing age and may exacerbate its effects.

The insulin-like growth factor binding protein-3 (IGFBP-3), which enhances IGF-1 action, also decreases, while IGFBP-1, which inhibits IGF-1 bioactivity, increases. An age-related decrease in basal and GHRH-stimulated GH secretion has been reported in male rhesus monkeys and rats. It has been postulated that in humans the decrease in GH action results in the muscle wasting and bone loss commonly seen with aging. GH and IGF-1 may play a role in learning and memory and have a neuroprotective effect in the aging brain. In aging rodents, GH treatment partially protects against ischemic brain injury. Higher plasma levels of IGF-1 are associated with better cognitive function in elderly human subjects. IGF-1 infusion improves cognitive performance in aging rats, and treatment with GHRH has been shown to improve cognition in the elderly. Low IGF-1 levels are associated with a high degree of cognitive impairment in Alzheimer's disease.

Serum prolactin levels decrease in females after menopause, whereas LH rises dramatically. Both pituitary content of LH and serum LH increase in intact animals. In human females, LH levels rise after menopause, in part because of decreased gonadal steroid feedback. However, the LH response to gonadotropin-releasing hormone (GnRH) actually decreases. Pituitary sensitivity to negative feedback by gonadal steroids may decrease, and conventional replacement therapy with estrogen in postmenopausal women fails to restore gonadotropin levels to premenopausal values.

In men, circulating prolactin levels are unchanged or increase slightly, while LH release decreases despite an increase in stored LH. This may be due in part to an increase in the sensitivity of gonadotropin-secreting cells to testosterone and dihydrotestosterone, which has been found in healthy older men and aging male rats.

The sex-specific changes in prolactin release may be secondary to changes in estrogen levels, which decrease with age in women and increase in aging men.

Aging is also associated with significant changes in LH pulsatile secretion. Age-related decreases in LH pulse frequency have been observed in human males and in male rats. Pulse amplitude is unaltered in humans but decreases in rats. Pituitary gonadotrophs isolated from old ovariectomized rats have a significantly lower LH content than young ovariectomized rats. LH beta mRNA is also decreased.

With increasing age, both stored and secreted FSH levels increase in both sexes. In older female rats the amplitude of FSH secretion on proestrus is less than 50% of the amplitude found in young rats.

TSH levels in the pituitary do not change with age, and circulating TSH is normal or slightly elevated. Diurnal variation is unchanged. Pituitary TSH sensitivity to thyrotropin-releasing hormone (TRH) and to changes in thyroid hormone concentrations decreases in the elderly. The age-related change in thyroid hormone sensitivity of the pituitary, along with decreased renal clearance of TSH, may result in elevated circulating TSH.

Age-related changes in GH, LH, and TSH may be secondary to changes in central nervous system (CNS) neurotransmitters and neuromodulators, including norepinephrine, serotonin, dopamine, β-endorphins, and enkephalins, which influence pituitary hormone secretion.

The corticotropin (ACTH) content may be slightly reduced in the pituitary with age, but basal ACTH secretion does not change. However, pituitary response to glucocorticoids shows a blunting of the negative feedback effects with age.

Pituitary Dynamic Testing

Although infrequently used, there are occasional indications for dynamic pituitary testing in the elderly. One should be aware of age-related changes in responsiveness, which are summarized in **Table 1**.

The ACTH response to corticotropic-releasing factor (CRF) or alternate stimuli is unchanged with age. TSH, prolactin, GH, LH, and FSH all show diminished stimulatory responses in dynamic testing in a significant proportion of individuals.

Growth Hormone Replacement

The systemic benefits of exogenous GH therapy in the healthy elderly remain unclear and controversial. Studies have not been able to demonstrate a clear anabolic effect of replacement of GH in elderly subjects, possibly because GH replacement cannot completely correct the alterations in binding proteins. Some studies have reported improvements in bone mineral density and muscle mass. Sarcopenia is related to increased tendency to fall, decrease in bone mineral density, decreased wound healing, and a decreased ability to maintain body temperature. Mechano growth factor (MGF) is a muscle-specific splice variant of IGF-1 that activates muscle stem cell proliferation, which is necessary for muscle regeneration. Treatment with exogenous GH plus resistance training has been shown to upregulate MGF in elderly muscle. Effects on muscle strength and quality of life have not been clearly documented. In addition, there is the concern that high normal serum IGF-1 may be associated with increased risk for breast and prostate cancers. Additional adverse effects include carpal tunnel syndrome, fluid retention, and decreased glucose tolerance. Endogenous overproduction of GH results in a decreased life span in mice and humans, and GH-deficient or -resistant mice exhibit a high level of resistance to oxidative stress and have increased longevity. Individuals with the A+ IGF-1 receptor gene polymorphism tend to have lower free IGF-1 levels, and these individuals are overrepresented in long-lived subjects. Therefore, it is still debatable whether long-term GH therapy will promote anti-aging or pro-aging effects.

GH may have a therapeutic role for short-term treatment of the frail elderly during acute illness, injury, or surgery. Several studies have shown acceleration of weight gain, an increase in muscle strength and endurance, and improved surgical recovery in malnourished or immobilized elderly patients.

Table 1 Age-related changes in anterior pituitary hormone response[a]

Hormone response	*Change*
ACTH response to CRF	N
ACTH response to insulin-induced hypoglycemia	N
ACTH response to intravenous metyrapone	N
TSH response to TRH in women	N
TSH response to TRH in men	↓
Prolactin response to TRH	↓
GH response to GHRH	N or ↓
GH response to insulin-induced hyperglycemia	↓
GH response to arginine infusion	N
GH response to levodopa	↓
LH and FSH response to GnRH	↓

[a] ACTH, adrenocorticotropic hormone; CRF, corticotropin-releasing factor; TSH, thyroid-stimulating hormone; TRH, thyrotropin-releasing hormone; GH, growth hormone; LH, luteinizing hormone; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; N, no change; ↓, decrease.

Thyroid Gland Function and Dysfunction with Age

Thyroid Structure

There is an increased incidence of thyroid nodules with age. It is estimated that up to 90% of women over 70 years of age have thyroid nodules. Generalized changes may also occur, including increased fibrosis, flattened follicular epithelium, and increased colloid, as well as an increase in lymphocytic and plasma cell infiltration. In geographic areas of low iodine intake, the incidence of goiter increases markedly with age; up to 50% of the population may be affected.

Thyroid Hormone Economy

The metabolic response to thyroid hormones changes with age. Overall, there is a decreased response of the basal metabolic rate (BMR) to T_3 stimulation and a decrease in lipid peroxidation when corrected for caloric intake.

TSH secretory pulses exhibit reduced amplitude in normal elderly subjects, especially at night. Pulse frequency does not change. TSH bioactivity also decreases with age and may reflect age-related changes in glycation. In aging male Fischer 344 rats, immunoreactive serum TSH shows no change, but pituitary TSH-β subunit mRNA levels and TSH content decrease with age.

The TSH response to TRH is reduced in some groups of elderly men but is normal in others and in elderly women. This is apparently counterbalanced by an increased suppressibility of TSH by thyroid hormones in elderly humans. The ability of dexamethasone to suppress the TSH response to TRH is blunted in elderly men, suggesting that thyrotropes are also more resistant to glucocorticoids. This is of special interest because of the increased serum levels of glucocorticoids in response to several stimuli, which have been reported in elderly men due to age-related changes in the hypothalamus-pituitary-adrenal axis.

Thyroid gland responsiveness to TSH is not altered with age *in vivo*. The serum T_3 response to TRH-induced secretion of endogenous TSH is similar in young and elderly human subjects. However, a decrease in thyroid membrane high-affinity binding sites for TSH is observed in 24- to 26-month-old compared with 3- to 4-month-old rats. This is reflected in a decrease in TSH-stimulated adenyl cyclase activity in old rat thyroid membranes.

In rats, age-related decreases are seen in both TSH responsiveness to TRH and T_3 inhibition of the TSH response. T_4 declines with age, but this decline may be prevented by lifelong caloric restriction.

Several large studies in human subjects have documented no change in serum total T_4 and free T_4 during advanced aging in either males or females. Likewise, no change is seen in T_3 or reverse T_3 (rT_3) with increasing age. The changes in T_3 and rT_3 noted previously in elderly subjects may be a reflection of concurrent illness. Nutritional status may also affect these levels. Low caloric and carbohydrate intake correlate with elevations in rT_3.

The metabolic clearance of thyroid hormone decreases with age. The serum half-life of T_4 increases from a mean duration of 6.7 days in the third decade of life to a mean of 9.1 days by the seventh decade. Deiodination of both T_4 and T_3 is reduced. Sequential monodeiodination is also reduced. The decline in hepatic 5′-monodeiodinase activity may be due partly to decreased availability of reduced cofactor thiol groups, which decrease with maturation and aging.

The transport of thyroid hormone into brain and liver tissues is reduced in aged rats. T_3 transport across the plasma membrane is significantly reduced, while nuclear uptake remains unchanged.

Thyroid hormone action involves binding to specific DNA promoter and enhancer regions attenuating or augmenting the expression of specific genes. The encoded gene products include enzymes, transporters, harmones, and structural proteins.

T_3 stimulation of malic enzyme is reduced in aged rats. Malic enzyme mRNA is also reduced, suggesting a decrease in transcription rates or mRNA stability. Another enzyme that is stimulated by thyroid hormone is the Na^+/K^+-ATPase. Activity of this enzyme decreases with age in both renal cortex and liver. The enzyme may be partly responsible for the calorigenic effects of thyroid hormone; the decrease may contribute to age-related decline in thyroid hormone induced thermogenesis.

Cardiac relaxation slows with age. Ca^{2+}-ATPase activity and sarcoplasmic Ca^{2+}-ATPase gene expression are reduced in aged rats. The stimulatory effect of T_3 is also reduced. These changes may contribute to the age-associated slowing of relaxation. Aging and thyroid hormones also affect α- and β-myosin heavy chain (BMHC) gene expression. Both genes are highly expressed in neonates. The α-myosin heavy chain declines steadily with age and is stimulated by T_3. The effect of age on this T_3 response is unknown. BMHC also decreases after birth but rises again with aging. The effect of T_3 on this gene is decreased expression through binding to a negative response element in the gene encoding this isoform. With aging, the ability of T_3 to suppress BMHC is lost. The rat liver Spot 14 (S_{14}) gene encodes a small nuclear protein ($M_r = 17\ 010$) that regulates lipogenesis.

S_{14} gene expression increases with age. T_3 induces S_{14} gene expression; this response is blunted in older animals.

Thyroid Dysfunction: Clinical Aspects

Many clinical features of hypothyroidism are commonly found in the elderly, despite negligible changes in plasma thyroid hormone levels. These symptoms may reflect the decreased intracellular uptake of T_3 and alterations in gene activation/deactivation that are observed with aging.

On the other hand, numerous studies have shown a 3–4% incidence of unsuspected (subclinical) hypothyroidism in the elderly. Primary thyroid failure, usually secondary to chronic autoimmune thyroiditis, has been estimated to occur in 4.4% of the population over the age of 60 years. The prevalence of antithyroglobulin and antithyroperoxidase antibodies increases with age up to 70, then declines so that prevalence at age >100 years equals that found in controls <50 years. In one large study, 80% of elderly patients with high antithyroperoxidase antibody titers developed clinical hypothyroidism during a 4 year follow-up period. In contrast, elevated antithyroglobulin antibody titers do not appear to predict increased risk for hypothyroidism.

Hyperthyroidism is more difficult to diagnose in the elderly due to lack of classical clinical signs. Symptoms of hyperthyroidism, especially those secondary to increased adrenergic activity, are frequently blunted in older individuals. The reduced signs of adrenergic hyperactivity in elderly hyperthyroid patients may be the result of age-related desensitization of β-adrenergic receptors. The heart rate response is reduced in elderly subjects regardless of thyroid status. Low serum TSH is more common in the older patient, most often accomplished by a normal serum T_4 concentration. In one large study, 6 out of 50 elderly patients with low TSH became hyperthyroid during 4 years of follow-up.

Some of the effects of hyperthyroidism may be totally different in elderly individuals. Weight loss secondary to hyperthyroid status occurs in both young and older individuals. However, the etiologic pathway may be different. As many as 36% of elderly patients with hyperthyroidism experience anorexia. Using pair fed rats, weight loss in hyperthyroid older rats has been linked directly to decreased food intake in the aged rats compared with their younger counterparts.

A high index of suspicion, appropriate laboratory testing, and careful slow replacement of thyroid hormone when required will greatly facilitate the care of the elderly patient with thyroid disease.

Adrenal Gland Function and Disease with Age

Adrenal Cortex Structure

Structural changes take place in the human adrenal cortex with age. Gland weight declines slightly with age, and the cortex undergoes degenerative changes, including increased fibrosis, accumulation of lipofuchsin, epithelial cell dropout, mitochondrial fragmentation, and vascular dilation and hemorrhages. Cellular depletion is observed in the zona reticularis. An increased incidence of adrenal adenomas has been found on autopsy. Up to 50% of adrenal glands from aged subjects show small cortical nodules.

Adrenal Physiology

Hypothalamic CRF content does not change in rats or humans as a function of age, but baseline and stimulated infundibular portal CRF levels are increased in the rat. This increase may reflect the observed increase with age in a subpopulation of CRF neurons that also contain arginine vasopressin (AVP) and that are selectively activated by stress.

Glucocorticoids Aging of the hypothalamic-pituitary-adrenal (HPA) axis is highly species dependent. In aging dogs, ACTH and cortisol levels show hyperresponsiveness to CRF or stress. In aging rats, the ability to secrete ACTH and corticosterone in response to CRF or stress is reduced, but baseline levels of these two hormones are elevated. In male Fischer 344 rats, the pulse amplitude of pituitary ACTH secretion is decreased. Pituitary CRF receptor concentrations are significantly decreased without alterations in ligand affinity.

In humans, the pituitary ACTH response to exogenous CRF or to intravenous metyrapone does not change. However, a diminished sensitivity of pituitary ACTH to negative feedback by cortisol is suggested by several findings. Dexamethasone suppression of ACTH has a higher false positive rate; this is further exacerbated by coexisting dementia of Alzheimer's disease. Exercise endurance training also alters the suppressive effect of dexamethasone on cortisol and ACTH secretion in response to CRF, making it less effective.

Moreover, the increased cortisol response to CRF with normal levels of ACTH suggests decreased negative feedback with or without increased adrenal stimulation of cortisol secretion by ACTH. Challenges that alter CNS feedback to the HPA axis, such as trauma, physostigmine, or naloxone, tend to show a greater cortisol response in older subjects. Older subjects show a delayed recovery to baseline cortisol

levels following CRF or ACTH challenge post-surgery. The elderly have higher serum cortisol in response to depression or to perioperative stress than young subjects.

The limbic system modulates the HPA axis. In rats, aging is associated with selective loss of corticosterone binding neurons and glucocorticoid receptor (GR) mRNA in the CA3 hippocampal zone. Also with age, hippocampal inhibition of ACTH release is attenuated.

Hippocampal neurons have both mineralocorticoid receptors (MRs) and GRs. MRs and GRs may mediate coordinate but antagonistic effects on excitability by hippocampal neurons. In rats and dogs, limbic system MR binding capacity is markedly decreased with aging, whereas GRs are unchanged, altering the homeostatic balance and leading to HPA hyperreactivity during senescence.

Glucocorticoid target tissues also show age-related change. The affinity of hepatic cytosolic steroid receptors to dexamethasone and corticosterone is significantly reduced in aged rats, although receptor number does not change. Stimulation of tyrosine aminotransferase, a corticosteroid-induced enzyme, decreases with age. Impaired glucocorticoid receptor activation may be responsible for the decrease.

Changes in the HPA axis may also lead to altered immune function, including reduced tumor surveillance, with aging. Natural killer cell activity shows an age-related decrement both at baseline and in response to CRF in rats.

The adrenal gland may directly mediate the age-related reduction in stress tolerance. Restraint-induced expression of heat shock protein 70 (hsp70) in rat adrenal cortex declines throughout the life span of the rat. Hypophysectomy negates the hsp70 response, and ACTH replacement restores it, indicating a role for hsp70 in the physiological stress response.

There is evidence that persons exposed to elevated cortisol levels due to Cushing's syndrome or exogenous glucocorticoid therapy show a number of cognitive and physical impairments normally associated with aging. Age-related losses of adrenal steroid receptors have been hypothesized to result from cumulative exposure to glucocorticoids themselves. Administration of exogenous glucocorticoids or chronic stress accelerates hippocampal pathology, whereas adrenalectomy reduces it. Memory deficits, atherosclerosis, muscle weakness, osteoporosis, immune dysfunction, and cerebral atrophy have all been associated with excess levels of glucocorticoids. Exposure to chronic stress with its associated elevations in ACTH and cortisol may have similar consequences, and stress and aging may act synergistically to exacerbate each other.

Adrenal disorders are not common in the elderly. The three most prevalent ones are adrenal mass, glucocorticoid excess, and adrenal insufficiency. As in younger patients, a functioning adrenal mass is most likely a pheochromocytoma or aldosteronoma that can be evaluated by abdominal imaging and urinary measurements of catecholamines and their metabolites. Serum potassium should also be measured. Most tumors are non-functioning. Those that are functional and those greater than 4 cm or that are rapidly enlarging should be removed if the patient can tolerate surgery.

For evaluation of cortisol excess, 24 h urine free cortisol should be measured. If ACTH is also elevated, a tumor secreting ectopic ACTH is the most likely cause in this age group.

Acute adrenal insufficiency is rare; it usually occurs in the setting of severe acute illness. The elderly are more susceptible, especially in the setting of acute myocardial infarction, sepsis, or anticoagulation. Adrenal gland metastatic disease or tuberculosis can also cause adrenal insufficiency. A negative ACTH stimulation test will confirm the diagnosis, but this should be deferred if the patient is in acute adrenal collapse. The decreased clearance rate of cortisol may result in a decreased replacement dosage requirement of hydrocortisone or cortisone in the elderly.

Adrenal Androgens Plasma levels of dehydroepiandrosterone (DHEA) and DHEA sulfate (DHEA-S), the principal C19 steroids produced in the human adrenal, decline to less than 20% of their maximal value by age 60 in both women and men. This may reflect the decrease in size of the zona reticularis that is observed with aging and a concomitant decrease in cytochrome b_5, an accessory protein that stimulates DHEA synthesis.

Postmenopausal women compared with young cycling women have decreased product and precursor ratios for DHEA/17-hydroxypregnenolone and for androstenedione/17-hydroxyprogesterone, suggesting a reduction in 17,20-desmolase with age. The reductions in androstenedione are probably due to reduced ovarian secretion after menopause. In cows, p450 c17 mRNA and induction by ACTH are reduced with aging. In human males, DHEA secretion declines progressively between 20 and 96 years of age. Older men have serum levels that are 5–30% of levels seen in younger men. The age-related reduction in secretion rate of adrenal androgen in both men and women is reflected in reduced urinary 17-ketosteroid excretion.

In rodents, DHEA has antihypercholesterolemic, antiatherosclerotic, and antihyperglycemic effects. In

humans, age-associated decreases in adrenal androgen production may contribute to decreased immune function, osteoporosis, and atherosclerosis. Cognitive ability and bone mass density may also be affected. As noted previously, in contrast to the decline seen in DHEA and DHEA-S, production of cortisol remains fairly constant with age. This may further contribute to decreased immune function and increased susceptibility to infection, as DHEA has stimulatory effects on immune function while cortisol has some inhibitory effects, especially at very high levels, such as those associated with trauma or severe illness.

Prospective observational data suggest that low DHEA and DHEA-S can predict ischemic heart disease. However, randomized, placebo-controlled clinical trials in individuals age 60 years and over treated with 50–100 mg/day of DHEA have yielded very few favorable effects on mood, well-being, cognitive and sexual functions, bone mass, body composition, vascular risk factors, immune functions, or skin. The major limitations of these trials were their short duration (maximum 1 year) and the low number of study participants involved (maximum 280).

Widespread DHEA replacement in the elderly can not be recommended. However, subjects with adrenal insufficiency may benefit from DHEA replacement therapy. In one study, DHEA replacement in women with adrenal insufficiency decreased symptoms of depression and anxiety and improved alertness, mood, and sexual function. DHEA replacement did not change body mass index (BMI), waist-to-hip ratio, fat mass, lean mass, BMR, exercise capacity, insulin, or glucose.

Mineralocorticoids Aldrosterone secretion decreases with age, most likely secondary to a reduction in plasma renin activity (PRA), by about 50%. The reduction in aldosterone secretion is evident both at baseline and after salt restriction or standing or in response to ACTH. The aldosterone clearance rate also decreases with age, by about 20%. This may partially offset the decreased baseline secretion. However, the elderly are more prone to postural hypotension and dehydration. This is due, at least in part, to the decreased mineralocorticoid homeostatic response. Other contributing mechanisms are discussed in the later section on water balance.

Adrenal Medulla

In rats the adrenal medulla becomes hyperplastic with hypertrophy of individual chromaffin cells with age.

Secretion rates of epinephrine and norepinephrine (NE) from the adrenal gland under resting conditions in the rat increase two- to fourfold between the ages of 100 and 800–900 days. Aging also increases the plasma catecholamine response to stress in aged rats. Serum baseline NE but not epinephrine is elevated in 24- versus 3-month-old Fischer 344 animals. CRF-stimulated catecholamines are also elevated.

In addition, tyrosine hydroxylase (TH) activity and TH-mRNA are elevated in old rats compared with young ones. Exercise conditioning decreases both TH activity and mRNA in young but not old rats, suggesting that sympathoadrenal plasticity diminishes with age.

In humans, plasma NE may increase with age in the general population. This is accompanied by a decrease in platelet α2-adrenergic receptors and cardiac β-adrenergic transmission, implying down-regulation with age in the presence of elevated NE. Dopamine levels do not change. Others have found that NE levels do not increase in non-smokers between the ages of 25 and 65 years. However, elevated levels of both epinephrine and NE were found in healthy octogenarians compared with healthy 24- to 28-year-olds. Catecholamine excretion has been shown to decrease in those between 60 and 80 years of age. Smoking significantly elevates catecholamine levels and excretion.

The NE response to upright posture, tilt-table test, insulin-tolerance test, cold-pressor test, or glucose ingestion is increased in the elderly, whereas both the epinephrine and NE response to exercise at 75% maximal work load is decreased in healthy elderly male subjects as compared to their younger counterparts.

The Reproductive System

Male Reproductive System

In human males, reproductive system aging occurs at both gonadal and CNS levels. Primary changes in testicular function include decreased sperm production and testosterone (T) secretion. Impairment in Leydig cell function occurs with age, with a decrease in production of pregnenolone, the substrate for T synthesis. Plasma total T levels are below normal, defined as 250 ng/dL, in 7% of men age 40–60, 20% of men age 60–80, and 35% of men age >80. Sex hormone binding globulin (SHBG) also increases, reducing the bioavailable and free T.

Anatomic changes in the testes include thickening of the basement membrane of seminiferous tubules and thinning of the germinal epithelium, increased peritubular fibrosis, and germ cell arrest. The number of Sertoli cells is reduced, and both basal and induced inhibin-B levels decline as early as

the fifth decade. There is a decline in daily sperm production. Although grossly normal areas of spermatogenesis are usually preserved until late in life, there is evidence for an age-related increase in sex chromosome aneuploidies in human sperm. Chromosome breaks and point mutations increase exponentially with age in germ cells of human males, and there is a fourfold increase in total chromosomal structural abnormalities by age 45. Reduced T levels, resulting in diminished DNA topoisomerase II α activity with increased age, may increase the frequency of chromosomal non-disjunction or breakage.

The decrease in serum T may be secondary to both primary testicular failure and decreased LH secretion from the pituitary. Compared to young men, in healthy older men LH pulse frequency may be reduced. In the anterior pituitary of aged male Brown Norway rats, GnRH receptors show a significant decrease. This plus an age-related decrease in pituitary calcium second messenger mobilization may be responsible for the reduced LH. Finally, the gonadotropin-suppressing activity of T or dihydrotestosterone is increased in healthy elderly men and in aging male rats.

In contrast, FSH is elevated, reflecting decreased testicular functions, including sperm production and inhibin secretion by the Sertoli cells. Clomiphene citrate stimulates gonadotropin levels in elderly men, but both LH and FSH increase less in elderly men than in young men. Elderly men also show a smaller rise in total T, bioavailable T, and 17β-estradiol (E_2), indicative of a significantly diminished testicular response. Circulating activin increases with age, but its effect on reproduction is not clear.

Complex changes in steroid metabolism occur with aging. The metabolic clearance rates of both T and dihydrotestosterone are reduced. T reduction to 5β-metabolites is increased. There is also an increase in conversion of T to E_2. This, coupled with the fact that E_2 clearance is also reduced, leads to an increase in the E_2/T ratio in older men.

Age-related changes also take place in tissue uptake of sex steroids. Androgen receptor concentrations in the hypothalamus and pituitary, the testes, and the ventral and lateral prostate are reduced with age in the rat; receptor affinity in brain and prostate is also reduced. Expression of hepatic androgen receptors decreases, leading to a decrease in $\alpha 2\mu$ globulin mRNA, a biomarker of androgen action in liver.

Aging in men is associated with increased fat; insulin resistance; falls and fractures; decreased muscle mass and strength, physical performance and activity, and bone mineral density (BMD) and libido; and anemia. It is not recommended that all elderly men be treated with androgen therapy. However, clinical features of androgen deficiency may warrant replacement. These consist of lethargy, fatigability, decreased libido, depressive mood, tiredness, decreased muscle and bone mass, increased visceral fat, impotence, and cognitive impairment plus total $T < 200$ ng/dl. Testosterone therapy can increase BMD in hip and lumbar spine. Whether T increases cardiovascular risk is debatable, since epidemiological associations relate low, rather than high, T concentrations to cardiovascular morbidity and T may actually lower LDL.

Female Reproductive System

In contrast to the gradual onset of the male climacteric, menopause in the female is a more dramatic event. Cessation of menses is, however, the result of slowly progressive changes in ovarian and hypothalamic-pituitary function. The loss of inhibin restraint of FSH appears to be the initiating event that leads to menstrual cycle shortening and some of the hormonal dysregulation of the late reproductive years. Circulating activin increases with age, but its effect on reproduction is not clear. The median age for menopause in the United States is currently 51 years. But even prior to menopause, fertility declines with age. The conception rate at age 30–34 is only 73% of that seen between ages 20 and 24, i.e., 63% vs. 86% incidence of pregnancy after 12 months of unprotected intercourse. By age 40 the conception rate is only 50%. There is also a significant age-dependent decrease in embryo survival, which correlates with ovarian age.

The number of oocytes in the mammalian ovary declines with age. In the human ovary few follicles remain at the time of menopause. However, studies in mice reveal that dividing germ cells are present in the adult ovary, challenging the long-held concept that ovarian senescence is inevitable. Sclerotic changes occur in the medullar portion of the aging ovary. Hypophysectomy or food restriction, which is associated with low gonadotropin levels, prolongs the reproductive potential of animals.

There is a gradual reduction in ovarian response to pituitary gonadotropins beginning 2–5 years prior to menopause. Ovarian secretion of E_2 and progesterone decreases gradually, and suppression of gonadotropins by estrogen is reduced. The final cessation of cyclic ovarian function leads to markedly decreased estrogen following menopause. LH and FSH levels increase markedly. In addition, pituitary LH release in response to GnRH agonists is significantly reduced in aged female mice, and in older female rats the amplitude of FSH pulses is 50% of that found in younger rats.

Decline in the number of ovarian follicles leads to a decrease in inhibin levels. Circulating activin also increases with age. Alterations in inhibin/activin tone may perturb osteoblast and osteoclast development and uncouple bone formation from resorption. This may increase bone turnover even prior to the early menopausal transition when inhibin-B declines but serum E_2 is conserved.

The effects of declining estrogen include genital tract atrophy, impaired autonomic vascular tone, and loss of bone density. E_2 is a dominant regulator of GH secretion. IGF-1 declines in perimenopausal women and the IGF-1/IGFBP-3 ratio drops, reducing bioavailable levels of IGF-1.

Uterine changes occur secondary to altered ovarian hormones as well as altered uterine responsiveness to hypothalamic, pituitary, and ovarian hormones and may contribute to a decrease in fecundity with age. Both estrogen receptor numbers and nuclear binding of estrogen receptors are decreased in the aged rodent uterus. Progesterone receptors do not change.

In contrast to the marked decline in ovarian estrogen secretion, ovarian adrenal androgen secretion and peripheral steroid conversion continue. As a result, the normal premenopausal estrogen to androgen and estrone to estradiol ratios are inverted.

In the rat model of reproductive aging, changes are not seen in the number of GnRH-producing cells with age, and isolated hypothalami do not exhibit altered GnRH secretion. However, *in vivo* GnRH secretion may be reduced. The basic biochemical phenomena responsible for this change in secretion probably occur both within the GnRH-producing neurons and in response to altered cell–cell interactions. Several changes in gene expression occur within the GnRH neuron. Expression of galanin, a brain-gut peptide that colocalizes to a subpopulation of GnRH neurons, is markedly reduced in these cells in aged animals. Expression is linked to estrogen-progesterone levels, implying that the relative concentrations of these two hormones modulate age-related changes in GnRH neuron physiology.

In the CNS, *c-fos* acts as a transcription factor that activates a number of genes, including GnRH. In middle-aged female rats, expression of this gene in the hypothalamus during proestrus is markedly reduced compared with younger animals. Inputs from higher CNS neuroendocrine responsive centers may be indirectly responsible for the altered GnRH response with age in the intact animal. Widespread changes in dopaminergic and cholinergic neurons occur with aging, including areas such as the amygdala and hippocampus, which are involved in higher CNS regulation of reproductive and sexual function.

Proliferative changes in the ovarian epithelium, such as papillomatous outgrowths, are more common in the postmenopausal ovary. Up to one-third of postmenopausal women have stromal hyperplasia. In a small proportion of these patients, excess androgen production causes virilization. Ovarian thecomas occur most commonly in the sixth decade of life and can secrete estrogen or androgens. Estrogenizing thecomas can be associated with endometrial carcinoma. Lipid cell tumors of the ovary also typically occur in older women. Androstrenedione secretion by these tumors can cause virilization.

Estrogen Therapy

Age-related decline in ovarian function leads to decreased circulating levels of gonadal hormones, including E_2 and progesterone. Related signs and symptoms include irregular menstrual cycles with eventual loss of cycles, vasomotor instability, changes in hair, skin, and mucous membranes, cognitive and affective changes, decreased bone mineralization, urogenital dysfunction, changes in libido and sexual function, sleep disturbances, and headaches. After menopause, women also exhibit weight gain, decreased glucose tolerance, and an increased incidence of cardiovascular disease, including hypertension, and cerebral and myocardial ischemia.

Modern hormone therapy in the United States dates back to 1929. It has been estimated that between 1970 and 2002, approximately one-third of eligible women elected to use hormone therapy. Standard hormone therapy consists of a daily dose of estrogen, with progesterone added for women with an intact uterus, to prevent the development of endometrial dysplasia caused by unopposed estrogen. There are numerous options for route of administration of hormone therapy, as well as chemical form and dosage. These should be individually tailored based upon the desired therapeutic effects and potential risk factors. Reports of increased breast cancer risk and adverse cardiovascular events related to use of estrogens and progestogens by postmenopausal women have called into question the risk–benefit assessment of sex hormone therapy. This subject is highly controversial.

At menopause, women's risk for cardiovascular disease, osteoporosis, and glucose intolerance rises significantly and substantially. Estrogen therapies have clearly been shown to improve mood, cognition, sleep, vasomotor stability, and bone density. While prolonged estrogen exposure appears to increase the number of breast cancers detected, the overall risk of mortality from the disease is not increased.

Estrogen may also have a protective effect against the development of Alzheimer's disease (AD). The relative rate of AD in women using estrogen compared with non-users was 0.46 in one large study of 472 women followed for 16 years. Another study showed that women's sex-specific increase in risk for AD disappeared after 10 years of estrogen therapy. Advances in the early detection of AD, including imaging studies of brain metabolism and measurement of serum amyloid peptides, may better help to identify patients likely to benefit from estrogen therapy. Once dementia is established, however, estrogen may have no effect or may even accelerate dementia.

More than 20 observational studies with hormonal therapy in postmenopausal women have also reported a 30–50% reduction in the incidence of coronary artery disease. Estrogen reduces oxidation of LDL cholesterol and angiographic evidence of coronary disease. However, several randomized trials, including the Heart and Estrogen/Progestin Replacement Study (HERS) and Women's Health Initiative (WHI), failed to show a cardioprotective effect. Comparison of the randomized trials to earlier studies reveals significant differences in the patient characteristics. Patients in the observational studies were younger and healthier and had a lower average body weight. They were also experiencing menopausal symptoms.

Timing of hormonal therapy appears to be an important factor, as both women and non-human primates initiating therapy close to the time of loss of ovarian function show a reduction in cardiovascular events, while older women with established cardiovascular disease exhibit a small increase in vascular complications. This statement is further supported by the fact that analysis of a younger subset of patients with vasomotor instability from the WHI trial did not show an increase in vascular complications. Clear demonstration of the potential cardioprotective effects of estrogen may depend upon the timing of therapeutic intervention (perimenopause vs. long-standing hormone deficiency) and the exclusion for comorbidities including smoking and obesity. Further consideration needs to be given to the development of therapies that will retain the benefits and decrease the risks of treatment.

Female Androgen Deficiency Syndrome (FADS)

The prevalence of sexual dysfunction in women approaches 43%, and age is an important correlate. The underlying etiology of sexual dysfunction in women is complex. Nevertheless, hormonal changes such as loss of estrogens and androgens contribute significantly to some of the sexual difficulties experienced by aging women.

In women, direct ovarian production accounts for half the circulating T, while the other half is produced through peripheral conversion from adrenal precursors. Both ovary and adrenal gland contribute equally to circulating androstenedione, while 90% of DHEA is produced by the adrenal gland. Oophorectomy in premenopausal women reduces T and androstenedione levels by 50%, while in menopause, T changes minimally and androstenedione decreases by 50%. Total T, free T, and androstenedione are lower in women with central hypoadrenalism and hypogonadism secondary to hypopituitarism than in subjects with hypoadrenalism or hypogonadism alone.

Female androgen deficiency (FAD) is diagnosed when there are clinical symptoms, decreased bioavailable T, and normal estrogen status. The potential causes of FAD include diseases of ovary, adrenal gland, or hypothalamic-pituitary unit, or drug-related or idiopathic causes.

Optimal treatment of FAD is being investigated. Interventional trials with DHEA have shown limited effects in select populations such as those with adrenal insufficiency. T replacement therapy has been utilized in few double blind randomized trials. Improvements in sexual desire, vasomotor symptoms, and mood have been documented. However, potential side effects such as acne, hirsutism, deepening of the voice, and possibly increased cardiovascular or breast cancer risk are of concern.

The exact interplay between the estrogens and androgens as to sexual activity is not known, and the correlation between specific serum hormone levels and sexual activity is not always consistent. Controlled trials of estrogen and/or T therapy in FAD have shown an improvement in sexual function among natural or surgically menopausal women. However, long-term safety of hormonal therapy, optimal types, doses, and routes of therapy are not currently established.

Calcium and Bone Metabolism

Age-Related Changes in Physiology

The most common age-related histologic change in the parathyroid glands is an increase in the number of oxyphil cells and an increased incidence of oxyphil cell nodules. In young adults, bone resorption and formation are in balance so that bone mass remains constant. This equilibrium is altered by gonadal failure and aging in general, leading to a relative increase in bone resorption, bone loss, and osteoporosis.

Non-genetic age-related causes of bone loss with aging are multiple. These include decreased sex

hormone production, decreased vitamin D activation, and increased secretion of parathormone (PTH), decreased intestinal uptake of calcium and protein, decreased osteoblast activity, and decreased physical activity.

PTH secretion increases without a change in clearance, resulting in increased serum PTH in aged rats and in humans older than age 65. This is believed to be a compensatory change in response to reduced production of 1,25-dihydroxyvitamin D and reduced intestinal calcium absorption. Up to 90% of long-term care elderly patients have subnormal serum levels of 1,25-dihydroxyvitamin D, and many have elevated serum PTH levels. However, healthy elderly subjects may have normal levels of serum 25-hydroxyvitamin D and 1,25-dihydroxyvitamin D. Serum levels of 1,25-dihydroxyvitamin D, the most active form of vitamin D, have been reported to either decrease or remain unchanged in both men and women. Bone levels in women decrease after the age of 45. A decrease in the synthesis of 1,25-dihydroxyvitamin D occurs with aging. There is a decrease in 1α-hydroxylase in the kidney, which results in decreased conversion of 25-hydroxycholecalciferol to 1,25-dihydroxycholecalciferol. This is probably related to reduced responsiveness of the kidney 1α-hydroxylase to PTH.

Serum osteocalcin, a marker of osteoblast activity, may be normal or decreased in elderly humans in the setting of increased PTH. This suggests osteoblast resistance to PTH resulting in decreased bone formation and turnover.

Elderly women have a higher maximal PTH response to EDTA-induced hypocalcemia compared to young women. They also have a greater non-suppressible component of PTH secretion without a change in set point. Therapy with 1,25-dihydroxyvitamin D reverses the abnormal PTH secretory dynamics. Estrogen therapy will also attenuate the plasma PTH levels in elderly women.

Age-related impairment of renal function may falsely elevate immunoassayable levels of PTH due to decreased clearance of PTH metabolites. This problem has been largely circumvented by use of the two-site PTH immunoradiometric assay.

In aged rats, serum osteocalcin is decreased. Paradoxically, in rats, long-term ovariectomy increases bone osteocalcin mRNA. The significance of this finding is unclear. PTH levels also rise in aging rats. However, the set point for PTH release increases in aged male Fischer 344 rats. In aged rats, ionized calcium and 1,25-dihydroxyvitamin D levels fail to increase in response to PTH, indicating that both kidney and skeleton may show reduced response to PTH with aging. Aging reduces intestinal and skeletal receptors for 1,25-dihydroxyvitamin D in rats. Treatment with 1,25-dihydroxyvitamin D partially reverses the decrease in intestinal receptors. Vitamin D replacement also improves oral calcium absorption. In aged rabbits, the renal response to PTH is blunted. There is a decrease in the stimulatory effect via cAMP on the Ca^{2+}/Mg^{2+}-ATPase. This may lead to decreased calcium reabsorption and increased urinary calcium loss.

Calcium availability is decreased in the elderly because of decreased dietary uptake and synthesis of vitamin D, which contributes to decreased intestinal calcium absorption. Over 40% of adults over 50 years of age may be vitamin D deficient. For most adults, 5–10 minutes of direct sun or UVB exposure daily can offset this deficiency. Vitamin D deficiency contributes to calcium imbalance and can cause osteomalacia and muscle weakness. Vitamin D deficiency has also been associated with increased risk for cancer and cardiovascular disease. Surveillance for vitamin D deficiency should be done by yearly monitoring of 25-hydroxyvitamin D.

Intestinal absorption of calcium decreases with age, especially after age 70. Intestinal calcium uptake decreases in senescent rats as a result of decreased stimulation by 1,25-dihydroxyvitamin D and a decline in calcium transport proteins. GH and PTH act synergistically to increase intestinal absorption of calcium in aged female rats. IGF-1 increases Ca^{2+} transport across human intestinal cells *in vitro* independent of 1,25-hydroxyvitamin D and may mediate the effect of GH. Thus, this defect in intestinal transport may result, at least in part, from the decreased GH levels that are seen in aging. In addition, IGF-1 levels in femoral cortical bone have been shown to decrease in both men and women between the third and sixth decade of life. This may affect calcium transport into bone. Calcium imbalance in the elderly leads to increases in PTH and increased phosphate diuresis. PTH binds to specific receptors on osteoblasts, upregulating RANK-L (receptor for activation of nuclear factor-κB ligand) expression and downregulating osteoprotegrin (OPG). This leads to increased differentiation of osteoclasts and bone resorption.

Aging also affects calcitonin (CT) secretion in female rats. In old but not young rats, ovariectomy causes an increase in basal and Ca-stimulated CT levels. Estradiol reduces the plasma CT in response to hypercalcemia in old ovariectomized rats.

With increasing age, pluripotent mesenchymal cells present in bone marrow decrease differentiation into osteoblasts and chondrocytes and reciprocally increase differentiation into adipocytes. Therapeutic strategies to prevent bone loss may target factors that regulate progenitor cell fate.

Osteopenia

Skeletal development is maximal in healthy individuals at age 25 in women and at age 30–35 in men. Bone changes occur during normal aging in both men and women. These changes include alterations in the dynamics of bone cell populations, uncoupling bone formation and resorption, changes in bone architecture, accumulation of microfractures, and changes in mineralization and in the protein matrix. Aging also induces a decrease in skeletal mass. Osteopenia is defined as clinically significant bone loss. In addition to loss of bone mass, osteoporosis is accompanied by bone pain, spinal deformity, loss of height, and an increased incidence of fractures. In healthy males, radial bone mineral content (BMC) decreases by 1% per year between 30 and 87 years of age, whereas vertebral BMC decreases by 2.3% per year. Treatment with calcium carbonate and cholecalciferol for 3 years does not prevent the decrease in subjects with a high basal dietary calcium intake (>1100 mg/day). In addition, between the ages of 35 and 70 cortical bone strength in bending is decreased by 15–20%, and cancellous bone strength in compression is reduced by about 50%. Bone becomes increasingly brittle and fractures with less energy.

Susceptibility to clinically significant osteopenia is affected by many variables including genetics, nutritional status, body mass, exercise, and peak bone mass. Hormonal deficiency such as GH may contribute to lower than normal peak bone mass. Diabetes may be an additional risk factor for development of osteopenia. In rats, both aging and type 1 diabetes result in increased collagen-linked fluorescence in bone, a measure of non-enzymatic cross-links, which is correlated with decreased bone density, decreased serum osteocalcin, and increased bone fragility. Osteopenia can in part be prevented from progressing to osteoporosis by maintaining good nutritional status (protein, calcium, vitamin D) and adequate physical activity.

Gonadal steroid effects on bone may be sex specific. During development the bone metabolic response to gonadal hormones becomes gender dependent on androgens in males and on estrogens in females. Androgen deficiency causes osteopenia in aging male rats. This can be reversed by treatment with T, 5α-dihydrotestosterone, or E_2.

In aged ovariectomized rats, treatment with E_2 prevents loss of spinal bone mineral content. Calcitonin is less effective. However, N-terminal human PTH alone or in combination with E_2 or calcitonin increases BMC to sham-operated levels and increases mechanical strength. This is of special interest because E_2 treatment in oophorectomized women increases intestinal calcium absorption independent of 1,25-dihydroxyvitamin D, prevents BMC loss, and increases serum calcitonin levels. At least one large study has shown that bone mineral density in postmenopausal women can be maintained by estrogen replacement into the ninth decade of life.

Treatment with oral calcium and vitamin D is also effective. Treatment with 800 IU/day of vitamin D decreased the fracture rate in a group of French nursing home patients. Other studies using 1,25-dihydroxyvitamin D have shown improved calcium absorption and BMC with a significant decrease in fracture rates.

First-line treatments for both men and women with primary osteoporosis are calcium and vitamin D supplementation and alendrolate therapy. Other approved therapies include gonadal steroids, if deficient, and recombinant PTH or calcitonin.

Carbohydrate Metabolism in the Elderly

A decline in glucose tolerance with age is a common finding that leads to an increased incidence of type 2 diabetes (T2DM) in the elderly. If we define diabetes by an oral glucose tolerance test value greater than 200 mg/dl at 2 h with at least one additional value also above 200, then the percentage of affected males in the United States rises steadily from 5% at age 25 to over 30% at age 85. By age 60, 18.3% of persons have diabetes. Nearly 50% of individuals with T2DM are over the age of 65 years.

Elderly persons have reduced insulin sensitivity and impaired insulin-mediated glucose uptake in peripheral tissues, especially skeletal muscle. Impaired insulin action with age is not generally accompanied by change in insulin membrane receptors in target cells. Decreased target cell membrane insertion of the insulin-sensitive glucose transporter GLUT-4 may be responsible for the defect. Exercise in middle-aged subjects with T2DM has been shown to elevate levels of GLUT-4 in skeletal muscle and improve glucose tolerance. Exercise in elderly men has been shown to increase the resting metabolic rate and possibly decrease circulating insulin levels and insulin-to-glucose ratios, implying an increase in insulin sensitivity. These differences are inversely related to the percent body fat composition of subjects.

The pancreatic islets show an increased sensitivity to inhibition of insulin release by somatostatin. In rats, the impaired secretion is increased by treatment of islets with somatostatin antibodies. The insulin-to-glucose ratio is usually decreased, suggesting relative islet cell resistance to glucose-stimulated insulin release. The last phenomenon may be related in part to reduced islet cell adenyl cyclase activity.

The insulin clearance rate decreases modestly from a half-life of 11 min in the young to 13 min in the elderly. Glucagon clearance is not changed, and plasma levels of glucagon do not change with age in humans. In rats, secretion of glucagon from pancreatic islets increases with aging. The age-related change in glucagon secretion may be secondary to altered glucose homeostasis or to reduced pancreatic α-cell responsiveness to glucose or paracrine regulatory factors. In the elderly, the lipolytic and ketogenic but not the hyperglycemic responses to pulsatile glucacon are significantly reduced.

The prevalence of diabetic complications, including retinopathy, nephropathy, and neuropathy, increases with the duration of diabetes. Aging may accelerate the onset of complications due to synergistic effects of aging and diabetes on cellular metabolism. Both aging and diabetes can cause oxidative imbalance, leading to increased production of reactive oxygen species (ROS) and reactive nitrogen species (RNS). Increased ROS and RNS are associated with increased damage to DNA and impaired protein function.

Advanced glycation end products (AGEs) form spontaneously from glucose-derived Amadori products and accumulate on long-lived tissue protein. AGEs have been implicated in the pathophysiology of both aging and diabetes.

Pentosidine, a glycation reaction product found in skin and glomerular basement membrane, increases with age. Levels are further elevated above the 95% confidence limit in 80% of diabetics, both type 1 and type 2, compared with age-related non-diabetic controls.

Vibratory perception and thermal discrimination decrease with both age and diabetes. Autonomic distinction is also compromised by both factors. Both T1DM and T2DM patients develop superior mesenteric ganglioneuronal lesions prematurely and in greater numbers than non-diabetics.

A number of age-related coexisting disorders may complicate the management of diabetes in the elderly. These include hypodipsia, anorexia, visual impairment, impaired baroreceptor response, depression, altered renal or hepatic function, and multiple medications. Reduced thirst perception and polypharmacy increase the risk of hyperglycemic hyperosmolar coma. The elderly are more prone to hypoglycemia from use of sulfonylureas but may also have a more varied response to insulin. Variations in response to insulin with exercise are also heightened in the elderly. Dietary management may be more difficult, and exercise regimens should be tailored individually according to coexisting physical limitations such as organic heart disease.

In normal aging, the pancreas shows loss of compact structure of islets with hyalinization, increased amyloid deposition, and increased incidence of tumors, especially islet cell tumors. Hyalinization is found in almost 50% of diabetic patients over the age of 60. Islet amyloid polypeptide (IAPP or amylin) is co-secreted with insulin from the pancreatic β-cells. Amyloid deposits, which are associated with increased β-cell death and reduced β-cell mass, are present in the pancreatic islets of approximately 60% of elderly diabetic subjects. Most islet cell tumors, especially glucagonomas and somatostatinomas, are diagnosed in the fifth through seventh decades of life.

Water Metabolism in the Elderly

Multiple interrelated changes in water and electrolyte homeostasis occur with aging (**Table 2**). Elderly subjects show unusual thirst following dehydration, heat stress, or hypertonic saline infusion. There is a change in perception of thirst, possibly a deficit in the opioid-sensitive drinking drive, mediated through oropharyngeal receptors. Naloxone administration decreases fluid intake in young but not old subjects after overnight fluid deprivation; older subjects have a lower rehydration intake after placebo as well.

AVP secretion from the pituitary gland responds to salt (osmoreceptor) and fluid status (baroreceptor). Baseline AVP secretion in healthy elderly, both supine and ambulatory, may not differ from healthy young subjects when there is no age-related difference in serum osmolarity. However, some studies have shown an increase in baseline AVP with age. This may be a compensatory mechanism reacting to a decrease in vasopressin receptor sensitivity in the kidney. There is a rise in AVP following dehydration in both young and old. However, the lowest level of plasma osmolality that will initiate AVP secretion (osmotic threshold) is reduced in the elderly. In addition, the rehydration decrease in AVP found in young subjects is not seen in the elderly.

Table 2 Age-related changes in water and salt homeostasis[a]

Parameter	*Change*
Thirst	↓
AVP, baseline	↑ or no change
AVP, after dehydration	↑ (reduced threshold)
Renal response to AVP	↓
Renin-angiotensin	↓
ANP	↑
Renal response to ANP	↓ or no change
Aldosterone responsiveness	↓ (2°↓PRA)
Baroreflex sensitivity	↓

[a] AVP, arginine vasopressin; ANP, atrial natriuretic peptide; PRA, plasma renin activity; ↓, decrease; ↑, increase.

Older subjects also show a reduced AVP response to volume-pressure change with relative renal resistance to AVP. The decreased response may be due to changes in AVP receptors in the kidney. Decreased cyclic AMP (cAMP) generation in response to AVP is involved in the age-related impairment of urinary concentrating ability. This may predispose the elderly to dehydration when intercurrent illness causes increased water loss or limited access to water.

Another important physiological stimulus of AVP secretion is angiotensin II. With aging, plasma renin activity is decreased along with a reduction in angiotensin-converting enzyme activity. Thus, the elderly have a reduced capacity for generating angiotensin II, a potent stimulator of AVP secretion and thirst. Hypoangiotensinemia has been implicated as the pathogenetic mechanism of dehydration in a group of hypernatremic elderly patients.

Approximately 3% of elderly subjects develop nocturnal polyuria syndrome (NPS), characterized by deterioration of the 24 h rhythm of AVP, in which secretion is normally higher at night. AVP levels are very low or undetectable and may be lower at night than daytime. NPS is characterized by nocturia and sleep loss. It can be treated by avoidance of excessive fluid intake, dosing of any diuretic medications in the afternoon, and oral desmopressin at bedtime.

Aging is associated with a decreased ability to excrete salt and water, thus increasing susceptibility to volume overload in elderly individuals. Atrial natriuretic peptide (ANP) is secreted in response to volume expansion and has both diuretic and natriuretic actions. Baseline ANP has been found to be elevated in elderly humans and aged rats. The normal decrease in ANP following dehydration is blunted in the elderly. The source of increased ANP appears to be increased cardiac peptide synthesis, as mRNA levels and immunoreactive peptide are both increased in the left ventricle of aged rats. Young subjects exhibit a significant circadian rhythm for ANP, which elderly subjects do not have.

The effects of aging on ANP action in the kidney are controversial. A 2 h low-dose ANP analog infusion in one group of healthy elderly men failed to elicit the expected change in blood pressure or renal salt excretion, despite an increase in urinary cyclic guanosine monophosphate (cGMP). Others have found the natriuretic effect of native ANP to be preserved in aging despite a diminished renal hemodynamic response. Renal blood flow decreases and renal vascular resistance increases in young but not old subjects after a 2 h peptide infusion.

ANP suppresses vasopressin release and raises the threshold of vasopressin release in response to osmotic stimulation in both young and elderly individuals. High baseline circulating ANP levels may be in part responsible for the observed decrease in plasma renin activity (PRA). PRA is decreased up to 50% in the elderly, and reduction in PRA is probably the main cause of the decreased aldosterone responsiveness observed in the elderly.

Environmental Gerontology

H-W Wahl, Institute of Psychology, Department of Psychological Aging Research, University of Heidelberg, Heidelberg, Germany
L N Gitlin, Center for Applied Research on Aging and Health at Thomas Jefferson University, Philadelphia, PA, USA

Glossary

Environment – According to Lawton, the objective physical environment refers to all that lies outside the skin, that is inanimate, and that is measurable in centimeters, grams, or seconds. The subjective environment addresses the gamut of processes operating when aging individuals form cognitive and affective ties to their physical–spatial environments.

Environmental Attributes – Attributes characterizing the environment, the most important of which are safety, accessibility, orientation, privacy, and control.

Environmental Functions – As Lawton suggests, the different functions that environments can serve as people age, including maintenance, support, and stimulation.

Person–Environment Fit – The basic assumption that diverse aging outcomes are linked to different person–environment constellations, characterized by differential person and environmental attributes. The better personal attributes fit with environmental attributes, the better the expected outcome.

Introduction

Aging always occurs in a context. Environmental gerontology, as a major area within the wide array of aging research, places special emphasis on deriving an in-depth understanding of the interrelations between aging persons and their environments and how these relationships shape aging outcomes. The overarching aim of environmental gerontology is thus to describe, explain, and modify or optimize the relationship between the aging person and his or her sociophysical environment, a task accomplished within an interdisciplinary framework. Given that persons with declining competencies are especially vulnerable to their environments, a particular focus of environmental gerontology has been on person–environmental attributes such as safety, accessibility, orientation, privacy, autonomy, and personal control

among the very old and individuals with a high prevalence of physical and cognitive impairments and chronic illnesses. Nevertheless, the scope of environmental gerontology is expansive and considers aging processes within environmental contexts across the continuum of wellness, from the highly competent to the very frail. A range of theories has been suggested to address both the objective and subjective processes of aging individuals interacting in their environments. Theories considering the objective dimension of person–environment relations have primarily focused on level and type of competencies of aging individuals in relation to design characteristics and the press or demands of physical environments. Other theories have posited a range of psychosocial processes by which aging individuals form cognitive and affective connections and how these in turn affect health and well-being. Looking ahead, designing and optimizing environments for older people is one of the most critical societal tasks in view of the dramatic changes in the age structure throughout the world and the important role of the environment in supporting, promoting, and sustaining life quality. Because of this, aging research on person–environment relations will probably grow in importance in the future.

Mission and Ambition of Environmental Gerontology

Environmental gerontology strives to understand the role of the sociophysical environment in the maintenance and improvement of autonomy and well-being of aging individuals and, specifically, the relationship of persons to their environments, and its utilization and optimization. While environmental gerontology primarily considers the relevance of the full range of physical components of the environment for aging processes, also acknowledged is the strong, integrated role of the social environment, hence the term sociophysical. For example, the home environment is not only a physical structure, but also a place punctuated by pronounced intimacy with one's partner, social interactions, and the symbolization of attachment, normalcy, and loss. Thus, the term environment as used in environmental gerontology predominantly refers to the physical environment, but also acknowledges its interwoven nature with social and cultural accoutrements and implications. Moreover, environmental gerontology is founded in the basic principle that old age is a critical phase in the life course that can be characterized as being profoundly influenced by the sociophysical environment. That is, as people age, place matters more, and, importantly, it matters differentially based principally on a person's sociocultural background, somatic and psychic health, and cognitive and physical functional abilities.

Since aging had long been considered as a process driven chiefly by a genetic and biological program inherent in the organism, the explicit consideration of the sociophysical environment and how the aging process unfolds or manifests in different contexts was an important step in the historical development of gerontology. This paradigm shift, from viewing aging strictly from a physiological perspective to a more complex vision of its environmental expression, was mainly driven by the growing role of a social and behavioral scientific stance within gerontology beginning in the 1930s. In addition to considering biological and health changes or personality characteristics per se, it was also assumed that aging is strongly influenced by variables such as social relations, housing, neighborhood conditions, and urban or rural settings.

The overarching aim of environmental gerontology is to describe, explain, and modify or optimize the relationship between the aging person and his or her sociophysical environment. Environmental gerontology places a strong emphasis on day-to-day contexts of aging individuals, reinforcing the notion that this everyday world in natural settings deserves the full attention of gerontological research. A prototypical issue is that older people spend most time in their home environment, and as a consequence, housing characteristics, as the major setting in which aging unfolds, has been a major focus of research in environmental gerontology from its inception.

The task of explanation basically relies on German psychologist Kurt Lewin's fundamental definition of the life space as a function of the person and his or her environment ($B = f(P\ E)$). American environmental gerontologist M. Powell Lawton suggested an addition to the ecological equation ($B = f(P\ E\ P \times E)$) to account for the influence of person–environment interactions. This interaction term suggests that person-related competencies and needs operate or manifest differently in different environments and lead to dissimilar outcomes. For instance, having low or high mobility competence may not affect the autonomy of an individual to obtain a goal such as ascending stairs if an escalator is also available. However, if an escalator is not available, the autonomy of the low-mobility person may be highly threatened, whereas there may be no effect on autonomy for the person with high mobility.

The focus on modification and optimization reflects the aspiration of environmental gerontology to have a substantial and direct contribution to the improvement of quality of life in old age. Prototypical is the involvement of environmental gerontology

in advancing evidence-driven home modifications or the design of public spaces with the goal of enhancing autonomy and well-being as people age.

Given the broad array of goals of environmental gerontology, it is not surprising that it is founded upon and nurtured by a diversity of scholarly inputs, and that an interdisciplinary approach – covering disciplines such as psychology, sociology, architecture, social geography, occupational therapy, urban planning, health and social policy, technology, and design – is essential. As a consequence, overlap with other major research and practice areas in gerontology such as housing, institutional aging, or gerontechnology is obvious and necessary.

The Aging Person and the Environment – General Considerations

Although the interaction between aging individuals and their environments is a fundamental tenet of environmental gerontology, it remains helpful to consider basic issues specific to the person and the environment separately.

The Aging Person's Competencies and Needs as Related to the Environment

Considerations on the societal, demographic, and individual level provide an important backdrop for research pursuits in environmental gerontology. The number of people aged 65 or older will soon reach 20% of the American population, a number similar to many other developed countries. In addition, older people are the most diverse of all age groups, thus pointing to pronounced heterogeneity in lifestyles, needs, and preferences. Of equal importance is that the fastest growing segment of the older population continues to be the 85 and older group. Concomitantly, the number of persons who care for a family member steadily increases. Currently, one out of every three persons is or will be a caregiver of a loved one.

The implications of these trends for person–environment research are manifold. First, given the prominence of housing as the major day-to-day context of aging, research related to the potential and constraints of the home environment is an important avenue to preserving health and quality of life in later life. Designing and optimizing environments for the full heterogeneity of aging persons are among the most critical areas of research as well as societal challenges in the future. Second, the oldest old are at higher risk of requiring personal assistance, living alone, having a lower income, being socially isolated, living in homes in need of repair, and living in neighborhoods with a tendency toward decline. The link between environment and health is therefore particularly powerful for the oldest old, who also are at greater risk for chronic diseases and functional vulnerabilities that impact everyday living. In other words, the everyday difficulties imposed by age-related diseases such as mobility problems, sensory loss, or cognitive impairment significantly shape the dynamics of persons and environments; this is particularly true for very old people with varying degrees of functional abilities. A related point is that the home environment is rapidly evolving into the primary context in which medical, rehabilitative, and palliative care is provided. Third, independent of existing vulnerabilities and frailty, there has been and continues to be a strong desire of old and very old people to age in place, or remain in their familiar home environment or an environment of their choice for as long as possible and feasible for themselves and their family members. This desire may ultimately reflect an optimization strategy critical to late life that affords continuance and control over important aspects of daily life, including routines, self-care, and other potentially meaningful and self-defining activities. Seen from this perspective, person–environment considerations are critical to understanding the meaning of the good life in old age and the potential and limitations of private and professional caregiver arrangements.

Environmental Characteristics as Related to the Aging Person

Due to the emphasis in environmental gerontology on the physical environment, a definition of the environment is necessary and should specifically focus on this aspect of the life space. According to Lawton, the objective physical environment covers all that lies outside the skin, that is inanimate, and that is measurable in centimeters, grams, or seconds. A full set of empirical findings underscores how objective features of environments influence aging on a variety of levels. For example, older people who live in high-rise buildings or on higher floors report less satisfaction with their housing and tend to leave their homes less frequently. Distance to public transportation or green areas shapes the outdoor mobility and social interaction patterns of older people. Of equal importance is how the objective environment is subjectively experienced in affective and cognitive terms and personal meanings. How functional changes are experienced can be quite diverse in aging individuals faced with similar objective environmental conditions.

Empirical research has also underscored the importance of considering the role of the subjective experience of environments on an older person's behavior. For example, even very poor housing quality is associated with relatively high residential satisfaction and attachment to place and may not necessarily be a motivating factor for relocation. The use of outside environments may be shaped by feelings of safety and security that may or may not be justified based on objective crime rates or other objective safety characteristics.

A variety of attributes have been suggested as characterizing any type of environment. Safety of the environment is among the most important prerequisite for users. Accessibility of the environment is of vital importance to the participation in society by all citizens, but particularly old and disabled persons. Accessibility can be assessed based on existing norms and guidelines, aimed at ensuring that a majority of members of a given society (ideally all) are able to use environments independent of competence status. Orientation addresses the potential of the environment to guide navigation or way-finding. For example, nursing home environments can be designed to support way-finding even for persons with impaired cognitive capacity. Privacy refers to the possibility provided by the environment to retreat and have a place of pronounced and undisturbed personal intimacy. This is another prototypical challenge of institutional aging, but can also become an issue in private housing when pronounced personal care needs infuse small shared spaces. Control of environmental conditions addresses the possibility of exerting self-directed changes and achieving personal needs or life goals.

Additionally, environments can be categorized according to their different functions in promoting quality of life. Again, Lawton has made a convincing suggestion for a tripartite, overarching general classification scheme. First, environments can have a supportive function in compensating for lost competencies as people age. Second, environments can stimulate daily life, for example, by the experience of novelty caused by a new item in the home environment or by strolling in an attractive park area. Third, environments have a maintaining function; that is, they add to the aging person's striving for continuity and meaning. Seen from a life course perspective, the stimulating function of the environment can be expected to be more important for the young old, while the supportive and maintaining functions become increasingly critical as people pass from old to very old age.

A final consideration of environments has to do with different levels of analysis of person–environment interactions. On one hand, at the micro-level, it is important to focus on the aging person in his or her concrete home environment. At the macro-level, research driven by the urban–rural distinction and housing policies is important for the understanding of person–place relations as people age.

Understanding Person–Environment Relations as People Age: Major Conceptions and Findings

The in-depth understanding of person–environment processes and outcomes has so far not been achieved by one major theory; rather, a multitude of conceptual approaches that augment and build on each other in a pluralistic manner infuse the field.

Objective Approaches to Person–Environment Relations

One major assumption of person–environment relations is the environmental docility hypothesis, initially proposed by Lawton and Simon in 1968 and refined and graphically expressed in 1973 by Lawton and Nahemow's competence-environmental press model (**Figure 1**).

The competence-environmental press model provides a broad, overarching framework that allows different types and levels of competence such as sensory loss, physical mobility loss, and cognitive decline and environmental factors including housing standards, neighborhood conditions, and public transport to be considered. Perhaps the most important element of the competence–press model is its fundamental assumption that for each aging person there is an optimal combination of (still) available competence and environmental circumstances leading to the relative highest possible behavioral and emotional functioning for that person. A term frequently used for this in environmental gerontology is person–environment fit. The model also suggests that it is at the lower levels of competence that older people become the most susceptible to their environment, such that low competence in conjunction with high environmental press negatively impacts an individual's autonomy, affect, and well-being. A related point is that as competencies decline, the zone of adaptation narrows, such that environmental choices that can promote well-being become increasingly more limited although there is always an option. The competence–environmental press framework continues to provide the basic mechanism of person–environment relations as people age and has been supported by a considerable body of empirical

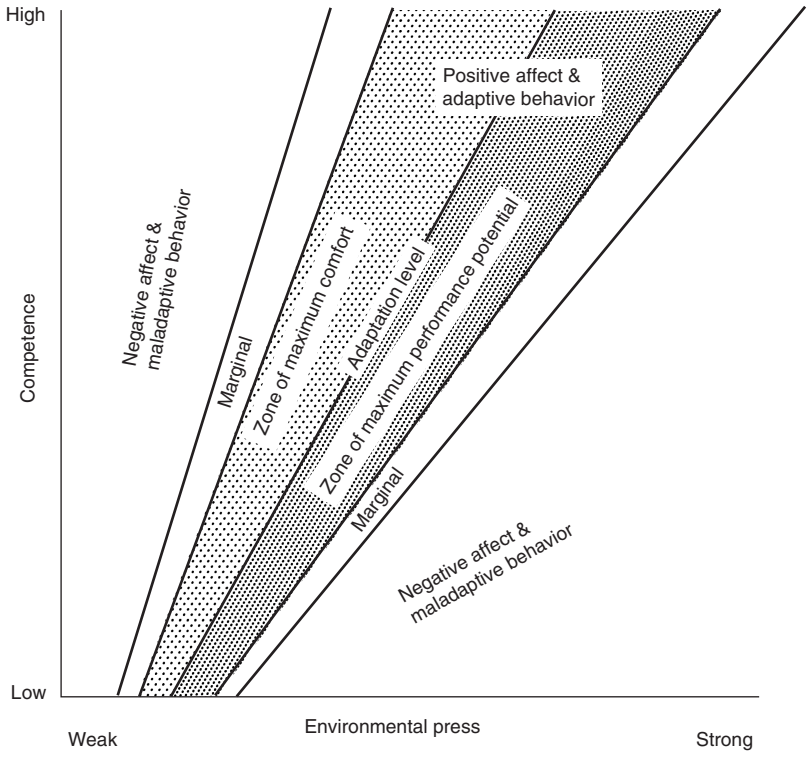

Figure 1 The competence-environmental press model as originally suggested by Lawton and Nahemow (1973). Redrawn from Lawton MP and Nahemow L (1973) Ecology and the aging process. research. For example, research on the impact of physical distances on social interaction patterns of elders in institutional settings shows that longer distances undermine social relations, thus highlighting the environmental docility as people age. Furthermore, the competence–press model has become a major driver in the practical world of designing and optimizing environments for older people.

In addition to putting emphasis on competence as is done in the competence–press model, other conceptions of person–environment fit as suggested by Carp and Kahana underscore the role of motivation in person–environment relations. The basic assumption is that misfits between given needs and given environmental options to fulfill these needs are linked with lowered behavioral functioning and well-being. Empirical support for this assumption has been reported by studies conducted in institutional settings as well as private home environments. For example, remaining autonomy in visually impaired elders was found to depend on how much the physical layout of home environments adds to the compensation of the vision loss. Furthermore, a distinction between an older person's basic versus higher-order needs has been suggested. Basic needs are related to basic issues of maintaining competence (e.g., maintaining independent self-care), while higher-order needs address issues such as privacy and affiliation. While person–environment misfit in the basic need domain predominantly results in reduced behavioral autonomy, misfit in the higher-order need realm may also undermine emotional well-being and mental health.

Social ecology concepts suggested by scholars such as Baltes assume close links between physical environments and the social behavior of persons acting in these settings. Institutions have formed an ideal arena for social ecology approaches, driven by the assumption that a behavioral setting in which care professionals regularly interact with residents has major consequences for their autonomy in the longer run. The empirical application of this model has produced profound insights into the role of the social environment in dependent behavior of nursing home residents by repeatedly identifying robust interaction patterns characterized as a dependence support script. According to this interaction script, staff tend to overly support or encourage dependent behaviors of residents, while independent behaviors are mostly overlooked.

The person–environment stress model argues that objective environmental conditions such as a lack of accessibility, privacy, or control in one's environment may provide the source for stress experiences. For instance, aging individuals may feel a psychological threat, apathy, reduced well-being, or depression as a consequence of such a stress experience. This model can be applied to family caregiving as well. For example, difficult to manage dementia-related behaviors and lack of control over daily routines reflect the objective environmental conditions that typically confront families of persons with dementia. These environmental stressors over and above subjective appraisals of the care situation may affect a caregiver and result in significant stress, anxiety, or depression.

Finally, relocation may be seen as the most radical alteration in person–place relations. The understanding of residential decisions and their outcomes in old age has attracted environmental gerontology from early on in the development of the field. Early research in the 1960s and 1970s provided by scholars such as Coffman was mainly driven by the relocation trauma hypothesis, in which mostly negative health effects of moving in later life were assumed. Relocation to an institutional setting was the prototypical case for applying the relocation trauma hypothesis. The empirical evidence, however, remained controversial and was plagued by methodological problems such as selectivity of study samples, overinclusion of the frail, and lack of control groups. Litwak and Longino suggested in 1987 a distinction between first, second, and third moves by relying on the assumption of a substantial association between chronological age and type and motivation of move. Whereas first moves often take place early in the aging process, i.e., close to retirement, and are usually prompted by the amenities associated with the desired place of residence, second moves, occurring in the 70s and early 80s, are predominantly characterized by moving back to the place of origin, reflecting a higher need for support and proximity to kinship. Third moves are often relocations to institutions due to frailties that are not compensable by family resources in very old age. As has been found in more recent research, relocation is driven in current cohorts of older people by a variety of motivations, among which higher-order needs such as access to participation in social, cultural, and educational opportunities appear to become increasingly important. A primary example is the so-called sunbelt movers, that is, the movement of mostly young old people to places better serving their needs in terms of climatic conditions and/or surrounding communities, as is found in so-called sun cities.

Subjective Approaches to Person–Environment Relations

In contrast to the foregoing approaches pointing mostly to the role of the objective environment, the gamut of processes operating when aging individuals form cognitive and affective ties to their physical-spatial environments has also found important conceptual and empirical consideration.

The classic approach addressing the cognitive-affective relation to the physical environment is reflected in the construct of housing satisfaction. As has consistently been found, elders, both healthy and frail, tend to score high in measures related to this construct, regardless of their objective home and neighborhood conditions. This has been coined the housing satisfaction paradox. A common explanation is that anticipating a move may be psychologically threatening for many older people. Thus, enhancing the evaluation of one's environmental quality becomes the only option to reduce the resulting cognitive dissonance of living in worsening conditions without being able to relocate.

In addition to residential satisfaction, which has been measured primarily in a unidimensional manner based on a single question, sophisticated approaches have emerged to provide a more nuanced understanding of the subjective world of aging in place. One widely acknowledged approach suggested by Rowles in 1983 has focused on the many faces of what he has coined insideness. According to Rowles, different types of insideness that speak to the transition of spaces into places can be empirically derived. Whereas social insideness arises from everyday social exchanges over long periods of time, physical insideness is characterized by familiarities and routines within given settings such as the home environment. A third element of insideness has been labeled autobiographical insideness, that is, places that carry a rich collection of memories and thus support the aging individual's sense of place identity. Empirical research has also shown that physical insideness is particularly important for aging individuals with chronically disabling conditions.

Rubinstein's conception of the meaning of home relies on the assumption that the active management of the environment in itself represents a major source of well-being as people age, especially for those who are frail or living alone. Rubinstein identifies three classes of psychosocial processes that give meaning to the home environment: (1) social-centered processes, ordering of the home environment based on a person's version of sociocultural rules for domestic order, (2) person-centered processes, expression of one's life course in features of the home, and

(3) body-centered processes, the ongoing relationship of the body to the environmental features that surround it.

Furthermore, place attachment has been defined as reflecting feelings about a geographic location and emotional binding of a person to places. As has been empirically found, place attachment seems to steadily grow across the life course, reaching its culminating point in very old age. This also underscores the point that forced relocation in very old age (third moves, particularly to institutions) due to a chronically disabling condition is a critical life event and a profound challenge for maintaining well-being and a sense of identity.

The Disablement Process and the Environment

The environment has a very specific and critical role in the disablement process. Despite variations in models of disablement, a similar process is proposed such that a pathway or trajectory from pathology (a disease state) to distinct but related and measurable consequences occurs. Specifically, pathology, defined as an interruption or interference of normal physiological and developmental processes, is viewed as resulting in neurological or physiological deficits, the basic consequence of which is impairment. Impairment, defined as an abnormality at the organ level (cognitive, motor perception, sensory or psychological function), may in turn impact or lead to a functional limitation. Functional limitations refer to restrictions in performing basic physical and mental actions. Physical actions may include mobility (e.g., walking), stooping, reaching, grasping, or sensory issues (e.g., trouble hearing, seeing, or communicating), whereas mental actions refer to cognitive and emotional functions (e.g., short-term memory, orientation in time and space, or affect). In turn, the impaired ability to perform such basic actions may lead to disability. Disability refers to having difficulty performing essential activities of daily life including basic and instrumental care, social recreational participation, and socialization. As such, disability may reflect a gap between a person's capability, the demands of a particular task, and the social and physical environment.

Verbrugge and Jette's widely acknowledged iteration of the disablement process dating from 1994 suggests two related notions of competency related to the environment: an individual's ability regardless of context, which is referred to as intrinsic ability, and an individual's ability as supported or constrained by the person's physical and social environment, referred to as actual disability. The implication is that the interaction between a person's intrinsic abilities and the built environment, including both its physical and social characteristics, yields actual disability. Thus, one conclusion is that disability is an outcome of potentially modifiable environmental factors and can therefore be minimized. Although Verbrugge and Jette's model does not articulate the specific pathways between human behavior and the physical environment, it provides a framework for such linkages to be examined and underscores that objective conditions (e.g., presence of external supports, home modification) may offset further disablement independently of and/or in conjunction with personal appraisals and social resources.

Approaching Person–Environment Relations on the Macro-Level of Analysis

The aforementioned approaches predominantly consider person–environment interactions on the micro-level of analysis; that is, the focus is on obtaining an in-depth understanding of the role of the immediate environment within which people age. However, as Bronfenbrenner's ecological theory of human development and other social science approaches suggest, in targeting person–environment relations, the micro-environmental level is undoubtedly influenced and shaped by macro-level environmental contexts, including the neighborhood at large, housing policies, economic standards, cultural values and beliefs, and social and long-term care service provision and policies. These factors all form the environmental context of aging with varying immediate and distal impacts on the everyday life of people as they age. The quality of neighborhood settings may strongly impact the physical range and timing of out-of-home activities as people age. An important consideration is the life course perspective. It could well be that persons initially live in high-quality neighborhoods that subsequently decline over time, placing people in the later years of their life at a disadvantage. Another classic research question is the urban–rural distinction and how this affects aging. For example, use of the outside environment may depend on public transportation possibilities, which may be more underdeveloped in rural than urban regions. On the other hand, the macro-level perspective also considers the diversity in cultural norms, and disadvantages in person–environment options in rural areas could be compensated for because of stronger intergenerational ties and higher prevalence of cohabitation of older and younger family members. Still, the consideration of person–environment interrelations is worth considering across countries, i.e., as a cross-cultural research

challenge. For example, the definition of barrier-free environments and respective legislative norms and regulations probably depends on the economic situation as well as on different cultural conceptions of autonomy and the role of physical environments compared to social environments such as the family system.

The Need for an Integrative View

There is no one theoretical accounting or approach that best captures the many facets and complexities of person–environment interrelations and that has driven empirical research in the field thus far. The heuristic fruitfulness of using the full family of concepts, theories, and analytic levels can be seen as follows. First, different concepts and theories point to the gamut of essential elements of environmental resources critical for quality of life in old age. In particular, the objective environment is more relevant for outcomes such as autonomous day-to-day functioning, whereas cognitive and affective bonding to the environment is related more to well-being, identity, and meaning as people age. It is, however, important to also address the linkages between objective and subjective person–place relations. Second, there is the need to consider the interrelatedness of different environments: home and outdoors, micro- and macro-environmental levels. It is reasonable to assume that a balanced view of behavior as shaped by the home environment as well as by out-of-home settings serves the purpose of understanding outcomes such as well-being or participation in the community and society at large. Third, physical and social environments, as echoed in the term socio-physical environments, must be seen as closely intertwined, each augmenting or unfolding with the other. The classic example is the strong impact of physical distance or barriers on social interaction patterns in old people. This basic insight still deserves more research based on a balanced view of the physical and social environment. Fourth, person–environment research is a strong driver of interdisciplinary aging research, requiring and enabling an integration of perspectives and disciplines as diverse as psychology, geriatrics, and architecture.

Outlook and Future Challenges

Person–environment interrelations are a major prerequisite for aging well. Given the steadily growing portion of older people with all their diversity in terms of cultural enactments, competence, needs, life situations, and living environments, environmental gerontology research and its application are closely linked to the challenges of aging societies now and in the future. Looking forward at forthcoming cohorts of older people, the dynamics of changing person–environment relations implicitly drives the aging policy debates. The home environments of the old and very old will become increasingly heterogeneous, and the classic distinction between community-residing and institutionalized most likely will not be sustained, with institutions becoming more home-like and homes assuming more functions of medical and social care. In addition, it is predicted that technology will assume a major role in the home and away, strengthening the potential for future aging in place for individuals with varying ranges of competency. As a consequence of these highly likely trends, environmental gerontology research will enter new territory, such as the interlinkages between traditional environments and new technology. Also, the role of virtual reality as a historically new person–environment interaction mode has increasing importance for persons as they age; the outcome of this remains to be seen in future environmental gerontology studies.

Epidemiology

K G Manton, Duke University, Durham, NC, USA

Glossary

Active Life Expectancy – The average number of years a member of a population may expect to live free of chronic disability.

Atherogenesis – The physiological process by which atherosclerotic plaques start and grow within an organism's circulatory system.

Carcinogenesis – The physiological processes leading to loss of growth control by cells in particular tissue systems that lead to the development of malignant cell clones or tumors.

Censoring – The systematic loss of cases in a study due to processes relevant to the study goals.

Compression of Mortality – Implies that there is a biologically fixed upper bound to the human life span near enough to a population's current life expectancy that further mortality reductions will be constrained by that limit.

Mortality Selection – The systematic loss of persons from a population due to high mortality risks being associated with specific characteristics under study.

Observation Plan – The logical structure under which data are collected to describe specific processes or event dynamics with particular characteristics.

Oldest-Old – An extremely elderly population often characterized by high rates of comorbidity and chronic disability. This group is often defined as persons either 85 and older or 95 and older.

Osteoporosis – The loss of bone mineral density, usually at later ages, and more often in postmenopausal females, due to hormonal changes.

Plasticity of Aging – The concept that the outcomes of biological processes underlying senescence and age-related health changes may be altered by exogenous factors.

Introduction

Epidemiology is the study of the causes and manifestations of disease in either free-living or experimentally

selected populations. Epidemiological methods, concepts, and data vary greatly with the specific diseases and population groups studied. For example, there are well-established epidemiological methods for the study of tropical diseases due to parasites and very different methods for examining the emergence of chronic diseases in developed country populations. This article considers a relatively new area of study, i.e., the epidemiology of aging.

Definition and Concepts

Epidemiology is the study of the effects of diseases on populations, their health and longevity, and the factors causing, and agents transmitting, disease. Classically, epidemiology was the study of disease caused by infectious organisms (i.e., the study of 'epidemics') – the rapid rise in disease incidence in a population due to a common exposure to a pathogen (or environmental toxin). Implicit in the classical concept was that there were 'host' factors determining the susceptibility of an organism to an exposure, commonly termed a pathogen (for a biological agent such as a parasite, bacteria, or virus) or an environmental hazard (for physical agents such as lead or asbestos exposure), which were transmitted to susceptible members of a population by an agent (e.g., mosquitoes for malaria or yellow fever; infected hypodermic needles for AIDS) often called the disease vector.

These and other epidemiological concepts are often modified in studying aging and chronic disease. Chronic disease epidemiology deals with disease processes, often with lengthy latency periods between exposure and disease manifestation with long natural histories of manifest, and evolving health consequences for the host. Many physiological mechanisms determining chronic disease progression involve more complex interactions, over longer periods of time, between the natural history of the disease and the physiological characteristics of the host than in infectious diseases. For example, both atherogenesis and carcinogenesis, after being triggered by exposures, could be manifest in self-sustaining 'pathological' physiological processes in the host. Interest has emerged in what has been termed 'frailty.' This is described by a general system dynamic underlying the failure of multiple organ systems that involves degradation in a number of basic metabolic parameters. This would define a relatively new type of health construct for epidemiologists in that the primary disease mechanisms are time-related failures of normal organ function and are modulated by long-term trends in environmental factors.

The interactions of disease, disability, and host characteristics in the epidemiology of aging are consequently more complex than for chronic diseases – in part because boundaries between declines in physiological function with age and age-related chronic disease processes become more difficult to define as the host's functional age increases. The need for specialized methods, data, and models also increases as, as in many developed countries, many more persons now survive to historically extreme ages. This is due to the fact that as life expectancy increases at later ages (e.g., above age 65 or 85), there is greater potential for the host physiology and the natural history of the disease to systematically change with age – and in ways that may not have been observed in the past. For example, in US Asian and Pacific Islanders, Census Bureau period life expectancy estimates for 1993 were 86.2 years for females and 80.2 years for males. This is higher than in Japan, the country with the highest life expectancy at birth (i.e., 85 years for females and 78 years for males in 2004), or in Okinawa, the Japanese prefecture with the highest life expectancy. In the small European country of Andorra, female life expectancy in 2004 was 86.6 years – 80.6 years for males. These life expectancies exceed what had been assumed to be the biological limit to human life expectancy as recently as 1980.

Not only are the US elderly (65+) and oldest-old (85+) populations growing rapidly, but also the fastest growing populations are even older. Kestenbaum found that the US centenarian population grew 7% per annum between 1980 and 1987, with that growth rate continuing – perhaps even increasing – after 1987. Similar rapid growth rates (i.e., 7–8% per annum) for centenarian populations have been observed for longer periods (i.e., two to three decades) in several European countries. Jenune suggested that no one may have survived to age 100 before 1800 and to age 110 before 1931. Thus, the emergence of large centenarian populations is a recent demographic phenomenon.

In addition, there is evidence of long-term (100+ years) declines in the age-specific prevalence of chronic disability and morbidity at late ages. Fogel and Costa and Costa found that chronic morbidity and disability prevalence declined 6% per decade for the 75 years between which Civil War veterans aged 65+ applied for pensions in 1910 and World War II veterans did so in 1985. Manton and Gu found declines in US chronic morbidity and disability prevalence over age 65 from 1982 to 1999. The rate of decline in disability prevalence was much faster (1.7% per annum) than earlier in the century, with a major acceleration in the decline (to 2.6% per annum) appearing to occur 1994 to 1999.

Thus, not only are there more very elderly persons, but the health of the extreme elderly population is systematically changing, providing evidence of the plasticity of human aging processes in individuals of extreme ages (e.g., to ages 95+) – with researchers now routinely observing disease – age interactions that had been extremely rare. Perls found that persons 95+ may be, on average, healthier than persons 20 years younger due to mortality selection. Fiatarone and colleagues found that physical function could be significantly improved at extreme ages (90+) by weight training supported by improved nutrition.

Until the 1990s, there had not been sufficiently large numbers of extreme-elderly persons in studies to analyze the trajectory of health processes at those ages. They were initially examined in intensive longitudinal studies of small (e.g., $N=273$ in the first Duke Longitudinal Study of Aging; $N=512$ in the Second Duke Longitudinal Study; the Baltimore Longitudinal Study of Aging) select elderly cohorts in local areas. A major task for epidemiological studies of aging is to discern the physiological consequences of age-related disease processes (e.g., chronic diseases such as cancer, whose risk increases as a function of the time exposed) from age-dependent processes (i.e., those related to physiological processes of senescence, e.g., the role of the telomere in affecting the fidelity of genetic trait transmission) at extreme ages in general populations. How these age–disease processes operate in the extreme-elderly population will have major consequences for US health and long-term care policy because of the high average per capita needs of those persons.

Also needed to study health at late ages are specialized longitudinal study designs to distinguish aging effects from age-related disease. For example, in studies of immune function change with age, the 'senieur' protocol was developed to exclude persons with 'latent' or early disease from control groups. Early clinical studies of aging processes found that representative samples of elderly populations give different estimates of the age rate of loss of physiological function than study populations with persons with existing chronic disease selected out to remove explicit chronic disease effects. Put differently, because the prevalence of chronic diseases increases strongly with age, it must be controlled at selection into a longitudinal study population to determine intrinsic rates of aging – as opposed to population rates of physiological change contaminated by chronic disease effects. For example, Kasch *et al.* found that the age rate of decline of cardiac function in physically active elderly populations increased at half the prior rate estimate. Kitzman and Edward, in examining changes in the myocardium with age, found that many changes once attributed to aging were caused by specific pathological processes. Other studies found relations between the shortening of telomeres in bone marrow progenitor repair cells and atherogenesis.

Another factor requiring study in the epidemiology of aging is that, along with the aging of the individual, there is a lengthy temporal trajectory – or natural history – of chronic disease processes. In infectious disease epidemiology, the natural history of a disease was often the life history of a pathogen progressing through stages of development (and degrees of infectivity) in different disease vectors (e.g., the natural history of the malarial plasmodium). This is different from studying either the cause of a chronic disease or changes in its manifestations in hosts of different physiological ages. For example, several studies found a significant prevalence of atherosclerotic plaques in young populations (e.g., in the Pathobiological Determinants of Atherosclerosis in Youth [PDAY] study at ages 15–34). Depending on interactions with risk factors (e.g., high- and low-density lipoprotein [HDL-LDL] ratio, smoking, diabetes, hypertension, factors affecting fibrinolysis, homocysteine metabolism, the production of free radicals and lipid oxidation, and growth factors affecting smooth muscles in arterial intima), atherogenesis proceeds at different rates in different persons at different ages. In interaction with stress and neuroendocrinological factors, ischemic disease of the myocardium may cause infarction, ischemia, and myocyte loss (death of myocardium). Surgical procedures and thrombolytic agents applied early in the ischemic infarction process may minimize loss of myocardium. In 2005, the use of progenitor bone marrow cells was found to modulate atherogenesis in children with genetic defects (Hurler's syndrome), with the prospect that such cell therapy may significantly delay onset of atherosclerosis in the elderly (*see* Atherosclerosis).

In highly industrialized societies such as the United States and Germany, the age-related evolution of the natural history of heart disease may be quite different. The 1988–91 National Health and Nutrition Examination Survey (NHANES III) documented the rapid achievement of many of the goals of the National Cholesterol Education program in the US population – reducing both the population mean cholesterol level and the proportion of the US population with elevated (>240 mg/dl) cholesterol. Gregg *et al.* documented declines in cholesterol, hypertension, and smoking over 40 years of the NHANES, with larger declines for people with high BMIs – only one risk factor (obesity) showed increases but accompanied

decreasing effects on mortality. In Germany, Hoffmeister and colleagues found that in cardiovascular disease (CVD), mortality declined 19% between 1984 and 1989 for persons 25–69 – mainly because of improved medical interventions and reduced case fatality rates, with some risk factors (i.e., total cholesterol and body mass index [BMI]) showing adverse trends. Thus, congestive heart failure (CHF) may be, in the future, more prevalent in those above age 70 in Germany than in the United States. In the United States, despite large decreases in stroke and coronary heart disease (CHD) mortality, CHF mortality and hospitalization rates continued to increase initially. The first declines were documented (in 1989) due to use of angiotensin-converting enzyme II (ACE-II) inhibitors but may also reflect population changes in lipoprotein profiles, the health effects of which may require 5 + years to become fully manifest (*see* Cardiovascular System; Cholesterol and Cell Plasma Membranes).

Concern has been raised that an obesity 'epidemic' is occurring in the United States that could reverse recent improvements in health (e.g., declines in disability from 1982 to 1999). Flegal found that the health effects of increases in BMI were overstated – especially in the elderly population. The net effect of abnormal (both under and over) body weight on US mortality was 25 000 deaths – making it the seventh-ranked mortality risk factor in the United States. The net effect was small, because the 'overweight' category – BMI of 25 to 29.9 – showed 86 000 fewer deaths than expected. Some evidence suggests that part of the long-term shift (increase) in the distribution of BMI may be associated with technophysiological evolution, in which environmental factors enhanced the rate of improvement in health – which was manifest in long-term increases in body size.

Critiques of the war on cancer are also undergoing revisions in that cancer mortality has been declining in the United States since 1990 – with declines (about 11%) continuing to at least 2004. These declines seem to be due both to improved treatment of diagnosed cancer (e.g., increased long-term breast cancer survival) and, as documented in NCI's SEER program, to reductions in cancer incidence (in part due to reduced smoking). It seems also that new cancer treatment technologies targeted to specific solid tumors (e.g., Herceptin to specific types of breast and pancreatic cancers) in adults have begun to show significant benefits.

The 'natural' history of certain cancers under treatment has also changed, in that, with improved surveillance to detect microdisease recurrence, it may be possible to intervene before recurrence becomes systemic. If a recurrence is detected early enough, therapies effective in treating early-stage disease may also prolong survival in early recurrent disease (*see* Cancer and Age). This may turn cancer into a chronic condition that is increasingly prevalent in the elderly rather than a major cause of acute deaths, as has been partly achieved in the United States for HIV.

Some cancers, such as prostate and multiple myeloma, have a strong age dependence, increasing in prevalence as the population ages. A predisposing condition for multiple myeloma, monoclonal gammopathies of unknown significance (MGUS), has prevalences as high as 19% in occidental populations aged 95 + . Thus, the process triggering these cancers may have a more direct relation to the genetic basis of the senescence of certain organ systems in specific racial groups (e.g., prostate cancer risk). Prostate cancer risk also rises rapidly with age and is less prevalent in Asian than in either White or Black populations.

A third factor in the epidemiology of aging is that instead of studying specific diseases, one may study age changes in the degree and type of disability of the host. This is significant in the epidemiology of aging because of the longer natural history of chronic disease processes, the greater likelihood of multiple diseases coexisting (and interacting), and the fact that a disease at the same stage may have different effects on the functioning of hosts of different physiological ages. Loss of function also may trigger lethal chronic disease. Colantonio and colleagues found loss of function to be a risk factor for stroke. Osteoporosis can lead to hip and vertebral fractures that cause disability and predisposition to diseases related to physical debilitation (e.g., pneumonia, peripheral circulatory disease, heart disease) (*see* Osteoporosis and Aging Related Bone Disorders).

Measuring functional loss is difficult in elderly populations because one is not assessing the presence or absence of a disease, but the impact over time of one or more of many predisposing diseases on the host's ability to perform specific life-sustaining functions (e.g., activities of daily living [ADLs] or instrumental ADLs [IADLs]). One also needs to assess functional changes over age (e.g., 'active' life expectancy) as well as discriminate quantitatively between different types and intensities of disability. Manton and colleagues showed how multivariate procedures could be used to identify the dimensions of function from batteries of functional and physical performance measures. There are conceptual issues involved in disability measurement that affect data collection. There is no overall 'gold standard' to validate the diagnosis of disability. Different researchers may make observations about disability that may have equal validity for each study's goals. For example,

self-reports of disability may better reflect the morale of the elderly individual and his or her self-perception of what his or her functional capacity 'should be.' This may predict the behavior of an impaired older person better than physical performance evaluations. That behavior may translate into further health and functional changes – especially in the very elderly (e.g., persons remaining active at later ages better maintain function and health).

A fourth area in the epidemiology of aging is the need to assess multiple interacting disease and disabilities. With age, the likelihood of manifesting a second (or third or fourth) disease increases. This is complicated, because in order to survive to such late ages as to incur comorbidities, the initial disease process must not be rapidly lethal. Thus, the presence of multiple comorbidities can be an indication of survival to late ages and possibly the prevalence of less aggressive forms of specific diseases (e.g., as in prostate cancer). This suggests that the threshold for defining disease, or a risk state, changes with age (e.g., changes in the criteria for hypercholesterolemia or systolic hypertension with age). This is an area of potential controversy because, although longitudinal studies may suggest decline with age in the risk associated with a particular risk factor level (e.g., a total cholesterol of 240 mg/dl), that decline may be the result of increased prevalence of chronic diseases with age. Alternately, persons in good health at late ages may have the same risk for a given risk factor level as a much younger person. This affects decisions about whether treatment of diseases should change with age. The Systolic Hypertension in the Elderly Program (SHEP) trials found that significant reductions in stroke were achieved by treating isolated systolic hypertension at late ages. In contrast, mildly elevated diastolic blood pressure (DBP) at late ages may indicate the ability of the heart to maintain perfusion even with some loss of arterial compliance – low DBP may imply impaired cardiac response (e.g., partial 'pump' failure).

A fifth concern in the epidemiology of aging is that effects of genetic factors may be different at later ages due to mortality selection. In twin studies, the maximum risk associated with a genetic predisposition to circulatory disease occurs in middle age. The risk of genetic factors tends to decline at later ages. This is likely due to lethal genetic manifestations of chronic diseases selecting out susceptible persons so survivors to late ages have more complex and subtle genetic predispositions to disease. Marenberg and colleagues showed this in a large Swedish study of CHD mortality risk in monozygotic (MZ) and dizygotic (DZ) twins. The relative risk of CHD death in MZ twins was about 15:1 in middle age – but was 1.0 at ages 85+. Similar age patterns of genetic effects were noted in other twin studies. Selection appeared to reduce the prevalence of the ApoE4 genotypes in Finnish centenarians, as well as thyroid autoantibodies in Italian centenarians and human leukocyte antigen (HLA) markers for adult-onset diabetes in Okinawan nonagenarians and centenarians. Similar effects of mortality selection on genetic risks are noted for specific cancers. Lung cancer associated with a genetic predisposition due to dysfunctions in the cytochrome P450 enzyme system had a prevalence of 69% at age 50 but 22% at age 70 (*see* Behavioral Genetics).

Conceptual Frameworks

These differences suggest that the epidemiology of aging requires specialized data, concepts, and methods to deal with the complex dynamics of multiple interacting disease and aging processes. This is illustrated in **Figure 1** by a model based on a generalization of the life table survival function (1_x) where there are 'survival' functions for morbidity and disability as well as mortality.

In **Figure 1** there are three survival curves for a hypothetical cohort. The outermost curve (C) reflects the proportion surviving to age x. The second (B) reflects the proportion of the cohort surviving to age x free of disability. The third (A) reflects the proportion surviving to age x without chronic morbidity. Areas between curves represent the number of person-years expected to be lived in a health state. For example, the area under curve C reflects the total number of person-years lived. Life expectancy is calculated by dividing the number of person-years lived by the initial cohort size. The area under curve B is the number of person-years lived without disability (but possibly with nondisabling diseases). Dividing this number of person-years by the initial cohort size yields 'active' life expectancy. The area under curve A represents the number of person-years lived free of morbidity. Division of this by the initial cohort size yields 'healthy' life expectancy.

Figure 1 is an idealization of health processes in a birth cohort because there can be many specific chronic diseases examined and because disability may vary considerably in type (e.g., cognitive impairment, lower limb impairment leading to problems with mobility) and intensity. The survival curves in **Figure 1** can be calculated in different ways depending on the data available. The most basic computations use life tables estimated from vital statistics data and disease and disability prevalence estimates from cross-sectional health surveys. Such procedures are limited in that health transitions and improvements

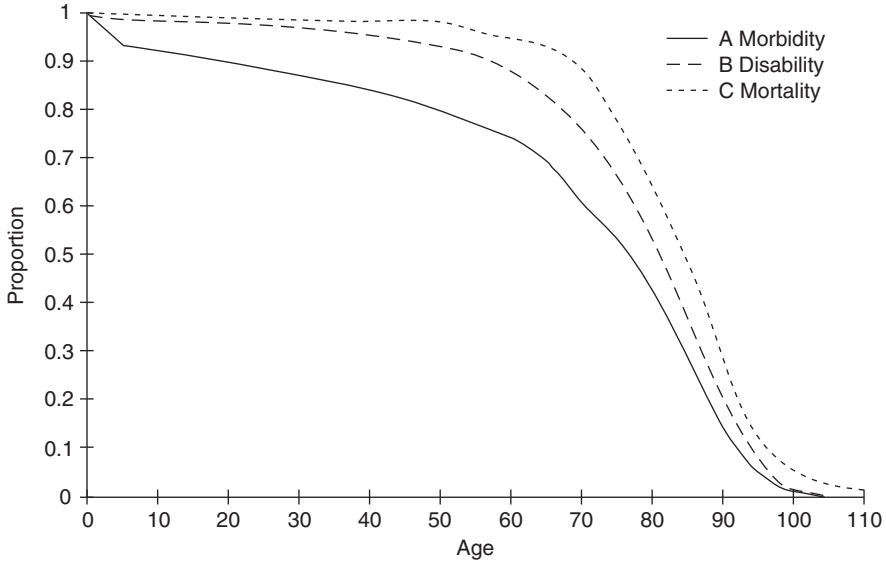

Figure 1 Theoretical relations of morbidity, disability, and mortality outcomes, represented by the change in survival over age.

in individual functioning are unobserved in cross-sectional data. To estimate models with bidirectional changes in health and function, longitudinal data are needed – with consideration of how the temporal structure of the observational plan detects health episodes of different durations. Nonetheless, **Figure 1** is useful to emphasize the changing linkage with age of mortality and disease dynamics. Even implementation with prevalence data gives useful summaries of the population impact of disease and disability at a point in time.

Fundamental to evaluating models like **Figure 1** are the effects of biological life span limits on the age linkages of mortality, disease, and disability. In many areas of epidemiology, life span limits are not important because ages that are truly extreme for humans as a species are not often studied. Studies of nonagenarians and centenarians are often restricted to small populations. The effects of life span limits are related to the rectangularization, or 'squaring,' of the human survival curve and to the 'compression of mortality.' This raises questions about the effects of life span limits on the age-specific linkage of mortality with other health events. Such questions have been termed the 'compression of morbidity' (i.e., whether the age at onset of disease or disability can be changed or delayed without increasing life expectancy). Some study designs may address this problem (e.g., in the National Long Term Care Survey of 1994, 1999, and 2004, oversamples of 540, 600, and 1584 persons age 95+ were conducted to improve precision of parameter estimates at extremely late ages). Another approach is to combine several similarly structured studies in a single analysis.

The concepts of morbidity and mortality compression raise the following additional questions:

1. Is there an upper limit to the age to which persons may survive?
2. What is the shape of the survival curve as the life span limit is approached (e.g., how does the variability in the distribution of ages at death change)?
3. How is the age relation of morbidity and survival curves affected as the life span limit is approached?

The maximum life span is difficult to identify (if a specific value exists) because one can only know the lower bound to the life span limit (e.g., a French woman died at a documented age of 122). Of greater interest is how individual life span potentials are distributed in a population. Manton and Tolley also raised questions about the formalization of concepts of survival curve rectangularization, suggesting that difficulties in formalization may prevent a rigorous statistical evaluation.

Questions about the compression of mortality involve the way in which the genetic heterogeneity in the maximum life span for individuals is distributed. This is important because it determines the irreducible variability in the distribution of those limits. If there is considerable irreducible (e.g., genetic) heterogeneity, then the survival curve may never rectangularize as in **Figure 2**.

Figure 2 shows the three survival curves from **Figure 1** and a 'rectangularized' survival curve, C^*. Though life expectancy is roughly the same for C and

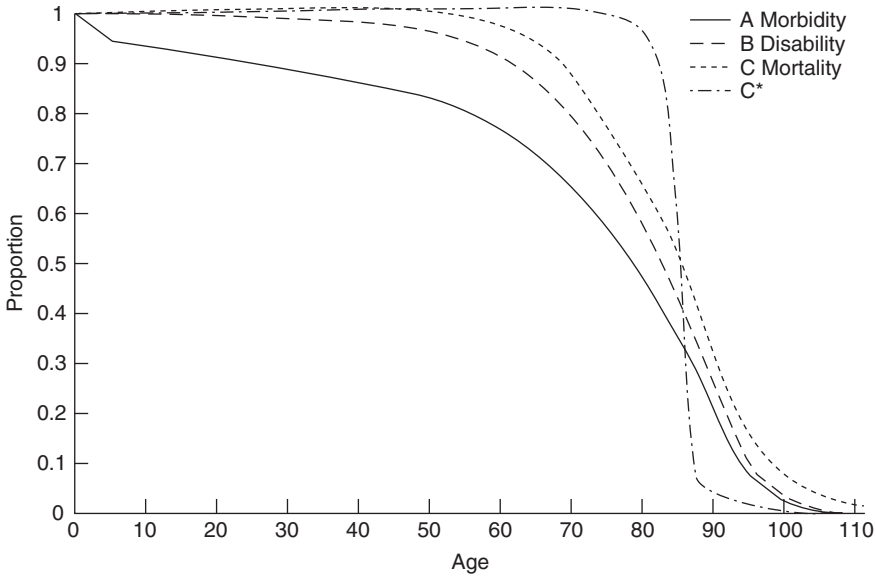

Figure 2 Theoretical relations of morbidity, disability, and mortality outcomes, represented by changes in their survival curve with the survival curve for mortality drawn to represent (A) a highly rectangularized mortality age pattern (C*) and (B) an age pattern of mortality with significant intrinsic heterogeneity.

C^* (i.e., the median life span is 90 years for both), survival curve C has more variability (i.e., the standard deviation for C is about 5 years; for C^* it is less than 1 year).

Empirically, as US life expectancy has increased, so has the variability of age at death; hence both life expectancy and the highest observed age at death increased. In one set of official Social Security life tables for 2000, female life expectancy was 78.7 years and was projected to increase modestly, by 2080, to 84.6 years ($+5.9$ years). For males, the increase was 6.6 years (i.e., from 71.6 to 78.2). The increase in life endurancy (i.e., the age to which 1 in 100 000 persons can expect to survive) is over 12 years for both males and females over the same period. Thus, the upper limit of the age-at-death distribution is expected to increase twice as fast (i.e., to 125 or more years) as life expectancy. This is different from what occurred from 1900 to 2000, when life expectancy increased 39.2 years for females and 25.2 years for males, whereas life endurancy increased only 7 to 8 years. This is because most life expectancy increases from 1900 to 2000 were due to mortality declines at early ages. After 2000, there was less potential for change at those ages. This again implies that the epidemiology of aging has to deal with phenomena that are historically unprecedented; hence, there will necessarily be a greater reliance on biological theory and ancillary data. Of course, a critical issue is how curves B and A will change over age as C changes. Perl suggested that the distance between the disability (B) and mortality (C) curves will be at its maximum at ages 75–85 and will decline above age 95.

There may be no simple model for the limited distribution of ages at death in that, at advanced ages, many genetic effects will interact in complex ways with the environment. Because humans have long life spans and live in heterogeneous environments, it is difficult to isolate genetic and environmental influences on disease risks to assess how health changes at late ages (i.e., age changes in the relation of the three curves above age 95). This is why new observational plans and data are needed.

The shape of the US survival, morbidity, and disability curves has practical implications for health interventions – both preventative and therapeutic. If interventions to change the relations of the curves are to have significant benefits, they must be introduced sufficiently far from the life span-limiting distribution and the associated morbidity and disability curves to produce a sizable effect over time.

Study Designs

Resolution of many of the issues raised previously requires special longitudinal observational plans. A problem in designing such plans is that many questions about aging and disease processes may be so detailed that experimental and clinical studies are needed to answer specific design issues before population studies of very elderly populations are fielded. For example, the role of antioxidants in preventing disease has been investigated in a number

of studies. Vitamin E may reduce circulatory disease by slowing atherogenesis and improving glucose metabolism, although the consumption necessary to cause such effects may be higher than the standard recommended daily allowance (RDA) (e.g., 100 vs. 30 international units). Certain chemical forms (isomers) of specific micronutrients may have different physiological effects. Prasad-Edward found that alpha tocopheral succinate (as opposed to alpha tocopheral acetate) may be a more powerful cellular redifferentiating agent than vitamin A. Other isomers of vitamin E were not as biologically active. Similar issues have been raised for vitamin D isomers in treating osteoporosis. Combined use of N-acetyl carnitine and R alpha lipoic acid have been suggested to alter mitochondrial functions and thus to improve age-specific levels of function in animal models.

It is unlikely that trials and population studies can evaluate all possible isomers and uses of micronutrients for altering age-related biological activity. The selection of the forms of micronutrients evaluated in population studies and the levels of supplementation examined will have to be informed by the consensus of experimental and laboratory results (*see* Diet and Nutrition).

Major issues in study design are differential rates of selection with age in populations and the temporal structure of the observational plan and its ability to identify disease and disability episodes of different durations. A major area for innovation in study designs of elderly populations is emerging because the quality of US population and mortality data is improving. This is due, in part, to the introduction of Social Security in 1935 and Medicare in 1965, which increased birth registration in the US population, and, at the ages of entitlement, the requirement to provide rigorous proof of age to receive benefits. Furthermore, the education of elderly cohorts (e.g., ages 85 to 89) has improved since 1980 and will continue to improve until at least 2015 – a time when those oldest-old cohorts will have high proportions of better educated persons. Because of these changes, age reporting in Social Security and Medicare mortality records is of excellent quality (up to at least age 100 for Whites) and will further improve as time passes.

This implies that a *de facto* computerized population registry is gradually developing in the United States, one whose quality of age reporting at late ages (e.g., 95+) increases with time since the innovation of its major components. Thus, there are computerized data systems containing lists of all Medicare-eligible persons from which samples of elderly persons can be drawn for health surveys and studies for specific points in time. This has advantages over the area-probability survey designs based on census data that are employed in many national health surveys. In list samples, specific elderly individuals are sampled. Because the Medicare list contains data on the age of the person, oversampling of persons at extreme ages can be done from the nearly complete listing of the US elderly population. A person-based sample means that residents in facilities of all types are included. Follow-up for reinterviewing can be done through Medicare files so that nearly 100% of persons from a prior sample can be tracked and the characteristics of non-respondents identified. In Medicare files, reported ages and dates of death are available – as well as information on Medicare-reimbursed use of health services. Analyses suggest ICD-9 (International Classification of Diseases, Ninth Revision) diagnoses in Medicare files reliably report on disease incidence functions.

In area probability samples, households in an area are sampled; hence characteristics of individual elderly non-respondents are not directly available. The lack of an administrative list sample also means follow-up of individuals – and identification of decedents – is more difficult and likely less complete. Because censuses are done only every 10 years, sampling must be based on estimated population characteristics at points in time potentially distant (e.g., 9 years) from when the census data are drawn.

Thus, the availability of Medicare-based list samples allows one to draw national samples and to better track them. Mortality selection and population representativeness can be assessed more completely and on a near real-time basis. This allows for national longitudinal sample survey designs like that of the National Long-Term Care Survey (NLTCS) (**Figure 3**). The NLTCS has been conducted in 1982, 1984, 1989, 1994, 1999 and, most recently, 2004. Survey records are linked to Medicare service use and mortality files for the entire period. Since the NLTCS is a true longitudinal survey, bidirectional individual health transitions are observed. Because individuals are sampled, persons living in both the community and in institutions of all types are sampled. This was a difficulty in the 1984 Supplement on Aging (SOA) and the 1986, 1988, and 1990 LSOA follow-up (i.e., the 1984 SOA sample was only of community residents so that an institutional sample had to be accumulated over time – as in the current Health and Retirement Survey).

There are three types of supplementary sample in the NLTCS. The first, because the US prevalence of chronic disability was unknown in 1982, required drawing a sample of 35 000 individuals (of a total of 55 000 initially drawn from Medicare lists) to get 6000+ detailed community interviews in 1982. There

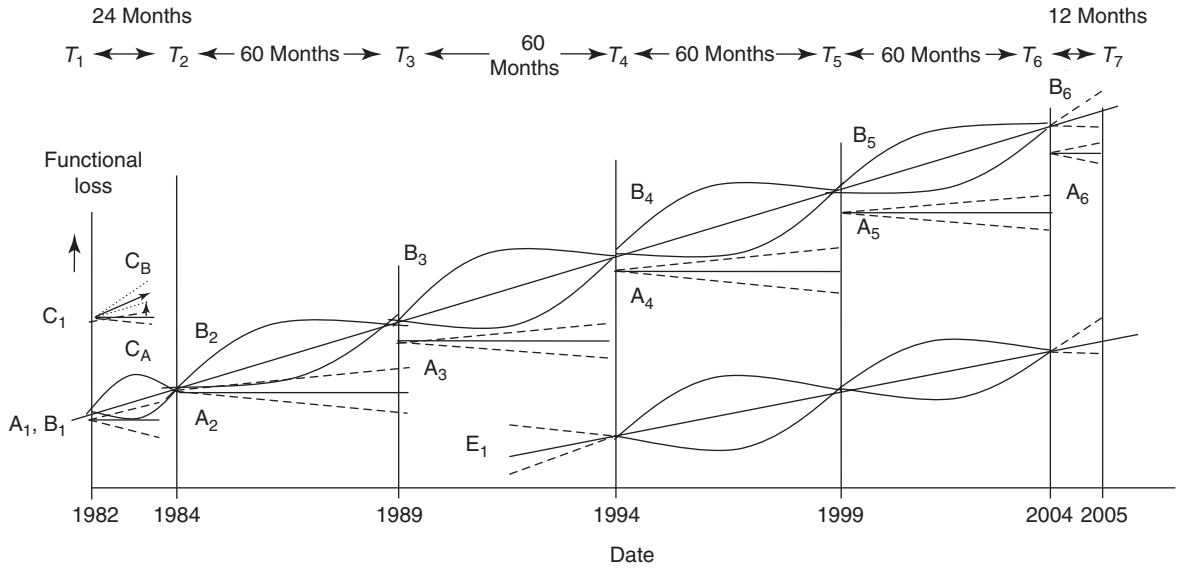

Figure 3 Temporal organization of the 1982, 1984, 1989, 1994, 1999, and 2004 NLTCS Longitudinal Observational Plan and illustrative trajectories of functional loss with time, and changes in the range of uncertainty about the level of functional loss relative to the time position between assessments.

were 26 623 persons who in 1982 were screened and reported no chronic disability. This sample was larger than needed to meet statistical power requirements for estimating disability incidence rates between 1982 and 1984. Consequently, in 1984 only 12 100 persons in the non-disabled sample component were rescreened. The remaining cases define a reservoir of persons, all 65+ in 1982, who could be drawn from for screening at future dates (i.e., 1989, 1994) to maintain the sample size of very elderly (e.g., 85+) persons who have high mortality. Second, to ensure that each cross-sectional sample was representative of all persons 65+, new samples of about 5000 persons passing age 65 between surveys were drawn from Medicare files and screened for disability. Thus, all NLTCS waves represent the total US 65+ population at each survey date. Third, starting in 1994 two additional sample supplements were drawn – persons age 95+ and healthy persons screening out.

With 22 years of follow-up (1982–2004), it becomes possible to make comparisons of the health of very elderly cohorts. Five-year intervals are long enough for significant changes in health and functioning to emerge in the population. Though a 5-year interval misses health transitions occurring in inter-survey intervals, persons in episodes of all lengths are captured in each sample. The shorter transitions occurring between surveys are also represented in linked Medicare service use, diagnosis, and vital statistics files.

Because the likelihood of sampling a health episode is related to its length, the proportion of short episodes sampled will be small. The weighting of individuals to produce national estimates of health transitions is complex, because the interview period is approximately 4 months and attrition of sample members within an interview period has to be considered. Because the exact dates of death within an interview period can be linked to survey responses in a prior NLTCS interview, left censoring bias can be reduced.

It is possible to systematically supplement the samples and make weight calculations because the US population proportions at any point in time are known from Medicare lists and service records. For census-based samples, the population proportions are 'known' only every 10 years; between censuses only estimates are available. Thus, in the 1994 NLTCS, a supplementary sample of 540 persons age 95+ could be drawn to improve the precision of health change estimates at late ages. In 1999, the 95+ oversample was 600 persons, while in 2004 this was increased to 1584.

The content of core disability and health conditions in the NLTCS was held constant over time in order to monitor health changes over time. Within the time limits for respondent burden in a face-to-face interview of elderly persons, it was possible in the NLTCS to ask supplementary batteries of questions. Because all disabled persons are interviewed in person, proxy response rules are easier to implement. An in-person interview is also a better modality for establishing the status of a very disabled person than a telephone interview (e.g., for sensory-impaired persons).

In the 1999 NLTCS, funding was received for a pilot biomarker study that was actually fielded in 2001.

In **Figure 3**, there is a joint distribution of continuous monitoring of vital status (and Medicare service use) between surveys and detailed assessments at survey times. Can information from this joint distribution be used to improve estimates of mortality risks and health transitions over time? Some estimates can be made directly (e.g., 5-year rates of disability improvements and decrements for specific ages and by gender). With appropriate analytic models calibrated during the NLTCS interim period and with responses linked to Medicare records, it is possible to extract more information from the observational plan about complex underlying health processes using disability functions calibrated from Medicare service use and diagnostic data that is available for any time between interviews.

For example, detailed assessments of physical function were made in each NLTCS interview. With detailed batteries of functional items, multivariate procedures could be used to (1) identify K reliable dimensions of functioning from J items and (2) calculate scores, calibrated as a function of age and data, representing the degree to which a person is characterized by each dimension. With sets of scores calculated for individuals, it is possible to examine two different models, both illustrated in **Figure 3**, to evaluate continuous changes in health. First, the disability scores could be assumed to be constant for an individual over an interval (i.e., changes occur instantaneously at the time of the next survey). This implies that uncertainty about a person's status increases until the next assessment – then it drops to zero. This is represented by the lines connecting A_1 to A_2, etc. Alternately, a model can be assumed to describe changes in an individual's disability scores between two surveys as a function of Medicare records. In **Figure 3**, between NLTCS observations B_2 and B_3, scores are assumed to change linearly. This implies – because information at the beginning and end of the observation period is used – that uncertainty about the state of the person in the intersurvey period is at a maximum in the middle of the interval and then decreases to zero when new measurements are made. Medicare data may reduce uncertainty (narrow the 'uncertainty' envelope) at any point in the interval.

Analytic issues remain for 'left-' and 'right'-censored cases. Left-censored cases are represented by the 'age-in' samples (i.e., persons passing age 65 before an interview) (e.g., E_1). Left censoring is less of a problem in a longitudinal survey because prior states of persons are often known – an important rationale for continuing longitudinal studies and surveys. Right-censored cases are represented either by persons dying between surveys (person C_B) – or by the status of persons after the last interview (e.g., B_5). Both problems can be resolved by assuming that persons whose observations at a future (or past) survey were censored had the same rate of change on the K scores as did persons observed at both times – after cases are matched on disability scores (and other demographic – e.g., age, sex – and social variables) at the time when both cases were observed. In this way, a monthly disability trajectory can be imputed up to the time of death for person C_B. Imputed values for the disability scores at the month prior to death can be used to estimate disability-specific mortality functions. Because persons who die (i.e., are right censored) are not observed at two time points, uncertainty about imputed disability scores increases to the time of death, or other censoring (e.g., end of follow-up; B_6).

This approach uses the 5-year interview data to make inferences about more short-term health transitions by estimating monthly rates of change for the continuous disability scores. If, in contrast, the survey information is used only to classify persons as disabled or not disabled, then there is no information on the rate of health changes between surveys to determine when an event occurred in the interval. The use of continuous change in scores, assuming that the model of change is reasonable, avoids that problem. Use of the linked Medicare service use files in a dynamic model further informs estimates of between-survey disability changes. For example, for a 95-year-old person starting in good health (e.g., no ICD-9 diagnosis in the Medicare records), there is a greater likelihood of a change in disability than for a 65-year-old person in good health. However, health and functional change may be more rapid for a 70-year-old with an ICD-9 diagnosis of diabetes than for a healthy 95-year-old – with rates also possibly different for males and females and for different types of disability.

The combined use of models and mixed data observational plans may be the only practical way of studying longitudinal health changes in elderly community and other study populations. This is because in a given local community, the number of extreme-elderly ($95+$) may be limited and the rates of changes at late ages (e.g., >90) so rapid that any interview (or assessment) period short enough to adequately capture those rapid changes in a small population will lack the necessary statistical power.

Using a model of continuous time changes in health and function also facilitates use of ancillary data from select community and clinical populations. That is, the assumed mathematical structure of underlying health changes allows data across populations – and over age and time – to be systematically combined

with that joint distribution, providing more statistical power to resolve questions than from using the studies individually.

Summary

The special data and analytic problems intrinsic to the development of an epidemiology of aging were reviewed (i.e., an epidemiology considering interactions of aging and disease processes up to the biological limits of human survival). These specialized data collection and analytic procedures are needed when exploring health changes at the extreme ages observed in human populations. In middle-aged populations, the same analytic problems exist, but with smaller effects – e.g., at age 50 the effects of selection on disease–risk factor relations on estimates of the hereditability of disease traits exist, but will be small for populations with life expectancies over 70 years.

The applicability of such methods also depends on gender, because in females age changes in hormonal status are abrupt because of menopause. For example, the risk of osteoporosis increases rapidly for postmenopausal females. Less well understood are the complex patterns of risk factor–disease interactions that menopause may stimulate in females. Moon and colleagues posited a strong interaction of osteoporotic changes and atherogenesis in postmenopausal females. In addition, changes in female body iron stores may interact with osteoporosis and atherogenesis to affect disease risks. Thus, the need for specialized analytic procedures may occur at younger ages in females due to rapid hormonal (and associated physiological) changes at menopause (*see* Endocrine Function and Dysfunction).

In contrast, selection effects in males may become relatively more rapidly manifest than in females because of females' longer life expectancy. For example, although the incidence of chronic disability may be similar at ages 60 to 80 for males and females, the female prevalence of disability tends to be higher because women survive longer at each disability level at each age. Determining whether special procedures are required for a specific analysis requires a case-by-case evaluation, because the underlying processes they are meant to deal with can initiate at relatively early ages. Thus, there is a continuum of needs for age-specialized epidemiological data collection and analytic methods.

R Munarriz, Boston University School of Medicine, Boston, MA, USA

Glossary

Erectile Dysfunction (ED) – The persistent or repeated inability, for a duration of at least 6 months, to attain or maintain an erection sufficient for satisfactory sexual performance.

Epidemiology and Definitions

Erectile dysfunction (ED) is defined as the persistent or repeated inability, for a duration of at least 6 months, to attain or maintain an erection sufficient for satisfactory sexual performance. This National Institutes of Health (NIH) definition deemphasizes intercourse as the only objective parameter of sexual function and allows for a broader interpretation of ED.

It is estimated that between 18 and 30 million men in the United States are affected. Aging and concomitant other medical problems such as atherosclerotic vascular disease, hypertension, diabetes mellitus, hypercholesterolemia, heart disease, and cigarette smoking are associated with a higher prevalence of ED. Specifically, the Massachusetts Male Aging Study (MMAS), a population-based questionnaire survey of 1290 men between the ages of 40 and 70, revealed the presence of ED in 52% of the volunteers.

The National Health Social and Life Survey (NHSLS) is a more recent epidemiological population survey of 1410 men aged 18 to 59 that reported a 31% prevalence of male sexual dysfunction. Premature ejaculation (21%), hypogonadism (5%), and ED (5%) were the three most common male sexual dysfunctions noted in this important study.

In order to compare the independent effects of aging on ED to the effects of comorbidities typically associated with aging, a group of investigators performed an evaluation of ED in men 65 to 75 years of age in comparison to men older than 75 years of age.

The findings indicated that age alone increased the relative risk of sexual dysfunction (relative risk of 2.2 for men 65 to 75 years old and 7.9 for those older than 75). In addition, self-reported poor health, diabetes, and bowel or urinary incontinence increased the risk of sexual dysfunction in all age groups. The authors thus demonstrated that aging, as well as the comorbidities that are often associated with aging, may independently or synergistically contribute to ED.

Anatomy

The penis is composed of the paired corpora cavernosa (erectile bodies) and the corpus spongiosum, the tissue that surrounds the urethra. Ejaculation is facilitated by the rhythmic contractions of the bulbospongiosus muscles surrounding the corpus spongiosum in the bulbar region of the penis. The tunica albuginea is the fibrous tissue surrounding the outer covering of the corpus cavernosum. Pathologic fibrous tissue plaque formation in the subtunical layer (Peyronie's disease) results in decreased elasticity of the tunica albuginea, penile curvature, and veno-occlusive ED. Lacunar spaces are specialized, widely communicating endothelial-lined vascular spaces in the interior of the corpus cavernosum that are surrounded by the trabeculae consisting of connective tissue and corporal smooth muscle.

Blood vessels and nerves run between the tunica albuginea and the Buck's fascia, a thick, elastic layer that surrounds the tunica albuginea. Penile blood supply comes from the internal pudendal artery and its three terminal branches: the bulbo-urethral, cavernosal, and dorsal penile arteries. The accessory pudendal artery is a source of additional blood supply to the corpora cavernosa and may have a critical role in men who have undergone radical pelvic surgery with compromised pudendal arterial blood supply. Within the corpora, the cavernosal artery branches into the helicine arterioles, resistance vessels that open into the lacunar spaces.

Venous blood from the corporal sinusoids drains initially into a series of subtunical venules that coalesce into emissary veins. The latter pierce through the tunica albuginea and empty into the deep dorsal vein, directly or via the circumflex veins. Extratunical venous drainage occurs via the deep dorsal, cavernous/crural, and superficial dorsal veins. Through the emissary and circumflex veins, most of the venous flow from the distal corpora drains into the deep dorsal veins that empty into Santorini's vesicoprostatic plexus. The cavernosal and crural veins drain the proximal corporal bodies and lead to Santorini's vesicoprostatic plexus and the internal pudendal vein. The superficial dorsal vein drains blood from the pendulous penile skin and glans and communicates with the deep dorsal vein. In each corpus cavernosum, bundles of smooth muscle cells embedded in a matrix of connective tissue and fibroblasts form a series of endothelium-lined blood-filled lacunar spaces. In the flaccid state, the trabecular smooth muscle and the central cavernosal and branching helicine arteries within each cavernosal body are constricted and lacunar venous blood passes unimpeded from the subtunical to the emissary to the extratunical veins.

Somatic innervation of the penis occurs via the pudendal nerve, which is composed of efferent fibers that innervate the striated musculature of the perineum and afferent fibers from the penile and perineal skin. In the erect state, increased blood flow to the penis is facilitated by sacral parasympathetic stimulation and subsequent dilation of the cavernosal and helicine arteries. Concomitant relaxation of the trabecular smooth muscle greatly increases the compliance of the cavernosal bodies and allows the lacunar spaces to expand and accommodate the enhanced blood flow. The subtunical venules become stretched and compressed, thus forming the primary site of venous outflow resistance (the veno-occlusive mechanism) during penile erection. The cavernous and crural veins (the deep system) are the main drainage system of the corpora cavernosa and a main source of leakage or failure-to-maintain venogenic ED.

Erectile Physiology

Penile erection is a neurovascular event that is governed by the delicate balance between the contractile and relaxation properties of the corporal smooth muscle. Normal erectile tissue is composed of trabecular smooth muscle (approximately 50%) and extracellular matrix providing a fibroelastic framework. The corporal smooth muscle is contracted in the flaccid state and relaxed in the erect state. Following sexual stimulation, initially contracted helicine arteriolar smooth muscle undergoes relaxation. Receptor-mediated smooth muscle relaxation is initiated by the generation of cyclic nucleotides (cGMP and cAMP) by guanylate and adenylate cyclases, activation of protein kinase G, and a series of molecular events that lead to the eventual inhibition of the sarcoplasmic reticulum Ca^{2+} ATPase (SERCA) pump and intracellular Ca^{2+} sequestration within the sarcoplasmic reticulum.

Relaxation of arterial and trabecular smooth muscle results in dilation of the cavernosal and helicine arteries, increased arterial blood inflow across the endothelial cells lining the lacunar spaces, and penile

engorgement. Penile rigidity is achieved through the increased resistance to the outflow of blood as the trabecular walls expand against the tunica albuginea and the plexus of subtunical venules is compressed (i.e., the veno-occlusive mechanism).

Conversely, the contractile response of the smooth muscle cell is ultimately determined by the interaction between myosin cross-bridges and actin filaments, a process that is mainly governed by the level of intracellular free Ca^{2+}. Release of Ca^{2+} from internal stores is facilitated by the binding of vasoconstrictor agonists to specific plasma membrane receptors and subsequent activation of various intracellular signal transduction pathways. Extracellular Ca^{2+} may also enter the cell through voltage-gated Ca^{2+}channels. Free Ca^{2+} binds calmodulin and promotes its association with myosin light chain kinase (MLCK). Calmodulin-activated MLCK phosphorylates the regulatory light chain of myosin (MLC) to initiate cross-bridge cycling and contraction.

Central Mechanism of Erection

Erection may occur as a result of local sensory stimulation of the genital organs and/or by central psychogenic stimuli. Most of the critical cerebral regulatory functions for erection occur in the hypothalamus and the limbic system. Sexual drive and psychogenic initiation of erection occur in the medial preoptic area of the brain. The medial preoptic area and the paraventricular nucleus within the hypothalamus are involved in the integration of the visual (occipital area), tactile (thalamus), olfactory (rhinencephalon), and imaginative (limbic system) input; they send neural projections to the thoracolumbar sympathetic and sacral parasympathetic centers of the spinal cord.

The locus caeruleus and nucleus paragigantocellularis (nPGi) in the brain stem exert an inhibitory effect on sexual arousal, whereas both dopamine and oxytocin are thought to play important roles in mediating the pre-erectile response in the medial preoptic area and the paraventricular nucleus, respectively. Inhibition of serotonin release from the nPGi nerves projecting to sacral segments of the spinal cord may be involved in depression of sexual function by serotonin reuptake inhibitors (SSRIs). Somatic sensation from genital skin is collected by the pudendal nerve, the afferent limb for reflexogenic erections. The autonomic nerve fibers that arise from the sacral parasympathetic center (S2–S4) make up the efferent limb for this reflex, innervating the penile smooth muscle. Control of penile erection is likely to be regulated by synergistic function of both the reflexogenic and the psychogenic erectile mechanisms.

Following sexual stimulation, the first event in the corpora cavernosa is neuronal-mediated arterial filling. This enables neuronal and endothelial-mediated trabecular smooth muscle relaxation. The subsequent volume change stretches the subtunical venules, creating venous outflow resistance and increased intracavernosal pressure. Elevation in intracavernosal pressure with continued filling further compresses the subtunical venules. Additional arterial filling results in axial penile rigidity, defined as the ability of the erect penis to resist deforming or buckling from vaginal-mediated axial loads. Factors that determine axial penile rigidity include intracavernosal pressure, penile tissue mechanical properties, and penile geometry. Detumescence is brought about by neuronal-mediated smooth muscle contraction with restoration of corporal venous drainage.

Peripheral and Neurogenic Mechanisms of Erection

Erectile function in the penis is regulated by autonomic (parasympathetic and sympathetic) and somatic (sensory and motor) pathways. Innervation of the penis occurs through three sets of peripheral nerves: the sympathetic, parasympathetic, and the pudendal nerves. The main role of the sympathetic system in the regulation of the erectile process is in the initiation and maintenance of arterial and trabecular smooth muscle contraction (the flaccid state). The sympathetic nerves (T10–L2) responsible for detumescence and maintenance of flaccidity project to the corpora, the prostate, and bladder neck via the hypogastric nerves.

The major excitatory input to the penis is provided by the parasympathetic nerves originating from the S2–S4 spinal cord segments. These nerves exit through the sacral foramina and pass forward lateral to the rectum as the pelvic nerve (the efferent pathway) and are joined by the preganglionic parasympathetic nerves originating from S2–S4. The pelvic nerves synapse with postganglionic nonadrenergic, non-cholinergic (NANC) nerve fibers in the pelvic plexus and give rise to the cavernous nerve of the penis that innervates the corpora cavernosa.

Stimulation of the pelvic nerves causes a marked increase in flow through the pudendal arteries and entrance of blood into the cavernosal spaces. Penile stimulation in a healthy man will cause reflexogenic erections that are primarily controlled by the sacral parasympathetic nerves originating in the spinal cord segments S2–S4. The afferent limb of the erection response is mediated by the dorsal penile nerve

(a branch of the pudendal nerve), which transmits sensory impulses to the spinal cord.

Nitric oxide (NO) is the primary mediator of NANC parasympathetic input. NO directly activates guanylate cyclase and is apparently synthesized on demand with little or no storage requirements.

It has been demonstrated that, in addition to guanylate cyclase, NO has other intracellular targets with which it can interact directly and may modulate the contractility of smooth muscle cells independently of the cGMP pathway. The levels of cGMP are regulated by phosphodiesterases (PDEs), a superfamily of hydrolytic enzymes that act on cyclic nucleotides and terminate signal transduction. Several PDE subfamilies with different cyclic adenosine monophosphate or cGMP specificities and tissue localizations have been identified in mammalian tissues. PDEs hydrolyze both cGMP and cyclic adenosine monophosphate; they play a key role in the physiology of erection.

Current FDA-approved oral medications for treatment of ED are inhibitors of the type 5 phosphodiesterase (PDE5).

Pathophysiology of Erectile Dysfunction

Vasculogenic Impotence

Atherosclerosis is a common cause of organic impotence. General vascular risk factors such as smoking, hypertension, cigarette smoking, diabetes mellitus, and hypercholesterolemia may cause arterial ED. Direct blows to the perineum related to falls, sporting accidents, or bicycle injuries, as well as blunt trauma from pelvic fractures related to motor vehicle accidents, may cause arterial occlusive disease to the common penile or cavernosal artery. The typical clinical presentation is that of a patient who complains that erections take longer to develop (diminished spontaneity) and are less rigid compared to previous erections.

Elongation and compression of the subtunical venules against the tunica albuginea are prerequisites for the veno-occlusive trapping mechanism necessary for erection. The ability to achieve maximal corporal volumes at low intracavernosal pressures is regulated by normal function of this outflow mechanism, a process that is dependent on the completeness of trabecular smooth muscle relaxation and the expandable mechanical properties of erectile tissue.

A functional venous leak may be induced by an increase in corporal smooth muscle tone from stress or anxiety. Similarly, increased trabecular connective tissue content secondary to chronic ischemia plays a central role in the pathogenesis of venous leak or venogenic ED. Ultimately, fibrosis of the erectile tissue causes decreased expandability of erectile tissue with subsequent poor stretching of the subtunical venules, poor venous outflow resistance, and failure to maintain penile rigidity. This pathology is most commonly associated with various systemic disease processes such as atherosclerosis. Direct corporal trauma from pelvic or perineal injuries, or from injuries to the penis while erect (fractured penis), may result in site-specific corporal fibrosis.

Diabetes Mellitus

Diabetes mellitus is a common cause of organic impotence. ED is reported in up to 75% of diabetic patients and occurs 10–15 years earlier than in the general population. Patients with insulin-dependent juvenile diabetes may have peripheral neuropathic impotence, with abnormal sacral evoked responses in 30 to 85% of patients. Those with non-insulin-dependent, adult-onset diabetes usually have vasculogenic impotence, but a combination of the neuropathic and angiopathic effects of diabetes is probably responsible for the dysfunction in most cases. Morphological alteration of the nerves, injury to the endothelium, as well as smooth muscle cell damage secondary to hyperglycemia have been shown. Diabetic patients have a marked increase in the threshold for response to vibrotactile stimulation.

Renal Failure

ED affects approximately 50% of dialysis-dependent uremic patients. Following renal transplantation, reversal of the chronic anemia, improvement in uremic neuropathy, or correction of abnormalities in zinc metabolism may result in improved erectile function. Hyperprolactinemia secondary to decreased clearance and increased production seen in end-stage renal disease has also been associated with erectile dysfunction.

Depression

A strong association between depression and ED has been demonstrated in a study in which, compared to men suffering from benign prostatic hyperplasia (BPH) alone, patients with ED were 2.6 times more likely to report depressive symptoms. In another study, Araujo *et al.* concluded that the relationship between depressive symptoms and ED in middle-aged men was statistically significant and independent of important aging and para-aging confounders such as demographic, anthropometric, and lifestyle factors, health status, medication use, and hormones. Despite these associations, a clear cause-and-effect

relationship between ED and depression has not been established.

Neurologic Lesions

Disturbances in the neural arm of the complex interaction between the vascular and neurologic events required for a normal erection can cause ED. This can occur at the following levels:

1. Intracerebral (Parkinson's disease, cerebrovascular events): Efferent pathways from the medial preoptic area or the hypothalamus may be affected.
2. Spinal cord (e.g., spinal trauma, multiple sclerosis, myelodysplasia): Cord lesions are the most common cause of neurogenic impotence. With injuries below T12, psychogenic erections may occur in approximately 25% of patients. Those with upper motor neuron lesions cannot achieve psychogenic erections. In general, approximately 30% of patients with cervical spinal cord lesions, 70% of patients with thoracic lesions, and 50% of patients with lumbar lesions are able to have erections. Patients with high cord lesions typically have short-lived erections that do not involve the corpus spongiosum and are non-ejaculatory. Sexual dysfunction may be seen in up to 75% of multiple sclerosis patients; in rare cases, ED may be the sole presenting symptom of multiple sclerosis. Reflexogenic erections, commonly seen in patients with upper motor neuron injuries, may occur following tactile stimulation below the level of the lesion.
3. Peripheral (e.g., iatrogenic, alcoholic neuropathy, diabetes): Damage to the cavernous nerves during radical pelvic surgery, such as radical prostatectomy, is not uncommon.

Endocrine Disorders

The reported incidence of endocrinopathy as the primary cause of ED ranges from 1 to 35%. Isolated testosterone deficiency is rare and is often accompanied by marked loss of libido. Interestingly, even among men with documented ED, the incidence of abnormally low serum testosterone levels has been historically small (6.6%). Despite the clear association of ED with aging, no consistent correlation of total testosterone levels with erectile condition had been identified. The serum testosterone level can affect sexual desire, frequency of nocturnal erections, and frequency of intercourse.

Other endocrinopathies with potential effects on erectile function include hypogonadotropic hypogonadism (Prader-Willi and Laurence-Moon-Biedl syndromes), hypergonadotropic hypogonadism (Klinefelter's syndrome, mumps orchitis, and surgical orchiectomy), and hyperprolactinemia (pituitary adenomas, craniopharyngiomas, or drug therapy).

Trauma

Pelvic fracture with ruptured posterior urethra and perineal trauma such as injuries associated with bicycle accidents are examples of injury-related ED. In pelvic fractures, damage to the neurovascular bundle, internal pudendal, or common penile arteries may lead to erectile pathology.

Postoperative/Iatrogenic ED

Aortic or peripheral vascular surgery may impair blood flow through the hypogastric arteries and thus cause arterial insufficiency. Occasionally, renal transplantation may cause ED, especially if a second contralateral transplantation is performed with end-to-end hypogastric artery anastomosis (impaired penile blood flow). In most instances, however, renal transplantation improves sexual function by reversing the chronic renal failure anemia and uremic neuropathy.

Vascular compromise as a cause of ED can also be seen after pelvic irradiation: accelerated occlusive atherosclerosis of the pelvic vessels, as well as fibrosis of cavernosal erectile tissue secondary to irradiation of the crural region, may contribute to postirradiation ED. Surgical (cavernosal-spongiosal) shunts to treat refractory priapism, certain neurosurgical procedures such as lumbar laminectomy, sacral rhizotomy, and pudendal neurectomy (especially if the sacral roots S2, 3, and 4 are injured), abdominoperineal resection of the rectum, and radical prostatectomy or cystoprostatectomy are also associated with postoperative ED.

Benign Prostatic Hyperplasia, Lower Urinary Tract Symptoms, and Erectile Dysfunction

A strong association between ED and lower urinary tract symptoms (LUTS) was shown in a study by Braun *et al.* in which 72% of men with LUTS had ED, whereas only 38% of those without LUTS had ED. In a study of 1274 European men, both ED and ejaculatory dysfunction were common and quite bothersome in those with LUTS. Ejaculatory function is increasingly regarded as a major contributor to the quality-of-life issues associated with sexual function.

Drugs and Medications

Various medications are associated with erectile dysfunction. **Table 1** lists some of these agents. A variety of medications and drugs have been found to cause drug-induced ED. Among the antihypertensive

Table 1 Partial list of medications that can cause erectile dysfunction

Centrally acting agents
α-methyldopa
Clonidine
Ethanol
Marijuana
Narcotics
Phenothiazines
Reserpine
Tricyclic antidepressants
Anticholinergic agents
Antihistamines
Antimuscarinic agents
Phenothiazines
Tricyclic antidepressants
Antiandrogenic agents
Cimetidine
Cyproterone acetate
Disopyramide
Estrogens
Ketoconazole
Spironolactone
Hyperprolactinemic agents
α-methyldopa
Estrogen
Haloperidol
Imipramine
Metoclopramide
Opiates
Phenothiazines
Reserpine
Sympatholytic agents
Alpha blockers
α-methyldopa
β-blockers
Bretylium
Guanethidine
Reserpine, clonidine
Agents with other properties or unknown mechanism causing ED
Digoxin
Epsilon-aminocaproic acid
Naproxen
Thaiazides

medications, thiazide diuretics and β-blockers are common culprits implicated in ED. Antipsychotic medications, tricyclic antidepressants, and the SSRIs have been shown to cause ED. However, in comparison to the other antidepressants, bupropion, an antidepressant of the aminoketone class, is relatively free of adverse sexual effects.

Evaluation

The ideal evaluation protocol is a biopsychosocial approach that encompasses the complete sequence of male sexual function: hypogonadism, ED, ejaculatory dysfunction, LUTS, and various psychosocial issues including depression, relationship factors, partner issues, and social stressors. The importance of gaining an insight into potential partner issues as a contributor to ED cannot be overemphasized.

Sexual History

The onset, duration, and circumstances of ED must be elicited. Questions are posed concerning erection quality during intercourse, masturbation, and nocturnal erections. Validated sexual questionnaires may be helpful tools in the evaluation of erectile function. Associated abnormalities (or changes) in ejaculation, libido, or orgasm should be noted. A psychogenic etiology is suggested by sudden onset of impotence or the presence of impotence under some circumstances, but normal erectile function at other times. A gradual deterioration of erectile quality with preservation of libido is more likely to be caused by an organic risk factor. Most patients with impotence can ejaculate despite poor-quality or absent erections.

Medical History

Inquiry is made about the patient's past and present medical problems, including diabetes mellitus, hypertension, smoking, hyperlipidemia, and liver, renal, vascular, neurologic, psychiatric, or endocrine disease. A history of abdominal, pelvic, or perineal surgery or trauma including possible bicycle injury is informative. Use of androgenic steroids and related substances by athletes mandates inquiries about these agents, as they are associated with decreased serum testosterone levels and decreased libido.

Psychological Evaluation

A brief psychosocial history is mandatory to gain insight into potential personal, interpersonal, social, and occupational roots of sexual problems. When deemed appropriate, an interview with a psychologist or sex therapist may be helpful to uncover personality disorders or the relation of psychological factors to ED (e.g., performance anxiety causing ED or organic ED leading to anxiety). The couple's expectations of the planned therapy are assessed.

Physical Examination

In addition to a focused examination of the genitalia, the general body habitus and status of secondary sexual characteristics should be assessed. The presence, size, and consistency of the testes are determined by palpation. The presence of small testes may suggest hypogonadism as a cause of ED. Gynecomastia may be present in patients with androgen deficiency or estrogen excess. Vascular insufficiency is

suspected with absent peripheral pulses in the lower extremities. Careful examination of the penis, including evaluation in the stretched and non-stretched positions is performed to assess adequacy of length, fibrotic plaques in the tunica albuginea (Peyronie's disease), or deformity of the corporal bodies. Pinprick testing of the penile and perineal skin may provide information about the sensory function of the pudendal nerve. Similarly, eliciting the bulbocavernosus reflex provides information about the integrity of the sacral reflexes. A digital rectal examination of the prostate to screen for prostate cancer is wise in men older than 50 (40, if African American or with a positive family history of prostate cancer).

Laboratory Tests

Hormonal status and evaluation of the integrity of the hypothalamic–pituitary–gonadal axis is performed by checking the serum testosterone, luteinizing hormone (LH), and serum prolactin levels. Standard serum chemistries, complete blood cell count, and lipid profiles may reveal vascular risk factors. The serum prostate-specific antigen (PSA) should be ordered in men over the age of 50 (40, if African American or with a positive family history of prostate cancer) to screen for possible prostate cancer. A higher incidence of prostate cancer in men with ED has not been demonstrated. Therefore, this test is done for routine male screening, rather than ED-associated prostate cancer screening. If both LH and testosterone levels are decreased, hypogonadotrophic hypogonadism is suspected and warrants consultation with an endocrinologist. If a low serum testosterone is confirmed, it is mandatory to check serum prolactin levels to rule out the presence of pituitary adenomas.

Specialized Diagnostic Testing

The need for specialized testing was dramatically changed by the introduction of sildenafil in 1998. As a general rule, although these diagnostic modalities help uncover pathophysiological mechanisms and further confirm the impressions discovered on the initial evaluation, their disadvantages, including cost and associated potential complications, have led to reduced indications for routine testing. Examples of tests performed by ED specialists include nocturnal penile tumescence (NPT) testing for a general assessment of organic vs. psychogenic ED, penile biothesiometry (vibration testing) for evaluation of the somatosensory pathway, and vascular testing (duplex Doppler ultrasonography, or, less frequently, dynamic infusion cavernosometry). Rarely, selective internal pudendal arteriography is indicated if arteriogenic ED is suspected in a candidate for microvascular arterial bypass surgery.

Treatment

Sex Therapy

Patients with evidence of psychogenic ED and no discernible organic cause should be encouraged to undergo a short course (6–12 weeks) of sex therapy with their partner. Professional evaluation of relationship distress, sexual performance concerns, and dysfunctional communication patterns is likely to enhance sexual function. In organic ED, behavioral sex therapy may be combined with various other forms of therapy in selected cases to optimize patient response. Performance anxiety may continue to play a significant role in a couple's sexual life after medical or surgical treatment; therefore, behavioral sex therapy must not be routinely abandoned in the presence of organic pathology.

Nonsurgical Therapy

Phosphodiesterase Type 5 (PDE5) Inhibitors Sildenafil, introduced in the United States in 1998, was the first US Food and Drug Administration (FDA)-approved phosphodiesterase type 5 (PDE5) inhibitor for the treatment of ED. Vardenafil and tadalafil are the other PDE5 inhibitors that have been approved for the treatment of male ED. All three are contraindicated in men who take any form of nitrates.

Sildenafil Sildenafil is a reversible inhibitor of PDE5. In response to sexual stimuli that activate the NO/cGMP pathway, inhibition of PDE5 leads to increased intracellular cGMP (decreased catabolism) and enhancement of cavernosal smooth muscle relaxation and erection. As with the other PDE5 inhibitors, it is taken on demand (prn). The recommended initial dose is 50 mg taken 1 h before sexual activity. The maximum recommended dose of sildenafil is 100 mg, no more than once per day, independent of the dosage used. Patients older than 65 years of age, those with renal or liver insufficiency, and patients receiving drugs that inhibit cytochrome P450 (erythomycin, cimetidine) should start with a 25 mg dose. Sildenafil inhibits PDE5 more selectively than many other PDE isozymes; however, it is only about 10 times more selective for PDE5 than for PDE6. This characteristic may be the basis for abnormal changes in color vision observed with higher doses or plasma levels of sildenafil. Sildenafil reaches maximum plasma concentrations within 30 to

120 min (median: 60 min) of oral dosing in the fasted state, but absorption may be reduced by a high-fat meal. The elimination half-life of sildenafil and its major active metabolite is approximately 4 h and no more than one dose should be taken per 24-h period. There is a 29% reduction in the maximum plasma concentration (C_{max}) when the drug is taken with a high-fat meal and the time to achieve the t_{max} will accordingly increase by 60 min. It is therefore recommended that sildenafil be taken on an empty stomach for optimal efficacy.

Sildenafil may be prescribed under careful medical supervision in patients who have suffered a cardiovascular event, myocardial infarction, or severe arrhythmia within the previous 6 months, or in patients with hypotension ($<90/50$), severe hypertension ($>170/110$), cardiac insufficiency, unstable angina, or retinitis pigmentosa. Sildenafil may be taken with caution in the following groups: patients receiving complex antihypertensive regimens; those with coronary artery disease, borderline blood pressure, or renal or liver insufficiency; and patients who use drugs that inhibit cytochrome P450. Sildenafil has been reported to improve significantly the symptoms of ED with varying etiologies and levels of severity; the postmarketing data are consistent with the results of the initial clinical trials. Sildenafil is reported to be effective and well tolerated in patients with a wide range of medical problems, including spina bifida, diabetes, cardiovascular disease (including those taking β-blockers, angiotensin-converting enzyme inhibitors, or calcium channel blockers) and those with parkinsonism.

Sildenafil should not be taken within 4 h after α-blockers. The most common side effects of sildenafil are headaches (16%), facial flushing (10%), dyspepsia (7%), nasal congestion (4%), and diarrhea (3%). Coadministration of sildenafil and nitrates (i.e., nitroglycerin, isosorbide dinitrate) is contraindicated.

Vardenafil Vardenafil is an FDA-approved, highly potent and selective inhibitor of PDE5 that demonstrates high bioavailability and rapid absorption. The median time to maximum plasma concentration of vardenafil is 0.6–0.9 h for all doses. Half-life is similar to sildenafil (i.e., approximately 4 to 5 h). C_{max} of vardenafil may be reduced by 20% following consumption of a high-fat meal (57% fat), but is unaffected by a meal of 30% (or less) fat. Vardenafil is contraindicated with the concomitant use of nitroglycerin or other organic nitrates. The bioavailability of vardenafil is increased by cimetidine and other cytochrome P450 inhibitors. A pivotal phase III study of the safety, tolerability, and efficacy of vardenafil as a treatment for ED in patients with diabetes mellitus reported intercourse success rates independently of HbA1c levels and of baseline ED severity.

Tadalafil Tadalafil is another FDA-approved selective PDE5 inhibitor for the treatment of ED. Perhaps the most distinguishing feature of tadalafil is its long half-life (17.5 h). Absence of significant food interaction and longer duration of efficacy have led to widespread public acceptance and capture of a significant global market share in a brief time frame. The results of at least two tadalafil studies indicate that, following a 20-mg dose, an erection can be achieved as early as 16 min and responsiveness lasts for up to 24 h, increasing spontaneity by enabling a man and his partner to have sex whenever they choose within at least a 24-h period. Others have found that tadalafil continues to enable men with ED to have sex as late as 36 h post dose.

In doses ranging from 2 to 25 mg, on-demand tadalafil was well tolerated and significantly improved erections in 81% of men with mild to severe psychogenic, organic, and mixed ED as compared with 17% of those who took placebo. Headache and dyspepsia were the most commonly reported adverse events. Most adverse events were mild to moderate in intensity and attenuated with further treatment. Myalgia is an uncommon adverse event that occurs slightly more frequently in association with tadalafil than with the other available PDE5 inhibitors. Tadalafil has a much higher selectivity for PDE5 than for the retinal enzyme PDE6, which likely explains why there were no visual changes associated with tadalafil in this and similar studies.

Yohimbine Yohimbine hydrochloride is an α_2-adrenergic blocking agent that was widely prescribed prior to the availability of the PDE5 inhibitors, but has not been shown to be more effective than placebo.

Vacuum Erection Device The vacuum erection device (VED), a non-invasive first-line therapy, has been approved by the FDA for over-the-counter distribution. The advantages of VED include simplicity of use, low cost, relative safety, and the ability to start treatment immediately. Patients with significant peripheral vascular disease are generally not good candidates for VED. The reported adverse events include difficulty with ejaculation, penile pain, ecchymoses, hematomas, and petechiae. Inconvenience, premature loss of penile tumescence and rigidity, penile pain, and pain during ejaculation have been reported as reasons for discontinuation.

Intracavernous Pharmacotherapy Most patients suffering from ED may potentially be treated with intracavernous injection of vasoactive medications. Safety and efficacy have been established in multiple studies, including those associated with the 1995 FDA approval of alprostadil (prostaglandin E1) as therapy for ED. Although penile self-injection therapy is highly effective (70–90%), there is a high dropout rate. Intracavernosal pharmacotherapy with vasoactive medications is contraindicated in patients on monoamine oxidase (MAO) inhibitors, patients with hypersensitivity to these agents, and those prone to secondary priapism (e.g., sickle cell disease/trait, leukemia, or multiple myeloma). Alprostadil alone or in combination with papaverine and/or phentolamine mesylate may be injected intracavernosally. Most studies show increased efficacy for the three-drug combination regimen compared to monotherapy. Onset of erection is usually around 10 min from the time of injection, and duration may range from 30 min to 6 h with the therapeutic goal of achieving an erection that is rigid enough for satisfactory vaginal penetration and lasts from 30 min to 1 h.

Priapism is an uncommon but potentially serious complication that can lead to permanent corporal fibrosis. Priapism of less than 24 h in duration can usually be managed without surgery by corporal aspiration and intracavernosal injection of α-adrenergic agents.

Transurethral Therapy

Alprostadil Intraurethral alprostadil is a relatively safe second-line therapy for the treatment of ED. In a double-blind, placebo-controlled study of 1511 men, 65.9% of patients had erections sufficient for intercourse, and 50% achieved successful intercourse in the home situation. A medicated pellet containing alprostadil is inserted intraurethrally with an applicator. Advantages include ease of delivery compared to intracavernosal injections. As a general rule, most specialists do not consider transurethral therapy to be as effective as intracavernosal injections. Penile pain and hypotension-related symptoms are the most frequently reported adverse events.

Surgical Therapy

Penile prosthesis surgery and microvascular arterial bypass surgery are the two main categories of surgical therapy for ED. Operations to reduce the venous outflow resistance (venous surgery) in patients with corporal veno-occlusive dysfunction have been performed but are generally unsuccessful and have not demonstrated long-term efficacy.

Penile Revascularization Microvascular arterial bypass surgery for ED (penile revascularization) is currently the only modality that has the potential to permanently cure patients. However, it is still considered experimental by the American Urological Association and is only performed in specialized centers with much experience. Most ideal candidates are young men with a history of perineal or pelvic trauma in whom arteriography reveals a localized common penile artery lesion. Those with generalized vascular pathology are poor candidates for this operation, since the same atherosclerotic pathology will likely affect the revascularization segment in the years following surgery. Revascularization is achieved by microsurgical anastomosis of the inferior epigastric artery to the dorsal penile artery. Appropriate selection of candidates for revascularization with adherence to strict criteria will yield excellent long-term patency and patient satisfaction when the operation is performed by an experienced microsurgeon.

Penile Prosthesis Surgery Penile prostheses are indicated for the treatment of organic ED due to a variety of causes. Most surgeons perform this operation as a last resort and recommend a trial of less invasive modalities including oral pharmacotherapy or intracavernosal injection before moving on to prosthesis surgery. There is a definite role for penile prostheses in the management of ED that is refractory to conservative measures. Even in the most challenging cases, experienced implant surgeons have reported successful prosthesis placement in severely fibrotic corpora by utilizing a variety of techniques.

Inflatable Prostheses Excellent functional and cosmetic results are achieved with multicomponent penile prostheses. Component inflatable prostheses consist of a pair of inflatable cylinders, a reservoir, a pump, and tubing to connect these components. The cylinders are implanted within the corpora, the pump within the scrotum, and the reservoir behind the rectus abdominis muscle in the perivesical space. Compressing the pump achieves active transfer of fluid from the reservoir into the cylinders. Pressing a release valve on the pump allows passive flow of fluid back to the reservoir and achieves detumescence. Significant design alterations over the years since the introduction of these prostheses have reduced mechanical failures and improved safety and efficacy such that they now compare favorably with non-inflatable rod-type devices.

Non-inflatable Prostheses Non-inflatable prostheses do not provide the cosmetic results provided by the multicomponent inflatable devices. However, the lower cost and relative ease of implantation make

them desirable in selected cases. The semirigid devices are typically made of pure silicone rubber that may be wrapped around a central coiled wire or have a core construction of articulating segments with metallic cables running through them. The polytetrafluoroethylene-coated rings are interlocked and connected by a spring-loaded cable, which can lock the rings in a straight column when activated and unlock for a relaxed flaccid state. Device chips and cracks may contribute to the failure rate of these implants, while the stiffer design may contribute to the higher rates of device erosion compared to inflatable prostheses.

Ethics and Euthanasia

N S Jecker, University of Washington School of Medicine, Seattle, WA, USA

Glossary

Active Euthanasia – Acting to induce a patient's death.

Assisted Suicide – Providing a patient with the means necessary to end his or her life.

Involuntary Euthanasia – Ending a patient's life in violation of the patient's wishes.

Non-voluntary Euthanasia – Ending a patient's life without knowledge of the patient's wishes.

Passive Euthanasia – Refraining from acting to sustain a patient's life.

Voluntary Euthanasia – Ending a patient's life in accordance with the patient's wishes.

Introduction

'Euthanasia' means 'a gentle and easy death' or 'the means of bringing about a gentle and easy death.' In current usage, euthanasia refers specifically to active euthanasia, defined as performing an action intended to bring about a gentle and easy death. For example, a physician who administers a lethal injection for the purpose of ending a patient's life performs an act of euthanasia. Euthanasia as it is currently used can be distinguished from assisted suicide, which involves providing persons with the means necessary to end their own lives. Euthanasia also differs from what has historically been called 'passive euthanasia,' which involves refraining from an action, such as cardiopulmonary resuscitation, necessary to sustain a person's life.

Whether active or passive, when an effort is made to end another person's life, this effort may either conform to a competent patient's wishes (voluntary euthanasia) or violate a competent patient's wishes (involuntary euthanasia). A third possibility is that the patient's true wishes are not or cannot be known (non-voluntary euthanasia). This article reviews ethical considerations relevant to active voluntary euthanasia; it does not address related issues, such as assisted suicide and withholding and withdrawing life-sustaining treatment, in much detail. Unless otherwise noted, references to 'euthanasia' refer to voluntary active euthanasia.

Ethical Arguments Supporting Voluntary Active Euthanasia

Autonomy-Based Arguments

Ethical arguments supporting euthanasia often appeal to the ethical principle of autonomy, which requires respect for the voluntary wishes of a competent patient. According to one interpretation, a principle of autonomy requires others not to interfere with the autonomous choices of competent individuals. So, for example, a terminally ill patient who wishes to hasten death should not be prevented from doing so. A stronger interpretation of the principle of autonomy holds that we ought to offer positive assistance to competent individuals in their efforts to carry out their autonomous choices. According to this stronger interpretation, respect for patient autonomy lends support to taking positive steps to meet a patient's autonomous request for aid in dying, whether in the form of assisted suicide or euthanasia. Yet autonomy-based arguments for assisted suicide or euthanasia apply only to a limited group of persons, namely, persons able to form autonomous and voluntary preferences about terminating their lives.

These remarks make evident that when a principle of autonomy is interpreted as supporting euthanasia, it does not support hastening the death of someone who suffers from depression or other mental impairments that interfere with autonomy. Nor does euthanasia sanction terminating the life of a minor child. Arguments invoking autonomy also restrict assisted suicide or euthanasia to persons who are competent at the time assistance is requested, prohibiting such assistance when it is based on the prior request of a now incompetent patient. For instance, advocates of autonomy-based arguments do not generally support meeting a request for euthanasia from a person who is newly diagnosed with Alzheimer's disease and expresses through a living will a preference that her or his life be terminated in the future when mental processes deteriorate to the point that life is no longer worth living. Not only would it be difficult to apply a living will of this kind to specific situations, it has also been argued that in the case of severe dementia, the previously competent person is not the same individual as the later demented person to whom such a request would be applied.

Compassion-Based Arguments

Further support for euthanasia can be found by appealing to ethical considerations of compassion for the suffering of others. This approach calls attention to the fact that despite our best medical efforts, some patients suffer terribly at the end of life. For example, even when health-care providers can prolong life, they may be unable to alleviate a patient's pain and suffering without causing intolerable side effects. Under these circumstances, it has been argued that the only way to respond compassionately to suffering is to hasten a patient's death.

It is important to distinguish between acting for the purpose of relieving suffering, on the one hand, and acting for the purpose of causing death, on the other hand. Actions that hasten death do not always qualify as euthanasia, because euthanasia requires acting for the purpose of hastening death. Hence, a physician who administers a morphine drip in order to alleviate a patient's suffering does not perform euthanasia, even if the physician anticipates that morphine will gradually curtail a patient's breathing and cause death. Likewise, a physician who operates on a patient in order to restore function, foreseeing the possibility that complications of surgery may cause death, does not commit an act of euthanasia if the patient dies on the operating table. When supporters

of euthanasia invoke compassion-based arguments, they are not claiming that compassion justifies causing death, but that compassion justifies acting in order to cause death.

Appealing to compassion lends support to euthanasia only in a limited range of cases. Thus, arguments based on compassion do not give ethical warrant to ending the life of people who wish to die but are perfectly healthy and are not experiencing pain or suffering. Nor can compassion-based arguments justify terminating the life of permanently unconscious persons, because such persons do not experience pain or suffering.

Ethical Arguments Opposing Voluntary Active Euthanasia

Slippery Slope Arguments

In response to the preceding arguments, opponents of euthanasia hold that permitting one person to terminate another person's life will inevitably lead to various ethical abuses. One form this argument takes is called the psychological slippery slope. According to this line of reasoning, if persons begin to take human life in a certain limited class of cases, this will weaken their psychological inhibition against killing and lead to taking human life in other cases. For example, if society permits physicians to end the lives of competent patients who request to have their lives ended, in the future physicians will feel less averse to ending the lives of incompetent patients who are considered a financial or emotional burden on others. The soundness of this argument depends upon the truth or falsity of the empirical prediction it asserts.

Unlike the psychological slippery slope, the logical slippery slope argument does not rely upon a factual claim about the actual effects of permitting people to end others' lives. Instead, the logical slippery slope holds that persons who conclude that euthanasia is ethically permissible in certain cases are logically committed to holding that it is ethically permissible in other, more troublesome cases. For example, those who defend euthanasia by appealing to the ethical principle of autonomy will find it difficult to refuse to meet a request for euthanasia from a competent person who is perfectly healthy and 'tired of life.' If such a request expresses an autonomous decision, there appears to be no way to appeal to autonomy to forbid meeting this request.

Although appeals to compassion can justify refusing requests for euthanasia from healthy persons who are not suffering, opponents of euthanasia point out that compassion-based arguments are also vulnerable to slippery slope objections. This is because an appeal to compassion cannot be used to limit euthanasia to persons who are competent and request death. After all, the pain that an infant or mentally impaired person experiences presumably warrants no less compassion than the pain of a mentally competent adult.

By combining autonomy-based and compassion-based arguments, advocates of euthanasia can justify significant restrictions on euthanasia. However, certain restrictions remain difficult to support. Neither autonomy-based nor compassion-based arguments can justify restricting euthanasia to patients whose deaths are imminent. This is because people may autonomously choose to die even when they have many years ahead to live. And the prospect of suffering for a long time would appear to incite more, not less, compassion that then prospect of suffering for a few weeks or months.

Sanctity of Life Arguments

Another argument against euthanasia begins with the premise that human life in any form possesses an inherent worth and dignity. Hence, even when a person is suffering terribly or wishes to die, taking that person's life is wrong because it destroys something of immense value. According to this argument, the intrinsic value of human life is not contingent on whether a person's life is useful or subjectively valued. So, for example, even when disease renders someone unable to pursue life goals, that person's life continues to be valuable because the value of human life is intrinsic, not contingent on its results or accomplishments. Likewise, even when someone no longer values life and desires to die, ending that person's life would end something of value.

A principle ascribing intrinsic value to human life gains support from both religious and secular considerations. Whereas religious thinkers may argue that the value of human life stems from the fact that human beings are a divine creation, secular thinkers may argue for the value of human life on the ground that human beings are the highest achievement of an evolutionary process that took millions of years to unfold. Alternatively, rather than appealing to the historical origins of human life, support for the sanctity of human life may be based on comparing a future world with human beings to a future world without human beings. If most people prefer the former world to the latter world, it might be argued that most people implicitly accept the proposition that human life has intrinsic value.

Arguments opposing euthanasia that are based on the sanctity of human life present serious challenges to autonomy- and compassion-based arguments. Against autonomy-based arguments, this approach

suggests that even if a competent person prefers to die, ending life causes that person to lose something of value. Against compassion-based arguments, the sanctity of life principle implies that a life wracked with pain and suffering is still a life and therefore continues to be of great value.

The Practice of Voluntary Active Euthanasia

The paucity of empirical data on physician-assisted death makes it difficult to know how widespread the practices of euthanasia and assisted suicide are. Likewise, a dearth of empirical evidence makes it difficult to say how common alleged abuses of ethical guidelines governing these practices might be.

In the Netherlands, physicians have long practiced euthanasia and assisted suicide more openly than physicians in other societies do, and the practice of euthanasia was rarely prosecuted although it was until recently a crime. In 2002, the Dutch Parliament exempted physicians from criminal liability for practicing euthanasia and assisted suicide provided that certain conditions were met. These conditions include, for example, that the patient's request is voluntary, that the patient experiences lasting and unbearable suffering, and that the patient is informed about the situation and prospects and believes that there is no other reasonable solution. The law in the Netherlands also requires the physician to exercise due care in terminating life or assisting with suicide, including consulting with an independent physician who sees the patient and gives his or her written opinion. Despite these guidelines, empirical studies show that Dutch physicians sometimes act to end their patients' lives without discussing this decision with a patient, usually because the patient is incompetent and lacks the capacity to participate in such a discussion.

In the United States, the American Medical Association has taken a stand against 'the intentional termination of the life of one human being by another.' Nonetheless, public debate about physician-assisted death has arguably moved in the direction of greater tolerance for euthanasia. Although in 1950 only 34% of Americans supported euthanasia of incurably ill patients when both patients and families requested it, from the 1970s onward a growing majority of Americans have supported it. In 1991, for example, 63% of people in the United States supported euthanasia under these circumstances.

US law also appears to be moving in the direction of greater tolerance for assisted death. In 1994, for example, Oregon passed an initiative allowing physicians to prescribe, but not administer, lethal medication to competent, terminally ill patients who repeatedly request aid in dying. In the neighboring state of Washington, a US District Court ruled in the same year that a state statute making physician-assisted suicide a felony violates the US Constitution. These decisions may mark an important shift of legal and public opinion on this issue.

Ethics and Medical Decision-Making

M B Kapp, Southern Illinois University Schools of Law and Medicine, Carbondale, IL, USA

Glossary

Authenticity – Letting the patient be true to his or her own values.

Autonomy – Self determination especially regarding the integrity of one's own body.

Informed Consent – A shared interactive decision making process involving both the health care provider and the patient as full participants.

Materiality/Patient Oriented Standard – Disclosing to the patient any information that might make a difference in the decision-making reasoning of a reasonable, average patient in similar circumstances.

Reasonable Professional Standard – Disclosing to the patient the information that a reasonable, prudent physician would disclose to a patient under similar circumstances.

Introduction

Older individuals, most often in collaboration with their family members and friends, face a variety of important decisions at various points in their lives. These decisions concern multiple matters, such as financial planning and management, insurance, place and partners of residence, driving, activities, and the details of supportive services. Frequently, older persons are confronted with complicated medical decisions that arise in response to acute or chronic ailments (*see* Ethics and Euthanasia). The process of medical decision making may involve a number of ethical (as well as legal) considerations for the older person *qua* patient, relatives, friends, and health-care providers.

The ethical and legal implications of medical decision making overlap, but are not identical. They overlap both in the sense that ethical principles underlie legal doctrines (that is, we do legislate ethics all the time) and in the sense that the law generally sets the boundaries or parameters within which ethical decision making, based on a balancing of normative principles of right and wrong, must take place.

To a significant extent, the ethical (as well as legal) implications of medical decision making are generic, in the sense that they apply to adults of all ages. Principles and rules developed to deal with medical decision making for younger adults apply with full force to older persons, who do not lose their ethical standing or legal rights just because they have achieved older age. However, the patient's advanced years may in some instances raise issues that demand particular attention by the involved parties; this article tries to highlight such instances.

Informed Consent

An exploration of the ethical ramifications of medical decision making for all adult patients must begin with the doctrine of informed consent. Informed consent lies at the core of medical ethics today and in many ways has heralded the modern era in medical ethics. The informed consent concept originates with the principle of autonomy (self-determination, especially regarding the integrity of one's own body) and envisions a shared, interactive decision-making process involving both the health-care provider and the patient as full participants.

Informed consent is not a recently created idea. Plato referred to the requirement of informed consent to distinguish between the treatment of slaves and freemen. The informed consent concept was opposed by Hippocrates (in favor of physician-knows-best paternalism toward patients). Interest in the concept was renewed in seventeenth century European political philosophy, but opposition to it by the American Medical Association led to its dormancy in the American medical context until well into the twentieth century. Today, there is broad agreement in the United States that, in the arena of clinical medicine, informed consent is a concept essential to the American commitment to individual rights and an evenhanded relationship between patients and health-care providers. In addition to its foundation in autonomy, the informed consent doctrine has been justified by reference to the ethical principles of authenticity (letting the patient be true to his or her own values), privacy (the right to be left alone), beneficence (doing good for others), and nonmaleficence ("First, do no harm").

It is important to note that commitment to the informed consent doctrine and its ethical predicates is not universal. In numerous other cultures, the process of medical decision making is driven by other, opposing values, such as medical paternalism or a belief that families, rather than individual patients, ought to make the decisions. Professional caregivers in the United States must be sensitive to

these cultural considerations, which may be particularly strong for older, especially immigrant, patients and their families.

In their legal formulation, the substantive components of the informed consent doctrine have evolved on a case-by-case basis as a matter of individual state common (judge-made) law. Additionally, the majority of states have enacted statutes and/or promulgated regulations enumerating their jurisdiction's specific details regarding informed consent, for clinical care generally and/or within particular settings such as nursing facilities or public mental institutions.

The doctrine of informed consent applies to diagnostic and therapeutic medical interventions, as well as research-related activities involving a patient's participation (discussed later). For a patient's decision about a medical intervention to be considered ethically and legally valid, three interrelated but separate elements must be present. First, the patient's participation in the decision-making process and the final decision regarding intervention must be voluntary – that is, not unduly dictated by force, fraud, duress, or other real or threatened ulterior form of constraint or coercion. Second, the patient's agreement must be properly informed. Before proceeding, the health-care professional is obligated to disclose sufficient information about the proposed intervention to empower the patient to make a knowledgeable, intelligent consent or refusal. The third essential element of legally valid consent is that the patient presently be cognitively and emotionally able to understand and manipulate pertinent information in order to make effective choices concerning personal medical care.

In terms of the informed component of the informed consent doctrine, there are two competing standards for determining how much information about a proposed medical intervention must be shared with the patient beforehand. The medical custom or reasonable professional standard asks what information a reasonable, prudent physician would disclose to a patient under similar circumstances. By contrast, the more recently developed materiality/patient orientation standard asks what information might make a difference (that is, might be material) in the decision-making reasoning of a reasonable, average patient in similar circumstances.

The philosophical rationale, promoted by patients' rights advocates, for the progression in informed consent doctrine in close to a majority of jurisdictions from a reasonable physician to a patient-oriented standard of information disclosure is the belief that the latter approach better promotes the ethical ideal of patient autonomy, while the former approach reinforces the negative practice of physician paternalism that tends to impinge on patient autonomy. There is a fundamental distinction between the two approaches. Physicians make treatment decisions based on their calculations of likely patient benefit, as affected by the particular personal characteristics of the patient being treated. Patients, by contrast, focus on the personal consequences of a decision, especially the risks and costs associated with various ways of addressing their health problem. Under the autonomy principle, the factors most important to the patient must guide the decision calculus.

Under either the materiality or reasonable physician standard, the basic elements of information disclosure included within the health-care provider's fiduciary or trust obligations to the patient clearly include the following: diagnosis or nature of the problem; nature and purposes (that is, expected benefits) of the proposed intervention; reasonably foreseeable risks associated with the intervention, specifically, their likelihood of happening and potential severity if they do materialize; reasonable alternatives and their benefits and risks; and (because there is a recognized right of informed refusal) the probable risks and benefits of not undergoing the proposed intervention.

There are other informational items that some ethical commentators and courts have argued ought to be included as a necessary part of the informed consent process. These include complementary and alternative medicine alternatives, which are increasingly popular with older individuals; the cost implications of the proposed intervention for the patient (an item of importance especially to many older persons); the particular provider's personal experience and success rate with the specific intervention recommended; other provider-specific information; the provider's financial incentives arguably impacting the patient's care; the level of uncertainty in the medical community regarding the particular intervention; and the role, if any, that defensive medicine considerations are playing in the health-care provider's treatment proposal.

When informed consent to particular medical interventions is indicated by the spoken or written words of the patient (or the patient's legally authorized surrogate, as discussed later), the consent is characterized as express. However, there are many situations in which the patient's permission does not need to be put into words, but instead may be implied from the totality of the circumstances. This occurs when, through actions, the patient signifies a wish (or at least a willingness) to receive the specific intervention by voluntarily submitting to it in a way that the health-care professional can reasonably rely

on to conclude that the intervention has been authorized. Implied consent is appropriate for most routine, non-risky, non-invasive kinds of medical interventions. It is not an exception to the general informed consent doctrine; it is just a different (created by behavior instead of words) form of permission.

Express consent is more appropriate when the proposed medical intervention is intrusive and/or significantly riskier than ordinary, everyday life. With a very few exceptions created by particular state statutes for certain kinds of interventions (such as testing for the HIV virus or AIDS), express consent in the form of spoken words by the patient is quite ethically and legally adequate, as long as it is voluntarily and competently given on the basis of sufficient information. For particularly intrusive or risky interventions, the health-care provider may choose to document the patient's consent by requesting that the patient sign a separate piece of paper labeled a consent form, in addition to making a progress entry in the patient's medical record. Voluntary accreditation standards with which the provider complies, such as those of the Joint Commission on the Accreditation of Healthcare Organizations, may require the use of separate written consent forms for particular categories of medical interventions.

Patient Incapacity and Surrogate Decision Making

Usually, the health-care provider is obligated to discuss all relevant information and negotiate diagnostic and treatment plans directly with the patient. Sometimes, though, the patient is not mentally capable of assimilating pertinent information and engaging in a rational, voluntary decision-making process about the proposed and alternative medical interventions. This situation is likely to occur in the case of older persons who have impaired cognitive or emotional capacity as a result of a dementia, depression, or other age-related mental disorder. It makes little sense to talk about autonomous decision making by individuals who do not have the ability to act autonomously. However, when the patient personally lacks adequate decisional capacity, the health-care provider is not relieved of the duty to dispense with informed consent; rather, the provider must work with someone else who is willing and able to act as a surrogate or proxy on the patient's behalf.

Assessing decisional capacity in older persons may be a particularly complex and difficult task, and no simple mechanical capacity-measuring device has been invented yet to make the exercise automatic. Nonetheless, certain general guidelines for conducting this type of assessment may be delineated.

The ethical principles of autonomy and beneficence are not best served when capacity is determined on the basis of the patient's clinical diagnosis or category, or on the basis of agreement with the wisdom of the patient's specific choice of treatment, and certainly not when a determination of incapacity is based simply on the patient's advanced years. Rather, the focus should be on the patient's functional ability – that is, on the thought processes undertaken in arriving at the patient's good or bad decision.

In such a functional inquiry, among the basic questions to be asked are the following: (1) Can the person make and communicate (in any understandable form) any decisions at all? (2) Is the person able to offer reasons for the choices made, indicating that some degree of reflection and consideration were exercised? (3) Are the reasons cited as underlying the individual's choices based on logic and factually accurate suppositions? For example, in one case an older woman who refused to consent to amputation of her gangrenous leg, because she denied the existence of any medical problem other than dirt on her leg that could easily be washed away, was properly deemed to be incapacitated from making her own autonomous medical decisions. (4) Can the patient appreciate the ramifications (that is, the likely risks and benefits) of the options presented and the choices expressed, and the fact that these ramifications apply to that patient? (5) Does the individual, in fact, comprehend the implications of his or her choices?

A patient's current cognitive and emotional capacity needs to be assessed on a decision-specific basis; in other words, an individual may be capable of making some decisions (such as whether or not to follow a low-salt diet) rationally, but not other decisions (such as whether or not to undergo bypass surgery). Thus, capacity should not be treated as a global, all-or-nothing matter applicable to all decisions. Partial or limited capacity is possible. The question is whether the patient is capable enough to make the particular decision in question.

In addition, capacity may fluctuate within a specific patient according to variables such as time of day, day of the week, physical location, acute and transient medical problems, other persons available to support or coerce the patient's choice, and medication reactions. Older individuals may be especially vulnerable to fluctuations in capacity induced by these factors. In many cases, some of these factors may be susceptible to manipulation by caregivers so that discussions with the patient about care can take place under the most lucid circumstances possible. When feasible, health-care providers should try to maximize the patient's ability to participate in

medical choices (for example, through changes in the timing of drug administration) before they turn to a surrogate acting on behalf of the patient.

There are certain mechanisms available to maximize one's prospective autonomy. The older person (although this is not restricted to older persons) may use legal advance planning instruments to take steps, while still mentally capable, to anticipate and prepare for eventual incapacity by voluntarily delegating or directing future medical decision-making authority. The durable power of attorney consists of a written document in which an individual (the principal) may appoint an agent, or attorney-in-fact, to make future decisions (including medical decisions) for the principal. Every state has enacted one or more statutes that explicitly authorize the use of a durable power of attorney to empower the agent to make medical decisions on the patient's behalf, should the patient lose decision-making capacity.

Several ethical principles form the foundation for such legislation. Autonomy, as observed earlier, is the precept that individuals ought to have control and integrity over what happens to their own bodies. To exercise autonomy in the medical decision-making sphere, the patient needs information about alternatives and potential outcomes. In the case of mentally incapacitated patients, the patient's autonomy is best served by informing a surrogate (ideally one chosen by the patient) of the patient's own preferences and then expecting that surrogate to make specific clinical decisions based on the patient's substituted judgment (namely, choosing what the patient would choose if contemporaneously able to make and express personal decisions).

Durable powers of attorney fall into two categories. An immediate power comes into effect as soon as the agent is named. By contrast, in a springing power, the legal authority transfers (springs) from the patient to the agent only on the occurrence of some specified future event, such as declaration of the principal's incapacity by a designated number of examining physicians. The patient should be informed by attending health-care providers when they have decided to act as though decision-making authority has sprung to the designated agent, so that the patient can utter a protest, if desired, to the agent's power.

The durable power of attorney, which is a proxy directive, is distinguishable from a living will, which is an instruction-type directive. In the latter device, a competent patient documents his or her wishes regarding future medical treatment rather than naming an agent to make future treatment decisions in the case of incapacity. These two kinds of legal devices are not mutually exclusive, and patients may be encouraged to execute them in tandem because the living will can help an agent named under a durable power of attorney to exercise the patient's substituted judgment more accurately (*see* Ethics and Euthanasia).

When a patient is decisionally incapable but has not previously executed a living will or appointed a health-care decision-making agent, in a majority of the states, health-care providers may rely on legislation empowering family members and specified other persons to make medical decisions for incapacitated persons. In states that have enacted family consent statutes, the approved procedure ordinarily consists of documenting unanimous agreement among the attending physician, specified relatives or others (listed in a stated order of preference), and sometimes consultant physicians as well. The legislative trend in this direction was fueled by the United States Supreme Court's decision in *Cruzan* (1990), holding that the extent and conditions of proxy (including family) medical decision-making authority are a matter of state legislative, rather than federal constitutional, policy. In almost all of the states without family consent statutes, courts nonetheless recognize as a matter of common law or the state's own constitution the family's authority to exercise the incapacitated patient's decision-making rights on his or her own behalf. Most of these cases establish legal precedent for other families to act in other, future cases without the need for prior court approval.

When there is no durable power of attorney, family consent statute, or judicial precedent empowering the family to act, or in those relatively rare circumstances in which family members strongly and irreconcilably disagree about the best course of care for their decisionally incapacitated loved one, creation of a guardianship or conservatorship may be advisable to transfer decision-making power officially from an incapacitated patient to a proxy. However, the formal legal process (with its attendant financial, time consumption, and emotional costs) should not be initiated unless and until extralegal approaches, such as mediation or the involvement of an Institutional Ethics Committee, have been attempted in an effort to reach a sufficient level of harmony among all the interested stakeholders.

The guardianship/conservatorship process, when as a last resort it becomes necessary, entails appointment by a state probate court of a surrogate (the guardian or conservator) who is authorized to make certain decisions on behalf of a decisionally incapable person (the ward), ordinarily in response to a petition filed by the family or a caregiver. This appointment is combined with a review by the probate court of the sworn affidavit or live testimony of a physician who is familiar with the patient.

This form of intervention usually is benevolently inspired, as translated into the state's inherent *parens patriae* legal power to protect the vulnerable from harm. Nonetheless, because creating total (plenary) guardianship usually involves extensive deprivation of an individual's basic decision-making rights, the least restrictive/least intrusive alternative doctrine makes a limited guardianship preferred whenever feasible. Under this autonomy-inspired doctrine, the state should deprive individuals of their rights only in the least intrusive or least restrictive manner available, consistent with the legitimate social goal of protecting the individual against harm. Probate courts possess the authority to limit the proxy's power to decide only those particular types of decisions the ward personally is incapable of handling rationally.

Traditionally, the guardian has been required to make decisions consistent with the guardian's view, as a trust agent, of the patient's best interests. Many states still expect guardians to act according to the best interests standard. The modern trend in proxy decision making, though, has been toward enforcement of a substituted judgment standard. Under this approach, as previously explained, the guardian is obligated to make those decisions that the patient would make, according to the patient's own preferences and values to the extent that they can be accurately ascertained, if the patient were presently able to make and express competent decisions.

Decisions Concerning Participation in Research

Thus far, the discussion has concentrated on the ethics of making decisions when the medical interventions proposed are intended and expected to benefit the diagnostic or therapeutic treatment of the particular patient involved. However, sometimes an older person is asked to participate as a human subject in a biomedical or behavioral research protocol entailing an intervention (experiment) whose primary aim is to systematically collect data from which generalizable conclusions may be drawn that the investigators hope will benefit other people (whose identity is presently unknown) at some point in the future. An important secondary aim of a treatment research protocol may be to benefit the present participants (for example, in cancer drug trials when standard treatment has failed or does not exist), but the participants' main role in this research situation still is as a source of data.

Because participation in research protocols, no less than in the diagnostic or therapeutic context, ordinarily requires the voluntary, informed, and competent consent of each participant, there is a general ethical consensus that, whenever feasible, researchers should enroll only those participants who themselves are able to give or deny consent to participation. In other words, individuals with seriously compromised decisional capacity should be considered for recruitment only for those research protocols that are devoted to studying problems specific to the decisionally compromised population.

The disproportionate prevalence of dementias and other severe mental disabilities among the elderly presents a legal and ethical dilemma when research does specifically address the problems of the cognitively and emotionally impaired. On the one hand, progress in developing effective treatments and cures for medical and psychological problems associated with dementia requires that research projects be done in which individuals suffering from the exact problems of interest be the basic units of study. At the same time, paradoxically, those very problems that qualify an individual for eligibility as a subject in such a research project often make it impossible for that person to engage in a rational and autonomous decision-making process about his or her own participation as a research subject. This irony is made more difficult by the fact that research participants generally are more vulnerable to possible exploitation, and therefore need even more protection, than patients in therapeutic situations because of, among other things, the researchers' potential conflicts of interest.

Federal regulations covering biomedical and behavioral research require that informed consent for participation be obtained from the "subject or the subject's legally authorized representative" (45 Code of Federal Regulations Sec. 46. 116). However, a subject's legally authorized representative is defined in circular terms to mean an "individual or judicial or other body authorized under applicable [presumably state] law to consent on behalf of a prospective subject" (45 Code of Federal Regulations Sec. 46. 102(0)). Thus, state law, even when ambiguous or unspecific, controls in this arena.

A number of alternative mechanisms for proxy decision making in the research context are possible. These devices include a durable power of attorney for research participation, reliance on family consent statutes, informal resort to available family members as surrogate decision makers, guardianship with specific authorization for research decisions, explicit prior court orders authorizing the incapacitated subject's participation in research protocols on a case-by-case basis, an independent patient advocate supplied by the organization sponsoring the research or by a government agency, and selection of a surrogate

by the institutional review board (IRB) or a long-term care facility's resident council.

In making decisions about whether to enroll a decisionally incapacitated elder in a biomedical or behavioral research protocol, a proxy ideally will be guided by the substituted judgment standard, which entails knowing or being able to reasonably infer whether the incapacitated person him- or herself would have elected to participate, if that person were now able to make and express his or her own autonomous choice. When applying the substituted judgment standard is not reasonably feasible, because there is no realistic way to know or infer what the incapacitated individual would authentically desire regarding enrollment in a particular research protocol, rather than engaging in unbridled speculation about those desires, the proxy should perform a best interests analysis. In determining the incapacitated person's best interests regarding possible research participation, the proxy should take into account (among other things) the ratio of likely burdens or risks for the research participant versus the possible benefits to that person and others now and in the future emanating from the research findings.

Some have suggested that special procedural safeguards are necessary to protect vulnerable, cognitively impaired human volunteers from injury due to research participation. These safeguards might encompass heightened IRB involvement in the protocol approval process, enhanced IRB activity in the ongoing monitoring and supervision phase of the research, including serving as a forum for appeals and objections by participants or investigators, and requiring individual participant assent (that is, giving participants a veto power) even when informed proxy consent to research participation has been obtained. An important question, especially since the participants of interest are mentally impaired, concerns the definition of assent to be used, namely, whether the failure to actively object to participation in a protocol is enough to be interpreted as an implied form of assent, or whether some more positive manifestation of agreement is necessary.

Summary

Older individuals, or those authorized to speak for them, are likely to confront a panoply of decisions about consent to or refusal of offered diagnostic, therapeutic, and research interventions intended to address acute or chronic medical conditions. The complexities of medical decision making by and for older persons engender challenges implicating the sometimes conflicting ethical principles of autonomy, beneficence, non-maleficence, and social or distributive justice. The individual, family members, health-care providers, clinical investigators, and agents of society all have a significant role to play in promoting the decision-making rights of older persons while protecting them by attempting to maximize their benefits and minimize their exposure to harm.

Glossary

Ethnic Groups – Social groups that are distinguished on the basis of national origin, culture, or religion.

Racial Groups – Social groups that are distinguished on the basis of physical factors such as facial features or skin color and that are used to restrict access to valued resources or power.

Introduction

Gerontologists have been giving increased attention to the heterogeneity of the aged population, especially with respect to race and ethnicity. This interest is based to a large extent on the tremendous growth in the numbers and proportions of people of color and diverse ethnic origins in the United States, Canada, Australia, and the United Kingdom, as well as in other Western societies. In the United States, non-Hispanic Whites accounted for 88% of the 65 and older population in 1980. This figure dropped to 83% in 2003 and is projected to be only 61% by the year 2050.

Although African American elderly are the largest component of the minority elderly population, they are projected to show only modest increases in their numbers in the foreseeable future. On the other hand, Hispanic elderly should outnumber African American elderly by the year 2020, and one in six elderly Americans are expected to be of Hispanic origin by the year 2050. The fastest growing segment of the elderly population is Asian and Pacific Islanders, who are expected to grow from 2% of the older population in 1995 to almost 8% by 2050.

What is often neglected both by researchers and policy makers is the great diversity within the above ethnic categories, especially among Hispanics and Asian Pacific Islanders. In 2004, for example, 51% of Hispanic elderly were of Mexican origin, 16% Cuban, 12% Puerto Rican, and 20% Central American and other Hispanic. Because of immigration patterns, the next generation of Hispanic elderly (those currently ages 55–64) will be increasingly Mexican and decreasingly Cuban. Although Hispanics share a common linguistic background and the overwhelming majority are Roman Catholics, they nevertheless vary widely in such characteristics as education levels, poverty status, geographic concentration, and immigrant status. There is similar diversity among older Asians. In 2000, 30% were of Chinese origin, 21% Filipino, 18% Japanese, 10% Asian Indian, 8% Korean, and 7% Vietnamese. Future generations of Asian elders will be increasingly Vietnamese and Asian Indian and decreasingly Japanese. Asian and Pacific Islanders are from a variety of linguistic, religious, and cultural backgrounds. Finally, American Indians originated from roughly 500 tribes that differed in cultural, social, and economic characteristics. In addition there is substantial ethnic diversity in the non-Hispanic White elderly population, which remains understudied and underappreciated.

Research on ethnicity, race, and aging can be separated into ethnogerontology and minority aging studies. Ethnogerontology studies how the aging process is shaped by culture and the beliefs of groups, including Italian American elderly and Jewish elderly as well as Hispanics and African Americans. Minority aging studies focus on the groups defined by the

US. Census that have been the targets of social exclusion in recent history (Hispanics, African Americans, Asian Americans, Pacific Islanders, American Indians/Alaska Natives). Ethnogerontology has a stronger focus on diversity in aging, while minority aging studies have a stronger focus on disparities in old age.

The growing size of older racial and ethnic populations in the United States poses challenges to both gerontologists and policy makers. This article provides a brief overview of what is known about the status and well-being of America's racial and ethnic minority elderly, focusing on such important areas as physical health, mental health, social relationships, and economic status, principally from a minority aging studies focus. It begins by outlining a historical overview of the field of ethnic and minority aging and conceptual approaches to studying ethnic diversity.

Studying Ethnic and Minority Populations

Much of the field of gerontology has grown without adequate attention to the population's racial and ethnic diversity. Serious attention was first given to aging among African Americans in the 1960s, when advocacy groups highlighted the disadvantages in health, income, life satisfaction, and housing for older African Americans by applying the concept of double jeopardy. Attention to Hispanics, mostly Mexican Americans, began in the 1970s, and it was not until the 1980s that Asian and Pacific Islanders, American Indians, and European-origin ethnic groups began to receive substantial attention in the gerontological literature. The last three broad categories continue to be understudied. Aging among ethnic and minority populations is also receiving increasing attention in other Western countries.

Inequality has been a core concept in the study of racial and ethnic elderly, usually in comparison to White elders. The popularity of the double jeopardy hypothesis in the 1970s and 1980s emphasized the larger multiple hierarchy stratification system in the nation. Although differences between minority groups and the majority are clearly evident, differences between groups in health, income, and psychological well-being have not typically been found to increase with age. This may be due to higher early mortality in disadvantaged populations, which leads to greater selective survival into old age. It may also be due to the lower starting point in the health and wealth of minority populations, which leaves them less room for decline than in the majority population (called floor effects in statistics).

There has not been any conceptual framework that has become popular in studies of racial and ethnic elderly since double jeopardy was discarded in the 1990s. Instead, the field has continued to be dominated by a services-oriented problem focus with a tendency to emphasize disparities. The literature on aging in minority populations is dominated by research on health status and health services, including issues such as caregiving. There is less research on issues related to income, housing, and transportation. The field only occasionally draws on concepts and approaches from related disciplines, such as social capital, globalization, racialization, cultural studies, network analysis, and feminist theory. This is likely the result of much of the research being conducted in professional schools and programs, with academic departments paying limited attention to race and ethnicity as it involves the older population.

Research on disparities in the older population continues to grapple with the question of the extent to which health differences are the result of race or ethnicity per se, or whether those social categories are simply proxies for economic and educational differences between populations. Work that focuses on the diversity of values and ideas about health and the treatment of disease commonly adopts a more ethnographic type of approach of describing the variations to increase awareness of different worldviews. When work on ethnicity takes a comparative approach, there is a heavy emphasis on acculturation.

Physical Health

Mortality and Life Expectancy

The most common indicators of health differences employed in the literature have been mortality rates and life expectancy figures. Mortality rates for African Americans have consistently been worse than those for non-Hispanic Whites, although the gap has steadily declined throughout the last century. Figures for Hispanics, American Indians, and Asian Americans no longer support a disadvantage of these groups, especially among people of Asian origin, who are estimated to have a life expectancy at birth of 83 years. However, the quality of mortality estimates for these groups is more questionable than the quality of estimates for African Americans and non-Hispanic Whites. This is especially the case with the American Indians; misclassification of ethnicity on death certificates leads to significant underestimates of mortality rates for this population.

African Americans have historically had higher mortality rates than Whites. These differences decline with age, to the point of a reversal at very advanced ages. The age of this mortality crossover

has been slowly rising over the years. If the crossover is the result of selective survival, as many argue, the rising age of the crossover suggests that the relative health of African American elders is improving and that they are receiving better medical care when they do fall ill. It does not mean that health disparities in old age are about to disappear, but it does suggest movement in a positive direction.

Although the accuracy of the estimates of the life expectancy of Hispanic populations has been questioned, accumulating evidence over the past 25 years suggests a Hispanic life expectancy at birth that is at least equal to that for non-Hispanic Whites. This has been observed for all three major Hispanic populations: Mexican Americans, Cuban Americans, and Puerto Ricans. This is considered an epidemiological paradox because Mexican Americans and Puerto Ricans have much lower mortality overall and for key conditions such as heart disease and cancer than would be expected given their overall risk factors, such as low incomes, low education, low rates of health insurance, and disproportionate employment in hard and dangerous occupations.

The apparent favorable mortality profile of Hispanics has been attributed to protective cultural factors, selective immigration, and selective return migration. Protective cultural factors include healthier diets, lower rates of tobacco and drug abuse, and stronger social ties. Selective immigration is supported by recent data that suggest that immigrants at any age are healthier than those who remain in their home country. At the same time, there are recent studies that indicate, at least among Mexican Americans, a 'salmon bias,' or return migration to Mexico of less healthy Mexican-origin persons, which may account for much of the mortality advantage of Mexican Americans. Selective immigration may very well be the prime reason behind the favorable mortality situation of most Asian-origin populations. Selective Asian immigration both selects healthier individuals to come to the United States and selects those with technical skills that are in high demand, contributing to a relatively favorable economic situation of most Asian origin groups. The starkest exception to this favorable health and sociodemographic trend is the Hmong, who fled a war-torn country over a short time period with few skills outside of agriculture.

Official estimates of the life expectancy of the American Indian population suggest that it has increased to the level of the general population, although again these estimates are based on data of questionable quality. The misclassification of ethnicity on death certificates seriously underestimates American Indian mortality rates. At a minimum, American Indians have exhibited remarkable progress in recent decades owing a great deal to the success of the Indian Health Service in controlling infectious diseases and providing acute care.

Morbidity and Functional Health

Mortality is often used to describe the health of populations because the government collects data on all deaths, providing a useful data source over time and across populations of varying sizes. But death is a rather crude indicator of health. Data on the prevalence of chronic conditions and disabilities provide a better insight into the health of populations.

Good sample-based population data have been regularly collected on several groups of racial and ethnic elderly for the past 15 years. National data are collected by a number of both longitudinal and cross-sectional national surveys and are complemented by several population-specific longitudinal surveys such as the Hispanic Established Populations for Epidemiologic Studies of the Elderly. Older African Americans consistently show higher rates than non-Hispanic Whites of major health conditions, including hypertension, diseases of the circulatory system, and diabetes. They also have the highest rates of functional limitations, both upper body and lower body. While the gap in disease and disability rates diminishes when Black–White population differences in wealth and other socioeconomic characteristics are controlled, most studies continue to find that race has some independent effect that leads to poor health. This may be the result of the stress and social exclusion associated with race, across socioeconomic status, in the United States (*see* Epidemiology).

Hispanics present a more complex pattern of disease and disability in old age. The favorable mortality situation of Hispanics does not fully translate into a favorable morbidity situation, but the picture here is not very clear because of variable quality and scope of data. Most evidence suggests that Hispanic men have a lower prevalence of heart disease and major cancers, but it is not clear why. With the exception of Cuban Americans, Hispanics are clearly disadvantaged socioeconomically, have very high rates of diabetes and obesity, and engage less in exercise. In addition, recent data from a large study of Mexican American elderly show that hypertension is at least as prevalent among them as it is among the general elderly population. Smoking and alcohol consumption rates among Hispanic males are also high. Any advantages in diseases of the heart and cancer among Hispanic males cannot be explained by known risk factors and may very well be related to selective immigration (*see* Alcohol and Drugs; Cardiovascular System; Cancer and Age).

In contrast, diabetes rates are considerably higher in Mexican American men and women than in non-Hispanic men and women at any age. Recent data on Mexican American elderly show that both male and female diabetes rates decline significantly from ages 65–74 to ages 75 and over, a situation that is not present among non-Hispanic Whites. This underscores the great negative consequences of diabetes in early old age among Mexican Americans and the high rates of mortality associated with it. A similar pattern for diabetes is observed among African Americans, who also have high rates of diabetes.

Disease rates for Asian American elderly overall are similar or better than those of non-Hispanic Whites. There are less data for this population because of their relatively small population size and their geographic concentration, often resulting in insufficient sample sizes for analysis from national surveys. Another limitation of national surveys is that they rarely collect data in Asian languages, and the majority of older Asian Americans (with the exception of Japanese Americans) are limited-English speakers. Data from the California Health Interview Survey, which included interviews in Mandarin, Cantonese, Vietnamese, and Korean, show older Asian Americans overall with a higher rate of diabetes than non-Hispanic Whites, although it is lower than the rates for the other minority groups. Other conditions, including heart disease, stroke, and cancer, have rates similar to or lower than those of non-Hispanic Whites. The variation within the older Asian population is evident in California, where Filipino American elders have higher rates of heart disease and arthritis than the other Asian subgroups.

In addition to mortality and disease prevalence, functional health is important among the elderly because it affects their ability to live independently. African Americans consistently have the highest rates of disability across all measures and have the highest rates of retiring from work because of disability. This may be related to their higher rates of chronic diseases and the severity of those conditions, their lower overall socioeconomic status, and/or the worse medical care they receive for a variety of chronic illnesses.

Recent data suggest that the functional health of Mexican American elderly, in terms of needing assistance with activities of daily living (ADLs), appears to be better than the functional health of African American elderly but slightly worse than non-Hispanic White elderly. With respect to four instrumental ADLs (IADLs) (meal preparation, shopping, using the telephone, and performing light housework), elderly Mexican Americans appear to be more impaired than either non-Hispanic Whites or African Americans (*see* Disability, Functional Status and Activities of Daily Living).

Diversity in functional status has been observed across elderly Hispanic subgroups. In one study, older Cuban Americans were found to have the lowest rates of limitations in ADLs and IADLs, while Puerto Ricans reported the highest rates. Older Mexican Americans had rates of limitations similar to Cuban-origin elders for ADLs but similar to Puerto Ricans for IADLs. The prevalence of functional limitations among these groups confirmed that their functional health tends to be worse than that of the general population of elderly persons.

The poorer functional health of African American, Mexican American, and Puerto Rican elderly is consistent with data on self-assessed health, which show poorer self-assessments than in non-Hispanic White elderly. In light of the socioeconomic, health, and access to care disadvantages of minority elderly, the poorer self-assessments appear to be realistic and not pessimistic because of the socioeconomic and cultural factors that predispose them to report poorer health.

There are limited data about the functional status of Asian American and American Indian elders. Pooled data from the National Health Interview Survey suggest that activity limitations for older American Indians are as high or higher than those of older African Americans, and remain higher than those of non-Hispanic Whites even after controlling for income, education, gender, and age. The same data show significantly lower rates of activity limitations for Asian American elders, with the caveat that the respondents to this survey exclude most Asian-language limited-English speakers. Data from the California Health Interview Survey, which includes several Asian languages, show a similar pattern of advantage for Asian Americans' rates of needing assistance with ADLs compared to non-Hispanic Whites.

Mental Health and Psychological Well-Being

Although the area of mental health and psychological well-being broadly defined has been central to the development of gerontology, our understanding of how ethnic and minority elderly fare in this area remains limited because of the absence of systematic data. The literature has predicted disadvantages among ethnic and minority elderly because of greater difficulties adjusting during old age given their disadvantaged situation in the larger society. Yet the evidence does not consistently support this prediction. Because most research is based on subjective

evaluations of psychological well-being that are made with important reference groups in mind, inequalities in objective conditions do not always translate into inequalities in subjective assessments (*see* Mental Health; Psychological Well-Being).

Even when research has focused on relatively more objective measures of psychological well-being, such as measures of depressive symptomatology, no clear-cut differences have been observed between African Americans and Whites at any age. The same is the case with respect to Mexican Americans, except that older Mexican American women appear to have relatively high rates of depressive symptomatology. In addition, there is some evidence of lower depressive symptomatology among the foreign-born, which supports the 'healthy migrant' effect also observed with regard to physical health. At the same time, recent older immigrants (within 10 years) appear to fare worse than people immigrating earlier in life. This is especially the case among women (*see* Depression).

There is also inconclusive evidence with regard to the mental health and well-being of the elderly from the various Asian Pacific Islander groups. Although some evidence suggests greater problems among recent immigrants, other evidence suggests that older immigrants experience more problems with the passage of time because of increasing isolation from the larger society as well as the increasing acculturation of the children. Children appear to fare better with the passage of time as they become assimilated and acculturated into the host society.

Systematic assessments of the mental health of American Indian elderly are also lacking, although there is an indication of high rates of depression among older women that is related to personal losses, social isolation, and acculturative stress. Kunitz and Levy found no differences in the prevalence of depression between elderly Navajo and the general population. They did find, however, that persistent depression was more prevalent among Navajo elderly women, although they acknowledged difficulties in assessing depression among men because it may be obscured by alcohol use, an observation also relevant with respect to the general population.

One area in which racial and ethnic differences in mental health status have been identified is cognitive impairment. African American and Hispanic elders have been identified as having higher rates of cognitive impairment than non-Hispanic Whites. The higher African American impairment, in particular, may be partly an outcome of their higher rates of small strokes, which is related to higher rates of cerebrovascular disease, which is associated in turn with higher rates of hypertension and diabetes.

Social Relationships

Conventional wisdom suggests that the elderly in ethnic minority populations are advantaged in their social relationships, particularly family and intergenerational relationships. African American, Hispanic, Asian American, and American Indian elderly all have been found to benefit from higher rates of coresidence with adult children and from social support from their extended families. Yet coresidence is often a matter of survival among these groups rather than simply a cultural preference. At the same time, lower coresidence among non-Hispanic Whites is evidence of their greater socioeconomic independence from their children. Research has shown over the years that although elderly in ethnic and minority populations have closer relationships with their children, they nevertheless report higher rates of unfulfilled expectations of filial responsibility than is the case among non-Hispanic White elderly, who appear more satisfied with what their children do for them. Clearly, availability of family members in the household or in close proximity is great support to ethnic and minority elderly who have few other resources, but it is not always a sign of an advantage in intergenerational relationships (*see* Social Networks, Support, and Integration).

Economic Status

Underlying much of the variation among the elderly from various ethnic origins is their great diversity in economic status. Clearly, relative to non-Hispanic White elderly, significantly higher proportions of African American elderly, most Hispanic elderly, and American Indian elderly live in poverty and have lower incomes. These differences reflect differences in educational background, occupational status, and past discrimination. Economic status differences are even greater with respect to wealth measured by net worth. One consequence of the economic condition of these groups is that they are disproportionately reliant on government programs for income, housing, transportation, and health care. Since African American and Hispanic elders rely disproportionately on Medicaid, Supplemental Security Income, public housing, and public transportation, they are particularly sensitive to changes in those programs.

Asian Pacific Islanders overall are more secure economically, although family incomes in these groups are spread over a larger number of family members than among non-Hispanic Whites. At the same time, given their greater proportion of foreign-born people, the economic status of Asian Pacific Islander elderly is negatively influenced by lower

Medicare coverage. Finally, much economic variation exists among the various Asian Pacific Islander groups that has not been adequately explored among the older population.

Conclusion

High rates of immigration from a variety of national origins are changing the complexion of the elderly population in the United States and other Western societies. This trend in the United States is being driven especially by Hispanic and Asian immigration, although there are pockets of immigrants from the former Soviet Union that bring a different ethnic mix as well. This immigration contributes to both disparities and diversity within the older population. While disparities are considered unjust and are the targets of programs to eliminate disparities, diversity in cultures, values, and beliefs can enrich a society. The challenge for scholars and policy makers is to protect diversity while reducing disparities. For this to occur, we need to improve our conceptual models for each separately and in tandem.

Examination of racial and ethnic differences in health suggests wide, continuing disadvantages for African American elderly but not for Hispanic elderly, at least with respect to mortality. American Indians have also narrowed the mortality gap, but little is known about their morbidity and functional health status. The mortality situation of most Asian Pacific Islander elderly appears to be favorable and may very well reflect a healthy immigrant effect also thought to benefit Hispanics.

Much less is known about mental health and psychological differences between groups because of a scarcity of data, especially on more objective indicators. With respect to social relationships, ethnic and minority elderly appear to be advantaged because of higher coresidence rates and greater contact with adult children; this coresidence and contact often signify a lack of options relative to non-Hispanic White elderly.

There is no question regarding the lower economic status of African American, most Hispanic, and American Indian elderly. Low incomes are compounded by even lower levels of net worth, which can be so important to the economic security of the elderly. Since these lower incomes contribute to worse health outcomes, especially for African Americans and American Indians, improving the socioeconomic status of minority groups would have a broad impact on improving the health and quality of life of minority elders. But the data suggest that disparities will remain even if incomes are equalized, which leads to the need for additional efforts to reduce racial segregation and social exclusion in the society.

Although the importance of understanding within-group diversity has been emphasized, especially among Asian Pacific Islanders and American Indians, national surveys that include adequate numbers representing the various subpopulations are impractical because of cost considerations. Although large studies of the elderly in the largest of these groups are possible and needed, smaller and more intensive ethnographic studies of the smaller groups will go a long way toward developing an understanding of the characteristics and needs of the elderly.

Finally, research on ethnic and minority elderly needs to give greater attention to the immigrant experience and how it influences the elderly, both positively and negatively. Elderly immigrants from a variety of ethnic and cultural backgrounds face a number of similar experiences that have not been adequately understood or incorporated into our conceptual frameworks.

Evolution and Comparative Biology

M R Rose and C L Rauser, University of California, Irvine, CA, USA

Glossary

Allele – A variant form of a gene.

Antagonistic Pleiotropy – Occurs when multiple effects of a genetic change are opposed in their impact on fitness.

Drosophila – A fly genus commonly used in laboratory research.

Fitness – Net reproductive rate of an organism, weighted according to the growth of the population as a whole.

Fitness Component – A character that numerically defines fitness, e.g., fecundity at a particular age.

Germline – The cells in an individual that become gametes or offspring.

Late Life – A distinct phase of life that happens at ages after aging ceases.

Malthusian Parameter – The asymptotic growth rate of a population growing without any ecological limitation. Often equal to fitness.

Mutation Accumulation – The increase in frequency of deleterious mutations at later ages due to the weak force of natural selection at those ages.

Soma – The part of the organism that does not produce offspring directly, i.e., that is not germline tissue.

Introduction

Aging and late life, like all other biological characteristics, evolve. However, the evolutionary mechanisms underlying aging and late life are different from those underlying all other prominent features of organisms. Aging and late life evolve through the dereliction of natural selection at later ages, so that normal categories of biological thought, such as 'function,' 'adaptation,' and 'purpose,' cannot be relied on in the study of aging and late life. This idea forms the basis of the evolutionary theory of aging and late life, with which this article begins. Experimental tests of this theory are then discussed. Finally, the comparative biology of aging and late life is reviewed.

Evolutionary Theory of Aging and Late Life

Definition of Aging

From the perspective of evolutionary biology, the most important feature of the organism is its fitness: net reproductive output, measured from one generation to the next. This variable is usually very hard to measure. Instead, evolutionary biologists commonly study components of fitness, such as viability and

fertility. The characters of interest to an evolutionary biologist studying aging are the age-specific components of fitness: age-specific survival probability and age-specific fecundity. The definition of aging that is normally used in evolutionary biology is a persistent decline in age-specific fitness components, both survival and fertility characters, as a function of age, in which this decline is not due to any external factor, such as deteriorating environment, pathogens, and so on.

Definition of Late Life

Late life is a post-aging period of life that is characterized by the cessation of aging. From an evolutionary perspective, late life is a distinct phase of life, like aging, and the characters of interest are also the age-specific components of fitness: age-specific survival probability and age-specific fecundity. However, the major difference between late life and aging is that there is no longer a decline in these age-specific fitness components in late life. That is, age-specific survival and fecundity stop declining and 'plateau.' The onset of late life can be defined as the age at which age-specific fitness components stop deteriorating, on average.

Evolutionary Theories of Aging

Evolutionary discussions of aging date back to A. R. Wallace and A. Weismann in the nineteenth century. Since these authors were writing before the advent of theoretical population genetics, the core of modern evolutionary theory, their ideas are often incoherent or opaque.

One of the major errors made at that time was the proposal that aging evolved to eliminate elderly individuals to make way for the young. This is an idea that is still cited today, at least by authors without training in evolutionary biology. The key mistake in this proposal is that it presumes that, without aging, there would be an abundance of elderly, infirm organisms in natural populations. For the vast majority of species in natural populations, however, this is not likely to be the case, because disease, predation, accident, and bad weather normally remove individuals before significant aging has occurred. Therefore, physiological mechanisms of aging do not usually remove older individuals from the population.

By the middle of the twentieth century, R.A Fisher, J. B. S. Haldane, P. B. Medawar, and G. C. Williams had developed a different kind of evolutionary theory of aging. Their proposals were based on the idea that natural selection should operate with less effectiveness on later fitness components because these characters would be expressed less often, per lifetime, than early fitness components, simply because the probability of survival from birth to any age falls with age. In 1941, Haldane proposed that the human genetic syndrome of Huntington's disease was common relative to many other genetic diseases, despite its lethality, because it was not expressed until middle age, after most of its carriers would have reproduced. Verbal hypotheses like these set the stage for the development of the formal evolutionary theory of aging, which was to follow in the last third of the twentieth century.

The mathematical population genetics of aging were developed primarily by W. D. Hamilton and B. Charlesworth in publications that appeared from 1966 to 1980. In this formal analysis, it was shown that Darwinian fitness is often given by the Malthusian parameter associated with a particular genotype. Given the particular age-specific fitness components for a genotype, its Malthusian parameter is given by r in the following equation:

$$\sum e^{-rx} l(x) m(x) = 1 \qquad [1]$$

where the sigma indicates summation proceeding over all positive values of x; x indicates age; $l(x)$ is the probability of survival from birth to age x; $m(x)$ is fecundity at age x; and e is the natural exponential. Effectively, the Malthusian parameter is a sort of averaged net fecundity over the life span, allowing for losses due to mortality and the effects of parallel growth in the entire population.

The mathematical analysis of Hamilton and Charlesworth went on to calculate the impact on fitness, determined by the Malthusian parameter, of age-specific changes in fitness components. They found that, when there is a proportionally uniform change in an age-specific survival probability, such as a 10% reduction, the impact on fitness was differentially scaled as a function of age according to the expression

$$s(a) = \sum_{x=a+1} e^{-rx} l(x) m(x) \qquad [2]$$

where a is the age at which survival probability is changed. Age $a+1$ is the age at which the summation starts. Note that after the last age at which offspring are produced in the population, $s(a)$ is zero forever after, and before the first age at which offspring are produced, $s(a)$ is always exactly one. Between the first and last ages of reproduction, $s(a)$ progressively falls (**Figure 1**). This result shows that the force of natural selection acting on survival falls

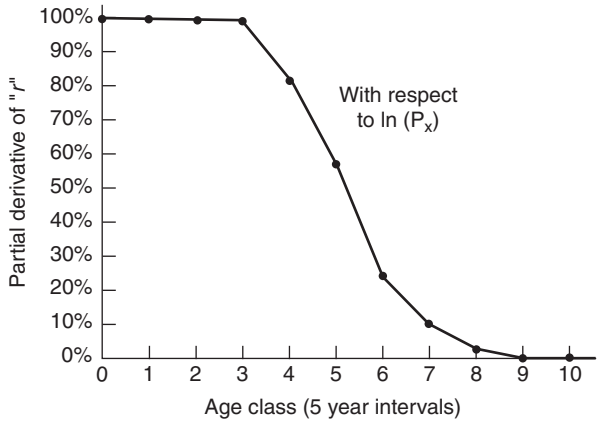

Figure 1 The force of natural selection, calculated in terms of the impact on fitness (*r)* of a proportionally uniform change in age-specific survival probability [*P*(*x*)]. This curve might characterize a species that started reproduction after 20 years of age. The curve plotted shows the force of natural selection relative to its impact before the onset of reproduction, neglecting any absolute scaling effects related to generation time. Qualitatively similar results will arise for any sexually reproducing species, though the width of the initial plateau, the rapidity of the subsequent decline, and the point at which zero is reached will vary.

with adult age, at least when the assumptions of this analysis are met.

A similar analysis for effects on age-specific fecundity gives a comparable 'scaling equation,' as follows:

$$s'(a) = e^{-ra}l(a) \qquad [3]$$

In this case, if population growth is not negative, then the force of natural selection once again declines with age. But if population growth is strongly negative, then the force of natural selection may indeed increase with age for a time. This corresponds to a situation in which a population is declining rapidly toward extinction, so that two offspring produced when the population size is 600 are 'worth' less to natural selection than two offspring produced some time later when the population size is 60. In the latter instance, the offspring are a larger proportion of the population. However, these cases normally are rare, since populations declining rapidly to extinction will often become extinct, rendering them unobservable. The typical pattern remains one in which the force of natural selection acting on fecundity declines with age.

From these results, population geneticists have been able to explain the evolution of declining age-specific fitness components, or aging. These results are very general, among demographies, and have no physiological content. In particular, they do not require or predict the action of any particular mechanism of physiological deterioration. The evolutionary theory of aging accounts for aging in terms of a pervasive failure of adaptation, the particulars of which must be as idiosyncratic to species as the particulars of adaptation for those species are. For this reason, evolutionary biologists have generally been extremely skeptical of proposals that attribute 'the cause of aging' to any specific physiological mechanism.

Evolutionary Theory of Late Life

The first observations of a late life phase came from human age-specific mortality rate data. It had been noted for years that late life mortality rates did not conform to normal aging patterns. That is, age-specific mortality rates stopped increasing exponentially at late ages and stabilized at some rate below 100%. It was not until 1992 that J. R. Carey and colleagues demonstrated this 'plateauing' in late life age-specific mortality rates in several large cohorts of medflies that late life first began to be accepted as a phase of life distinct from aging.

The same mathematical evolutionary theory described previously was expanded by L. D. Mueller and M. R. Rose to include late life. Recall that this theory is based on the declining age-specific force of natural selection on survival probabilities. According to this theory, survival probabilities should decline during the first part of adulthood, or in terms of mortality rates, age-specific mortality rates should exponentially increase. This occurs because the force of natural selection acting on survival is rapidly declining during those ages. However, after the last age at which offspring are produced, $s(a)$, or the force of natural selection acting on survival, is 0 for all remaining ages. Mueller and Rose predicted that age-specific mortality rates should mimic the plateau in the force of natural selection at late ages and also plateau because the force of natural selection is no longer able to distinguish fitness differences in survival at different ages within late life.

As with the force of natural selection acting on survival probabilities, C. L. Rauser and colleagues noted that the force of natural selection acting on fecundity, as described previously, asymptotically declines to zero at late ages. The age at which $s'(a)$ declines to zero is dependent on the last age of survival in the environment in which evolution has occurred, rather than the last age of reproduction, as with survival. Therefore, age-specific fecundity should stop declining and plateau at late ages, similar to the plateau in age-specific mortality rates, because the force of natural selection acting on fecundity is so low at late ages that it cannot distinguish fitness differences in fecundity.

The expansion of the evolutionary theory of aging to include late life has been paramount in the understanding of both aging and late life. Although a more formal mathematical derivation of the late life theory is necessary, this theory, as it has already been interpreted, readily allows for testable predictions regarding age-specific fitness components of late life. Now evolutionary biologists must be concerned with not only why aging happens, but also why aging ceases at late ages.

Population Genetic Hypotheses of Aging and Late Life

Subordinate to the general evolutionary theories of aging and late life are alternative population genetic hypotheses for the evolution of aging and late life. These hypotheses presume the validity of the evolutionary theories, particularly that the force of natural selection declines with adult age until late ages, when it approaches zero. These hypotheses are not incompatible with one another; they could be simultaneously valid. There are two population genetic mechanisms of primary interest, although others have been proposed. They are antagonistic pleiotropy and mutation accumulation.

Antagonistic Pleiotropy Antagonistic pleiotropy arises when alleles that have beneficial effects on one set of fitness components also have deleterious effects on other fitness components. Both Medawar and Williams argued for the importance of this population-genetic mechanism in the evolution of aging during the 1950s. The underlying concept is one of trade-off: alleles with beneficial effects must in some way 'pay' for those benefits with bad side effects.

Charlesworth and Rose analyzed the action of antagonistic pleiotropy mathematically with regards to aging. They showed that the declining force of natural selection would lead to a tendency for selection to fix alleles that have early beneficial effects, but later deleterious effects. This biases evolution toward the production of vigorous young organisms and decrepit old organisms. In addition, antagonistic pleiotropy may lead to the maintenance of genetic variability for aging and related characters, which is of great experimental significance. At the theoretical level, antagonistic pleiotropy is an important possible mechanism for the evolution of aging. However, the empirical work does not show that it always arises.

Mueller and Rose quantitatively demonstrated that the slowing of age-specific mortality rates in late life can arise from antagonistic pleiotropy in numerical simulations. As yet, there is no comprehensive analytical theory for the role of antagonistic pleiotropy in the evolution of late life.

Mutation Accumulation The other cogent population genetic mechanism for the evolution of aging and late life is mutation accumulation. Mutation accumulation arises when the force of natural selection has declined to a point at which it has little impact on recurrent deleterious mutations with effects confined to late life. Medawar was the main advocate of the importance of this mechanism in the evolution of aging. Charlesworth analyzed mutation accumulation mathematically, showing that the frequency of deleterious mutations would rise with adult age because of the declining force of natural selection at late ages. This population genetic mechanism also tends to maintain genetic variability for aging, like antagonistic pleiotropy.

Mueller, Rose, and Charlesworth all addressed the role of mutation accumulation in late life and demonstrated that it can generate mortality rate plateaus. This theory is more complete than the corresponding theory of antagonistic pleiotropy.

Experimental Studies of the Evolution of Aging and Late Life

Laboratory Evolution of Aging

Development and Design of the Experimental Approach Unlike many areas of biology, the evolutionary theory of aging provides a strong, mathematically developed base on which to plan experiments. One of the most elegant experimental approaches in gerontology is the manipulation of the force of natural selection to shape the evolution of aging patterns. This experimental strategy was first proposed by E. B. Edney and R. W. Gill in 1968. Some preliminary experiments of this kind were performed in the 1960s and 1970s by J. M. Wattiaux, R. R. Sokal, and Rose. Properly replicated experiments were not performed until the 1980s, particularly by Rose, L. S. Luckinbill, and R. W. Arking. These experiments are now routine in evolutionary gerontology, almost always using fruit fly species of the genus *Drosophila*.

The design of these experiments depends on the manipulation of the age of reproduction. When the timing of reproduction is maintained for a number of generations, the force of natural selection will be focused at that age. For example, normal fruit fly culture involves reproduction at 14 days of age, when cultured at 25°C, with just a few hours for egg laying allowed. This focuses the force of natural selection on that relatively early age. Genetic effects expressed

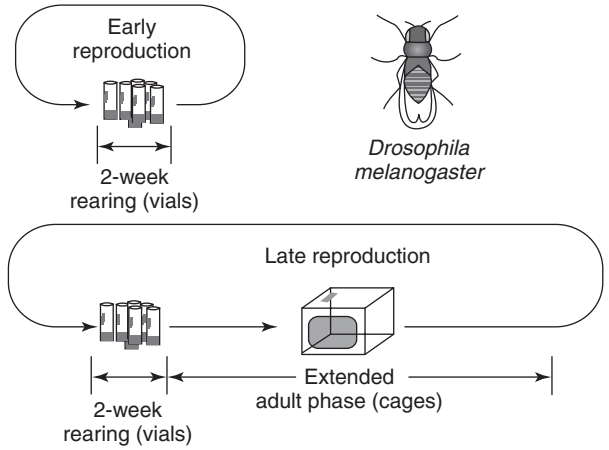

Figure 2 Method of selecting on fruit fly cultures for different times of reproduction. The early reproduced flies are reared in vials as a cohort, emerging at about 10 days when reared at 25°C. After a few days for mating among the adults, females are allowed to lay eggs in new vials at 14 days of age. These eggs are laid over just a few hours and the adult flies are then discarded, allowing the eggs to start the next generation as a synchronized cohort once more. Late-reproduced flies are reared in vials as a cohort, like early reproduced flies, until 14 days of age. The adults are then transferred into large Plexiglas cages, where they are kept as an aging cohort, without replacement, for an additional period of time. During this time, all eggs are discarded shortly after they are laid. After a prolonged adult period, the surviving females from a cage are given the opportunity to lay eggs over 1 or 2 days. These eggs are then used to start the next generation as a synchronized cohort.

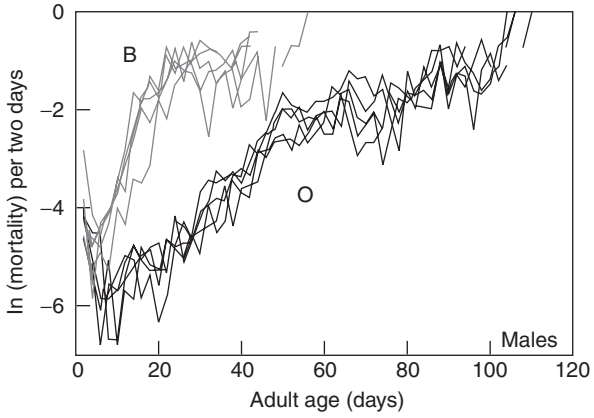

Figure 3 The mortality results obtained with different regimes of culture maintenance are shown for male populations of *Drosophila melanogaster*. Early reproduced (B) populations have lower mean and maximum longevities, compared with late reproduced (O) populations. The early reproduced (B) populations also have an earlier age at which mortality rates stop increasing and plateau, compared with the late reproduced (O) populations. About 20 years of selection had been imposed on the different populations prior to these assays. Both groups of populations descended from a common ancestor and were replicated fivefold. Data are from Rose MR, Drapeau MD, Yazdi PG, Shah KH, Moise DB, Thakar RR, Rauser CL, and Mueller LD (2002) Evolution of late-life mortality in *Drosophila melanogaster*. *Evolution* 56: 1982–1991.

at later ages, much after 14 days, are subject to negligible natural selection. This type of experimental regime allows the evolution of relatively early aging.

An alternative experimental regime is to keep adult flies alive for some time before they are allowed to contribute offspring to the next generation. This is done by discarding any eggs that they lay until they have reached the age allowed for reproduction, which can be as late as 10 weeks from emergence of the larva. Note that this procedure does not require that the fruit flies be kept virgin; mating is allowed, just not successful reproduction. This regime allows for the evolution of relatively late aging. The contrast between this procedure and that used with early reproduction is shown in **Figure 2**.

Effects of Changing the Force of Natural Selection The results of changing the age at which selection is strong have been striking for aging. **Figure 3** shows typical data for fruit flies. Mean and maximum life span dramatically increase when the force of natural selection is experimentally strengthened at later ages, as the evolutionary theory predicts. In addition, female fecundity, male virility, flight endurance, locomotion, stress resistance, and so on are also enhanced. This is an extremely important result for our understanding of aging. It reveals that aging is not a by-product, accidental or otherwise, of an unmodifiable biochemical process. Rather, aging is an easily modified product of evolution.

Experimental Population Genetics of Aging

Given the preeminence of natural selection in determining patterns of aging, the next major experimental question is the population genetic mechanisms that underlie the evolution of aging. As outlined previously, there are two main hypotheses, antagonistic pleiotropy and mutation accumulation. The evidence that has been brought to bear on these hypotheses has been of two main kinds: (1) correlation between relatives and (2) indirect responses to selection. In addition to the choice between these hypotheses, there is the issue of the number of genetic loci involved in the evolution of aging. A number of different methods have been used to address this question.

Correlation between Relatives One of the classic techniques in population genetics is the study of the correlations between relatives for characters that are, in part, inherited. This technique can also be used to study the degree to which two or more characters tend to be inherited together. When they are, this usually indicates some degree of pleiotropy among

the alleles affecting these characters. In particular, correlated inheritance is indicative of the pattern of pleiotropy, with positive correlations indicating that alleles affect two characters in the same direction, and negative correlations indicating that alleles affect two characters in opposite directions, on average.

The antagonistic pleiotropy mechanism for the evolution of aging requires that some early and late characters exhibit negative genetic correlations with respect to each other. This pattern has been found in a few cases, notably between early fecundity and longevity in fruit flies. However, a positive correlation has been found in many more. Artifacts may be responsible for some of these latter results, particularly inbreeding and novel environment effects, both of which bias genetic correlations toward positive values.

Mutation accumulation requires that genetic correlations between early and late characters be approximately zero. The problem for this hypothesis is that these genetic correlations tend to be strongly positive among newly occurring mutations or intermittently negative in long-established genetic variation. Mutation accumulation also requires that heritable genetic variation increases with age. This result has been found in some fruit fly experiments, but not in others.

Both antagonistic pleiotropy and mutation accumulation mechanisms receive weak and inconsistent experimental support from genetic correlations. An important factor, however, is that they may act simultaneously and, in so doing, cancel out the predicted effects of both mechanisms on correlations between relatives.

Indirect Responses to Selection To some extent, selection experiments are better able to detect the simultaneous action of antagonistic pleiotropy and mutation accumulation. When, for example, postponed aging has evolved as a result of later reproduction in fruit flies, it is often observed that antagonistic pleiotropy causes an immediate reduction in early fecundity. With antagonistic pleiotropy, it is expected that some early, functional characters will be depressed by the laboratory evolution of postponed aging. The observation of this pattern in a number of instances, together with evidence obtained from correlations between relatives, indicates that antagonistic pleiotropy is, in some cases, an important mechanism in the evolution of aging.

The effects of mutation accumulation can also be observed in laboratory evolution experiments. For example, when later reproductive opportunities are denied, it is expected that after many generations later fecundity should be reduced, due to the accumulation of alleles with late-acting deleterious effects. This result was obtained by Mueller in fruit flies denied later reproduction for more than 100 generations. Other such long-term deteriorations have been obtained by Rose and colleagues for other characters, especially stress resistance. Mutation accumulation evidently can act over hundreds of generations to undermine functional characters when the force of selection is reduced, making it an important mechanism for the evolution of aging.

The Number of Genes Affecting Aging Earlier evolutionary theorists, such as Williams and J. Maynard Smith, argued that an extremely large number of loci are likely to affect aging. This idea gave rise to some pessimism among evolutionary biologists concerning the feasibility of postponing aging. The success of laboratory evolution experiments in producing organisms with genetically postponed aging, however, forced a reexamination of earlier assumptions.

Luckinbill and colleagues as well as E. W. Hutchinson, J. E. Fleming, S. D. Pletcher and colleagues, and Rose examined the number of alleles affecting aging in fruit flies using a variety of experimental techniques. Only effective factor estimation suggested that the number of loci is small, but the result probably arose from arithmetical artifacts. Other estimates have given values in the hundreds of loci for *Drosophila*. At present, the best answer to the question of the number of genes controlling aging is 'many.'

Experimentally Testing the Evolutionary Theory of Late Life

Since the definitive discovery of late life in 1992 and the theoretical analysis of the evolution of late life by Mueller and Rose in 1996, experimental studies have tested predictions of the evolutionary theory of late life. Both mortality rate and fecundity patterns in late life have been measured using populations of fruit flies with different ages at which the force of natural selection declines to zero, as described earlier. Thus far, all such experimental studies have strongly corroborated the predictions inferred from evolutionary theory.

Effects of Changing the Force of Natural Selection The effects of changing the age at which the force of natural selection is strong have been striking for both aging and late life. The evolutionary theory of late life predicts that changes in the last age of reproduction should correspond to changes in the age that mortality rates stop increasing and plateau. **Figure 3** shows the data from one such pairwise comparison. Rose and colleagues showed that the age at which mortality rates stabilize (i.e., the start of

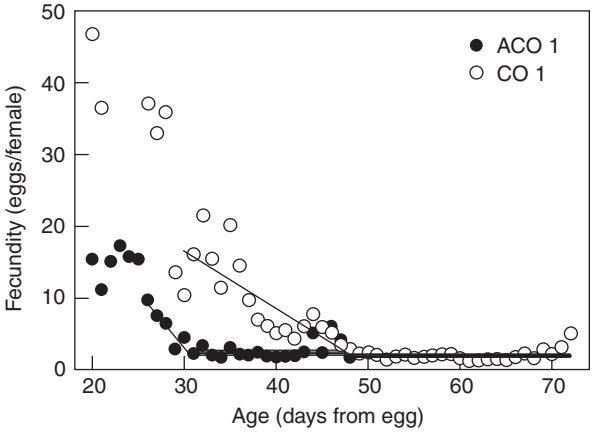

Figure 4 The fecundity results obtained with different regimes of culture maintenance are shown for female populations of *Drosophila melanogaster*. The early reproduced (ACO) population and later reproduced (CO) population both demonstrate a decline in fecundity followed by a plateau in population fecundity at late ages. In addition, the early reproduced (ACO) population has an earlier age at which fecundity stops declining and plateaus, compared to the later reproduced (CO) population. The results presented here are similar for five independent comparisons between populations cultured for early or later reproduction (data not shown). Data are from Rauser CL, Tierney JJ, Gunion SM, Covarrubias GM, Mueller LD, and Rose MR Evolution of late-life fecundity in *Drosophila melanogaster*. *Journal of Evolutionary Biology*. In press.

late life) is later in populations in which the force of natural selection is experimentally strengthened at later ages.

The evolutionary theory of late life also predicts similar results for fecundity probabilities. That is, fecundity should stop declining and plateau at late ages before it declines to zero, and the plateau in fecundity should correspond to changes in the last age of survival in the population's evolutionary history. Recall that the last age of survival is just after the last age of reproduction in the populations of fruit flies described previously because of the way in which these populations are maintained. Rauser and colleagues have shown that populations having different ages at which the force of natural selection acting on fecundity collapses have corresponding transitions to late life fecundity plateaus (**Figure 4**).

Population Genetic Mechanisms in Late Life Both theoretical and experimental analyses have revealed that late life patterns are greatly affected by natural selection. The next question is whether the population genetic mechanisms that underlie the evolution of aging also underlie the evolution of late life.

With antagonistic pleiotropy, genes having a positive effect on early age fitness components also have a detrimental effect at later ages. Therefore, with antagonistic pleiotropy involving late life, a shift to an earlier age of reproduction should result in a rapid shift in the age at which fitness components stabilize at late ages. Rose and colleagues and Rauser and colleagues demonstrated such rapid shifts in the onset of late life in mortality and fecundity, respectively, in *Drosophila*. These experiments also incidentally provide support for the evolutionary theory based on the force of natural selection because the ages at which the force of natural selection decline to zero, or the start of late life, evolutionarily shift with the age of reproduction.

With mutation accumulation, mutations that affect later ages are expected to accumulate within a population. It is also assumed that most of these mutations will have a recessive effect on the specific age class that they affect. Therefore, the effects of mutation accumulation can be observed in late life if crosses between populations that have been maintained at exactly the same age of reproduction, independently, show differences in late life patterns compared to the populations from which these crosses originated. However, Rose and colleagues did not observe such differences in late life survival probabilities after performing all possible crosses for five genetically divergent populations. Although their experiment did not support mutation accumulation as a genetic mechanism in the evolution of late life, it did not necessarily refute it. Consequently, the jury is still out regarding the involvement of mutation accumulation in the evolution of late life.

Comparative Biology of Aging and Late Life

Presence and Absence of Aging

Comparative Predictions of the Evolutionary Theory of Aging The evolutionary theory of aging is unusual among theories of biology in that it makes some absolute predictions. The experimental corroborations of the prediction that the pattern of aging should evolutionarily respond to manipulation of the force of natural selection have already been mentioned. With even greater strength, the evolutionary theory of aging predicts that all species that exhibit a well-defined separation of germline from soma must age. Conversely, the evolutionary theory predicts that all species with strictly symmetrical fissile (splitting in two) reproduction must be free of aging. (This does not imply absolute immortality, since such organisms could still die from disease, predation, or mechanical injury.) These two predictions can be tested extensively using comparative data.

However, many species exhibit neither a well-defined soma nor fissile reproduction. Colonial

coelenterates, such as corals, or grasses may have fairly ambiguous delineation of 'organisms.' Still other forms may combine fissile with sexual reproduction. In these cases, the evolutionary theory does not provide any simple prediction about the pattern of aging. Fully developed population genetics theory could, of course, be formulated to address any of these 'hybrid' cases, and some progress along these lines has been made by M. E. Orive. There is no fundamental violation of theory, only some difficult special cases.

Aging in Sexual Metazoa There are very large taxonomic groups in which aging is predicted to be universal. The most common type is probably the metazoa that reproduce only sexually and lack any sort of vegetative 'spreading' such as that exhibited by corals. In such forms, the life of each organism begins from an egg that develops into an immature animal and ultimately into a sexually mature animal. Sometimes a derivative asexual, typically parthenogenetic, form evolves from such a sexual species, but the essential life cycle is maintained, with nothing approaching fissile reproduction. Among other prominent examples, both the insects and the vertebrates exhibit this type of life cycle.

Insects and vertebrates are two of the most intensively studied groups of species. There are hundreds of thousands of insect species, many of which have been studied because of their economic importance. There are far fewer vertebrate species, but they have been studied with even greater zeal than the insects. Often actuarial or physiological aging is not detected in wild populations of these organisms. For example, several fish species have been studied in which some individuals sampled from the wild appear to have attained great age without signs of physiological aging, notably sturgeon, ocean perch, and rockfish. However, no cohort of fish maintained in the laboratory free of contagious disease until death has failed to detect aging. For mammals, the evidence for the ubiquity of aging is strongest with respect to both the numbers of species studied and the quality of their care. Among all of these organisms, over the many studies that have been conducted, none have been shown to lack aging. There are no reputable refutations of the prediction of the evolutionary theory of aging that all these species must age.

Aging in Strictly Fissile Forms At the other end of the evolutionary spectrum with respect to aging are the fissile species. It is important to understand that the concept of fissile here does not mean merely asexual reproduction or budding. It is now well known that budding yeast exhibit aging, as does the asexual protozoan *Tokophyra*. When asexual reproduction is sufficiently asymmetrical, there may be a pseudo 'adult' producing 'juvenile' offspring. When this occurs in a way that can give rise to differential evolution of such adults and juveniles, then aging can evolve. The cases in which aging cannot evolve, according to the theory, are those with strict symmetry between the products of fission, as in the fissile yeast *Saccharomyces pombe* and free-floating bacteria. In these cases, if aging were to occur, it would extinguish all the descendant lineages, wiping out any such aging lineage, because senescent deterioration would then deteriorate from cell division to cell division. This outcome would be opposed by natural selection acting with full force, which would thus halt such aging among surviving lineages. As required by theory, all such cases of strictly symmetrical fission do not apparently exhibit aging. Once again, however, this does not guarantee immortality; it is not a refutation of the evolutionary theory of aging to show that a particular bacterium eventually dies.

Correlated Evolution of Aging and Other Characters

Quantitative Patterns of Aging One of the most fertile seedbeds for gerontological speculation over the last century or more has been patterns of aging among species that exhibit it. For example, it is usually found that birds live longer in captivity than mammals of a similar size, and this has provoked speculation about relationships between the physiology of flight and that of aging. It is also known that larger mammals tend to live longer than smaller mammals. Longer-lived, larger mammals also tend to have lower fecundity, per brood or per year. Finally, in the 1950s, G. A. Sacher claimed that more cephalized (larger brain weight relative to body weight) mammals tended to live longer. This again led to speculation about the physiological advantages of large brains.

With respect to these patterns, the evolutionary theory of aging makes no absolute predictions. Varied evolutionary mechanisms could generate patterns of this kind. Thus, any particular pattern of aging among aging species does not constitute any kind of test of the evolutionary theory of aging. However, this theory may be helpful in interpreting such findings.

Artifacts in Comparative Biology While it might be supposed that evolutionary biologists must be strong advocates of the use of between-species comparisons, in fact, evolutionary biologists have developed a number of profound criticisms of the comparative

method. One is that the statistical degrees of freedom can be greatly overestimated in comparative studies. If one studies 80 species of insects compared with 60 species of mammals, a naive analysis of the data would yield striking correlations between life span, type of skeleton, and number of limbs, given the more than 135 degrees of freedom. But in fact there are no degrees of freedom in this study, because there are only two independent points of data, and no absolute hypotheses with which to compare them. Fortunately, evolutionary biologists have developed methods for correctly calculating the statistical power of any particular comparative analysis. Unfortunately, the corrected values for degrees of freedom are often much less than the initial assumptions.

A second major problem with many comparative analyses is that they are confounded with spurious variables that are already known to have an effect on the characters of interest. The most common of these is body weight, which in mammals, for example, usually increases with (1) the size of most bones, (2) brain size, (3) longevity, (4) brood interval, and so on. If a biological variable that also positively depends on body size is studied for its bivariate correlation with longevity, it may be found to correlate positively with longevity, all other things being equal. However, with enough effort, this problem can be largely obviated using multivariate statistical methods.

Third, comparative correlations between characters can be generated by both (1) pleiotropic effects of genetic variants evolving in response to an unknown selection mechanism and (2) ecologically correlated selection mechanisms acting on genetically independent characters. Determining which of these two has been involved in the comparative patterns of aging in a particular taxon will be difficult. For example, it has been suggested that the greater longevity of large mammals is due to an unknown physiological advantage of larger size. It has also been suggested by Charlesworth that the greater longevity of large mammals arises because they have lower mortality rates in nature, which is known to be common, thereby preserving a higher intensity of natural selection at later ages and the evolution of relatively delayed aging. Evaluating these two alternative hypotheses across some dozens of mammalian species is a daunting task.

All of these points together suggest that comparative patterns of aging are among the worst possible sources of inference concerning aging. It is easy to obtain findings that are entirely artifactual, while it is difficult to distinguish between competing hypotheses.

Comparative Natural History of Aging It is difficult to maintain that there is much if any profundity about comparative patterns of aging, leaving aside the issue of the presence or absence of aging. In well-studied groups, like the mammals, it is generally the case that most species array themselves along a continuum stretching from small, fecund, short-lived organisms, such as mice, to large, low-fecundity, long-lived organisms, such as elephants. Within this overall spectrum there are deviations, most dramatically the bats, which on average live much longer than comparable terrestrial mammals. This is an illustration of the general pattern that flightless species age faster than those with flight, even within groups like birds or mammals. It is also the case that species equipped with poison or armor frequently live longer in captivity than comparable species without these adaptations.

The explanation that the evolutionary theory of aging can offer for these patterns is that taxa that have mortality reduction because of a characteristic adaptation, like flight in most birds, may thereby, for purely mathematical reasons derivable from Eq. [2], have an increased force of natural selection at later ages. This increased force would then lead to the evolution of relatively slower aging, all other things being equal. Such mortality reduction can also arise from poison fangs in snakes, armor in turtles, or great body size in elephants. Moreover, this evolutionary effect could have nothing to do with any immediate physiological benefit arising from poison, bulk, or wings.

Cessation of Aging in Late Life

The cessation of aging at late ages has been found in a number of organisms, including fruit flies, medflies, beetles, wasps, nematodes, yeast, and humans. These organisms also all undergo normal aging. Although the discovery of late life is relatively recent, it seems to be common among aging organisms.

Exercise and Physical Activity

C Der Ananian and T R Prohaska, University of Illinois, Chicago, IL, USA

Glossary

Exercise – Planned, structured, and purposeful training designed to improve fitness.

Flexibility – Range of motion for a joint or multiple joints.

Physical Activity – Any bodily movement produced by the muscles that results in increased energy expenditure.

Introduction

Increasing regular physical activity is becoming widely recognized as one of the most important strategies for improving and maintaining the health and well-being of older adults. There is an extensive body of literature documenting the health benefits of physical activity across diverse older populations as well as programs and strategies to promote physical activity in this population. Although increasing physical activity is a national health priority, the majority of older adults do not meet the current recommendations for physical activity. The purpose of this article is to provide a summary of what is known about physical activity and exercise among older adults. The sections that follow present current levels of physical activity among older adults, including their activity preferences, the role of exercise in chronic disease management, and the determinants of physical activity in the aged. Gaps in knowledge are identified along with recommendations for directions in research.

A variety of terms are used in reports describing the prevalence of physical activity, including general physical activity, leisure-time physical activity, exercise, and sedentary behavior. Physical activity, which is defined as any bodily movement produced by the muscles that results in increased energy expenditure, is the more inclusive term and covers a broad array of activities. Exercise is a subcategory of physical activity and is characterized as planned, structured, and purposeful training designed to improve fitness. Leisure-time physical activity, another subcategory of physical activity, is any type of physical activity engaged in during an individual's spare time and does not include occupational activity. Lifestyle activity (i.e., gardening, yard work, housework, climbing stairs, and parking further away) may contribute to health benefits when combined with other forms of moderate-intensity activities such that at least 30 min of moderate-intensity activity is accumulated. The most common forms of exercise reported for older adults are aerobic or endurance exercise and strength or resistance training. Less reported forms of exercise include balance and flexibility training.

Importance of Aerobic, Strength Training, Range of Motion, and Balance Exercises

The current recommended level of aerobic activity for adults age 60 and older is 30 min of moderate-intensity activity, such as brisk walking, on 5 or more days per week. Older adults are also encouraged to engage in resistance training on 2 or more days per week. However, to obtain optimal health benefits, it is important for older adults to engage in four types of exercise: endurance or aerobic exercise, strength training or resistance exercise, flexibility exercises, and balance exercise. Combining aerobic exercise with strength training, flexibility, and balance exercises ensures that all components of the musculoskeletal system are fit and will enhance physical functioning in

older adults. To ensure cardiovascular adaptations and changes in cardiovascular disease risk factors, older adults should include large-muscle, rhythmic aerobic exercises such as walking, running, swimming, or cycling in their exercise routine. Initiating and maintaining regular light to moderate aerobic exercise may reduce the rate at which physical functioning declines and improve the quality of life for older adults. More favorable health benefits from aerobic training occur when exercise is performed at the moderate to vigorous level. Few adverse events occur from exercising at this intensity; however, progression to this level should be gradual and dependent on the health status and initial fitness level of the individual. Older adults should also be encouraged to lead an active lifestyle, accumulating moderate-intensity activity through both lifestyle activities and moderate-intensity exercises.

Strength training on 2–3 days per week is essential for preserving muscular strength and physical functioning. Strength training should target all of the large muscle groups and should be of sufficient stimulus to improve strength but not cause injury. Strength training is necessary to slow the progression of sarcopenia, which is a decline in muscle mass that occurs with aging. Strength training is suggested to combat the weakness, frailty, and declines in physical functioning associated with sarcopenia. Numerous health benefits can be obtained from strength training, including the maintenance of or increased muscle mass in older adults and improved insulin action, bone mineral density, energy metabolism, and physical functioning. Strength training has also been demonstrated to reduce the symptoms of chronic illnesses such as heart disease, arthritis, and type 2 diabetes and to improve sleep. Furthermore, strength training may enhance an older adult's ability to engage in moderate-intensity aerobic exercise.

Flexibility is an often-overlooked yet essential component of exercise training for the older adult. Flexibility, which encompasses the range of motion of a joint or multiple joints, declines with aging due to structural changes in the tissues that affect function of the joint. Flexibility exercises can improve the properties of the muscle and/or connective tissue, reduce joint pain, and enhance muscle recruitment patterns. These physiological changes are associated with increased range of motion of the joints and improved mobility.

Balance exercises are also highly recommended for older adults due to the high incidence of falls within this population. Postural stability declines with age, and poor postural stability is associated with risk of falling. The optimal type and dose of balance exercises needed to reduce risk of falls and to improve postural stability are not yet clear. However, the research has shown that a broad-based exercise program that includes walking or dancing, strength training, flexibility, and weight transfer will enhance postural stability. Additionally, tai chi has been shown to enhance balance in older adults.

Prevalence of Physical Activity among Older Adults

Despite the multitude of health benefits associated with regular exercise, older adults tend to be the least active segment of the population. Combined data from the 1994 and 1996 Behavioral Risk Factor Surveillance System (BRFSS) survey indicated that more than one-third of adults aged 55–74 and 46% of adults over the age of 75 were inactive. The good news is that the prevalence of no leisure-time physical activity as assessed by the BRFSS is on the decline, particularly among older adults. Since 1989, the prevalence of physical inactivity has declined by 15 and 7% among men and women aged 50–59 years, respectively; 10 and 6% among men and women aged 60–69 years; and 10 and 12% among men and women 70 and older, respectively. However, whether this decline in the prevalence of physical inactivity translates into an increase in the prevalence of older individuals obtaining sufficient exercise to obtain health benefits is less clear. Data from the 2001 BRFSS indicated that 38% of men and 27% of women over the age of 75 were meeting the recommendations for moderate-intensity physical activity. These prevalence estimates are similar to those obtained from the 1990 National Health Interview Survey (NHIS), which found that 40% of men and nearly 26% of women over the age of 65 met the recommendations for physical activity. Furthermore, participation in aerobic activities is more common than strength training. Only 11% of those age 65 years and older report doing strength or resistance training 2 or more days per week.

Data have also been collected on walking patterns since 1987. Walking is the most common form of activity among persons of all ages and is the most frequently reported type of activity among older individuals who meet the recommendations for physical activity. From 1987 to 2000, there was a 3.5% increase in the percentage of men and a 4.8% increase in the percentage of women over the age of 65 who reported walking for physical activity. However, there was no increase in the percentage of individuals who met the recommendations for physical activity through walking within any age group.

Epidemiological evidence also suggests that certain subpopulations of the older population are less active

than others. Data from the combined 1994 and 1996 BRFSS indicated that the prevalence of physical inactivity was higher for African Americans than Caucasians. Nearly 50% of African Americans age 55 or older were inactive. Gender differences in the prevalence of physical inactivity were observed among Caucasians only. Caucasian women 65 and older had a higher prevalence of physical inactivity than men (31 and 36.3% for men and women 65–74 years of age, respectively; 37.1 and 47.4% for women and men 75 years of age and older, respectively). In general, people with higher body mass indexes (BMIs) or poorer perceived health are more inactive. Similarly, older adults with disabilities or chronic illnesses are less active than their healthy counterparts. Findings from the 2001 BRFSS survey found that 43.4% of adults aged 50 or older without any disabilities met the current Centers for Disease Control and Prevention/American College of Sports Medicine (CDC/ACSM) recommendations for physical activity and 17% were inactive. In contrast, among those aged 50 or older with a disability, only 28.8% met the recommendations for physical activity and nearly 36% were inactive. Likewise, among individuals age 65–74 with arthritis, only 26% met the recommendations for physical activity compared to nearly 32% of those without arthritis. Individuals 75 and older with arthritis were the least active segment of the population, with nearly 42% classified as inactive. The prevalence of physical activity or inactivity among older adults with other chronic illnesses is harder to delineate. There is little information in the literature about the national prevalence of physical activity among older adults with specific chronic illnesses such as cardiovascular disease, diabetes, or cancer. Likewise, there is little known about the prevalence of physical activity among older Hispanic, Asian, or American Indian adults.

Impact of Physical Activity on Health

Older adults can be faced with a variety of physical, mental, and emotional challenges and are often faced with life-changing circumstances. Hence, it is easy to understand why health-protective behaviors such as exercise may not be a priority within this age group. However, maintaining a regular exercise routine is essential for older adults. Aging is associated with several health conditions, including cardiovascular disease, diabetes, obesity, cancer, and arthritis. Key to improving both the primary and secondary prevention of these and other chronic illnesses and disabilities is regular participation in exercise.

There is strong and consistent epidemiological evidence demonstrating the relationship between regular participation and positive health outcomes. Early epidemiological studies often focused on the crude relationship between self-reported occupational and/or leisure-time physical activity and health outcomes such as cardiovascular disease. For example, transportation workers with sedentary jobs (e.g., drivers) had higher rates of heart disease compared to workers with less sedentary jobs (e.g., ticket takers). It has also been shown that there is a relationship between caloric expenditure from leisure-time physical activity and heart disease. Individuals who expended 2000 kcal/week had the lowest risk for heart disease. Other epidemiological studies focused on the relationship between cardiovascular fitness and health outcomes. Whether the studies looked at fitness or exercise patterns, epidemiological evidence indicates that regular participation in exercise is associated with lower rates of overall and cardiovascular mortality, cardiovascular disease, stroke, hypertension, non-insulin-dependent diabetes, dyslipidemia, and breast and colon cancers. There is also strong epidemiological evidence demonstrating that individuals who are sedentary are at higher risk for developing chronic illnesses. In fact, inactivity doubles the health risks and has a disease burden comparable to smoking.

While epidemiological studies have allowed for the detection of an association between exercise and fitness levels and health outcomes, they do not provide information on the optimal dose, type, or frequency of exercise required to achieve these health outcomes. This is why intervention research and training studies are important to fill the gaps. Intervention research allows investigators to manipulate the intensity, dose, and/or frequency of exercise to determine the minimal amount necessary to achieve health outcomes. Intervention research needs to be conducted at both the primary and secondary prevention levels. That is, interventions need to be conducted within relatively healthy but sedentary older adult populations and among older adults with chronic illnesses. Intervention outcomes in these populations should focus on not only health- or disease-related outcomes, but also on functional status (e.g., gait, balance, losses of function, independence), mental health status, cognitive functioning, quality of life, and prevention or delay of age-related declines.

To date, most intervention studies conducted with healthy older individuals have focused primarily on health- or disease-related outcomes, although in recent years many have begun focusing on functional outcomes. In healthy older adults, physical activity interventions have been able to increase activity levels, at least for the short term. These increases in physical activity have been associated with improvements in

fitness, flexibility, muscular strength, gait and balance, functional status, improved quality of life, improved blood pressure, and decreased risk of falls. Many have also demonstrated improvements in cardiovascular risk factors and psychological factors.

Intervention studies conducted among older individuals with chronic illnesses are less common. The majority of research on the benefits of exercise within the context of chronic illness has focused on heart disease, hypertension, peripheral vascular disease, arthritis, osteoporosis, and diabetes. A limited number of studies have been conducted among people with cancer, stroke, cognitive impairments, and disabilities. Some of the strongest evidence for the benefits of exercise comes from cardiac rehabilitation programs. Individuals with heart disease who participate in an exercise-based cardiac rehabilitation program have reduced all-cause and cardiac mortality, lower total cholesterol, triglyceride, and systolic blood pressure levels compared to individuals who attend non-exercise rehab programs. It is estimated that individuals who attend an exercise-based rehab program have a 20% reduction in all-cause mortality and a 25% reduction in cardiac-related mortality. A recent meta-analysis of exercise interventions in hypertensive individuals demonstrated that moderate-intensity aerobic exercise is associated with a 2% reduction in systolic blood pressure. Interventions focused on peripheral vascular disease have demonstrated increased functional capacity, determined by an increase in time to pain during walking, after participating in an aerobic exercise program. Likewise, aerobic exercise has been shown to increase insulin sensitivity among diabetics, resulting in improved management of diabetes. A large number of studies have been conducted among older people with arthritis, and both strength and aerobic exercise have been associated with improved physical functioning, including postural stability and gait, decreased pain, increased range of motion, increased muscular strength, decreased fatigue, and improved quality of life. Participation in weight-bearing exercise and strength-training interventions is known to help maintain bone mineral density among individuals with osteoporosis. Finally, recent intervention studies have also focused on frailty. Participation in exercise programs, including chair-based, strength, or aerobic, appears to positively impact frailty by improving physical functioning, strength, balance, and quality of life.

Other areas that have been less frequently studied in which exercise has the potential to positively influence health include cancer, stroke, disability, and cognitive impairments. While few studies have been conducted among older adults with cancer, the effects appear promising. Thus far, studies have shown that exercise has the potential to decrease fatigue; promote weight loss; improve health-related quality of life, physical functioning, and mood; and modify coronary heart disease risk factors. More research needs to be done on the long-term effects of exercise on cancer recurrence and reduction of cancer-related risk factors, as well as on the optimal dose of exercise needed to improve the health, physical functioning, and psychological status of individuals with cancer. Likewise, few randomized trials have been conducted among people who have had strokes, and the evidence to support the efficacy of aerobic exercise in stroke is insufficient. Related to cognitive function, aerobic interventions have been shown to have a positive impact on executive function in older adults. More intervention research is warranted for areas of study in which little is known about how to determine the optimal dose, intensity and duration of exercise to maximize the health outcomes, and what characteristics of the program and/or setting influence exercise intervention participation.

The effect of exercise on mental health status has also been examined. While the evidence of the association between physical inactivity and depressive symptoms in older adults is strong, the evidence of a direct causal role of physical activity on reducing depression is promising but insufficient at this time. In a review of exercise training and depression in older adults, it was reported that exercise reduces depressive symptoms in older adults but not significantly more so than health education/social control referent groups. However, one study reported that aerobic exercise significantly reduced depression and was just as effective as antidepressant medication in older adults. Given the high prevalence of depression among older adults and the impact of depression on health and well-being, additional randomized trials examining the role of aerobic and resistance exercise on depression are warranted.

While an abundance of intervention research has been conducted, one caveat to the research is that the majority of the interventions have been premised on the current recommendations for physical activity. Most interventions have encouraged participants to engage in moderate-intensity exercise on 5 days/week for at least 30 min/day. Few interventions have tried to manipulate the dose, intensity, or volume of exercise. For example, one study examining cardiovascular risk factors in older adults compared high-intensity group or home-based exercise (3 days/week for 40 min at 73–88% peak treadmill heart rate) to moderate-intensity home-based exercise (5 days/week for 30 min at 60–73% peak treadmill heart rate). All three groups showed improvements in fitness but not

high-density lipoprotein (HDL) cholesterol at the end of year one. After 2 years, both home-based groups showed improvements in HDL levels; however, the improvements were more pronounced in the lower-intensity group, indicating that a greater frequency of exercise is associated with more favorable improvements in cholesterol. Because few studies have attempted to manipulate physical activity parameters, it is unknown whether some individuals could benefit from a lower dose of physical activity or how these individuals may differ from individuals requiring higher doses of physical activity. It is also not known how different diseases will respond to varying amounts of exercise. Future research studies should focus on manipulating the dose, intensity, frequency, or volume of exercise to get a better understanding of the dose response necessary to improve health within different diseases and within different subpopulations.

Correlates of Physical Activity

A considerable body of literature has been generated as to the underlying determinants associated with regular physical activity among older adults. These factors can be organized into three general domains: (1) psychosocial social and motivational factors, (2) environmental factors, and (3) exercise program characteristics. These correlates have been examined in those who do and do not exercise and in studies examining the initiation and maintenance of regular physical activity. Except for the psychosocial determinants of physical activity, relatively few of these studies have examined the causal relationship through randomized control studies.

Important motivational determinants of physical activity include self-efficacy, social support, concerns about safety, performance feedback, and related perceptions and beliefs. Self-efficacy for exercise is one of the most investigated and strongest motivational determinants of exercise. Older adults are more likely to start and maintain exercise activities when they feel they are capable of performing the exercise and when they are able to perform the exercise with no health risk. Concerns related to self-efficacy are particularly important among frail older adults and those with chronic illnesses. Perceptions of outcome efficacy (beliefs of obtaining desired outcomes) are also associated with exercise among older adults. Together, self-efficacy expectancy and outcome efficacy are the foundation for social cognitive theory, which is the most common theory guiding exercise programs for older adults.

Social support is another determinant of exercise for older adults. Observational studies have demonstrated that support for exercise from family and friends is associated with increased physical activity. Programs that include a social support component (e.g., an exercise partner) contribute to adherence to exercise routines. Related to social support, positive reinforcement also contributes to adherence with exercise and physical activity among older individuals. Examples of reinforcement strategies used in exercise programs include telephone-delivered motivational counseling, recognition of attendance and accomplishments, and the inherent positive feedback when the person becomes aware of the health benefits of exercise participation. Regular physical activity is more likely to occur and be maintained for older individuals when multiple psychosocial motivational techniques are used.

Finally, knowledge about physical activity and beliefs about the benefits of exercise are associated with physical activity. Those who perceive greater benefits of exercise and fewer barriers are more likely to participate in regular physical activity. Also, poor health and functional status and concerns about one's health result in a greater likelihood of declining participation in and non-adherence to exercise programs.

Several environmental barriers to regular physical activity have been identified among older populations. In terms of walking for exercise, older adults report barriers in both the built and natural environment. Concerns for safety, a lack of enjoyable scenery, and neighborhood characteristics (e.g., hills, unattended dogs, not seeing others walking for exercise) are associated with less walking for exercise among older persons. As might be expected, accessibility to desired locations such as a beach or park promotes walking. Being within walking distance (i.e., within one half mile) to businesses also facilitates destination walking. Elderly in lower socioeconomic status (SES) neighborhoods walked more than those in higher SES neighborhoods. Finally, several of these environmental factors (e.g., weather, neighborhood walking) have also been associated with adherence to group-based exercise programs with older women.

In terms of exercise program characteristics, there is some evidence that older women prefer home-based over group-based physical activity programs. Evidence suggests that the majority of older adults prefer programs that are lower in intensity and convenient.

Life Span Transitions and Physical Activity

How life span transitions may influence physical activity among older adults is just beginning to be

understood. Major life transitions such as loss of spouse, retirement, and becoming a caregiver are associated with changes in perceptions of self, changes in social roles and responsibilities, and changes in resources – all potentially affecting physical activity. Decreases in physical activity have been associated with the onset of the caregiver role. A major reason for exercise program attrition among minority older adults is due to becoming a caregiver. Older adults faced with other priorities and increased responsibilities report limited time for physical activity. The association between physical activity and marital status has been mixed. However, there is evidence that older women who lose their spouse and remain unmarried report a slight increase in physical activity. Compared to older persons who continue working, a greater percentage of those who retire participate in regular physical activity and leisure walking. This increase was reported for African American and Caucasian as well as female and male older adults. Vigorous physical activity does not significantly increase with retirement. Causes for changes in physical activity among these life span transitions are not well understood. Additional research should be directed at identifying the underlying mechanisms accounting for the changes in physical activity.

Settings for Physical Activity among Older Adults

Crucial to designing effective interventions among older adults is the need to understand what settings older adults encounter during their daily routine that could be used as a place to promote physical activity. Ideally, to enhance the likelihood of success for community-based physical activity programs, interventionists should utilize the facilities within communities that are frequented by the target population. For older adults, there are several settings that could easily be used as locations for an intervention. Senior or congregational meal centers are highly utilized by the older adult population. Many senior centers already have fitness equipment as part of their setting, making them an ideal place to offer fitness programs for older adults. The Fit and Strong Program is one example of an intervention that successfully used senior centers to increase physical activity among people with arthritis. Assisted living facilities, retirement communities, and nursing homes provide another setting for targeting older adults. These settings provide the benefit of targeting individuals who are frail and impaired and most in need of physical activity. For example, assisted living facilities would provide an ideal setting to promote chair-based exercise interventions and interventions aimed at reducing falls and improving physical function. Church-based programs have been successfully used to increase physical activity in older adults. The efficacy of tailoring physical activity programs to African American adults within the church setting and the feasibility of using churches to engage older African Americans in physical activity have been demonstrated.

Other community-based settings that have potential to increase physical activity include malls, fitness centers and gyms, and parks. Many malls offer walking programs and clubs, and malls are cited by 37% of people who walk as a preferred location for walking. Malls are temperature controlled and offer a safe environment for physical activity. Increasing the availability of exercise programs for seniors at local fitness centers, gyms, and recreation centers may also be important for increasing physical activity. While there is a preponderance of fitness centers, few offer affordable programs tailored to the needs of older adults. Increasing the presence of senior fitness programming may help to increase exercise participation.

The health-care provider's office is also an ideal setting for promoting physical activity to older adults. The average adult visits their physician three times per year. Due to the substantial burden of chronic illnesses among older adults and the likelihood of them visiting their primary care physician to manage these illnesses, the physician's office should be a primary source of information about exercise. However, national data indicate that only 31% of adults over the age of 65 actually receive advice from their physician to increase their exercise level. In 2002, the United States Preventive Services Task Force found insufficient evidence to recommend for or against behavioral counseling for physical activity in the doctor's office. The reason for this finding rested primarily on the lack of evidence for a sustained effect on physical activity and the mixed quality of the studies. However, this does not mean that physician counseling is ineffective. Further, the report suggests that higher-quality research is needed and that a better understanding of the intensity of the physician counseling is needed to promote physical activity as part of this research. For example, one recent randomized trial found that older adults who received both advice from a physician and telephone-based exercise counseling increased their physical activity more than those individuals who received solely physician counseling.

Due to the high levels of frailty and social isolation among older adults, the home cannot be ignored as a setting for promoting physical activity. Simple chair-based exercise programs such as Strong for Life have

been developed for frail older individuals who are homebound. This program was found to be efficacious in clinical trials and was also successfully disseminated through community-based social service agencies. The fact that Strong for Life is based on videotapes and uses easily obtainable equipment, Therabands, makes it an ideal option for increasing physical activity among homebound older adults.

Evidence-Based Physical Activity Programs

The field of physical activity promotion for older adults has become more sophisticated over the years, transitioning from an individualized approach for increasing physical activity to a more ecological approach. Efforts to increase physical activity at the community level have been advanced by the development of the National Blueprint for Increasing Physical Activity among Adults Age 50 and Older, which provides a comprehensive framework for groups interested in helping adults 50 and older start and maintain an exercise program. **Table 1** provides examples of effective, evidence-based physical activity programs. To date, the majority of community-based programs promoting physical activity have focused on changing individual behavior within a community-based setting. These individually based programs have typically been designed to examine how physical activity can improve fitness, function, or health, or they have used a lifestyle approach in which participants are encouraged to accumulate 30 min of moderate-intensity activity on at least 5 days per week. Important to the design of the lifestyle intervention approach is the issue of choice. The participants in lifestyle interventions are encouraged to choose the type of activity in which they would like to engage (e.g., existing programs within the community or exercising at home) rather than having the type of exercise predetermined. Other suggested forms of community-based interventions include the dissemination of established successful programs into community-based settings and changing the context or the environment of settings to enhance physical activity. However, few studies have been done on examining the dissemination of evidence-based programs or on changing the environment to increase physical activity for adults. A better understanding of the practicality of disseminating evidence-based programs and the

Table 1 Examples of evidence-based physical activity programs

Program name	*Author(s)*	*Target population*	*Current dissemination status*
Active Choices	Stanford Prevention Research Center	Middle-age to older adults	Widely disseminated program in more than 25 community and health settings; dissemination within senior centers currently being evaluated
Active Living Everyday	Blair SN, Dunn A, Marcus B, Carpenter R, and Jaret P	Sedentary adults (of all ages)	Widely disseminated by a variety of organizations such as worksites, hospitals, community health programs and colleges, and senior residences; dissemination within senior centers currently being evaluated
CHAMPS	Stewart AL, Mills KM, Sepsis PG, King AC, *et al.*	Older adults (65 +)	Tested in senior centers, congregate homes, and physician offices
Fit and Strong	Hughes S, Seymour R, Campbell R, *et al.*	Adults with arthritis	Currently being disseminated to senior centers within the Chicago area as part of a dissemination trial
PACE (People with Arthritis Can Exercise)	Arthritis Foundation	Adults with arthritis	Widely disseminated to individuals and within community-based settings via the Arthritis Foundation; effectiveness trial currently in progress
Strong for Life	Jette AM, Harris BA, Sleeper L, *et al.*	Homebound, frail seniors	Large-scale dissemination is planned within the state of Illinois

Table 2 Summary gaps in research on physical activity and aging

1. Limited research on physical activity among diverse ethnic older populations, including Hispanic, Asian, and American Indian older adults
2. Little understanding as to how life transitions (e.g., retirement, loss of spouse, caregiver status) may influence physical activity
3. Need to understand the benefits of physical activity on persons with chronic illnesses such as cancer, cognitive impairment, stroke, and disability
4. Need for information on factors associated with long-term adherence to exercise and an active lifestyle
5. Limited information on the dose–response effect of exercise among older adults, especially among those with a chronic condition or multiple chronic conditions
6. Minimal understanding of how settings and environments influence physical activity
7. Need for a broader set of measures to evaluate the impact of physical activity focusing on the priorities of older exercise participant and the agency/community groups providing the programs
8. Need for research on effective strategies for translation and dissemination of physical activity programs with proven efficacy and effectiveness

environmental aspects related to physical activity promotion is needed.

Summary and Conclusions

The research base for physical activity among older adults allows for several conclusions on what is and is not known. To review, there are considerable data on the prevalence of specific types of physical activity among a variety of groups of older adults. There is also considerable information on the determinants of physical activity and exercise in older populations, especially the social cognitive factors motivating the onset and maintenance of physical activity. There is also strong evidence on the benefits of specific forms of physical activity among healthy older adults and those with specific chronic illnesses such as arthritis, diabetes, and hypertension. Finally, the field has made considerable progress in designing comprehensive community-based physical activity programs for older adults based on randomized intervention trial findings demonstrating efficacy and effectiveness.

While significant progress has been made, major gaps in the research remain. **Table 2** provides a summary of the gaps addressed in this article. As noted earlier, the majority of the research on physical activity with older adults is based primarily on white and female groups and, to some degree, older African Americans. The lack of information on physical activity among other minority groups such as Hispanic and Asian older adults is a major gap given the growing ethnic diversity of the older population. Research on physical activity and life transitions is in an early stage of development and should be promoted given the potential changes in physical activity noted. Also, a life transition approach would promote tailored interventions specific to the needs of older adults. An important advancement in exercise with older adults is the effort to examine the benefits of exercise among older adults selected based on specific chronic illnesses. This research has focused on a select few chronic illnesses and could easily be expanded to address a broader set of chronic conditions. This research should include primary prevention as well as secondary and tertiary prevention intervention.

With few exceptions, the majority of exercise intervention trials have examined adherence over a limited time frame (1 year to 18 months). There is a need to better understand how a long-term lifestyle change in physical activity can be promoted among older adults in order to obtain lasting health benefits and improvement in disability. Many older adults will not reach the recommended levels of physical activity, and yet may benefit from some level of activity. Also, some may obtain benefits with less than recommended levels of exercise intensity, duration, and frequency. Additional research should focus on the dose–effect of exercise among older adults so they are better informed about the value of less than ideal activity. As noted earlier, characteristics of the built and natural environment influence physical activity among older adults. Research on the role of the environment in physical activity for older adults is just beginning. Concerns over the person–environment fit are particularly relevant for older adults due to functional limitations (e.g., vision, gait alterations, and balance).

To date, physical activity and exercise programs have focused on outcomes based primarily on measures used in research (e.g., $VO_{2\ max}$, timed chair rise, 6-min walk). As exercise programs move from clinical trials to community-based programs, additional effort should be directed to focusing on outcomes meaningful to the older participant. Tailoring outcomes to the priority of the older participant will help to promote outcome efficacy, thereby increasing exercise adherence. Finally, there are several quality comprehensive physical activity programs with proven effectiveness and efficacy. These community-based

programs are at various stages of diffusion and dissemination into the wider community. Additional research should focus on the most effective strategies for bringing these programs to targeted older adults in various community settings. Addressing this as well as the other gaps noted in **Table 2** should increase the proportion of older adults participating in regular physical activity and will contribute greatly to the health and well-being of older adults.

Extracellular Matrix

K M Reiser, University of California, Davis, CA, USA

Glossary

Collagen – Family of large structural proteins, characterized by triple helix conformation, which provide tensile strength to tissues and organs and serve as a matrix for growth and proliferation of cells.

Elastin – Highly insoluble structural protein capable of reversible expansion and contraction, essential for physiological functioning of deformable tissues such as blood vessels, skin, and lung.

Extracellular Matrix – Intricate network composed of the structural proteins collagen and elastin in association with proteoglycans that serves as the scaffolding for tissues and organs throughout the body.

Proteoglycan – Family of non-fibrillar connective tissue components associated with collagen and elastin in the extracellular space, consisting of a core protein with one or more glycosaminoglycan side chains covalently attached.

Introduction

The extracellular matrix serves as the scaffolding for tissues and organs throughout the body, playing an essential role in their structural and functional integrity. Its predominant components are the large, insoluble structural proteins collagen and elastin. Although the matrix was originally thought to be relatively inert, it is now apparent that the matrix undergoes profound structural changes are over time. Much progress has been made recently in understanding the molecular basis of these changes, despite formidable technical difficulties in analyzing the matrix proteins. The mechanisms responsible for matrix alterations are also still poorly understood. Although we know that some of these structural changes are under genetic control, many are not, such as the series of reactions between matrix proteins and sugar molecules to form complex colored and fluorescent compounds. As the matrix structure changes over time, so do its physical and chemical properties, such as solubility, flexibility, and mechanical strength. As a result, tissues and organs throughout the body also undergo changes in structure and function. In addition, age-associated changes in matrix affect key properties of the resident cell populations. In summary, many changes we associate with the aging process are attributable either directly or indirectly to cumulative structural changes in the extracellular matrix.

Introduction: Why Is Aging of the Extracellular Matrix Important?

Aging is characterized by profound changes in the extracellular matrix, the complex network of long-lived structural proteins and glycosaminoglycans that serves as the scaffolding for virtually every tissue and organ system. It has long been postulated that the process of matrix aging may have more than phenomenological significance, and that within its intertwined pattern of cause and effect may lie the key to understanding fundamental mechanisms of aging in the organism as a whole. One of the earliest unifying hypotheses of aging, advanced almost 50 years ago, proposed that aging was initiated by the development of irreversible cross-links in matrix macromolecules that accumulated over time and led inexorably to the degenerative changes associated with aging. In these early studies, structural changes in matrix macromolecules were inferred from changes in their physicochemical properties. Since then, the tools of modern molecular biology have begun to reveal the molecular basis for many age-associated phenomena previously observed only at the microscopic and macroscopic level. Recent studies suggest that the original concept that the matrix might serve as a kind of clock that both regulates and reveals biological age retains considerable validity.

Why is the matrix so suited to the role of biological timekeeper? First, the matrix is truly the common ground of an organism, present in all tissues and organs from the earliest developmental stages until death. Second, the two major matrix proteins, collagen and elastin, have extremely long half-lives *in vivo*. Third, collagen and elastin are subject to extensive post-translational modification, ranging from hydroxylation and glycation of individual residues to the formation of complex cross-links and adducts. Few other proteins besides collagen and elastin possess all three of these qualities: ubiquity, longevity, and plasticity. How are these characteristics related to aging? The long half-life of these proteins means that a given molecule may continue to undergo structural modification over many years. As a consequence, the collagen and elastin molecules in an individual organism accumulate a set of modifications that serve as a kind of permanent record of the innumerable interactions between the organism, with its unique genetic endowment, and its uniquely experienced environment. This record, however, is far from inert. As the matrix changes, so does its effect on proliferation, migration, response to cytokines, and gene expression of resident cell populations. Age-associated changes in matrix also profoundly affect tissue and organ system function. Because of the ubiquity of matrix, these effects on cells and tissues occur throughout the body, ultimately affecting the organism at the systemic level. Thus, the molecular memory of an organism's experience in the world, recorded in the code of matrix modification, assumes increasing power to direct that experience; it is this transit – from recorder of events to regulator – that lies at the heart of the aging process in matrix. To the extent that we can learn the language of matrix memory, we may find new ways to change the message that has, thus far, been so inexorably determined by the passage of time.

Assessment of Matrix Aging: Commonly Used Methodologies

Our conceptual understanding about a phenomenon is often shaped by the tools available for investigation and by the choice of tools used. The investigation of matrix aging provides a particularly apt illustration of the pitfalls that can occur when the limitations of analytic techniques are ignored or, worse, when these very limitations have been mistakenly used to draw inferences about the subject of study. Even a cursory examination of the primary literature

on matrix aging reveals a vast number of contradictory reports. Some of the inconsistencies are attributable to differences in study design (particularly differences in the age range of animals studied), whereas some are due to methodological shortcomings, including failure to recognize inherent limitations, failure to recognize implicit assumptions in the assay of choice, and, as a consequence, failure to consider alternative explanations for a particular finding. Thus, before one can attempt to draw any general conclusions from the very large literature, one must have some understanding of the rationale for the limitations of commonly used analytical techniques used in studying the effects of aging on the matrix.

Histochemistry

Light microscopy is one of the oldest techniques for studying the effects of aging on the extracellular matrix proteins. Although qualitative information can be obtained that may be helpful in determining experimental strategies, there are many pitfalls that significantly limit the conclusions that can be drawn from such data. In older studies, histochemical studies using non-specific stains such as hemotoxylin-eosin were sometimes used to investigate the effects of age on the amount and distribution of collagen in different tissues. Discrepancies between such studies are most likely due to the lack of consensus concerning the definition of collagen fibers, differences in staining techniques, and differences in tissue preparation. Attempts have also been made to categorize components of the matrix on the basis of their staining properties, giving rise to distinctions between such entities as reticulin, collastin, and basement membrane collagen. Again, there is little consensus as to the definition of such terms. More recently, the discovery that many tissues were composed of more than one genetically distinct collagen aroused interest in the use of special stains that were believed to have specificity for a particular collagen type. Mason's trichrome and van Gieson's stain are generally assumed to be specific for type I collagen, whereas Gomori's stain (silver impregnation) has been referred to as type III specific. However, it is now evident that these stains cannot be used for quantitative assessment of changes in collagen type distribution due to inconsistencies in their ability to stain specific collagen types. For example, silver impregnation is capable of staining newly synthesized type I collagen, but not mature fibrils. Furthermore, the staining properties of the more recently discovered collagen types (types V–VI) are unknown. Although there have been attempts to develop more elaborate panels of staining procedures that could be correlated with different collagen types, this approach seems particularly fruitless given the ever-increasing number of genetically distinct collagen types being identified.

Histological assessment of age-associated changes in elastin poses equally difficult problems. Historically, elastic fibers have been characterized by their ability to take up such stains as Verhoeff-hematoxylin, resorcin-fuchsin, and orcein, due to the presence of aldehyde groups and/or strongly hydrophobic regions. However, although some investigators draw inferences about elastin from the use of such stains, it should be emphasized that elastic fibers are not synonymous with elastin. Elastic fibers have been shown to be composed of elastin and elastic fiber microfibrils, which in turn comprise several genetically distinct proteins, including fibrillin and the so-called microfibrillar-associated proteins. There is at present little information as to how these microfibrillar components interact with and affect elastin structure. Thus, histochemical studies of age-associated changes in elastic fibers cannot be construed as providing much structural information as to what happens to elastin during aging.

Finally, there are several general limitations inherent in any type of histological assessment of the effects of aging on matrix. First, it is very likely that the staining properties of collagen and elastin are affected by the profound structural changes that occur with aging, thus making it questionable whether young and old tissue can be directly compared by histochemical techniques. However, no data are available concerning this issue. Second, problems in true random sampling and quantification of staining intensity further reduce the usefulness of histological techniques in assessing age-associated changes in matrix.

Mechanical Properties

Histochemical studies are clearly limited by their descriptive nature and by their inability to provide either precise quantitative data or information about events in the matrix occurring at the molecular level. In contrast, mechanical properties can be measured very precisely in collagen. Furthermore, changes in such mechanical properties as thermal contraction force, ultimate load, tensile strength, breaking strength, and strain may be assumed to reflect changes at the molecular level. Thus, the hypothesis that aging resulted from irreversible cross-linking of macromolecules provoked considerable interest in investigating the effects of aging on the mechanical properties of collagen. If indeed progressive cross-linking is a

central event in the aging process, then an assay that indirectly reflected degree of cross-linking might have predictive value as a marker of longevity. However, although numerous studies have shown that mechanical properties such as thermal break time are highly correlated with chronological age within a given species, there are no convincing data that these parameters are correlated with longevity.

One of the major disadvantages of these mechanical assays is the necessity of obtaining collagen in fiber form, as most collagen in the body cannot be isolated as intact fibers, nor can elastin, due to its extreme insolubility. Thus, the lack of correlation between mechanical properties of collagen and longevity may arise from the fact that only fibrillar type I collagen present in tendon is being assessed. It is possible that changes in mechanical properties in this collagen do not accurately reflect age-associated changes occurring in parenchymal tissue containing complex mixtures of fibrillar and non-fibrillar collagen types.

Solubility

In part to circumvent the limitations inherent in assays of mechanical properties, several investigators developed methods for precise quantification of collagen solubility, a parameter that has long been observed to increase with age. Urea, neutral salt buffers, and acids of varying strength have all been used to solubilize collagen. Rate of solubilization by enzymatic digestion has also been extensively used, sometimes with enzymes such as pepsin, which are not specific for collagen, but more often with highly purified collagenase. Solubilization is significantly correlated with chronological age within a given species. However, attempts to correlate solubility with longevity have not been as fruitful. Furthermore, studies have also shown that results obtained with one solubilizing agent may not be consistent with results obtained using another. For example, collagenase digestibility of rat collagen decreases very little after rats reach maturity, whereas solubility in urea decreases markedly with age. This discrepancy between effects of different solubilizing agents was not observed in longer lived species such as humans, monkeys, and dogs, raising the possibility that extrapolation from data obtained in a short-lived species to a long-lived species must be done cautiously.

Electron Microscopy

Advances in electron microscopy and the development of quantitative morphometric techniques have provided potentially powerful new analytical tools for analyzing the effects of aging. However, this analytical approach suffers from some of the same problems as light microscopy, in that a terminology has developed based upon descriptive features rather than on well-defined chemical entities. The relationship of such terms as unit collagen fibrils, microfibrils, reticular fibers, and primary fibrils to molecular concepts of collagen structure remains very unclear, despite attempts to correlate fibril diameter with collagen type, degree of glycosylation, and composition of intervening ground substance.

Electron microscopy has perhaps been most fruitful when used in conjunction with X-ray diffraction studies and chemical analyses in elucidating the molecular structure of collagen fibrils. Collagen exists *in vivo* in the form of fibrils measuring 50–2000 Å. Both low angle X-ray diffraction and electron microscopy indicate an axial period of about 640 Å, within which characteristic repeating bands can be observed after staining. These striations within a period result from the distribution of charged residues, whereas the periodicity results from the self-assembly of tropocollagen units during fibrillogenesis into five-stranded helical microfibrils, in which each tropocollagen unit overlaps its neighbors by a multiple of the distance 640 Å (the quarter-stagger model). The native fibril consists of aligned microfibrils packed side to side; presumably other types of fibrils result from different arrangements of the microfibrils or from interactions with other macromolecular components of the matrix. This type of integrated approach is being used to analyze the changes in molecular packing that result from the post-translational changes that occur during aging. For example, it has been shown that nonenzymatic glycation leads to expansion of the microfibrillar assembly.

Biochemical Studies

During the last 20 years, the explosion of knowledge in biochemistry and molecular biology has resulted in the development of many new methods for studying the effects of aging on synthesis and deposition of matrix proteins. As with other approaches, there are many methodological pitfalls in commonly used biochemical assays that can seriously skew the data, and which have resulted in conflicting reports about the effects of aging on virtually every aspect of matrix biosynthesis.

Collagen Content Early methods for measuring collagen content of tissues such as gelatinization or hot trichloroacetic acid precipitation are not very precise. One of the first specific assays developed for

measuring collagen involves quantifying hydroxyproline, an amino acid residue that comprises approximately 15% of the total amino acids present in collagen. Hydroxyproline is, for most purposes, a reasonably specific marker for collagen, as the amount present in elastin and in the Clq component of complement – the only two other potential sources – is negligible by comparison. Assays based upon oxidation of hydroxyproline to pyrrole, which is quantified colorimetrically, are most often used. Even in this fairly straightforward assay there may be pitfalls, particularly with respect to selecting an appropriate denominator term. If hydroxyproline is expressed as a concentration (per unit tissue weight or unit tissue volume, per gram of total protein or DNA, for example) rather than on a per organ basis, net changes in total collagen may be masked by the effects of age on the denominator term. It may be impossible to compare studies using different denominator terms, as different results may be obtained. Hydroxyproline values may also be significantly affected by tissue preparation; for example, tissues that are either edematous or contaminated with blood may give falsely high values in this assay, as colored impurities from heme absorb light at the same wavelength as the pyrrole chromophore. Gross contamination of a sample with blood, on the other hand, may result in spuriously low values.

Elastin Content Elastin has been less well defined chemically than collagen, in part because, unlike collagen, it is extremely difficult to solubilize in intact form. As a consequence, many approaches have been developed for biochemically measuring elastin, resulting in widely variable estimations of elastin content for several tissues and organs. For example, estimations of lung elastin content vary from 1 to 47%, depending on the assay used, as illustrated in **Table 1**. Probably the most commonly used method for quantitating elastin is the Lansing procedure, in which elastin is isolated on the basis of its insolubility in boiling sodium hydroxide. Several variations of the method exist in which insoluble non-elastin material is separated from elastin in the final precipitate, including solubilization of elastin with potassium hydroxide (KOH) and elastase digestion. Another approach is to measure nitrogen content of the final precipitate and assume elastin is 16.34% nitrogen. Enzymatic methods for quantitating elastin have also been used, such as digestion of crude tissue preparations with trypsin and collagenase to remove non-elastin proteins. More elaborate versions of this method include sequential treatment of tissue with guanidine, collagenase, guanidine plus a reducing agent, and 6 M urea with sodium dodecylsulfate. All of these methods suffer from the potential loss of elastin during the harsh extraction procedures or the persistence of non-elastin material in the final product. These difficulties are especially pronounced when examining complex tissues and organs containing multiple matrix components. Quantification of elastin by measuring its unique cross-links, desmosine and isodesmodine, have been used as an alternative approach that avoids the problem of including non-elastin material in the final calculation. However, the implicit assumption is that the elastin being quantitated is fully cross-linked, and that the number of desmosines per chain is constant.

Table 1 Effects of aging on elastin content of human lung

Age (years)	*Elastin (% dry wt)*	*Effect of age*	*Assay technique*
2–80	1–13	↑	Lansing
1–65	8–15	↑	Acetone extraction, Lansing
19–92	35–47	↑	Cold alkali or ether extraction, autoclave
15–83	8	→	Lansing, expressed per unit volume
15–83	8	↑	Lansing, expressed per mg tissue
41–71	18	→	Nitrogen content of insoluble lung

Collagen Synthesis and Turnover In addition to serving as a marker for collagen content, hydroxyproline also provides a useful marker for measuring collagen synthesis. The effects of age on collagen synthesis have been studied *in vitro* using short-term tissue explants. If radiolabeled proline is used as the isotope, the accumulation of labeled hydroxyproline during a defined time period provides a good index of the extent of collagen synthesis. Rate of collagen synthesis (generally expressed as microgram of labeled hydroxyproline per gram of protein per hour) can also be determined using these techniques. Potential sources of trouble in this assay in tissue explants include unexpected effects of age on the precursor proline pool size in a given tissue or organ and failure to distinguish between changes in synthesis and changes in intracellular degradation.

In contrast to the relatively straightforward techniques used to study the effects of aging on collagen synthesis *in vitro*, studies of collagen biosynthesis *in vivo* represent one of the most contentious areas of investigation, with wildly divergent conclusions regarding the stability of the matrix. At issue is the question of how collagen ages: is some or all of the

collagen that is synthesized when the animal is young present in old age? Alternatively, is all of the collagen in the body in a state of dynamic equilibrium? Despite decades of investigation, this issue remains far from resolved. Perhaps this is not surprising in view of the difficulties in designing experiments free of artifact, as well as in unambiguously interpreting the data from such experiments. Early studies on collagen metabolism and turnover supported the notion that there might be a pool of immortal collagen that is present in the organism throughout life and that becomes increasingly cross-linked over time, thus accounting for the progressive changes associated with aging. Such studies generally involved long-term pulse-decay experiments with labeled amino acids, such as proline, lysine, or glycine. Label reutilization appeared to be minimal, based on plasma-specific activities determined less than 1 week after injection. These conclusions regarding collagen turnover were seriously questioned when studies showed that label recycling, particularly of proline, might be much greater than originally estimated. Several new approaches were developed to circumvent the problem of label recycling, many of which are still in use. One approach involves repeated administration of the labeled precursor during the period of rapid growth, either immediately postnatally or *in utero* and then waiting until the animal is middle-aged or older to harvest tissue. Variations of pulse-chase techniques have also been used to minimize label recycling, including the administration of very large doses of unlabeled precursor to dilute any recycled label. Some investigators utilizing such pool expansion techniques have concluded that the matrix, far from containing immortal pools, seems almost volcanic in its constant activity, with rapid turnover of collagen throughout adulthood. These conclusions, however, directly contradict studies of turnover utilizing a very different approach: tracking the metabolic fate of collagen labeled with ^{18}O, a radiolabeled precursor that by definition cannot be recycled at all. Studies using ^{18}O labeling in rodents provided definitive proof that some of the collagen molecules that are synthesized during the neonatal period are still present in old age, and are found exclusively in the pool of insoluble collagen, thus suggesting they have undergone progressive cross-linking. How can we reconcile these observations with the data obtained from the pool expansion approach? It is possible that flooding the animal with unphysiological doses of the unlabeled precursor amino acids may affect collagen metabolism in some way. However, the simplest explanation is that the pool expansion data have been erroneously interpreted. Because these techniques do not distinguish between intracellular and extracellular collagen, it is likely that the extremely rapid turnover of label does not reflect turnover of matrix collagen, but rather the very rapid intracellular breakdown of procollagen (collagen that still has extension peptides attached to it) before it is even secreted from the cell. Rapid intracellular degradation of procollagen has been reported in all connective tissue cells, with levels of breakdown ranging from 10 to 40% of newly synthesized procollagen.

Interestingly, there has been far less disagreement concerning elastin turnover, although presumably some of the concerns regarding label reutilization are similar. Most studies have shown that turnover is extremely slow, and best measured in years.

Enzymatically Mediated Cross-links The elucidation of cross-linking pathways in collagen and elastin and structural characterization of specific cross-links has led to a particularly intriguing area of investigation. The first step in cross-link formation is the oxidative deamination of epsilon amino groups on selected lysine residues (and hydroxylysine residues in collagen) by the extracellular enzyme lysyl oxidase. The resultant aldehydes are then capable of undergoing further reactions with unmodified lysine and hydroxylysine residues to form cross-links characterized by a Schiff base-type double bond. Further stabilization of these cross-links occurs through rearrangement and additional reactions to form tri- and tetrafunctional cross-links. Formation of these cross-links is tightly regulated, as they are synthesized at only one or two sites on the chain. Although collagen and elastin have similar cross-linking pathways, elastin lacks any cross-links derived from hydroxylysine; in addition, elastin contains two mature cross-links not found in collagen, desmosine or isodesmosine.

Accurate quantification of cross-links was initially hindered by their scarcity: there may be only one cross-link residue for every 6000 to 10 000 amino acids. However, the development of high-pressure liquid chromatography led to the development of relatively rapid and accurate techniques for quantifying almost all of the structurally characterized cross-links. Despite these technological advances, there remain many pitfalls in the analysis of cross-links, which most likely account for the conflicting results concerning amounts of cross-links in different tissues and species. Accurate assessment requires rigorous attention to standard preparation, including use of standards to control for variability at all stages of analysis from tissue preparation through hydrolysis; analysis of effective reducing capacity of every isotope batch used for reductive labeling; frequent checks of column efficiency and column regeneration

or replacement as soon as performance decrement is noted.

Studies of the effects of aging on enzymatically mediated cross-links led to somewhat surprising results. The reducible cross-links, so called because of their characteristic Schiff base-type double bond, were found to decrease rapidly during the postnatal period in most tissues and species. Known maturational products of these cross-links, the tri- and tetrafunctional cross-links, were found, in many cases, to show a corresponding increase in number during this time. However, these so-called mature cross-links did not continue to increase throughout the life span; in many cases, they leveled off or even declined in number during old age. Thus, although enzymatic cross-linking clearly underwent changes with age, the magnitude of these changes, particularly during the last part of the life span, did not seem to correlate with the progressive changes in physicochemical properties of the matrix. Many attempts were made to discover novel mature cross-links that could account for the observed changes in matrix associated with aging. Based on indirect evidence, entities such as compound M, poly CB-6, and the Ehrlich chromogen have been suggested at various times as possible candidates. These studies illustrate an important caveat concerning identification of a compound as a cross-link: unless a compound can be directly shown to link two collagen chains (i.e., through sequential digestion, such that one can show that the putative cross-link joins peptide fragments from two separate chains), it cannot be considered a proven cross-link.

Sugar-Derived Cross-links The hypothesis that progressive, irreversible cross-linking was a key feature of aging appeared to be inconsistent with the studies reporting that lysyl oxidase-mediated cross-links showed relatively few changes near the end of the life span. However, cross-links have been identified in collagen that arise from an entirely different pathway, in which the initiating event is the non-enzymatic addition of sugar molecules to lysine and hydroxylysine residues. The sugar adducts then undergo fragmentation to form deoxyglucosones. These highly reactive compounds serve as propagators of a series of reactions that ultimately generate an array of fluorophores and chromophores known collectively as advanced Maillard products or advanced glycation products. Although these reaction pathways have been of considerable interest to food chemists since the turn of the twentieth century, it has only been relatively recently that attention has focused on non-enzymatic glycation of proteins *in vivo*. The effects of glycation on long-lived macromolecules such as collagen have been of particular interest, as it has been shown that glycation affects collagen solubility, tensile strength, rupture time, ability to bind to ligands, and conformation (*see* Glycation).

Early studies of non-enzymatic glycation of matrix reported that aging was associated with increasing levels of glucose adducts on collagen throughout the life span. However, more recent studies by several investigators have not confirmed the earlier reports. These conflicting results are most likely due to differences in the specificity of the analytical techniques used. For example, in many of the earlier studies the investigators used the thiobarbituric acid assay, which is subject to interference by a number of compounds, including free glucose and glycosidically bound carbohydrates. In later studies, more specific techniques have been used for quantification, including the furosine assay and affinity chromatography followed by high-pressure liquid chromatography to isolate the glycated residues. Despite this evidence that the thiobarbituric acid assay is not reliable for quantifying glucose adducts on collagen, it continues to be used for this purpose.

As interest developed in the biological consequences of non-enzymatic glycation of proteins, attention was also focused on maturational products of glycated residues. Although the accumulation of yellow-brown chromophores and fluorophores (browning products) in aging collagen was first reported over 25 years ago, these compounds were initially thought to arise from oxidative reactions of tyrosine residues. The association between browning products and non-enzymatic glycation of collagen has only been investigated relatively recently. In virtually all tissues and species studied, browning products have been found to increase with age. In these studies, the fluorophores and chromophores are inferred to be Maillard products from indirect evidence, such as spectral similarities to known Maillard products or similarities in chromatographic behavior.

Although attempts have been made to characterize specific browning products, isolation and analysis of such compounds as they exist *in vivo* has proven very difficult, owing to low yields, difficulties in isolating the desired compounds, and the ease with which artifacts may be generated. For example, the first report of a structurally characterized advanced glycation product present *in vivo* turned out to be erroneous, for the reported compound was actually an artifact of hydrolysis. In general, unless physiological conditions of temperature and pH are used to isolate putative compounds for analysis, the risk of artifact generation is high; any reports of newly characterized glycation products isolated from tissue

should be cautiously evaluated with this caveat in mind. Only one advanced Maillard product found in collagen *in vivo* has been isolated and fully characterized, a trifunctional fluorophore known as pentosidine. Pentosidine has been shown to increase throughout the life span in several different tissues and species. Pentosidine, however, is present in very low levels (by comparison, enzymatic cross-links are approximately ten times more numerous), thus making it unlikely that pentosidine itself accounts for age-associated changes in the properties of collagen.

Elastin is characterized by a marked degree of autofluorescence, which increases with age in most tissues studied. Whether or not this fluorescence is due to accumulation of advanced glycation products remains unclear, due in part to the extreme difficulty in preparing elastin for analysis without generating artifacts. This fluorescence has been attributed to various compounds such as dityrosine, lipid peroxidation products, quinones, and reactive carbonyl products.

Immunofluorescence

We have seen that one of the major difficulties in correlating histochemical and electron-microscopic analyses of matrix with biochemical analyses has been the discrepancy between descriptive definitions of matrix components based on their visual appearance and structural definitions based on biochemical analysis. To some extent these difficulties are resolved when immunological identification of matrix components has been combined with light or electron microscopy. Immunological probes have been used to identify specific collagen types, specific collagen chains, and even some of the advanced glycation products.

There are a number of antigenic sites in collagen and procollagen (another name for collagen molecules whose extension peptides have not been cleaved), located in both helical and non-helical regions. Because there is cross-species reactivity, antibodies for use in human tissue can, for example, be raised against collagen chains purified from bovine tissue. When purified collagen is used as the antigen for preparation of polyclonal antibodies, the antisera produced contain a high titer of antibody for the immunizing antigen. However, moderate levels of antibody reactive with other collagens or procollagens are also present. Thus, purification on immunoadsorbent columns is essential to remove cross-reacting antibodies, following which the specificity should be documented by passive hemagglutination and by radioimmunoassays.

Antibodies have also been prepared that react with advanced glycation products. The so-called AGE (advanced glycation end product) antibody is prepared by injecting rabbits with glycated albumin; the resultant antibodies react with proteins containing advanced glycation products (as assessed by their fluorescence) but not with unmodified proteins. There is serious question as to the interpretation of data utilizing this antibody. A monoclonal antibody is also available for pyrraline, an advanced glycation product that has only been isolated and characterized from proteins incubated with sugar *in vitro*. Although immunohistochemical analysis of tissues with the pyrraline antibody suggest it is widely distributed *in vivo*, it has proved impossible to isolate it from tissues due to its lability.

Although immunological techniques are a powerful addition to routine histochemistry, there are many potential pitfalls. First of all, the anticollagen antibodies must be highly purified, as any cross-reacting antibodies would render a study virtually useless. Even then, interbatch differences in specificity and affinity of anticollagen antibodies and fluorescein-labeled antibodies means that valid comparisons can only be made within a single series. There is no standardized substrate for validating type-specific antibodies. As noted, there is serious question as to what is actually being detected with the AGE-antibody. Another problem may arise when tissues rich in elastic fibers are analyzed. Such fibers have a strong autofluorescence that may interfere with evaluation of immunofluorescence. Finally, making of antigenic determinants in the tissue to be analyzed can seriously interfere with interpretation of results. It is certainly possible that accessibility of antigenic determinants decreases in old tissue due to blocking by proteoglycans, for example, or the accumulation of glycation products. Finally, there is a large degree of subjectivity in interpretation of results as well as potential problems in random sampling.

Survey of Age-Associated Changes in the Extracellular Matrix

Given the discussion of methodological pitfalls described previously, it is evident that the literature on age-associated changes in the matrix cannot be summarized in a table that restricts itself to a simple listing of species, tissue, parameter, and the effect of aging, although such an approach would make the vast literature seemingly more accessible. Ideally, the validity of each study's conclusions should be considered individually with respect to general pitfalls (age range studied, number of sampling points, adequate sample size for assay variance, particularly if

variance increases with age) and pitfalls specific to the assays used, including a careful consideration of whether other age-associated changes in the organism may interfere with the assay of interest, thus possibly invalidating a comparison of young and old animals.

Despite these difficulties, particularly in comparing one study with another, we can draw several general conclusions: synthesis and deposition of collagen and elastin occur predominantly during the period of early growth and development; synthesis levels then continue at low levels that change little in old age. Collagen becomes progressively more insoluble with age, and autofluorescence increases in both collagen and elastin. Enzymatically mediated cross-links undergo their most significant changes during the first half of the life span in most tissues and species, mature enzymatic cross-links either change little during aging, or sometimes exhibit a biphasic pattern, in which peak levels are reached in middle age, followed by a gradual decrease. In contrast, sugar-derived cross-links accumulate very slowly in most tissues and species during the first half of the life span, with more accelerated accumulation during aging. In some cases significant increases may not occur until the last 10% of the life span. There is considerable species specificity and tissue specificity with respect to both the timing and the magnitude of the changes as illustrated in **Tables 2 and 3**. **Table 2** provides an example of changes in tissues in a single species, and **Table 3** shows changes in a single tissue among several species.

Modulation of Matrix Aging

There has been no shortage of effort expended on discovering a way to slow or reverse aging of the matrix, given that virtually all of the visible signs of aging are attributable to age-associated changes in its components. Approaches may generally be categorized as either replacement strategies or prevention strategies. For example, there has been considerable interest in attempting to slow aging at the systemic level by administration of growth hormone or insulin-like growth factor. There is evidence that some parameters such as muscle mass may increase, and it is possible that stimulating synthesis of new matrix may improve connective tissue function. Adequate long-term studies of the efficacy or safety of these agents are not available.

Preventive strategies have focused on glycation and oxidation as the primary culprits in degenerative changes of the matrix. From this perspective, agents developed for treatment of diabetes (which is characterized by rapid accumulation of advanced glycation products on connective tissue) may have relevance to aging in the normal population. Several agents have been found to inhibit the initial formation of glucose adducts on collagen, including acetylsalicylic acid, acetic anhydride, ibuprofen, glutathione, and the dibasic amino acids lysine and arginine. However, there have been no long-term trials designed to investigate the effects of these agents in aging. Data suggesting that fructation of collagen may contribute to accumulation of browning products have led to an interest in the use of aldose reductase inhibitors to inhibit biosynthesis of fructose. These agents have met with only limited success in diabetes. Recently there has been interest in aminoguanidine, a hydrazine compound that appears to bind to the reactive deoxyglucosones, thus theoretically preventing their progression into more advanced Maillard products. However, conflicting reports regarding its efficacy in preventing diabetic complications have appeared, and long-term safety has not been adequately studied.

Antioxidant administration has also been enjoying a resurgence of interest as antiaging agents. Although

there is some evidence that vitamin E may decrease non-enzymatic glycation of matrix, convincing long-term results are not available. Furthermore, it is unclear that administration of large doses of exogenous antioxidants will alter levels of oxidative stress, due to the tightly regulated homeostatic mechanisms of the antitoxidant defense system.

Dietary manipulation is another approach potential for slowing aging. It has long been known that feeding rodents a diet restricted in calories will extend their life span by about 20%. Very recently it has been shown that such lifetime caloric restriction significantly reduces the accumulation of advanced glycation products on matrix in tissues and organs throughout the body. The relationship between life extension and reduction of advanced glycation products remains to be elucidated. Other dietary manipulations may also be beneficial. Very recent studies have shown that the source of carbohydrate in the diet may significantly influence the accumulation of glycation products in matrix as well as the level of oxidative stress. Rats whose sole source of carbohydrate was fructose had significantly more advanced glycation products on their collagen and significantly higher levels of circulating lipid peroxide products than rats whose carbohydrate source was glucose, even after only 6 months on the special diet. Rats fed mixtures of sugars had intermediate values. Whether these dietary manipulations have similar effects in humans remains to be seen (*see* Diet and Nutrition).

Summary and Conclusions

Given the many caveats regarding methodological pitfalls, species specificity and tissue specificity, are there any generalizations we can make about the effects of age on the extracellular matrix? It is perhaps a truism to say that the more we have learned, the more complex the process appears to be, involving a seemingly endless recursive series of feedback loops between different reaction pathways. However, there are a few general patterns we can discern that appear applicable to most tissues and species. During the postnatal period, there is rapid synthesis of matrix molecules, some of which are destined for turnover and replacement, whereas others enter the pool of insoluble matrix, where they remain throughout the animal's life. Enzymatic cross-linking serves as the dominant influence during the first part of the life span, stabilizing and shaping the matrix such that its characteristic properties will best serve the functional needs of the tissue in which it inheres. In middle age, however, the matrix comes increasingly under the sway of stochastic forces that inexorably twist it in unpredictable ways that no longer adhere to the rules of biological design. Recently, the contributions of glycation and oxidation to this process have been the focus of particular interest, and agents designed to intervene in these reactions are being developed. However, perhaps because of the inherent complexity of the process, successful strategies available for attenuating these changes in matrix have not yet been developed. We evidently have much to learn about the intricate mechanisms of this strange clock that keeps unseen time beneath our skin.

Glossary

Environmental Assessment and Modification – A fall prevention strategy that identifies and removes potential hazards.

Extrinsic Risk Factors – External or environmental risk factors.

Fall – Event resulting in a person inadvertently coming to rest on the ground or another lower level.

Intrinsic Risk Factors – Risk factors arising from inside the body.

Risk Factor – A characteristic found significantly more often in individuals who subsequently experience a certain adverse event.

Introduction

A fall is defined as an event resulting in a person inadvertently coming to rest on the ground or another lower level. Falls are typically associated with tripping or slipping; however, in older persons falls have multiple precipitating causes and predisposing risk factors. A fall may be the first indicator of an acute medical problem (infection, postural hypotension, cardiac arrhythmia), may indicate progression of a chronic disease (parkinsonism, dementia, diabetic neuropathy), or simply may be a marker for the onset of normal age-related changes in vision, gait, and strength. Moreover, most falls experienced by older persons have multifactorial and interacting causes (e.g., a trip over an electrical cord contributed to by both a gait disorder and poor vision).

Epidemiology of Falls

Incidence of Falls

Prospective studies have reported that 30 to 60% of community-dwelling older adults fall each year, with about half of fallers experiencing multiple falls. Fall incidence rates for community-dwelling older populations range from 0.2 to 1.6 falls per person per year, with a mean of about 0.7 falls per year. Incidence rises steadily after middle age and tends to be highest among individuals 80 years and older. These incidence rates are based on self-reported data, which may underestimate the true incidence of falls.

Incidence rates in institutionalized elderly populations are generally higher than in community-living elderly populations. This difference is due both to the older age and frailer nature of institutionalized populations and to the more accurate reporting of falls in institutional settings. In surveys of nursing home populations, the percentage of residents who fall each year ranges from 16 to 75%, with an overall mean of 43%. Annual incidence of falls in long-term care facilities averages about 1.6 falls per occupied bed (range from 0.2 to 3.6 falls). Incidence rates from hospital-based surveys are somewhat lower, with a mean of 1.4 falls per bed annually (range from 0.5 to 2.7 falls). This variation in incidence rates between the institutionalized populations most likely reflects differences in case mix, ambulation levels, reporting practices, and institutional fall prevention policies and programs.

Fall-Related Mortality

Accidents are the fifth leading cause of death in older adults (after cardiovascular, cancer, stroke, and pulmonary causes), and falls constitute two-thirds of these accidental deaths. About three-fourths of deaths due to falls in the United States occur in the 13% of the population aged 65 and older. Fall-related mortality increases dramatically with advancing age, especially in populations over 70. Older men have a higher mortality rate from falls than older women, and nursing home residents 85 years and older account for one out of five fatal falls. The estimated

1% of fallers who sustain a hip fracture have a 20 to 30% mortality rate within 1 year of the fracture.

Fall-Related Morbidity

A key issue of concern is not simply the high incidence of falls in elderly persons, since young children and athletes have an even higher incidence of falls, but rather the combination of a high incidence and a high susceptibility to injury. This propensity for fall-related injury in elderly persons is due to a high prevalence of clinical diseases (e.g., osteoporosis) and age-related physiological changes (e.g., slowed protective reflexes) that make even a relatively mild fall particularly dangerous. While most falls produce no serious injury, community surveys have reported that over half of falls result in at least minor injuries, and between 5 and 10% of community-dwelling older persons who fall each year sustain a serious injury, such as a fracture, head injury, or serious laceration. The proportion of reported falls that result in serious injuries is similar in community-dwelling and institutionalized populations, but the range is wide (1–39%) because of differences in reporting practices. These injuries are often associated with considerable long-term morbidity. Among community-dwelling fallers with hip fractures, studies have shown that between 25 and 75% do not recover their prefracture level of function in ambulation or activities of daily living.

In addition to physical injuries, falls can produce other serious consequences for the elderly person. Repeated falls are a common reason for the admission of previously independent elderly persons to long-term care institutions. Fear of falling has also been recognized as a negative consequence of falls. Surveys have reported that between 30 and 73% of older persons who have fallen acknowledge a fear of falling. This post-fall anxiety syndrome can result in self-imposed activity restrictions among both home-living and institutionalized elderly fallers. Loss of confidence in the ability to ambulate safely can result in further functional decline, depression, feelings of helplessness, and social isolation.

Risk Factors for Falls

Intrinsic Risk Factors

A risk factor is a characteristic found significantly more often in individuals who subsequently experience a certain adverse event than in individuals not experiencing the event. Intrinsic risk factors (risk factors arising from inside the body) can include age-related changes as well as acute or chronic diseases. The most commonly reported risk factors from case-control studies conducted in community-living and institutionalized populations are listed in **Table 1**, along with the mean relative risk of falls for persons with each risk factor. It should be noted that some of these are directly involved in causing falls (e.g., weakness, gait and balance disorder), while others may be markers for contributing factors (e.g., prior falls, assistive device, age $>$ 80).

Among these studies, lower extremity weakness (detected by either functional testing or manual muscle examination) was identified as the most potent risk factor associated with falls, increasing the odds of falling, on average, over four times (4.4, range from 1.5 to 10.3). Not only potent, leg weakness is also very common in older persons. As a whole, healthy older people score 20 to 40% lower on strength tests than young adults, and the prevalence of detectable lower extremity weakness ranges from 57% among residents of an intermediate-care facility to over 80% among residents of a skilled nursing

Table 1 Risk factors for falls identified in 16 studies[a] examining multiple risk factors: results of univariate analysis

Risk factor	*Significant/total*[b]	*Mean RR-OR*[c]	*Range*
Lower extremity weakness	10/11	4.4	1.5–10.3
History of falls	12/13	3.0	1.7–7.0
Gait deficit	10/12	2.9	1.3–5.6
Balance deficit	8/11	2.9	1.6–5.4
Use assistive device	8/8	2.6	1.2–4.6
Visual deficit	6/12	2.5	1.6–3.5
Arthritis	3/7	2.4	1.9–2.9
Impaired ADL	8/9	2.3	1.5–3.1
Depression	3/6	2.2	1.7–2.5
Cognitive impairment	4/11	1.8	1.0–2.3
Age $>$ 80 years	5/8	1.7	1.1–2.5

[c] Relative risk ratios (RR) calculated for prospective studies. Odds ratios (OD) calculated for retrospective studies.

facility. Weakness often stems from deconditioning due to limited physical activity or prolonged bed rest, together with chronic debilitating medical conditions, such as heart failure, stroke, or pulmonary disease.

Individuals who have already fallen have a threefold risk of falling again within 1 year. While recurrent falls in an individual are frequently due to the same underlying cause (e.g., gait disorder, orthostatic hypotension), they can also be an indication of disease progression (e.g., parkinsonism, dementia) or a new acute problem (e.g., infection, dehydration).

Gait and balance disorders are also common among older adults, affecting between 20 and 50% of people over the age of 65 years. Among nursing home populations, nearly three-fourths of residents require assistance with ambulation or are unable to ambulate. Both gait and balance impairments were found to be a significant risk factor for falls, associated with about a 3-fold increased risk of falling, and use of an assistive device for ambulation was associated with a 2.6-fold increased risk of falling.

Visual impairment has been found to increase the risk of falling about 2.5 times. About 18% of noninstitutionalized persons 70 years and older have substantial visual impairment. The primary causes, most of which are treatable, include cataracts, glaucoma, and macular degeneration.

Arthritis, the most common chronic condition affecting persons 70 years and older in the United States, increases the risk of falling about 2.4 times. The relationship between arthritis and falls is most likely related to the gait impairment and weakness that are often associated with arthritis.

Functional impairment, usually indicated by inability to perform basic activities of daily living (ADLs) (e.g., dressing, bathing, feeding oneself), has been shown to double the risk for falling. In the community, ADL impairment affects 20% of persons over age 70. In the nursing home setting, the prevalence of functional impairment is higher, with 96% of nursing home residents requiring assistance with bathing and 45% requiring assistance with eating.

Cognitive impairment and depression have both been identified as independent risk factors for falling, associated with about a twofold increased risk of falling. Confusion and cognitive impairment are frequently cited causes of falls and may reflect an underlying systemic or metabolic process (e.g., electrolyte imbalance, fever). Dementia can increase falls by impairing judgment, visuospatial perception, and orientation ability. Falls also occur when demented residents wander, attempt to get out of wheelchairs, or climb over bed side rails. Cognitive impairment affects between 5 and 15% of persons over age 65, and the prevalence rises with age and among institutionalized populations.

The risk of falls has also been shown to nearly double for individuals over the age of 80. This is probably due to the rising prevalence of multiple risk factors associated with age.

The relationship between medication use and falls has also been examined in many studies. A recent meta-analysis found a significantly increased risk from psychotropic medication, class 1a antiarrhythmic medications, digoxin, and diuretics. Several studies also have shown strong relationships between use of multiple medications and risk of falls.

Additional risk factors associated particularly with falls likely to cause injury include being female, having low body mass (both probably largely related to osteoporosis), and having higher activity levels.

Studies have also shown that the risk of falling increases dramatically as the number of risk factors increases. In a study by Robbins, involving both an institutionalized and outpatient population, many risk factors were individually significantly related to falls. Multivariate analysis enabled simplification of the model so that maximum predictive accuracy could be obtained by using only three risk factors (i.e., hip weakness assessed manually, unstable balance, and taking four or more prescribed medications) in a branching logic, algorithmic fashion. With this model the predicted 1 year risk of falling ranged from 12% for persons with none of the three risk factors to 100% for persons with all three risk factors.

Extrinsic Risk Factors

Extrinsic risk factors for falls include environmental factors, footwear, and restraints. So-called accidental falls, or falls stemming from environmental hazards, are common in both home and institutional settings. However, most falls in this category stem from interactions between environmental hazards or hazardous activities and increased individual susceptibility to hazards from intrinsic risk factors. Although the environment outside the home certainly contains many fall hazards, impaired older adults are most likely to fall inside their own homes – perhaps because they spend more time inside and may be more careless there. These in-home falls generally occur on a level surface during activities that require only low to moderate displacement of the individual's center of gravity (i.e., standing, walking, transferring, bending, or reaching). Within nursing homes, most falls occur in the bedroom at the bedside or in the bathroom. Certain activities commonly associated with falls in these locations include arising from bed, ambulating to and from the bathroom, and transferring to a bed,

chair, or toilet –activities known to be associated with intrinsic fall risks from postural changes and vasovagal reflexes. Environmental hazards that frequently contribute to these falls include wet floors (due to spills or episodes of incontinence), poor lighting, bedrails, and improper bed height. Falls have also been reported to increase when nurse staffing is low and during shift changes, presumably due to lack of supervision, and following meals, likely related to the phenomenon of postprandial orthostatic hypotension.

Footwear is an important, but commonly unrecognized, risk factor for falls. Ill-fitting shoes (e.g., too tight or too loose), shoes with high or narrow heels, or shoes with worn soles can all alter gait and balance and subsequently increase fall risk. Shoes that are left untied can contribute to trips. Leather soles can contribute to slips. In addition, not wearing shoes (e.g., going barefoot or wearing socks) has been shown to significantly increase fall risk. Footwear should fit properly, be low heeled, and have a non-slippery sole.

Another environmental factor that can contribute to fall risk is the use of physical restraints, such as soft restraining vests and bedrails. For many years physical restraints were commonly used to prevent falls in nursing homes and hospitals. However, evidence has shown that physical restraints may actually contribute to falls, injuries, and mortality in certain instances when patients attempt to climb over bedrails, or when they untie or slip out of soft restraints. By limiting mobility, restraints also can contribute to weakness, gait and balance impairment, and confusion, thereby further increasing fall risk. There has been a move away from the use of physical restraints, and it is now generally recognized that the adverse effects on functional status and quality of life outweigh any potential benefit in preventing falls.

Fall Prevention Strategies

Multidimensional Fall Risk Assessment

Recent guidelines on fall prevention and treatment have been published by the American and British Geriatrics Societies after careful review of extensive published evidence. The purpose of these guidelines is to assist clinicians in the assessment of fall risk and the management of older patients who are at risk of falling and who have fallen. The guidelines recommend that a fall risk assessment should be an integral part of primary health care for older persons. However, the intensity of the assessment will vary with the target population. For low-risk community-dwelling populations, the guidelines recommend that all older patients should be asked at least once a year about falls. Older persons who report a single fall should be observed for mobility impairment and unsteadiness using a simple observational test. Those patients who demonstrate mobility problems or unsteadiness should be referred for further assessment. High-risk populations (e.g., older persons who seek medical attention because of a fall, report multiple falls in the past year, have abnormalities of gait and/or balance, or reside in a nursing home) should have a more comprehensive and detailed assessment.

The goals of the detailed multidimensional fall risk assessment are twofold: (1) to diagnose and treat patients after a fall and (2) to identify risk factors for future falls and implement appropriate interventions. Most of these risk factors can be easily assessed in the physician's office using basic examination techniques or standardized instruments (**Table 2**). The fall assessment should incorporate the basic principles of comprehensive geriatric assessment, namely, a multidimensional assessment to quantify medical, psychosocial, and functional capabilities and problems in order to develop a comprehensive plan for therapy.

The multidimensional fall risk assessment includes the following: a history of fall circumstances and medical problems; review of medications; mobility assessment; an examination of vision, gait and balance, and lower extremity joint function; a basic neurological examination, including muscle strength and mental status; and assessment of cardiovascular status. Other components of the fall risk assessment can include functional performance tests and an environmental assessment of the individual's living location.

Optimally, the multidimensional fall assessment will uncover direct causes and/or contributing risk factors amenable to medical therapy or other corrective interventions. Because of the multifactorial nature of falls, there is no standard approach to treatment or prevention. In cases where the cause of a fall is due to an obvious acute problem, treatment may be relatively simple, direct, and effective (e.g., discontinuing medication that causes postural hypotension, cataract surgery). However, patients with multiple risk factors will often require a combination of medical, rehabilitative, environmental, and/or behavioral intervention strategies (e.g., treating syncope, removing environmental hazards, prescribing strengthening exercises, and supplying a properly fitted cane).

Exercise Interventions

Numerous studies have shown that exercise can improve important fall risk factors such as muscle

Table 2 Clinical approaches to specific causes or common risk factors discovered in the fall assessment

Cause/risk factor	*Evaluation*	*Therapeutic measure*
Weakness		
	• Review medical problems and medications • Complete neurological examination (quantify severity; identify central deficits, neuropathies, myopathies) • Physical therapy (PT) evaluation for therapeutic recommendations	• Treat reversible causes • Exercise regimen • Prescribe appropriate assistive devices
Gait/balance deficit		
	• Neurological examination (including gait analysis) • PT evaluation for therapeutic recommendations • Orthopedic, foot and footwear evaluation	• Treat reversible causes • Gait and/or balance training • Prescribe assistive device
Visual deficit		
	• Vision examination	• Corrective lenses, surgery, low-vision aids, and/or environmental adaptation
Environmental hazards		
	• Environmental assessment (home visit or self-completed checklist)	• Remove hazards • Adaptive aids
Postural hypotension		
	• Review medical problems and medications (rule out infection, dehydration, autonomic dysfunction, anemia, drug effect)	• Correct treatable problems (medication, dehydration, infection) • Teach adaptive behavior (slow rising, raised head of bed)
Confusion/delirium		
	• Dementia/delirium evaluation (quantify severity; identify toxic/metabolic problem, rule out structural lesion) • Functional evaluation	• Treat reversible problem • Environmental safety adaptations
Syncope/arrhythmia		
	• Full syncope evaluation (rule out cardiac arrhythmia, valvular deficit, metabolic abnormality)	• Treat underlying problem
Dizziness/vertigo		
	• Medical evaluation and medication review • Neurological evaluation • Vestibular evaluation	• Treat underlying problem • Prescribe exercises for benign postural vertigo, if appropriate

weakness, poor balance, and gait impairment in both healthy and impaired older adults. Subsequently, exercise has become a widely studied fall prevention intervention. Different exercise models have been evaluated, including exercise groups and individualized home programs, among healthy and impaired populations.

Group exercise programs designed as fall prevention interventions typically are held two to three times per week for about an hour and are supervised by a physical therapist or trained exercise instructor. Most group programs include a combination of exercises to improve flexibility, strength, and balance, and some level of aerobic conditioning. Progressive strength training generally focuses on lower and upper extremity large muscle groups and may use body weight, ankle weights, weight machines, or elastic bands for resistance. Balance training often includes a range of static and dynamic exercises (e.g., standing on one foot, tandem stand, ball games, movement to music) and functional activities (e.g., reaching, bending, transferring). To improve aerobic conditioning, exercise programs have used whole body exercises, walking and stair climbing, and stationary bicycles. Although performed in a group setting, exercises are usually individualized to the participant's abilities.

Home exercise programs are structured so that participants learn the exercises from a trained exercise professional during a home visit or group session and then perform the exercises unsupervised in their homes. Home exercise programs typically include the same types of exercises as the group programs, only fewer and often at a lower intensity. Home exercise programs also frequently incorporate a walking program.

Tai chi is another type of exercise that has been studied as a means of improving balance and reducing risk of falling. Tai chi consists of a series of slow, rhythmic movements that require trunk rotation, dynamic weight shifting, and coordination between upper and lower extremity movements. Tai chi has been studied in group and home programs.

Environmental Assessment and Modification

Environmental assessment and modification is another promising fall prevention strategy, used as a means of identifying and removing potential hazards (e.g., clutter, poor lighting, throw rugs) and for modifying the environment to improve mobility and safety (e.g., installation of grab bars, raised toilet seats, lowered bed height). A number of self-administered home safety checklists, designed for use by older people in their homes, assist in identifying important hazards and offer suggestions for improving safety. These checklists are most appropriate for use with average risk and cognitively intact older adults.

For higher-risk populations, in-home environmental assessment by a nurse or occupational therapist provides an opportunity for the health-care professional to observe how an older person functions within the home, which may help identify safety problems that would not necessarily be identified with a self-administered checklist or interview.

In institutional settings, environmental safety policies and practices are generally in place to protect both patients and staff. Important safety issues for hospitals and nursing homes include adequate lighting and handrails in hallways, close monitoring for spilled liquids on the floors, unobstructed walkways, appropriate assistive devices in bathrooms (e.g., grab bars, shower chairs, raised toilet seats), furniture that is easy to rise from, and proper bed height.

Multifactorial Interventions

Multifactorial interventions are those that combine several fall prevention strategies into a coordinated program. Generally multifactorial interventions include some degree of fall risk assessment, followed by one or more risk factor modification strategies, such as exercise, education, and/or environmental modification.

Institutional Interventions

In institutional settings, fall risk assessment tools are commonly used to identify those who are at greatest risk for sustaining a fall or fall-related injury and to isolate specific risk factors that are amenable to intervention. There are many published assessment tools that are used to help health professions better target limited resources to those who would benefit most from preventive interventions. These instruments typically rank a person's risk for falling as high, medium, or low based on the presence or absence of such risk factors as cognitive impairment, mobility dysfunction, incontinence, acute/chronic illnesses, sensory deficits, medication use, and history of falling. The tools may or may not include physical assessments in addition to responses to questions that rely on self-report. Most screening tools are brief, are generally administered by a nurse on admission to hospital or a nursing home, and are usually updated on a regular basis or when there is a change in health status. Once a patient has been identified as being at high risk for falling, a nursing care plan is usually developed that includes interventions aimed at injury prevention. Such interventions can include indicating on the medical chart and the patient's door that the patient is at high risk for falls, moving high-risk patients to rooms that are close to the nursing station to increase observation, periodic reassessment of patients following new episodes of illness or change in medication, lowering side rails and bed height for patients who climb out of bed, increasing nurse-to-patient ratio, and fall prevention education for patients and staff.

Other promising strategies aimed at reducing falls and fall-related injuries in nursing homes include the use of vitamin D and calcium supplements to enhance bone and muscle strength and the use of special hip protectors (worn in undergarments shielding the greater trochanter of the hip) to prevent hip fractures due to falling.

Effectiveness of Fall Prevention Strategies

Prevention of falls and fall-related injuries is an important challenge for clinicians and researchers. The heightened interest in identifying effective fall prevention strategies has resulted in the publication of numerous randomized controlled trials. These intervention trials have been targeted to many different populations and have included a wide range of strategies. Study populations have included healthy older adults; individuals at risk for falling; community-living, hospitalized, and institutionalized populations; as well as caregivers and the home or institutional environment. Many different intervention strategies have been evaluated, often unique to the study site, and there is great variation in duration and intensity of the intervention, outcome measurements, and length of follow-up. This diversity in the published literature has made it difficult to determine which type of intervention is most effective for

preventing falls, and which target group of older adults will benefit most from which type of intervention. Fortunately, meta-analyses of randomized controlled trials have been able to summarize data from these studies and even assess the relative effectiveness of specific types of fall prevention interventions.

The results of a recent meta-analysis by Chang et al. indicate that multidimensional risk assessment combined with interventions directed toward reducing these risks was the most effective fall prevention strategy. When analyzed as a group, interventions using multidimensional risk assessment and risk reduction lowered the risk of falling by 18% and reduced the average number of falls by 43%.

The next most effective single intervention identified in this meta-analysis was exercise intended to improve balance, strength, flexibility, and/or endurance. Overall, exercise interventions reduced the risk of falls by 12% and the mean number of falls by 19%. Exercise was effective in reducing falls when used alone and when included as part of a multifactorial intervention. Types of exercise that have been found to be effective include tai chi and programs that combined balance and strength training.

While studies did not demonstrate that home modification alone will reduce falls, a number of multifactorial interventions that included home modification were effective, particularly among individuals who had a history of previous falls.

Individual intervention trials that have been most effective in reducing fall rates have involved multifactorial intervention programs, which is consistent with the concept that falls are usually the result of interactions between multiple intrinsic and extrinsic risk factors. Effective interventions generally have included risk assessment, tailored exercise or physical therapy to improve gait, balance, and strength, medication review and modification, and other elements such as education about fall risk factors, referrals to health-care providers for treatment of chronic conditions that may contribute to fall risk, and having vision assessed and corrected.

A meta-analysis based on five randomized controlled trials reported that vitamin D supplementation appears to reduce the risk of falls by more than 20% among ambulatory or institutionalized older adults. The hypothesized mechanism is from a direct beneficial effect of vitamin D on neuromuscular function. However, the studies did not measure vitamin D levels at baseline, so it is not clear whether this apparent benefit stemmed from treating a deficiency or from a pharmacological effect of the vitamin D in non-deficient individuals.

While hip protectors appear to be effective in preventing hip fracture in nursing home settings, their effect in community populations has not yet been demonstrated. This is likely because of poor patient compliance rates in the community. A meta-analysis based on six randomized trials concluded that hip protectors appear to reduce risk of hip fracture in selected high-risk populations where compliance can be closely monitored.

Frail Elderly

D Spini, University of Lausanne, Lausanne, Switzerland
P Ghisletta, E Guilley, and C J Lalive d'Epinay, University of Geneva, Geneva, Switzerland

Glossary

Comorbidity – The presence of coexisting diseases, which are clinically manifest yet unrelated.

Disability – Having difficulty in performing or being unable to perform basic and important tasks usually required for independent living, or activities of daily living (ADL; mobility, transfers, dressing, toileting, bathing, and eating), or instrumental ADL (IADL; shopping, transportation, home chores, money management, making appointments, taking medicines, and handling emergencies).

Resilience – This concept was originally applied to children and denotes the maintenance of normal development despite threats or risks due to nonnormative influences as well as the ability to recover from trauma. Resilience also includes the positive pole of individual differences in people's responses to stress and adversity. In elderly populations, resilience refers to the capacity to prepare for transitions or prevent life accidents, and, in case of problems, to restore and/or compensate for affected resources by activating other underused, existing resources.

Senescence – The biological process of growing old, associated with an increased vulnerability to stress, a susceptibility to disease, and the probability of dying. It is associated with the period in a person's life when physiological degenerative processes overtake regenerative processes.

Introduction

Frail elders are at high risk for adverse outcomes (falls, hospitalization, institutionalization, disability, death). They exhibit vulnerability to medical, psychosocial, or environmental stressors and are unable to regain equilibrium with the surrounding environment after a disturbing event such as a fall, an acute illness, or an emotional upheaval. Frailty is conceptualized as a multisystem reduction in reserve capacity. There is no current consensus on the measure of frailty; according to the adopted criteria and the characteristics of the sample population, the prevalence of frail elders (65+) varies from 7 to 25%. Although frailty is not confined to older adults, it increases with age. Frailty is more common in women and in those at the greatest social disadvantage.

Conceptualizations and Definitions of Frailty

Development of the Concept and Operationalization of Frailty

The concept of frail elder was hardly ever used before the 1980s. Until then, other terms with a strong physical and medical connotation were used, mainly to describe older individuals who were in need of assistance or who were disabled. These terms included the chronic sick, the disabled, and the incapacitated. In the late 1980s and especially in the 1990s, the concept of frailty became popular in the medical literature, and the number of its citations increased exponentially. This increase in use was due to the first attempts at an explicit definition of frailty. The first definitions were strongly medical in nature, underscoring the health-related problems of affected individuals. Frail elders were vulnerable to various stressors, subject to physical or mental problems of aging, unable to attend to their basic needs, required institutional care, and generally were dependent on others for sufficient daily functioning. In short, frailty became a close relative of disability in older individuals.

This definition originated largely from the geriatric community, and, accordingly, it was associated with general physical and mental health consequences on the individual level. Indeed, the geriatric community soon realized that one outcome of the remarkable increase in life expectancy was the increasing number of older individuals affected by similar conditions. The end expression of these developments was the need for information about older individuals who cannot be classified as aging successfully.

The necessity for knowledge fueled further research that attempted to address what the causes and symptoms of frailty were. The definitions of frailty were rather specific, focusing on basic components or mechanisms – mainly of a medical nature – thought to specifically define and describe the properties of frail elders. The first attempts to screen for frail elders were based on the limited measures of their capacity to function independently. In this line of research, only mobility and motor performance were assessed, with the additional objective of identifying inexpensive markers of frailty. These

definitions were based mostly on objective criteria assessed by geriatricians or medical doctors, hence concentrating all efforts on hospitalized and nursing home populations.

It soon became evident that highly specific characterizations of frailty were too limiting in scope and generally unsatisfactory for the purpose of further understanding and prevention. Multisystem definitions that considered various biomedical aspects of frailty and that were not limited to single indicators emerged and relied on the belief that concurrent impairments in several biological systems would lead to frailty. Frailty was described as a constellation of signs and symptoms rather than as a discrete clinical entity – to the point that it resisted a precise scientific meaning. In this context, the notions of vulnerability, loss of resilience, alteration in homeostasis, and decreased reserves were frequently employed to discuss frailty. Indeed, it was generally agreed that frailty was a state of high vulnerability and could lead to adverse health outcomes such as dependence, falls, need for long-term care, and death.

Frailty was also associated with a loss of resilience that affects the individual's capacity to maintain or recover from loss in order to regain equilibrium with the surrounding environment and with altered homeostatic responses to stress. Frailty could hence be defined as a syndrome of decreased reserve and resistance to stressors, resulting from cumulative decline across multiple physiological systems. Most of the conceptualizations of frailty are consistent regarding the loss of reserve beyond a given threshold. Accordingly, the capacity for older persons to withstand physical and emotional stressors or recover from acute illnesses depends on their reserve capacity. Disease in this regard is not a necessary condition of frailty, and often frail older adults may experience declines in physiological functioning in the absence of morbidity. However, frailty, with its associated decrease of resources, is certainly related to a higher risk of disease. Indeed, physiological reserves, whose decrements are inevitable with aging and are accelerated by diseases and an inadequate lifestyle (e.g., physical inactivity, heavy alcohol consumption, smoking, nutritional problems, social isolation), may reach a lower threshold limit below which an individual would be considered frail.

At the same time, biomedical definitions of frailty that integrated the notion of multisystem reduction in reserve capacity were proposed. These definitions posited that decrements in musculoskeletal functioning, aerobic capacity, cognitive functions, nutritional status, and neuroendocrine and immune system functions must be present to constitute frailty. Hence, various markers of frailty were recommended in relation to general physiological functioning relevant to everyday activities. Examples include low body mass index; loss of strength, endurance, and balance; slow gait speed; and low activity and energy. In particular, the loss of muscle mass and diminished muscle function (sarcopenia, literally melting flesh) has been suggested as a major cause of frailty. These markers, however, are not directly treatable because they are indicative of larger processes.

A parallel research agenda attempted to identify biological and physiological determinants and precursors of frailty at the incipient phase of the process – before clinical symptoms of frailty manifested themselves. At this level of conceptualization, frailty crosses biological theories of senescence, which may conceive of frailty as a consequence of free radicals, caloric restrictions, and hormonal levels, and stress theories of aging, positing that frailty mechanisms interact with changes in the hypothalamic–pituitary–adrenocortical axis (thereby affecting the way the cerebral cortex appraises the stressor and consequently how the hypothalamus stimulates the pituitary and adrenal glands, which are two basic components of the endocrine system that, with the nervous system, control bodily activities). From this perspective, sex differences in frailty prevalence may be interpreted as the consequence of sex differences in neuroendocrine reactivity, which is due to the postmenopausal increase in cortisol secretion in women who are not undergoing hormonal replacement therapy.

Empirical investigations focused on cytokine overexpression and hormonal decline, which reflect an altered homeostatic response to stressors. Evidence emerged of links between physiological markers and the major symptoms of frailty. For example, a dysregulation of cytokine formation can lead to loss of muscle strength, and leptin (a hormonal mediator) acts to reduce food intake and increase energy expenditure. While this line of research aims to stimulate new therapeutic interventions and promote primary prevention, it remains unclear whether these markers reflect aging itself or frailty.

More comprehensive, multidimensional conceptualizations of frailty consider the complex interplay of biological, physiological, physical, psychological, social, and environmental factors. Some authors believe that beyond physical frailty, mental, emotional, or social forms of frailty exist, or at least that frailty operates on not just a person's health, but also a person's psychological and social life dimensions. In particular, frailty may originate from or be exacerbated by specific conditions in the environment. These more recent conceptualizations necessarily consider subjective reports based on the direct

experience of older individuals, recognizing not only the reality of physical and biological conditions, but also how these conditions affect the individual. Community-dwelling populations are therefore often used when studying frailty, which reduces the risks of limited findings owing to sample selectivity regarding late-stage frail elders.

From this perspective, frailty becomes an object of investigation in psychological theories of aging. For instance, the theory of selection, optimization, and compensation (SOC) presupposes that to develop successfully (by maximizing gains and minimizing losses) individuals ought to coordinate the following: (1) the selection of and commitment to developmental trajectories with (2) the optimization of gains in resources of functioning levels and (3) the compensation in order to maintain the resources of functioning levels in the presence of losses. Proper application of the strategies suggested by SOC may delay the onset of frailty by ameliorating one's support (or resources) received from the surrounding cultural context. According to this approach, assessment and prevention strategies should not focus exclusively on the health of frail elders but should also consider their environment.

Theories of everyday competence attempt to explain how aging individuals function effectively in a given physical and social context by applying fundamental processes (e.g., cognitive resources) to relevant daily tasks. Here again frailty can be conceived as an improper balance between one's cognitive and psychological resources on the one hand and the available contextual resources on the other. How one copes and lives with frailty given one's means – as well as the resources of the surrounding environment rather than frailty itself – became of primary interest to some scholars.

The importance of the dynamic (and often systemic) interplay between older individuals and their environment may help to further explain the process of frailty. Frailty may be considered the result of older people dissociating themselves from their environment, resulting in role changes marked by a loss of autonomy that is often associated with interventions of the informal network (spouse, family, friends) and professional actors or institutions (home care, medical or social institutions, nursing homes, etc.). From this perspective, the emergence of frailty corresponds to the process described in the revised version of the theory of disengagement. According to this theory, the aging process is understood as an individual's forced or anticipated process of selection of activities and relationships. Frailty may be conceptualized as a normative aging process, which results in a selection of activities and relationships that work to maintain a certain level of well-being and continuity in the most meaningful spheres of life.

This broad approach has caused the number of fields studying frailty to expand, including the cognitive, emotional, social, and spiritual domains of life. Consequently, more recent empirical evidence on frailty has focused on, among others, sex differences that are not biological in nature, the quantitative and qualitative effects that frailty exerts on one's friendships, the preventive effect of psychological characteristics (such as positive affect on the advancement and treatment of frailty, and the precipitating effect that the fear of falling, rather than the act of falling itself, plays on the development of frailty), and the dangers of mistaking frailty and depression. Consequently, the exponential increase in frailty citations in the medical literature was paralleled, to a small degree, by analogous increases in the psychological and sociological literature. Frailty was no longer just a medical issue.

Related yet Distinct Concepts

For years frailty has been practically synonymous with disability and old age. General recognition of wide individual differences between old and very old age as well as in the development, presence, and significance of disabilities quickly challenged the simplistic equations that frailty equalled ADL or IADL disability and frailty equalled old age. Since then, it has been shown that disability is a probable outcome of frailty. This confirms the significance of frailty's predictive status in community-based populations, in which people are still relatively functional. An attempt was made to ameliorate the prediction of chronological age with respect to frailty by constructing an index of a person's biological age, which was defined as the total number of deficits that are quite different in nature. Although superior in prediction than chronological age, the biological age frailty predictor correlated very highly with its chronological counterpart and further was lacking in overall substantive meaning and therefore prevention utility.

Comorbidity has been linked to frailty all too often. Co-occurrence of frailty and comorbidity is indeed frequent. While comorbid diseases may contribute to the development of frailty, the presence of frailty may contribute to the development or progression of diseases. However, frailty can occur independently of comorbidity. For instance, some older adults experience symptoms such as sarcopenia and compromised immune functioning in the absence of morbidity.

Older patients diagnosed with psychological depression, which is assessed according to standard

psychological and psychiatric criteria for classifying mental disorders (e.g., DSM-IV-TR or ICD-10), may be at a higher risk for developing frailty or for not being able to cope, adapt, and develop resilience strategies to overcome frailty. Moreover, exhaustion, weight loss, and slowing and decreased activities have been recognized as characteristics of psychological depression and are at the same time included in definitions of frailty. Although depression and frailty are quite different, misdiagnoses may be frequent and parallels do exist. Either condition can be classified as a cause, consequence, or comorbidity of the other.

Models of the Development and Outcomes of Frailty

There are different types of models that describe frailty as a stage or a transition phase in the process of aging. The following sections focus on two distinct, but not exclusive, ways of describing this process: linear models of frailty and the cyclical model of frailty.

Linear Models of Frailty

One of the most diffused models of frailty is the linear model. This model has many variants, but most descriptions appear to rely on a former model: the model of the disablement process. This model describes a more or less irreversible declining process that starts from autonomy and can evolve toward impairment. This can then transform into a disability, to finally end in death. A handicap or a disability is then considered in many health-care systems to be the main criterion for an older person to be eligible for adequate treatment and follow-up. This well-known and influential model (one that is still dominant in gerontology among many researchers and practitioners and in institutions such as the World Health Organization) has influenced many descriptions of the process of frailty.

The linear model is usually deterministic because it assumes something like a causal and unidirectional chain from autonomy or independence to disability and dependence – associated in most cases with an increase in age. This position can also be found in models in which frailty represents an important intermediate stage between two extreme poles: autonomy and death (see **Figure 1**). It is important to note that in most of these models, frailty is not an all-or-nothing phenomenon, and different degrees of frailty are described (for example, frailty scales ranging from mild to severe). These degrees of frailty correspond to a series of episodic, progressive, and often irreversible losses. Frailty in some linear models includes a wide range of health and vitality states, which can be found in old and very old age, and between the states of autonomy, independence, vitality, and, finally, death. The process of frailty often corresponds to an accumulation of functional losses that progressively erodes the capacities of older people to perform diverse activities, resulting in an increasing need for help and care.

Another common characteristic of the linear model is its focus on the associated or causal antecedents of frailty as well as its outcomes. Studies describe a large number of possible factors that may explain frailty or that may even result from frailty. However, a main contribution of the linear

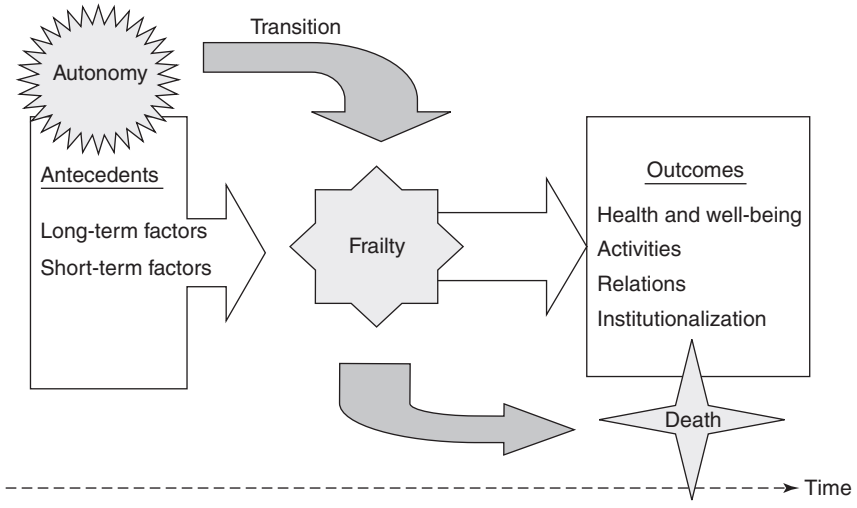

Figure 1 The linear model of frailty as an intermediate stage between autonomy and death: the impact of long- and short-term factors on frailty with its consequences on health and well-being, activities, relations, and institutionalization.

model is the identification of long-term and short-term factors.

Consistent with a life course perspective, diverse long-term biographic antecedents of frailty were identified. These may be related to biological or genetic resources as well as to long-term effects of physical (wear and tear associated with different behaviors, activities, or professional occupations) and social exposures (i.e., individuals in disadvantaged social positions are relatively more exposed to risks and threats of a different nature than those in more privileged ones). These risk factors may be related to the individual but may also be considered at the collective level, as some events such as epidemics, wars, economic depression, and cultural changes have had an important impact on the life trajectories of many members of whole birth cohorts.

This lifelong accumulation of damage is expressed in the concept of the allostatic load. An allostatic load and the repetitive exposure to various types of stress may wear down individual resistance. However, one must not infer that stress necessarily causes a long-term negative outcome for the elderly; mild stressors (e.g., caloric restrictions, exposure to cold temperatures) have been found to increase longevity in studies using animal models. Mild stressors may induce adaptive reactions and thus reinforce defenses and coping strategies.

On a short-term basis, frailty may also be explained by a large number of different biomedical and psychosocial factors, which range from micro-level factors such as molecules to macro-level social factors such as social class. These factors include past negative or declining health status (illness, strokes, chronic diseases such as diabetes or Parkinson's disease, a decrease in functional health, depression, dementia, poor dentition, weight loss, etc.), disruptive or traumatic events (falls, a death in the family, hospitalization, etc.), and various social factors (being a woman, social isolation, poor finances, etc.).

Other factors that are described as antecedents, mediators, or moderators include psychosocial adaptations to endogenous or exogenous stresses. These latter models have developed within the life span and social psychology traditions. They include the general processes of adaptation and self-regulation, such as the SOC model, primary control strategies (behavior–event contingencies achieved by an individual: the investment of time and effort, the recruitment of others' help, the use of technical aids, etc.) and secondary control strategies (an individual's effective influence over his or her emotions, motivational states, and mental representations; social and temporal comparisons; optimism; self-enhancement; control beliefs; coping strategies; religiosity; etc.).

This model is also concerned with the outcomes of frailty, which are also numerous and mainly negative (many have already been described as antecedents). Frailty has the potential to impact all spheres of the life course: health (physical health, cognitive functioning, vitality, death, etc.), well-being (satisfaction in different life spheres, happiness, positive affects, etc.), activities (daily, productive, leisure, cultural, etc.), the frequency and quality of different types of relationships (cohabitants, family, friends, neighbors, professionals, etc.), and exchanges (help, care, visits, etc.) (not all these dimensions have been investigated yet). Frailty has also been considered a predictor of institutionalization of the elderly in nursing homes, hospitals, or other care systems.

Cyclical Model of Frailty

One of the main issues with linear models of frailty is the problematic separation of antecedents and outcomes of frailty. One reason for this is that often short-term antecedents of frailty can also be considered its outcomes. For example, malnutrition, comorbidity, and falls are considered to be both frailty antecedents and outcomes. This is one of the reasons why systemic models have been developed recently. Systemic models emphasize the interactions and processes that relate different systems with respect to frailty.

In the cyclical model (see **Figure 2**), the main assumption is that the process resulting in frailty is generally due to senescence, but is often observed after the occurrence of a trigger event (e.g., a hip fracture, an illness, hospitalization). Generally speaking, most short-term antecedents of frailty are described in the linear model. An important feature of

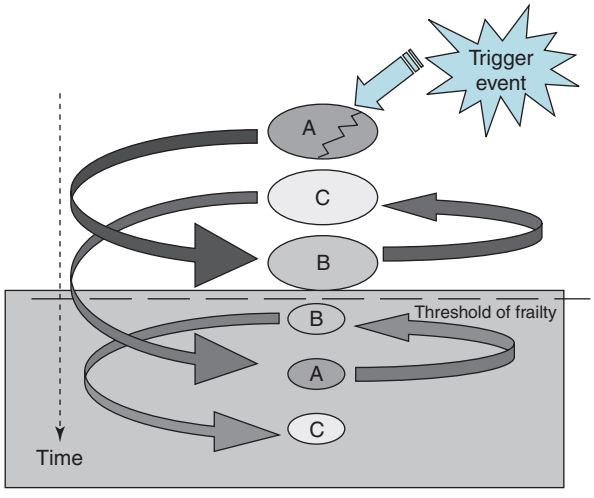

Figure 2 The cyclical model of frailty: a trigger event can initiate a spiral of decline in various resources (A, B, C) that results in frailty when a given threshold in reserves is attained.

this model is that frailty can be set in motion by a change (usually a decline) in different subsystems of the organism. This may occur in different types of systems (physiological, psychological, behavioral, etc.), yet it is in the domain of physiology that this hypothesis (a cycle of frailty) has been presented in greatest detail. This dimension is used in order to describe the cyclical model.

There is evidence for a general decline in the second part of a person's life span, which starts with the decline of a number of physiological characteristics (including creatinine clearance, forced expiratory volume, nerve conduction velocity, insulin sensitivity, muscle mass, strength, and maximum oxygen uptake or VO_2). This process of senescence accelerates around the age of 70 years and progressively erodes the reserves of different systems, which may result in less reactivity and resilience to stressors or even irreversible alterations. Some theories go as far as to generalize that a universally determined threshold of about 30% governs the functions of many body systems. When reserves are above this value, the system has the capacity to react to stress, and although an individual can be qualified as resilient, under this value of reserves the organism shows evidence of failure, which can usually be observed clinically. An important feature of the cyclical model is that in most cases, and across a large part of a person's life span, the individual tends to be resilient. Therefore, damages to the organism are in many cases reversible and can be successfully overcome. This is the case, for example, when some diseases, such as diabetes, cause a general dysfunction that can be treated efficiently, making the symptoms of frailty disappear.

Many of these markers of frailty are related to one another and constitute the key elements of a cycle of frailty, which suggests that deficiencies in several dimensions may accumulate because of their underlying linkages. In particular, this cycle establishes a formal pattern of linkages between mobility and the ability to energize metabolism, whereby inactivity can lead to loss of appetite and subsequent insufficient food intake, resulting in malnutrition. This in turn gives rise to muscular dysfunctions and further decreased activity.

The pathways leading to frailty are varied. Some older people may become frail because of the normative physiological changes in aging that are not based on any particular disease, in which case frailty may be reversible. Others may become frail owing to severe disease and comorbidity downsizing the disposable resources and hence becoming insufficient for reestablishment, in which case it is very likely that the process cannot be reversed and frailty will mark the latter stages of life. A notable exception is the case of a disease that causes symptoms of frailty and that can be partially or completely treated, if the treatment is followed by a restoration of general resources.

The cyclical model designates three main subsystems of frailty: sarcopenia (the process of decline in muscle mass associated with aging), immune dysfunctions (the organism's defense against pathogens and malignancies), and neuroendocrine deregulations (regulatory systems that monitor environmental and other sensory input and maintain homeostatic balance via nerve and endocrine signaling to end organ systems). When one of these subsystems is affected (as represented by the smaller ellipses in **Figure 2**), it has some impact on related subsystems (see B and C in **Figure 2**), which in turn impact the first one (A in **Figure 2**), and so on. These chain reactions, when they seriously challenge the reserves of the subsystem without a reaction of equilibration of the organism, may – after a given threshold is overcome – initiate the cycle of frailty, which is described as a downward declining spiral of the functioning of the organism.

Emerging Issues about Frailty

The emergence of the concept of frailty in gerontological research (with the subsequent clear demarcation between chronic disability and frailty in old age) points to the fact that the oldest-old are not necessarily disabled. But on the other hand, it asserts that a non-chronically disabled older person should not necessarily be considered a robust adult. Frailty may affect a person relatively early on in life, or it may be postponed up to a very advanced age, thanks to good genes, prevention (e.g., nutrition, physical and mental exercise, openness to life experiences), and appropriate strategies of adaptation (SOC, primary and secondary control, a meaningful and coherent identity, etc.). However, frailty appears to be the price that must be paid by most people who live a long life. From the life course perspective, the constantly increasing probability that a human being will live more than 80 years tends to institutionalize frailty as a normal stage of life.

But a set of questions remains to be answered concerning the nature of frailty as a process and concerning the relationship between frailty and chronic disability or chronic dependence.

- *Frailty, a state and a process*. Empirical research, as social policies, needs classifications that allow for the estimation of prevalence and incidence and comparisons across different contexts, populations, or periods of time. Currently, there is no

consensual definition of frailty, but any operationalization remains a working tool. Thus, it is wise to hypothesize that the process of frailty has already started before an older person is even classified as clinically or scientifically frail. And it is important to keep in mind that frailty is a dynamic, evolving, and sometimes reversible process. Rather than considering the performance level of certain functions in absolute terms, changes in suggested markers should be underscored at the individual level. These account for idiosyncratic properties, such as individual baseline measures specific to one's level of functioning in assessing markers of frailty over time. Moreover, focusing on individual assessments and rates of change in these markers respects the dynamic status often attributed to the process of frailty. Such an approach (i.e., one that is concerned with intra- and interindividual variability in trajectories leading from autonomy to various levels of frailty, and then from frailty to death) is desperately needed. It will enable future research to tackle important and unanswered questions. For example, does the transition to frailty generally occur abruptly and rapidly? We may examine the hypothesis of an avalanche-like destruction of the organism or a cascade-like decline in different dimensions of cognitive functioning in such a case. Or does it occur in a smooth and progressive manner? When and how does resilience in different yet related subsystems decrease in efficacy?

- *The link between frailty and chronic ADL dependence and the current organization of the life course's last stages*. Is a chronic disability the outcome of frailty, or does an older person become disabled without going through the process of frailty? Individual-based research reveals that in old age an abrupt transition from independence to chronic dependence seldom occurs and that in almost all cases the pathway to dependence transits through a durable stage of frailty. Conversely, does frailty necessarily lead to disability during old age, and if not, why? In other words, is it possible to die without going through a long-term stage of ADL dependence or an acute degenerative mental and/or physical process? The few existing studies scrutinizing the final years of life provide evidence that a very significant proportion of older people (about half) end their life without going through a stage of chronic dependence. From a life course perspective, some argue that frailty can thus be considered a normal stage in advanced old age, leading either to chronic dependence as the last stage before dying or to a chronic state of frailty close to death. But more research on larger samples and across different cultures is needed to check this provisory (and frail) state of knowledge. Further, the definition of chronic or long-term dependence may vary largely across studies (with durations ranging from more than a year to 3 months before decease), which directly affects the estimations of older people who have died while frail and those who have died after a stage of chronic dependence. Until now, studies concerning the frail elderly were mainly descriptive, and the few predictors of the end-of-life trajectories referred to ascribed characteristics of the individual (e.g., sex, age). An important step would be to establish the degree to which specific genetic factors, health antecedents, styles of adaptation, past behaviors, and lifestyle, but also social and service environments, orient life trajectories during old and very old age. Knowledge about such enabling characteristics – and not only about predisposing factors – would help to, echoing a now-classic statement in gerontology, add life to years and not years to life.
- *Methodological issues*. From a methodological point of view, research on frailty as a process and, more generally, research on the life trajectories in advanced old age would benefit from the following suggestions:

1. Special attention should be given to individual health transitions. Key questions concerning the duration of frailty, its reversibility, its degree of severity, and its necessary preceding role before ADL dependence can only be tackled by empirical data based on repeated measures at the individual level rather than on single assessments at the group level. Longitudinal research designs (preferably long-term) are thus required.
2. It is necessary to follow the elderly to the end of their lives when studying the relationship between frailty, the organization of the last stages of life, and dying. Life trajectories must then be reconsidered retrospectively. Longitudinal studies on the oldest-old should be organized in a way that enables researchers to secure the recollection of data up to the extinction of the sample. Access to the individuals' medical records provides valuable information on their health trajectory and health consumption.
3. Qualitative and quantitative changes between health statuses can not be effectively tested with classical statistical models. Advanced mathematical models, including linear and non-linear dynamical systems, allow researchers to model frailty as the quantitative accumulation of losses that occur with greater probability in older than in

younger ages and that may lead to a qualitatively different stage of life.

Implications for Policy and Practice

From an anthropological as well as a philosophical point of view, vulnerability is an ontological element of the human condition, and autonomy is an always-vulnerable achievement in life. Frailty, as defined previously, appears as the specific form that vulnerability takes when advancing through old and very old age. Coping daily with this increased vulnerability and preserving as much autonomy as possible is the great challenge during the last stages of life. It is a challenge that contemporary elderly and societies should tackle with continuity, but also with the consciousness concerning how normal frailty is in old age, especially in very old age.

With these preliminary considerations now stated, the interventions that partially prevent, postpone, or limit the impact of losses due to frailty may be envisaged with some confidence at different stages of the frailty process. There is strong evidence to support the claim that primary prevention can be achieved through an adequate lifestyle (though frailty appears sometimes in spite of healthy lifestyles) and in particular by a certain level of physical activity, mental exercise, a balanced nutritional program, the maintenance of social and emotional ties, and a general openness toward life. Lifestyle interventions may be the most effective way of preventing frailty, as they address multiple functional systems in contrast to specific disease-focused interventions (e.g., antihypertensive treatments). The process of frailty is certainly inevitable for the oldest-old. However, certain components of the lifestyle of the elderly may prevent or at least postpone frailty.

As frailty is also related to the individual's environment, many domains of life are concerned with the prevention of frailty. Trigger events such as falls can be prevented by adapting public buildings and means of transport to the needs of an aging population. Secondary prevention programs that include physical activity, memory training, and nutrition have shown good results in slowing the development of and even reversing some symptoms of frailty. Tertiary strategies of intervention are perhaps the most difficult to implement, as there is a lack of knowledge about the link between frailty and chronic disability. This is particularly true regarding the pathways from the former to the latter. More evidence on this issue would be a great contribution for policy aiming to avoid or at least limit the most negative outcome of frailty.

More generally, as frailty is a many-sided and multidimensional phenomenon that tends to mark a normal stage in the advanced lives of contemporary human beings, it appears that no general and uniform program should be developed to fight frailty in old and very old age. Social and health policies should recognize instead that frailty is an important characteristic of old age, and policymakers should find ways of implementing a flexible network of programs and services that will answer on an individual basis to the variety of needs, difficulties, incapacities, and demands of frail elders.

Gastrointestinal System: Function and Dysfunction

D Greenwald and L J Brandt, Montefiore Medical Center/Albert Einstein College of Medicine, Bronx, NY, USA

Glossary

Achalasia – Motility Disorder characterized by the absence of normal esophageal peristalsis and incomplete or absent relation of the sphincteric barrier between the esophagus and stomach.

Crohn's Disease – Chronic inflammatory bowel disease affecting any portion of the gastrointestinal tract, marked by strictures and fistulae.

Gastroesophageal Reflux Disease (GERD) – Esophageal dysfunction with symptoms of heartburn, regurgitation, difficulty swallowing, and chest pain.

Gastrointestinal System – Interrelated organs whose function is to achieve proper nutrition by the digestion and absorption of ingested nutrients, and whose normal function includes production of enzymes and hormones as well as proper motility and excretion of wastes.

Ischemia – When blood flow is insufficient to nourish the tissues resulting in their dysfunction or death.

Peptic Ulcer – A defect in the lining of the stomach, duodenum, or esophagus due to a combination of an excess of aggressive factors that cause ulcers or a decrease of resistance factors that protect against them.

Introduction

The gastrointestinal system consists of many interrelated organs. It serves a variety of functions, all of which are crucial to the proper working of the body. The primary function of the gastrointestinal system is to achieve proper nutrition by the digestion and absorption of ingested nutrients; normal function includes the production of enzymes and hormones as well as the maintenance of proper motility, including excretion of wastes. Dysfunction of the system is common and may be the result of an abnormality of one of the component organs or of a process that is disordered more generally and affects several organs simultaneously. Dysfunction of the gastrointestinal system is a frequent problem in the elderly and a major reason for visits to the health-care worker.

Function

Anatomy

The gastrointestinal tract is composed of both hollow and solid organs. The hollow organs are arranged as a continuous tube beginning with the mouth and extending to the anus. The solid organs are connected to the hollow organs by way of ducts. A schematic representation of gastrointestinal anatomy is depicted in **Figure 1**.

The proximal extent of the gastrointestinal tract is the oral cavity. As a bolus of food is taken into the mouth, the digestive process begins with chewing (or mechanical disruption of the food) and is closely followed by secretion of saliva. Saliva contains enzymes such as amylase that help break down starches into sugars. Openings into the oral cavity exist for secretions from the major salivary glands, including the parotid, sublingual, and submaxillary glands, as well as the minor salivary glands inside the lips. The food bolus is then swallowed as it is propelled backward by the tongue into the oropharynx, and then into the esophagus.

The esophagus is a tubular structure approximately 25 cm in length that serves as an anatomic conduit between the mouth and the stomach. The point at which the esophagus joins the stomach is termed the gastroesophageal junction. This is an area characterized by a sphincter muscle that functions as a one-way valve, allowing food into the stomach but not allowing gastric contents to reflux back up again. The esophagus is lined by layers of flat cells heaped upon one another, collectively known as a stratified squamous epithelium. Mucus-producing glands help

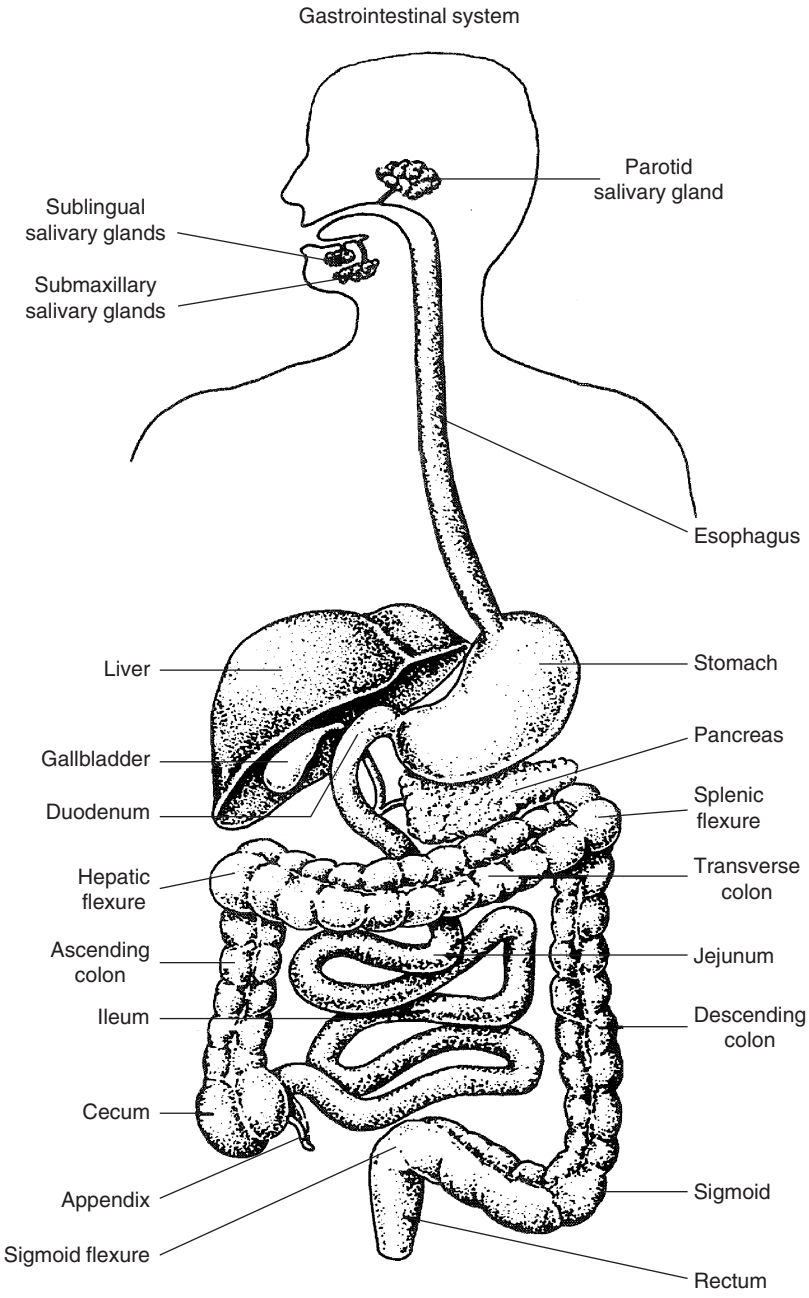

Figure 1 A schematic representation of gastrointestinal anatomy. Printed with permission from Solvay Pharmaceuticals, Inc.

the saliva lubricate the passage of food. Food is propelled through the esophagus and past the gastroesophageal junction by peristalsis to enter the stomach.

The stomach is located in the upper and midabdomen and is divided into four distinct regions: fundus, body, antrum, and pylorus. Although the lining of the stomach is composed of a single layer of tall (columnar) cells, each region of the stomach has a distinct microscopic architecture with specialized cells. For example, the fundus and body contain parietal cells, which make acid, and chief cells, which make pepsin, a digestive enzyme that breaks down proteins. G cells, which produce gastrin, a hormone that stimulates the stomach to produce acid, are located exclusively in the antrum. The pyloric sphincter is the anatomic as well as the functional landmark that separates the stomach from the small intestine.

The small intestine is the longest organ in the body. It measures approximately 22 feet and is divided into the duodenum, the jejunum, and the ileum. The longest segment is the jejunum. Like the stomach, the

lining of the small intestine is a single layer of epithelial cells of the columnar type; however, it has three specialized anatomic modifications to increase the surface area for absorption: the valvulae conniventes, which are bucklings of the lining of the small intestine; the villi, which are finger-like projections of the mucosa; and the microvilli, which are hair-like modifications of the superficial cell membrane at the brush border, or the barrier between the lumen and the cell. The ileocecal valve separates the small and large intestines and thereby slows the transit of nutrients through the small intestine, thus facilitating digestion. It also protects the small intestine from the bacteria of the large intestine.

The large intestine, or colon, is 4–5 feet long and extends from the ileocecal valve, usually located in the right lower quadrant of the abdomen, to the anus. The appendix is attached to the cecum. Although not important in the digestive process, the appendix may play an important role in the immune system early in life; it atrophies with advancing age. The large intestine is divided anatomically into several regions, including the ascending colon, transverse colon, descending colon, sigmoid colon, and rectum. The colon, like the small intestine, is lined with a columnar epithelium, but the microvilli on the colonic cells are much less prominent than those on the small intestinal cells. The most distal part of the gastrointestinal tract is the anus, and stool leaves the body after passing the anal sphincter. The lining of the anus consists of a stratified squamous epithelium, similar to that found in the esophagus and the skin; all these organs share some diseases because of their common cell type.

The other important structures that are part of the gastrointestinal system are the liver, pancreas, and gallbladder. The liver is located in the upper abdomen on the right and weighs approximately 4 pounds in men and 3 pounds in women. The liver produces bile, which helps digest fats, and the bile drains into the small intestine by way of the bile ducts. In addition to aiding in the digestion of foods, especially fats, the liver is the most important organ in the detoxification of drugs and medications. The gallbladder is located near the liver and is connected to the bile ducts via the cystic duct. It stores bile until it is needed for digestion. Finally, the pancreas is found in the mid-abdomen. It weighs about one-quarter pound, and its secretions drain into the small intestine by way of the pancreatic duct. It functions to help digest all major food classes by secreting a variety of enzymes: amylase to digest starch, lipase for fats, and trypsin and chymotrypsin for proteins. Of course, the pancreas also makes insulin that prevents diabetes.

Secretion and Digestion

The regulation of fluid balance is crucial to survival. Approximately 9 L of fluid enters the gastrointestinal tract per day. Of that amount, about 2 L is ingested by mouth. The remaining 7 L consists of fluids secreted by the various gastrointestinal organs. Ninety-eight percent of the total amount of fluid that enters the gastrointestinal tract is reabsorbed in the small intestine and the colon.

Of the secreted fluids, 1 L per day is generated in the mouth as saliva. Saliva contains salivary amylase, an enzyme that is useful in the preliminary breakdown of carbohydrates. Gastric secretion produces about 2 L of fluid per day, consisting primarily of acid and mucus. It has been the classic teaching that as one ages, the capacity to secrete gastric acid also diminishes. However, this adage has been questioned, and it is now believed that, if a person enjoys good health, the stomach will make a normal amount of acid. Sometimes it is difficult to know what normal is in an elderly person because the range of normal values that have been established is based on young, not old, adults. The liver produces an additional liter of fluid, bile. Bile is a complex fluid made up of electrolytes, bile acids, bilirubin, cholesterol, and lecithin; it helps digest fats. Output from the pancreas as pancreatic juice accounts for an additional 2 L of fluid per day and is central to the digestion of already partially degraded nutrients. Finally, an additional 1 L per day is derived from succus entericus or the fluids secreted by the gut itself. Only about 1–2 L of the original 9 L of fluid that enters the jejunum is left to pass into the colon, and of that amount, only 200 ml is excreted into the feces. Wet feces are passed as diarrhea, whereas overly dry feces result in constipation.

Many hormones play important roles in normal gastrointestinal function. These molecules serve to regulate various events in gastrointestinal physiology. Some hormones oppose the actions of other hormones, thereby leading to exquisite control via a continuous balance of regulatory and counterregulatory forces. For example, gastrin is a peptide secreted by the stomach and is the major hormonal stimulant to the production of acid by the gastric parietal cells. Gastrin also helps regulate the various muscle sphincters throughout the gastrointestinal tract and the motility of the digestive organs, their blood flow, and fluid balance. Somatostatin is an antagonist to gastrin release and therefore inhibits the production of acid by the stomach as well as some of the other functions of gastrin. Another hormone, cholecystokinin (CCK), is produced by cells in the duodenum and jejunum and regulates the release of bile from the

gallbladder. Secretin is produced in the duodenum and stimulates the flow of pancreatic juice. In general, hormones have multiple functions and complex interactions.

Digestion may be defined as the intraluminal breakdown of food. It proceeds in an orderly way from the mouth through the digestive tract. The purpose of digestion is to reduce complex nutrients into their simplest forms to allow for absorption by the small intestine. For example, starches and sugars are sequentially broken down from polysaccharides (many sugars) to oligosaccharides (few sugars), and then ultimately to monosaccharides (one sugar) before they are absorbed and then utilized.

Mastication (chewing) serves to break up large food particles, thereby increasing the total surface area of the food that will be exposed to digestive enzymes. In the mouth, salivary amylase initiates the preliminary digestion of carbohydrates. Once food passes into the stomach, further mechanical and chemical digestion occurs. Churning and grinding of particles in the gastric lumen mechanically reduces their size and is accompanied by chemical digestion in an acid environment.

The most important site of digestion of all dietary intake is the small intestine. The thick, semi-fluid mass of partly digested food (chyme) is delivered from the stomach to the duodenum at a controlled rate to allow for proper mixing with digestive enzymes. The hormones secretin and CCK stimulate the secretion of pancreatic enzymes and bile. These, in turn, facilitate further breakdown of food particles. In the small intestine, pancreatic enzymes such as amylase, lipase, and proteases, all acting under proper luminal pH, help to digest carbohydrates, fats, and proteins, respectively. Pancreatic amylase is the primary enzyme involved in carbohydrate digestion. It digests polysaccharides into short oligosaccharides. Protein digestion, which begins with acid and pepsin in the stomach, continues with the pancreatic proteases trypsin and chymotrypsin. Lipase acts within the pH ranges of the intestine to break down fats from triglycerides to glycerol and free fatty acids. In the liver, bile salts are excreted in bile, which then passes into the small intestine. Bile salts help to solubilize fat and fat-soluble vitamins by forming compounds known as micelles. Micelles are critical to the efficient transport of fats across the small intestinal absorptive surface. Finally, brush border enzymes, including disaccharidases (such as lactase, sucrase, and maltase), peptidases, and lipases, help to complete the digestion of nutrients into their simplest forms to permit their passage across the small intestinal wall.

Last, the process of digestion is enhanced by reabsorption of certain materials central to digestion, which, thereby, allows for their reuse. For example, the total amount of bile acids in the body is kept at a steady level, because more than 98% of bile salts produced by the liver are reabsorbed in the terminal ileum and recirculate to the liver by a pathway known as the enterohepatic circulation. The small amount of bile salts lost into the colon each day is replaced by an equal amount synthesized by the liver, thus keeping the total body pool of bile salts constant.

Nutrition and Absorption

After appropriate digestion of nutrients, the function of the gastrointestinal tract is to absorb these nutrients so they may be used for a variety of cellular processes.

Absorption occurs across the cells lining the small intestine and proceeds via one of several mechanisms. The first is passive absorption, in which material moves along an electrochemical gradient. The second is facilitated transport, in which absorption of one substance is coupled to the transfer of another substance. Finally, there is active transport, in which transport occurs against an electrochemical gradient and requires an expenditure of metabolic energy.

The primary nutrients are fats, carbohydrates, and proteins. All are absorbed in the small intestine. Complex fats are degraded to free fatty acids. Free fatty acids are relatively insoluble in water and require the help of bile salts to solubilize them, a process resulting in the formation of micelles. Micelles can transport fat through the relatively hydrophilic (water-permeable) small intestine into the absorptive cell, where the micelle is disrupted and the now free fatty acid is able to diffuse passively across the cell surface. Once within the cell, the fatty acids are resynthesized into triglycerides by the process of esterification. Then they are packaged for export from the cell in the form of chylomicrons and very low density lipoproteins and ultimately are carried to the liver by the lymphatics.

Carbohydrate absorption occurs in the small intestine, where monosaccharides are absorbed via facilitated and active transport. Proteins have specific carrier mechanisms allowing for their transport in the form of peptides and single amino acids.

Several other molecules absorbed in the small intestine are critical to the maintenance of normal body function. Calcium is absorbed primarily in the duodenum. Its absorption is regulated by vitamin D through the synthesis of a calcium-binding protein. Iron is absorbed in the duodenum by a carrier-mediated mechanism. Vitamin B_{12}, or cyanocobalamin, is absorbed after being bound to intrinsic factor, another substance that is produced in the stomach.

The vitamin B_{12}–intrinsic factor complex actually forms in the upper small intestine with the help of pancreatic juice and protects the vitamin B_{12} until it reaches the ileum, where it is absorbed. Folate is ingested in the form of polyglutamates in many foods. Brush border enzymes hydrolyze polyglutamates to monoglutamates that are transported by passive diffusion and a carrier-mediated process in the duodenum and upper jejunum, respectively. Last, fat-soluble vitamins such as vitamins A, D, E, and K are transported in micelles in a fashion similar to that of fat molecules.

Motility

The motility of the gastrointestinal tract is complex, and normal motility is critical to proper digestion. In order for gastrointestinal motility to be effective, it must be coordinated with other intestinal functions such as secretion and absorption, and it must be regulated and integrated in a precise fashion.

Swallowing is an exceedingly complicated process that involves coordinated movements of the tongue, the muscles of the mouth, and the posterior oropharynx, all modulated by multiple cranial nerves. A bolus of food moves down the esophagus in an orderly fashion in a motor pattern known as peristalsis. When a swallow is initiated, a peristaltic wave of contraction proceeds from the proximal esophagus to the distal esophagus, helping to propel the bolus of food downward. In a coordinated fashion, the lower esophageal sphincter relaxes when the peristaltic wave reaches it, thus allowing food to pass into the stomach.

Beyond the gastroesophageal junction, normal gastrointestinal motility occurs in two patterns: fasting and fed. In the fasting pattern, there are periods of relative rest that alternate with periods of contractile activity. The time of relative rest is known as phase I, and the active period is termed the migrating motor complex (MMC). The MMC consists of phase II, characterized by irregular contractions, and phase III, characterized by a short period of intense contractions. The MMC proceeds in an orderly fashion from the stomach to the distal small intestine. It is often called the intestinal housekeeper because of its action to sweep intestinal food contents onward.

The fed pattern is typified by frequent contractions that are somewhat irregular. This pattern starts immediately after a meal is ingested and replaces the fasting pattern at that point. The fed pattern is dependent on the type of meal ingested. For example, liquid meals produce considerably less prominent contractile activity than solid meals. The duration of this motility pattern depends on both the quantity and the type of food ingested. Once the stomach has emptied and the intestinal contents have been absorbed, the fasting motility pattern returns. The time it takes for half of a liquid meal to exit the stomach is about 20 min, whereas the comparable time for a solid meal is about 90 min.

The purposes of gastrointestinal motility following a meal are to allow for storage, to mix the food, to expose digested nutrients to the absorptive surface, and to evacuate the wastes. Toward these ends, different regions of the stomach and upper intestine act differently. The proximal stomach (the fundus) functions primarily as a reservoir for liquids and contracts in a predictable and orderly way to squirt liquids into the distal stomach, through the pylorus, and into the duodenum. A major function of the antrum is to grind and mix solid food. This task is achieved by coordinated contractions and relaxations of the antrum and the pylorus; liquids and very small solid particles (< 1 mm) pass the pylorus, while larger particles are rejected and subjected to repetitive churning. Once in the small intestine, the partly digested material, or chyme, progresses slowly but steadily as a result of intermittent contractions typical of the fed pattern.

The integration of the motor function of the gut is complicated. It is determined by controls at the level of the enteric, autonomic, and central nervous systems. The enteric nervous system is found within the wall of the gut in two plexuses, the myenteric and submucosal. The enteric system is coordinated by a means of cell-to-cell communication known as the paracrine system, as well as by the hormonal system, which has its stimulatory and inhibitory messages carried to its target cells via the bloodstream. The autonomic nervous system includes the sympathetic and parasympathetic nervous systems and mediates responses along reflex pathways. These systems are connected to the central nervous system. The brain, then, plays an important part in the coordination of integrated functions of the gastrointestinal tract. The precise roles of hormones and neuropeptides on the gut-related nervous system, although clearly important, are not yet well defined for many of the substances. Gastrointestinal motility is a complex and well-integrated activity that requires multiple layers of appropriate regulation for the entire system to function properly.

Dysfunction

Dysfunction of the gastrointestinal tract is a broad topic, encompassing a wide range of anatomic and physiological abnormalities. Dysfunction may be seen at any age, but there are important special

considerations that must be made when evaluating an elderly patient. Indeed, the same disease seen at different phases of life may appear quite dissimilar, and the possibilities for gastrointestinal dysfunction are significantly more extensive in the elderly than in a younger person.

The Oral Cavity

The mouth is an often-forgotten portion of the gastrointestinal tract in medical texts. However, knowledge of oral cavity dysfunction is important not only for the dentist but also for the gastroenterologist, and may be a clue to the cause of disease elsewhere in the body. Nutritional deficiencies, particularly the B vitamins (e.g., niacin, riboflavin), may present as glossitis (inflammation of the tongue) or angular stomatitis (inflammation at the corners of the mouth), respectively. Certain skin disorders such as pemphigus and pemphigoid often have coincident oral manifestations. Fungal infection of the mouth (thrush) is not uncommon, especially in elderly patients treated with oral antibiotics; viral diseases such as herpes simplex infections often are seen in patients who have an underlying malignancy. Finally, epidermal or squamous cell carcinoma of the lip and tongue is seen, especially in elderly men who have a history of heavy tobacco or pipe smoking.

The Esophagus

Gastroesophageal reflux disease (GERD) is the most common esophageal dysfunction. Its chief symptoms are heartburn, regurgitation, dysphagia (difficulty swallowing), and chest pain. Approximately 40% of the population of the United States reports an episode of heartburn at least monthly, and antacids are used frequently. GERD is usually well tolerated but may lead to serious complications, including esophagitis, strictures, ulcers, and cancer. The etiology of GERD is thought to involve four components: lower esophageal sphincter incompetence, abnormal esophageal clearance of acid and refluxed material, delayed gastric emptying, and the irritant effect of refluxed gastric contents. Symptoms of GERD may be quite troubling and may be confused with angina (i.e., chest pain of a cardiac origin). A hiatal hernia, or a defect in the anatomic structures that normally confine the stomach within the abdominal cavity, is frequently present in patients with symptomatic GERD.

Motility disorders of the esophagus often are found in patients who complain about chest pain or dysphagia. Achalasia is one such motility disorder and is characterized by the absence of normal esophageal peristalsis, as well as by incomplete or absent relaxation of the sphincteric barrier between the esophagus and stomach. Patients have difficulty swallowing that is progressive over years. An important consideration in the elderly patient is pseudoachalasia, which is an achalasia-like clinical picture that may be caused by a malignancy infiltrating the nerves at the level of the gastroesophageal junction. Other motility disorders also may produce significant symptoms: diffuse esophageal spasm, a condition in which muscular contractions are simultaneous (i.e., non-peristaltic), and the nutcracker esophagus, in which high-amplitude simultaneous contractions cause chest pain. Systemic diseases such as thyroid disease, diabetes, and scleroderma also may produce esophageal dysmotility. Some medications, most commonly certain potassium supplements, quinidine, non-steroidal anti-inflammatory medications, alendronate, and tetracycline, usually when taken without sufficient liquid to wash them out of the esophagus, can stick in and injure the esophagus, thereby producing an ulcer or stricture.

Swallowing difficulties may be caused by dysfunction at the level of the oropharynx, as well as by disorders of the esophagus or the gastroesophageal junction discussed previously. Oropharyngeal dysphagia is an important cause of such difficulties in the elderly. It may be caused by nervous system diseases (e.g., cerebrovascular accidents, Parkinson's disease, multiple sclerosis, and brain stem tumors), skeletal muscle diseases (e.g., polymyositis, or inflammation of the muscles), local anatomic factors (e.g., bone spurs and arthritis of the cervical vertebrae), and external pressure on the esophagus from the aorta either by an aneurysm or by the enlargement and uncoiling of the aorta that occurs with advancing age.

Esophageal tumors are among the most common malignancies in the world, yet they are relatively infrequent in the United States. They are often related to significant alcohol use and cigarette smoking and are more common in males than in females. One type of esophageal cancer, called adenocarcinoma, usually arises from abnormal tissue termed Barrett's epithelium near the gastroesophageal junction. Barrett's epithelium is a consequence of GERD, and occurs when the esophagus heals eroded, ulcerated areas with a tissue resembling the normal lining tissue of the stomach. In the esophagus, such gastric tissue has the potential to become malignant over many years. Periodic surveillance with an endoscope detects this premalignant tissue early and therefore permits therapy for such cancers earlier than would otherwise be possible. Unfortunately, however, most esophageal cancers are incurable at the time of diagnosis.

The Stomach

Peptic ulcer diseases (i.e., gastric and duodenal ulcers) are frequent medical problems. There are approximately 500 000 new cases and 4 000 000 recurrences in the United States each year. Approximately two billion dollars a year are spent on medications for ulcers, and it has been estimated that care for peptic ulcer disease represents about 10% of the total medical costs for all digestive diseases. About one-third of patients with peptic ulcer disease are older than 60 years at the time of diagnosis; its mortality in patients over age 75 is twice that of patients age 65–74, and more than 10 times that of patients age 45–54, although this must be viewed in light of the frequent coexistence of multiple diseases in the elderly individual.

A peptic ulcer may be defined as a defect in the lining of the stomach, duodenum, or, less commonly, the esophagus (as a result of acid reflux). It is due to a combination of either an excess of aggressive factors that tend to cause ulcers or a decrease of resistance factors that tend to protect against them. Duodenal ulcers are more common than gastric ulcers. Peptic ulcer disease is a significant problem in the elderly, in whom presentations may be atypical, the onset of disease may be severe with hemorrhage or perforation, and the prognosis is not necessarily as favorable as in the young because of misdiagnosis and a hesitation to be aggressive in therapy.

The aggressive factors in excess are acid and pepsin, but it is now believed that most gastric and duodenal ulcers in the elderly (as well as in the young) result from infection with a bacterium known as *Helicobacter pylori* or from non-steroidal anti-inflammatory drugs (NSAIDs); therefore, most ulcers are curable with antibiotics or by stopping the NSAIDs. Decreased resistance of the stomach epithelium is commonly induced by NSAIDs and cigarette smoking.

Disorders associated with reduced gastric secretion also exist. It generally has been believed that gastric secretion diminishes with advancing age, but this has been questioned, and it is now believed that the healthy elderly person has a healthy stomach that makes a normal amount of acid. In atrophic gastritis, inflammation of the lining of the stomach is present, probably caused by an autoimmune (self-destructive) mechanism. This leads to destruction of the acid-producing cells of the stomach. When these cells undergo atrophy, in addition to decreasing their acid production, they become incapable of producing intrinsic factor. The presence of intrinsic factor is crucial to normal vitamin B_{12} absorption; without it, vitamin B_{12} absorption is disrupted and pernicious anemia develops. Both atrophic gastritis and pernicious anemia are particularly common in the elderly. Moreover, the presence of atrophic gastritis has been linked to the development of gastric malignancies.

Gastric motility may be disordered in the elderly, resulting in a variety of symptoms. When gastric emptying is delayed, bloating, belching, and vomiting can develop as the stomach distends with retained food matter. If the partially digested material remains for a long enough period of time, a concretion known as a bezoar may form; bezoar formation is especially common in edentulous subjects who have had some gastric surgery and who eat foods that are difficult to digest, such as celery and oranges. Gastric motility is known to be delayed as a result of certain systemic diseases, most notably diabetes, and as a consequence of some gastric surgery. Medications often affect the movements of the stomach, and in the elderly, who frequently are taking multiple medications, motility disturbances are potentially important side effects.

Rates of gastric cancer, particularly involving the distal stomach, have been decreasing over the past several decades, but gastric cancer still remains an important cause of cancer death in the world. Success in curing gastric cancer is highly dependent upon the stage at which the cancer is detected. An important association is known between having had prior gastric surgery and the subsequent development, often 20 or more years later, of gastric cancer. This is a significant risk for the elderly patient who may have had surgery in the past for control of peptic ulcer disease. A sequential connection between chronic *H. pylori* infection, gastritis, gastric atrophy, and gastric cancer has been theorized, and it is hoped that cure of *H. pylori* will be followed by a decrease in gastric cancer.

The Small Intestine

Small intestinal dysfunction is characterized by maldigestion and malabsorption. Maldigestion may be caused by alterations in the production or function of the usual digestive enzymes, whereas malabsorption generally results from the loss of the normal absorptive surface of the intestine or disruption in the normal absorptive process. Intestinal function is well preserved with aging, and only the ability to absorb calcium and vitamin D may decrease to a clinically significant level. The ability of the small intestine to absorb monosaccharides has been shown to decrease with aging, and the pattern of fat absorption also appears to be different in the elderly, although such relative deficiencies do not lead to significant abnormalities; rather, they are merely curiosities of the aging process.

A variety of conditions lead to maldigestion, including pancreatic insufficiency, in which there is a lack of adequate pancreatic enzyme secretion needed for the normal digestion of fats, starches, and protein. Inadequate amounts of bile salts in the small intestine, which may occur in certain liver or bowel conditions, can lead to problems with fat digestion. Specific carbohydrate enzyme deficiencies may lead to carbohydrate maldigestion. Patients who have had prior gastric surgery may, as a result, have a gastric remnant that produces relatively little acid or that is ineffective in mixing digestive juices and food. Both of these situations may lead to decreased digestion.

Certain conditions lead to a loss of the normal absorptive surface of the small intestine. When the normal villous architecture of the jejunum is disrupted, the surface area becomes inadequate for proper nutrient absorption, and malabsorption occurs. This is clinically apparent when it causes chronic diarrhea, often accompanied by evidence of a deficiency of certain vitamins and minerals usually absorbed in the small intestine. Diseases that affect the small intestine and cause malabsorption include celiac sprue and lymphoma. An important concern in a patient with long-standing celiac sprue is an increased risk of malignancy. Both lymphoma and carcinoma can develop as a complication of sprue and affect the esophagus, stomach (carcinoma), or the bowel (lymphoma).

Diseases of the intestinal circulation are rare, but nonetheless represent an important cause of gastrointestinal tract dysfunction, especially in the elderly population. Ischemia occurs when blood flow is insufficient to nourish the tissues, and their dysfunction or death results. Although colonic ischemia is the most common form of intestinal ischemia, ischemia of the small intestine (i.e., acute mesenteric ischemia), is responsible for most of the ischemia-related mortality. In acute mesenteric ischemia, the amount of intestine deprived of blood supply is usually large, the diagnosis is usually made late, and the prognosis is poor, with a mortality rate of approximately 60–80%. This condition has been diagnosed increasingly as the overall population in the country has become older and as clinicians have become more familiar with the spectrum of ischemic diseases of the intestine. When a short length of the small intestine is deprived of blood because of such varied conditions as a strangulated hernia, vasculitis, or trauma, it is termed focal segmental ischemia of the small bowel. This condition usually requires surgical intervention but has a good prognosis. Last, chronic mesenteric ischemia, or intestinal angina, is a condition caused by atherosclerosis (or narrowing) of the mesenteric vessels. Patients with this problem develop abdominal pain or discomfort after eating, and the pain then slowly abates over several hours. They may develop malabsorption if the ischemic disease is long-standing and damages the absorptive lining of the intestine. This condition can be treated surgically, after which prognosis is good.

The Large Intestine

Despite anecdotes to the contrary, most healthy elderly persons move their bowels with normal frequency (i.e., five to seven times weekly). Nonetheless, diarrhea and constipation are common complaints with aging, just as they are in the younger years.

Diarrhea may be defined either as an increase in the volume or in the frequency or a decrease in the consistency of stools. Of the 9 L of fluid that passes through the small intestine each day, approximately 1–2 L enters the colon, and only 200 ml passes out of the body in the stool. In the elderly, complaints about increased frequency of bowel movements are actually often related to fecal incontinence due to constipation with run off of liquid stool around a rectal stool mass rather than to diarrhea.

Diarrhea usually is due to changes in the normal fluid regulation by the small and large intestines. Sometimes, diarrhea occurs when there is an accumulation of poorly absorbable substances in the colon. Examples of this in the elderly include intolerance to milk and dairy products caused by various enzyme deficiencies (such as lactase deficiency leading to lactose intolerance) and intake of poorly absorbable substances, such as sorbitol in diet candies or magnesium in antacids or laxatives (e.g., milk of magnesia). Diarrhea may also occur due to the active secretion of fluid that overwhelms the ability of the colon to reabsorb it; this may be caused by a hormone known as vasoactive intestinal peptide and certain bacterial toxins, such as cholera toxin. Inflammation of the lining of the intestine may lead to increased frequency of loose stools, which can occur in inflammatory bowel disease (ulcerative colitis or Crohn's disease) or in severe constipation, in which hard masses of dehydrated feces may irritate the intestinal lining and lead to an outpouring of mucus. Laxative use promotes loose stools, and studies have shown that surreptitious laxative abuse increases with aging. Antibiotics often cause gastrointestinal upset and diarrhea as side effects and are an important cause of colitis in the elderly. Alterations in intestinal motility may lead to diarrhea and, in the elderly, can occur in the setting of long-standing diabetes as well as in hypo- or hyperthyroidism (an underactive or overactive thyroid gland, respectively).

It generally has been believed that people become more constipated as they get older, but there is no scientific evidence to support this. In otherwise healthy old people, no abnormalities of the motor function of the large intestine have been shown. There are, however, alterations in the sensitivity and capacity of the rectum. Constipation is a term used to describe a relative lack or difficulty of bowel movements as compared to an individual's prior bowel pattern, and gastrointestinal tract dysfunction must be considered only when a change has occurred. In the elderly, constipation often is the result of decreased sensation to distension in the rectum, where stool is stored, so that large volumes of stool accumulate before the patient has the urge to defecate; this may even lead to fecal impaction. Immobilization, prolonged bed rest, long-standing laxative use leading to damage to the nerves of the colon, hypothyroidism, and depression all have been associated with constipation in older people, as have disorders of defecation due to abnormalities of the muscles of the pelvic floor. The latter is most common in elderly women whose pelvic muscles have been damaged by multiple childbirths earlier in life. Complaints of constipation, however, may also be indicative of a structural problem such as cancer, and because the incidence of cancer of the colon increases with age, a change in bowel habits is a key symptom that may help in the early detection of a colon tumor (**Tables 1** and **2**).

Table 1 Common gastrointestinal complaints in the elderly and their usual causes

Complaint	*Cause*
Chest pain[a]	Pill-associated esophagitis
	Tetracycline, quinidine, potassium, NSAIDs, alendronate
	Infections
	Fungus (*Candida*)
	Esophageal dysmotility
	Esophagitis, esophageal ulcers
	Gastroesophageal reflux disease
	Constipation
	Immobilization, prolonged bed rest
	Low-fiber diet
	Insufficient water intake
	Medications
	Pain medications, laxatives, antidepressants
	Hypothyroidism
	Colorectal malignancy
Diarrhea	Ingestion of poorly absorbed substances
	Magnesium-containing antacids
	Laxatives
	Sugar-free candies
	Infections, food poisonings
	Antibiotic-associated colitis
	Pseudodiarrhea
	Watery stool around an obstruction
	Fecal incontinence
	Hyperthyroidism
	Diabetes

[a] Must exclude cardiac sources first.

Diverticula are outpouchings of the wall of the intestine, usually found in the descending and sigmoid colon, just above the rectum. They are believed to arise in areas of weakness of the intestinal wall where high intraluminal pressures occur because of vigorous muscle contractions. The incidence of diverticular disease increases with advancing age to greater than 50% in the ninth decade of life. Population studies show that diverticula formation can be diminished by eating a high-fiber diet; there is no scientific proof that patients with diverticulosis should avoid fruits, nuts, seeds, and skins. Diverticulosis is progressive and the number of diverticula increase over time. Diverticulosis may be complicated by bleeding and by inflammation called diverticulitis.

Inflammatory bowel disease (i.e., ulcerative colitis and Crohn's disease) afflicts nearly two million people in the United States. Historically, inflammatory bowel disease has been said to have a bimodal age distribution, with a peak incidence in the third and fourth decades and then another smaller peak in the sixth

Table 2 Myths about gastrointestinal disease in the elderly

Myth	*Fact*
Pills can be swallowed without water	Adequate liquid is necessary to wash down pills to avoid pill-induced esophageal injury
With aging, the stomach no longer produces acid	The healthy elderly person has a healthy stomach that makes a normal amount of acid
Digestion becomes more difficult with aging	Intestinal function is well preserved with aging; only absorption of vitamin D and calcium decrease
Bowels relax with age; old people become constipated	No evidence of increased constipation or abnormal intestinal motor function in the healthy elderly

and seventh decades. It is now believed that much of the colitis that appears as a new entity in the population older than 50 is probably infectious or ischemic colitis and is not true inflammatory bowel disease.

Ulcerative colitis is a chronic inflammatory disease of the colon that almost always begins in the mucosa of the anorectal junction and extends proximally for a varying length. The disease is limited to the mucosa, or innermost layer, of the colon. Patients usually have bloody diarrhea as their chief complaint. There is an increased risk of cancer in patients with long-standing (i.e., lasting more than 10 years) ulcerative colitis, and that risk is progressive with increasing duration of disease. By contrast, Crohn's disease, the other chronic inflammatory bowel disease, is a chronic transmural disease that can affect any portion of the gastrointestinal tract from the mouth to the anus. The hallmarks of the disease are strictures and fistulae. Patients frequently present with abdominal pain, diarrhea, fever, or symptoms of bowel obstruction; however, in the elderly, presentations are more subtle and atypical than when disease onset is at a younger age, leading to delays in diagnosis or incorrect diagnoses. Patients who have the onset of either ulcerative colitis or Crohn's disease after the age of 50 may have a worse short-term prognosis than when the disease presents in younger patients; the need for surgical intervention may be more common in older patients with late-onset inflammatory bowel disease.

Colon cancer affects more than 150 000 people in the United States yearly and is a common malignancy in the elderly. It is usually slow growing and indolent and may not cause any symptoms or may come to attention only when slow bleeding has resulted in anemia, with consequent weakness, pallor, shortness of breath, angina, or dizziness. Other patients may develop signs and symptoms of large intestinal obstruction. The prognosis for a patient with colon cancer depends largely on the size and extent of spread through the body of the tumor at the time it is detected. Most colon cancer develops from polyps, and removal of precancerous polyps prevents cancer from developing. Thus, detection of polyps is important; hence the rationale for screening with colonoscopy beginning at age 50.

The Liver

Structural and functional changes occur in the liver with aging, and these may affect the manifestations of liver disease in the elderly. There is a progressive decrease in liver weight with senescence; it becomes more fatty; its ability to fight infection and metabolize drugs often diminishes; and blood flow to the liver is decreased. The spectrum and outcome of infectious and inflammatory liver disorders in the elderly appear to be different from those of younger people. For example, acute viral hepatitis due to hepatitis A and chronic viral hepatitis are seen less often in older patients but have a worse prognosis; disorders related to side effects of drugs are more common.

Liver dysfunction may be acute or chronic. The most common type of hepatitis in the elderly results from toxic agents such as medications, in contrast to hepatitis in the young, which is usually viral. Considering the frequency with which medications are prescribed, associated liver dysfunction is surprisingly rare but nonetheless represents an important problem; medications are estimated to cause up to 20% of cases of jaundice seen in elderly patients and are responsible for 25% of the cases of liver failure reported each year in the United States. Drugs frequently associated with liver inflammation include antibiotics, anesthetics, antihypertensives, and corticosteroids. Viral hepatitis is a more severe disease after the age of 60, with a higher incidence of progression to liver failure and coma and an increased mortality rate. Alcohol-induced liver damage remains a major problem worldwide, and the elderly are not exempt from the effects of this social toxin. Alcohol causes increased fat in the liver and may cause hepatitis and ultimately cirrhosis, but the course of alcoholic liver disease appears to be similar for both the young and the old. Liver dysfunction, with resultant jaundice, may occur in the setting of a severe systemic infection, in the postoperative patient, and with obstruction to the flow of bile from the liver to the intestine due to gallstones and tumors of the pancreas, bile ducts, and gallbladder. Finally, the liver may become swollen, and blood tests of liver function may be abnormal with congestive heart failure; these changes in the liver, even when severe, may show nearly complete reversal if the heart failure is controlled and improved.

Chronic liver disease is characterized by ongoing liver cell degeneration leading to scarring (i.e., fibrosis and cirrhosis). The cirrhotic process appears mostly the same in the elderly as in the young; it is often clinically silent and progresses without producing symptoms for many years. Once hepatic scarring has occurred, alterations in liver architecture are irreversible, and other systemic changes such as portal hypertension (hypertension within the internal vascular system) may follow. Causes of chronic liver disease include repeated acute insults with toxins such as alcohol, chronic obstruction of the bile ducts as in strictures (narrowings), iron overload, persistence of viral infections such as hepatitis B, C, and D, and

autoimmune hepatitis. Sometimes the etiology of chronic liver disease and cirrhosis is unknown and is referred to as cryptogenic. Cirrhosis from any cause may lead to the development of primary liver cancer; the liver also is the most frequent site of spread of cancer from other parts of the body. Finally, the liver may be involved in systemic illness, for example, in the fatty infiltration seen with diabetes mellitus. Such fatty change may result in slightly abnormal blood tests of liver function but rarely is clinically significant.

Gallbladder

More than 16 million Americans, or approximately 7% of the US population, have gallstones. Three hundred and fifty thousand cholecystectomies are performed annually, and hospital and related expenses total over $1 billion yearly.

The presence of gallstones (cholelithiasis) increases with advancing age such that about 30% of the population older than 65 years has gallstones. There is a female to male preponderance in the ratio of 3:1. In general, gallstones are composed primarily of cholesterol, which collects over a small focus of bilirubin, bile acids, or calcium. The stones form when bile, which is produced in the liver and stored in the gallbladder, becomes saturated with cholesterol. This is followed by the formation of a crystal, on which further precipitation of cholesterol occurs, causing the gallstone to grow.

Gallstones may be asymptomatic or they may give rise to inflammation in the gallbladder. Such inflammation, termed cholecystitis, may be either acute or chronic. Gallstones also may block the common bile duct, the tube that delivers bile from the liver to the intestine. Such blockage results in jaundice and infection, termed acute cholangitis. A syndrome seen primarily in the elderly, particularly in males, is cholecystitis without gallstones, called acalculous cholecystitis. This tends to occur in the setting of a coexistent serious illness, or perhaps after recent major surgery or severe trauma, when the patient is not allowed food by mouth for a prolonged period and the gallbladder is at rest.

Cancer of the gallbladder, a disease that favors elderly women, is associated with gallstones in 70–90% of cases. Unfortunately, it is rarely curable when diagnosed, even when it is found fortuitously at the time of gallbladder removal for other reasons.

The Pancreas

Inflammation of the pancreas, or pancreatitis, may be acute or chronic. Acute pancreatitis is usually related to gallstone disease or to alcohol ingestion; gallstones are more likely to be the problem in the elderly. Many commonly prescribed medications, including corticosteroids, certain antibiotics, and diuretics, also cause pancreatitis. Pancreatitis presents with significant abdominal pain and vomiting and can be diagnosed by blood tests (serum amylase and lipase) or a variety of imaging studies (ultrasound, computed tomography scan). The vast majority of attacks resolve, but some may lead to fulminant disease and death.

Chronic pancreatitis is often the result of repeated insults with a toxin, usually alcohol. In chronic pancreatitis there is ultimately calcification, fibrosis, and atrophy of the pancreas. Pancreatic function may be lost, and since pancreatic enzymes are responsible for a significant portion of nutrient digestion, there may be maldigestion of fats, carbohydrates, and protein. Patients with chronic pancreatitis frequently have severe abdominal pain, greasy foul-smelling stools, and diabetes. An association has been shown between chronic pancreatitis and pancreatic cancer.

Cancer of the pancreas is unfortunately a relatively common neoplasm. The incidence is higher in males, and there is a strong correlation with advancing age. These tumors usually are found when they obstruct the outflow of bile from the liver and thereby cause jaundice. Weight loss is common. When discovered in a person with jaundice and weight loss, these tumors are usually not suitable for an attempt at a surgical cure; only palliative and supportive therapy can be offered. Even when found during evaluation for an unrelated problem, cancer of the pancreas has a dismal prognosis.

Conclusion

Proper gastrointestinal function is vital, because it is only through normal digestion, absorption, and motility that adequate nutrition may be maintained. Gastrointestinal dysfunction is frequent in the elderly, however, and often different from that in younger populations. An understanding of the usual changes in function and dysfunction that accompany aging is important; the range of dysfunction in the elderly is broad, and making a correct diagnosis is often challenging.

Gender Roles

T Calasanti, Virginia Tech, Blacksburg, VA, USA

Glossary

Gender – Distinctions between masculinity and femininity.

Gender Relations – Dynamic, socially constructed power relations based on gender. Gender relations are embedded in social organization and interaction and have consequences for life chances.

Gender Roles – The sets of connected behaviors expected of women and men in specific situations.

Introduction

Research on gender and aging has progressed through several stages over the last few decades, and while each phase has emerged from the previous, all can be found in contemporary theory and research. Early work pointed to the contradiction between the preponderance of women in later life and their relative neglect by researchers. In the 1980s, scholars began to include old women in research more frequently, but this was accomplished in an 'add and stir' fashion that brought women into models derived from the study of men. Gender remained an individual, demographic attribute without theoretical explanation.

Feminist scholars focused on women's experiences as women described them and theorized that gender was a structural relation between groups. That is, when research begins with women's experiences, we see how their experiences differ from and are linked to men's. We come to realize that there is not one (male) model of retirement and that the retirement experiences of men and women each shape the other.

While gender relations disadvantage women in many of these areas, gender roles also provide women benefits that old men do not possess. For instance, old women are more likely to be widowed and living alone than men; because of gender relations in the family and work realms, they are also more likely to have lower incomes in old age, especially after the death of a spouse. These same gender roles also mean that women have more extensive social networks than men and are less dependent upon spouses for social integration or the performance of daily tasks. This broad approach frames this discussion of gender roles in later life, as well as why men and women might experience similar situations, including those related to financial status, retirement, caregiving, marital status and roles, and living arrangements, in different ways.

Gender Relations and Later Life

Gender

Research on gender roles and aging involves viewing maleness and femaleness as more than demographic or ascribed characteristics. It begins by distinguishing between sex – biological differences between males and females – and gender – cultural distinctions between masculinity and femininity. Gender is not a biological given, but is what people collectively agree that sex attributes mean. Societies construct men and women differently, and those differences reflect and perpetuate inequalities. To understand these inequities, scholars focus on gender relations: dynamic, constructed power relations embedded in social processes and institutionalized in social arenas, with

consequences for life chances. As a concept, gender relations emphasizes that gender serves as a social organizing principle and that men and women gain identities and power in relation to one another. Because they result from social interaction, gender relations are dynamic. What is considered masculine and feminine varies by culture, by time, and across groups within cultures – including age cohorts. This translation of sex into gender shapes men's and women's experiences across the life course and into old age.

Gender is embedded in social relationships at all levels, from individual interactions and identities to institutional processes. Societies organize on the basis of gender such that what is taken to be masculine and feminine influences and reflects a division of labor, the performance of which is evaluated and rewarded in a differential fashion. Thus, the gender identities that emerge in social interaction also serve to privilege men – give them an unearned advantage – while they usually disadvantage women, even as people resist and reformulate seemingly natural gender differences and meanings.

Gender relations are systematic, embedded in patterns of behavior such that they are taken for granted as simply the way things (i.e., families, jobs) work or the way things are. Thus, even though individuals enact them, gender relations are not dependent upon any one individual's actions or intentions, and they are often invisible. Because men's privileges are intimately tied to women's disadvantages, the situation of one group cannot be understood without at least implicit reference to the position of the other.

Gender relations underlie gender roles – behaviors that are expected of men and women in institutional situations (such as family, work, public, recreational, and other settings), based on their gender. Gender roles are upheld by ideologies (systems of beliefs) that justify the appropriateness of these behaviors. As one example, we relegate care tasks to women in a variety of situations, whether they involve physical activities such as cooking and cleaning or emotional carework. Women are the ones who should provide care within families (gender role) because they are, by their nature, more nurturing (ideology). Because we assume that girls are more nurturing than boys, we give girls dolls but give boys trucks. Then, when they grow up to emulate these beliefs and develop divergent skills, we take that as evidence that these differences are natural and that men's privileges in the family and work spheres are somehow more deserved. Further, because carework is natural and is performed out of love (ideology), it need not be remunerated. Women are segregated in carework professions and are paid less than men in positions of comparable worth for these reasons. The relatively low pay renders many women dependent on male breadwinners. The ability of men as a group to be breadwinners (gender role), to compete with other men for status and wealth and make significant wages, also rests upon the often invisible, unpaid carework and reproductive labor provided by women in family homes (gender role) out of love. Because these gender relations are embedded in the structures and collective beliefs of families, they do not depend upon any individual's intentions.

Gender Relations and Aging

While we can explore gender roles in a variety of institutions, their impacts on old age are most easily documented in the domestic sphere and the workplace. People engage in a wide range of activities that have economic value, whether or not they are paid. Which group is assigned which activities shapes both the composition and amount of resources available to them. For example, even though most women work for pay, they still bear primary responsibility for domestic labor, in part because no one else will do it and in part because of gender ideology; it is both women's work and one way they demonstrate their womanhood. Men can rely upon this labor, which enables them to better pursue their roles as breadwinners. Men's privilege within families is invisible and it translates into retirement privileges.

Recognizing that men's power is linked to women's subordination does not translate into straightforward or simple predictions about how gender influences the life course and old age. Instead, both gender positions carry with them opportunities and constraints, though it is certainly still true that, overall, men are more privileged. Gender is also linked with other hierarchies – such as race, ethnicity, sexuality, and class – in which the privilege of one group is tied, intentionally or not, to the oppression of others. These inequalities are not additive but intersect, as people experience the various relations that govern their lives simultaneously, not one at a time.

Age relations also constitute an axis of inequality, and thus old age disadvantages both men and women. As a result, even the most privileged older men will be disadvantaged relative to their younger counterparts. For example, ideologies regarding gender intersect with ageism such that men and women will attempt to preserve their youthful looks and thus not be excluded from social life. However, when and how this occurs varies by gender. Women are subject to a double standard of aging such that

they are viewed as old sooner than men. To a great extent, and despite women's inroads into the public realm, this results from the ideological equation of women's value with their attractiveness to men. Because such attractiveness is also equated with youth, an age component inheres; women are attractive to the extent that they also appear to be young. Much of the privilege of heterosexual womanhood is related to being White, in that White men of means seldom marry women of other racial groups. They also tend to marry much younger women.

For men, attractiveness to the opposite sex is a less important source of esteem than demonstrating that they can still perform in later life. To achieve status, women have had to align with powerful men, but men have had to compete with other men for status and wealth. While the essence of femininity may be about being, masculinity is about doing – performing. In this sense, ageist notions of masculinity and femininity influence the ways that both men and women experience later life as they strive to conform to gender roles and ideologies.

Table 1 Sex ratios (males per 100 females) of persons aged 65 and over, 2000: United States

Age	*Sex ratio*
65 and over	70.0
65 to 69	85.7
70 to 74	78.8
75 to 79	69.6
80 to 84	59.0
85 and over	40.7

Demographic Characteristics

The increased interest in women's aging experiences was partly spurred by the demographic reality that most old persons are women. **Table 1** shows that, in the United States, about 59% of those over age 65 are women. Put differently, there are 70 men for every 100 similarly aged woman. By age 85, this sex ratio is even more skewed; women comprise 71% of persons this age and older, and there are only about 41 men for every 100 women. This gender difference in life expectancy is reflected in **Table 2**.

Regardless of race or ethnicity, women outlive men at all ages. Thus, even though the race-based discrepancy slowly decreases with age, narrowing at age 65 and reversing by age 85, women consistently outlive men. Further, as evidenced by projections, this female advantage is not anticipated to decrease in the near future.

Not surprisingly, the gender composition of old people in the United States influences men's and women's marital patterns. As can be seen from **Table 3**, men are much more likely than women to be married in old age. Seven in ten (71%) men but only

[a]The racial categories reported here reflect those who selected single races only, and as compiled by the US Census.

four in ten (41%) women over age 65 are presently married. Instead, old women are most likely to be widowed (44.3%). By contrast, only 14.3% of men are widowed.

Of course, the proportions of men and women in these two marital statuses are related to age. Most people in the 65–75 age group, regardless of gender, are married. Men's likelihood of being widowed increases with age, but even in the 85+ group, more than half (56.1%) of men are married, while relatively few women of that age (12.5%) are.

These gender differences result both from the fact that women outlive men, on average, and from the social norms that dictate that men marry women younger than themselves. The differences in life expectancies mean that, once widowed in later life, it is more difficult for women to remarry.

Old men and women are about equally likely to be divorced, but the percentage within each gender declines with older age groups. This probably reflects different norms concerning the acceptability of divorce across these cohorts rather than differences in propensity to remarry. Regardless of gender, the never-married group is similar and consistent across age groups. Gender patterns in living arrangements in later life reflect those of marital status; thus, as **Table 4** reveals, old men are more likely to live with a spouse than old women. From another vantage, we see that older women are twice as likely to live alone as old men.

At the same time, gender patterns in living arrangements when not with a spouse vary by race and ethnicity. Generally speaking, minority group members are more likely to live with other relatives than to live alone (Black men are the lone exception), whereas White men and women are more likely to live alone. While these racial and ethnic patterns may reflect cultural differences, living alone requires some level of financial ability. Given the poorer financial position of minority women in particular (see the following section), it likely that economics plays a major role in these living arrangements.

Because widowhood rates increase with age, so too does the tendency for old men and women to live alone. Only 30% of women aged 65–74 live alone, compared to half of those over 75; similar, though smaller, differences accrue among men. Living alone has also risen over time; more men and women over age 75 live alone today (22.9 and 49.8%, respectively) than in 1970 (19.1 and 37%, respectively). This increase reflects the better health and finances of today's older cohorts and the desire to maintain autonomy.

Marital status and living arrangements influence gender roles to the extent that they shape roles available to older adults. Certainly, old men are more likely than old women to continue their marital roles, but the preponderance of married men also means that wives are more likely than husbands to serve as spousal caregivers. The preponderance of older Asians and Hispanics who live with others means that these groups are more likely to take on daily grandparenting roles than Whites and, to a lesser degree, Blacks. Old women are particularly likely to maintain their gender roles in such circumstances, as grandmothers are often called upon to provide child care and other forms of domestic labor.

Economic Security

Financial security is shaped by and influences gender roles across the life course and into old age. The expectations that men will focus on careers and the workplace and women will engage in reproductive labor as primary roles have important implications for financial status in later life. Although the median

income for those aged 65 and over is $14 664, this figure hides gender disparities. In 2003, the median income for old women, $11 854, was just 58% of men's median income, $20 363. In 2003, the US poverty threshold for an elderly individual was $8825, and 10.2% (about 3.6 million old persons) fell below this line. Old women were more likely to fall below this threshold (12.5%) than older men (7.3%).

Those who live alone are more likely to be poor: 18.6% compared to 5.8% of those living with families. However, women are even more vulnerable. In 2002, 15.6% of older men and 20.5% of older women who lived alone were poor, compared to only about 5% of married men and women. In addition, race and ethnic differences are such that non-Hispanic Whites (men and women) have the lowest poverty rates among those who live alone. In fact, Black and Hispanic men living alone have higher poverty rates (30.2 and 37.2%, respectively) than do non-Hispanic White women (17.4%). Minority women are the most disadvantaged; 45% or more of African American and Hispanic women who live alone are poor. In this sense, it is not only that two incomes can lift old persons out of poverty, but also that a man's income, to the extent that he is privileged by race and class, is more likely to be critical.

Sources of Income

Old women's greater economic vulnerability results from the fact that the sources of income in old age are gendered in terms of access and amounts. In the United States, the four main sources of income for those over 65 include Social Security, private pensions, earnings, and assets. In 2002, Social Security provided 39% of income; earnings, 25%; pensions, 19%; and assets, 14%.

Table 5 shows the importance of each of these sources to men and women's income security. (In reviewing these figures, note that they do not differentiate whether income received is based on an individual's or a spouse's work history. This results in inflated figures for women, who are more likely than men to receive income due to their spouse's work history, and provides higher figures than those reported later in this article.)

Though men and women enjoy similar access to both Social Security and asset income, they diverge in relation to private pension receipt and earnings. Men receive more income from each source, with the exception of assets. Women's median income from Social Security is 70% of men's, and they receive just over half of what men receive from private pensions. Wages received from employment do not diverge significantly from the inequalities experienced by younger women, except that in old age the gender gap is larger: women earn only 57% of what men receive. And although women get 81% of what men receive in asset income, this source of revenue is by far the least important, adding less than $1700 a year to men's or women's annual income.

A closer look at some of these sources demonstrates how gender relations shape men's and women's access to each and helps explain why old women have lower incomes and a greater likelihood of poverty.

Social Security Social Security is the most important source of income for most old people in the United States. It provides more than half of all income received for two-thirds of old people and almost half of the income received for four-fifths. Even more, it comprises 90% or more of all income for a full one-third of elderly people, and 100% of income for more than one-fifth (22%). Reliance on Social Security benefits is thus high for all but the richest quintile of old people, whose earnings and pensions add more income than Social Security.

Still, as **Table 5** makes clear, women receive less income from Social Security than men. These differences accrue even among those who collect benefits based on their own work histories: in 2003, monthly Social Security payments for retired workers averaged $1039 for men and $798 for women.

Table 5 Sources of income among men and women aged 65 and over in the United States, 2000

Sources of income	*Percent receiving income from source*		*Median income received*[a]		*Gender gap (women/men)*
	Men	*Women*	*Men*	*Women*	
Social Security	88.5	90.3	$11 040	$7750	70
Private pensions	46.7	29.5	$10 340	$5600	54
Assets	64.8	60.0	$1650	$1330	81
Earnings	22.4	12.3	$14 780	$8450	57

Source: Lee S and Shaw L (2003) *Gender and Economic Security in Retirement.* Washington, D.C.: Institute for Women's Policy Research.

[a]The median income figures are based on those who receive these sources of income only. Thus, the totals for these columns are higher than the median incomes of men and women, as many old persons do not receive income from each of these sources.

Gender inequalities in paid and unpaid labor are embedded in the Social Security program. Based on men's experiences of paid work and on a traditional model of the family, Social Security reinforces the gender differences contained in both domains. The original Social Security legislation covered only retired workers, as it assumed a form of gender relations wherein women always depend upon men in heterosexual (marital) relationships, and that women would be homemakers and men would be breadwinners. Because this legislation assumed a patriarchal family head who would provide for other members, men's presumed labor force history – a long-term, stable career with ever-increasing rewards – formed the basis of benefit eligibility and calculations. Thus, earnings levels and continuous employment are key to overall benefit levels, as are long-term marital bonds.

The inequities of these gender role assumptions become apparent when we examine how they translate into retirement income. First, a wife's benefit eligibility is based on marital status and the assumption that her job is to do domestic work. While such reproductive labor is implicitly acknowledged as underlying a husband's ability to work for money, it is still valued at half the level of his: a dependent spouse is entitled to only 50% of the breadwinner's benefit.

Second, the domestic division of labor influences retirement in terms of both the jobs that people take and their upward mobility. Among today's retirees, women often entered the labor force later than men, had to work particular shifts, turn down promotions, or enter particular types of jobs in order to maintain their domestic labor roles. Domestic labor time also has a negative impact on earnings. By contrast, this division of labor privileges men. In addition to higher pay levels, White, middle-class men can move into a more time-consuming position or to a different city, well-supported by their wives' unpaid work at home.

The calculation of retired worker benefits also reflects unequal gender roles. First, benefit levels are tied to earnings, such that the more a person earns, the greater the likelihood that the person will receive the maximum benefit ($1825 per month in 2004). However, on average, women receive lower wages than men across the life course, even when they work continuously. Not only do women tend to be clustered in low-paying jobs, but even when women and men are employed within the same occupations, women earn less. Such wage disparities are cumulative, influencing not only Social Security benefits but also women's ability to accrue wealth in other ways. The extent to which this labor market situation will change with younger cohorts is not clear. Although the gender gap in earnings is smaller among younger age groups, the differential remains significant and grows as these cohorts age, which might explain why, as a group, women's wages have stood at about 75% of men's for more than a decade.

Second, benefits are based on the earnings of the best 35 years of work, and, due to family obligations, women are far more likely than men to have worked fewer than 35 years and thus have years of zero earnings included in the equation. Thus, women who leave the labor market usually receive less pay upon their return and lower benefits later on, while men maintain their earnings and reduce the chance of having zero-pay years.

Finally, because Social Security legislation assumed only one breadwinner and tied benefits to wage levels, it ignored women workers from the start. As a result, couples with one (usually male) high-wage earner can receive higher benefits than couples with a similar household income that results from the paid labor of both spouses. Thus, gender roles shape retirement income in many ways. The assumption of a male breadwinner has served to justify women's lower wages and mobility, which in turn further justifies women's predominance in carework and other domestic obligations. Both women's and men's retirement income is firmly rooted in the gender division of labor.

Private Pensions Only about 50% of all workers have pension coverage on their current jobs. Further, defined benefit pension rules often have been based on assumptions similar to those embedded in Social Security, mandating continuous labor force participation and rewarding those with the highest wages. As a result, women's reproductive labor can preclude pension eligibility, and their work in lower-waged jobs, based on various gender role constraints discussed previously, leaves them with lower pension benefits.

The dramatic shift in type of pension coverage, from defined benefit to defined contribution plans, over the last 20 years presents additional problems for women as members of a lower-waged work force. To be sure, this change has meant that more women have access to private pensions, and by 2002, the gender gap in coverage among those aged 45–64 years of age had almost disappeared, with 51.7% of women and 55% of men reporting pension plan coverage. However, defined contribution most benefits those with high earnings, who tend to be White, middle-class men who can set more money aside. But they present drawbacks for lower-waged employees, who tend to be women. First, while employers may contribute to such plans, they often do not. For their part, low-waged workers do not have

enough expendable income to contribute much to their pension (and in some instances, are not required to do so). Thus, the amounts put into their pensions accumulate more slowly. Further, workers and not employers bear the risk of these plans. However, low-waged workers are less likely than their higher-paid counterparts to have the financial savvy to invest this money wisely, or to have the money to hire a consultant. And even with the best of advice, market changes are outside individuals' control. Finally, low-waged workers are those most likely to withdraw money from their pension, even while paying a stiff penalty, for family emergencies.

Thus, private pensions incorporate gender relations in the division of labor in several ways that penalize women for their reproductive labor, their segregation in particular jobs, and their lower level of pay. Women are less likely than men to collect pensions in jobs that do have such coverage, and, when they do receive pensions, the amounts are much smaller than men receive.

Retirement Experiences

The discussion of finances in later life illustrates one way that gender roles shape retirement. They also shape its meaning. For instance, although men and women both tend to talk about retirement as freedom, they diverge in terms of what this freedom entails. Many people regard retirement as a time of leisure. But many women, men of color, and members of the working class must continue to earn money, in both the formal and informal economy, and women continue their unpaid labor in the home. By contrast, more privileged men have the choice of whether to engage in paid work or domestic labor. The voluntary nature of these activities for them underscores the power differences based on gender, as well as race and class.

When women retire from the labor market, they feel freer because they have reduced their double burden. They maintain responsibility for domestic tasks but can now accomplish them in a more leisurely fashion than before. And while some retired men take on domestic chores, they generally do not take primary responsibility nor do as much as most women. In this sense, then, domestic labor is part of the retirement experiences of both women and men. While a woman's retirement is often characterized by continued domestic labor, married men's freedom to enjoy leisure time in retirement or choose to help with domestic labor is tied to wives' responsibility for the same.

Class and race matter in this regard. Women of higher class, the vast majority of whom are White, may maintain responsibility for domestic labor but can pay other women – working-class and often women of color – to do it. The labor market disadvantages of working-class White men and men of color may also preclude a leisurely retirement. The low rates of racial intermarriage, especially between Blacks and Whites, prevent most women of color from enjoying the privileges of heterosexual White womanhood – attachment to a high-earning man.

Some of those who collect retirement benefits return to paid labor as well. As can be seen in **Table 6**, labor force participation rates of pre-retirees have moved in opposite directions by gender, reflecting aspects of gender relations at home and at work.

When Social Security provisions were changed during the 1960s to allow the collection of reduced benefits at age 62, men were more likely to be employed in occupations that enabled the accumulation of wealth or pension funding that would allow them to retire earlier than age 65. At the same time, women – particularly White, middle-class, married women – began entering the labor force in unprecedented numbers. Subsequent cohorts have

Table 6 US labor force participation rates (percent), age 55 and over, by gender, 1963–2003

Year	*Men*				*Women*			
	55–61	*62–64*	*65–69*	*70+*	*55–61*	*62–64*	*65–69*	*70+*
1963	89.9	75.8	40.9	20.8	43.7	28.8	16.5	5.9
1965	88.8	73.2	43.0	19.1	45.3	29.5	17.4	6.1
1970	87.7	69.4	41.6	17.6	47.0	32.3	17.3	5.7
1975	81.9	58.6	31.7	15.0	45.6	28.9	14.5	4.8
1980	79.1	52.6	28.5	13.1	46.1	28.5	15.1	4.5
1985	76.6	46.1	24.4	10.5	47.4	28.7	13.5	4.3
1990	76.7	46.5	26.0	10.7	51.7	30.7	17.0	4.7
2000	74.3	47.0	30.3	12.0	58.3	34.1	19.5	5.8
2003	74.9	49.6	32.8	12.3	62.5	38.6	22.7	6.4

followed suit, spurred both by the women's rights movement and the economic necessity created by declines in the value of men's wages. These cohorts have swelled the labor force participation rates of older women as they aged. The continued need for two incomes and the greater acceptance of and opportunities for women's labor force participation (particularly in the low-waged service sector) mean that the gender gap in paid employment rates has narrowed at all ages. Indeed, in 2003, the labor force participation rate among those aged 55–61 differed by only 12% by gender, compared to a 46% difference four decades earlier.

Still, the percentages of men and women over age 65 in the labor force have been increasing since the 1980s. In 2003, 33% of men and 23% of women aged 65–69 were in the labor force. Gender roles influence decisions to remain in or re-enter the labor force, as well as the jobs old people seek. Such labor force engagement appears to be bimodal. Some continue to work as high-paid consultants, but a large number remain in low-paid, usually service jobs. White professional men are more likely to be in the former group, whereas women (as well as working-class men and men of color) fall into the latter. While both groups may work to sustain a lifestyle or simply to work, the latter group is far more likely to work out of financial necessity. Given the lower wages that women receive prior to retirement – women aged 50–64 earn about 64% of what men earn – they are far more likely to feel they must work. That they receive low wages in old age as well is reflected in the earnings reported in **Table 5**. Women's continued work in retirement, paid or unpaid, is not freely chosen when it is predicated on financial need that results from gender relations within the family and workplace.

Carework

Throughout the life course, carework – an activity that involves both the practical caring for and the emotional caring about – tends to be women's work. Women do the overwhelming majority of primary caregiving in all racial and ethnic groups, regardless of employment status. When both women and men perform carework, tasks tend to be gendered. Women engage in more personal care tasks and men focus on the instrumental. This reflects the broader divisions in domestic labor, in which women perform the more personal, bodily, indoor, and daily labor and men do more periodic and outdoor tasks.

However, these generalizations reflect all caregivers and caregiving relationships. Among older people, spouses are the preferred caregivers. Because women tend to marry men older than themselves and because those men have lower life expectancies, men are usually the recipients, not givers, of spousal care. But when spousal caregivers are compared, there are few of the gender differences reported previously. Husbands and wives spend about the same amount of time giving care and perform similar tasks. In the United States, where few public options other than family care exist, husbands are as likely as wives to engage in personal care, such as bathing and toileting, for their spouses.

Some scholars suggest that men who give care (regardless of their relationship with the care recipient) may handle it better. Caregiving women appear to report more stress, anxiety, depression, and physical problems than caregiving men. Because of their gender roles, scholars suggest, men approach caregiving more as a job – a series of tasks to be done and mastered – than as a matter of their identity as men. They may focus more on the caring for aspects, separating them from the caring about. They may be less emotionally involved and better able to take time for themselves, leading some researchers to suggest that men may 'care better by caring less.'

However, it remains unclear whether men suffer less stress than women. In line with the gender role dictates of stoicism, we know that men generally report stress and depression to physicians less readily than women. They may express stress in ways not tapped by research that has traditionally focused more on women, and qualitative research suggests that caregiving men talk about stress in different terms. In any case, preliminary research suggests that, based on gender roles, both the approach to caregiving and the outcomes are gendered. The fact that women perform most domestic labor tasks and build expectations of nurturing behavior into their identities means that women will be more used to performing some daily tasks and will maintain higher expectations of their caregiving that more quickly lead to stress. By contrast, men may indeed approach carework in a more managerial fashion, and while they may find learning new tasks stressful, they may also garner a sense of accomplishment in their daily tasks. Being nurturing is not an essential part of masculinity, so failure to gain compliance from a care recipient, or calm her down, for instance, does not violate a man's sense of self in the way that might occur among women.

Finally, a critical aspect of the level of stress – or reward – experienced in caregiving has to do with how care is received. While sparse, research points to the importance of marital gender relations in understanding how care-receiving spouses shape caregivers' experiences. Because women typically perform domestic labor, they understand as care recipients what

their husbands do for them and are likely to express gratitude. By contrast, care-receiving husbands have no such referent. The more that men must depend on their wives, the more that they may feel their masculine autonomy threatened. As a result, they can become more demanding and controlling. Thus, the power relations that characterize their marriages and give the husbands control may not cease when husbands become dependent upon wives for care, and caregiving wives still can feel constraints upon their time and decision making.

Marital Status and Gender Relations

Marital status structures the entire adult life course and influences psychological and physical well-being for both men and women. Although not all marriages are happy, being married usually ensures a companion, and older married persons express greater happiness than those who are unmarried.

At the same time, marriage tends to have greater positive effects for men than for women. Aside from the benefits that companionship itself brings, the gender relations in marriage also influence older men and women in particular ways. Being married provides financial security for older people, especially for women, given the greater income that men generate. And while being married enhances physical health, this is partly because spouses encourage healthier behavior. In this regard, women's caretaking roles make them most likely to engage in self-care and more likely to encourage healthy behaviors in husbands, in terms of lifestyles and listening to doctors.

Women's caretaking roles matter in other respects as well. Not only do women do more emotional labor in families and with their spouses, but they also are the kin-keepers in marriages, maintaining contact with children and other relatives as well as friends. As a result, husbands rely on wives as confidents more exclusively than vice versa. In short, while marriage provides benefits for both old men and women, women's domestic labor – which involves both physical and emotional work – keeps husbands integrated and healthier. Research finds that, compared to widowed, divorced, and never-married men, married men have the greatest levels of social interaction both within and outside the home.

Widowhood presents a specter of loneliness for men and women alike, and, as a result, widowed persons report lower levels of psychological well-being than married persons. That said, widowed men appear to report greater depression over time than women. This likely results from the different kinds of losses that husbands and wives experience, due to marital gender roles.

While gender relations over the life course make widows more vulnerable to poverty than widowers, they are also aware of the domestic labor that was required. For some, widowhood gives a new sort of freedom. Thus, many widows choose not to take on another burden of domestic and carework for a spouse. In addition, while women may also face the 'coupledom' that excludes single people, they usually have additional sources of support, including close bonds with their children. Women who want to maintain some of their new freedom while also having an intimate relationship may solve this quandary by enjoying a committed relationship while maintaining their own homes – an option increasingly popular in Europe.

By contrast, widowers must often learn how to do the work of daily living – both physically and emotionally. Domestic labor chores may fall entirely upon them, as does the kin-keeping and friendship maintenance. Their relative lack of domestic labor skills makes men more vulnerable to institutionalization in the 6 months following widowhood than women. Widowers who express disinterest in remarriage do so not to preserve autonomy, but because they realize their advanced age and poor health make them less marriageable.

Divorce combines the effects of widowerhood on older men with greater isolation. Strained relationships with children and the tendency to move after divorce can shatter their social networks. They tend to feel the most unhappy with their networks and report the most loneliness in old age. By contrast, and in keeping with marital roles, while divorced women often suffer financial hardships, they tend to have larger social networks and closer ties to children.

Conclusions

Men's and women's roles and experiences are linked. Understanding that widowhood inspires loneliness in women and men but may also present different challenges to them suggests more effective ways to help surviving spouses. Knowing that all caregivers suffer stress, but that the sources and expressions may differ, enhances our ability to intervene and offer support.

Not all men are privileged and not all women are disadvantaged. Gender relations intersect with other hierarchies such that White women, for example, might be better off than Black men in some realms. Some disadvantages can be sources of strength, just as struggling to maintain privileges can come at some costs. When we take a life course view, we can see, for instance, men's ability to garner authority and

wealth in the public sphere may render financial security in old age but may also hamper relationships and health, while women's caregiving roles may result in greater poverty but also greater support from informal networks.

Further research should show how gender intersects with other inequalities. Recent suggestions that men and women become more androgynous as they age – as well as research on this possibility – may well be based on models of femininity and masculinity more appropriate to younger ages. And some of what we know of the effects of gender roles and relations in younger years may not apply to old age. The burden of housework early in the life course weighs upon women in some ways but in later years may sustain their sense of femininity in ways that please them.

Social structures are not static; people resist and alter them as they live out their roles. Gender relations are dynamic; structural changes can be expected to influence experiences of gender and old age, just as the refashioning of gender identities will affect institutions such as families. Although women's greater labor force participation has not leveled the distribution of housework, men and women have changed their ideas about masculinity and femininity enough that men contribute more to child care. As a result, we can expect future cohorts to demonstrate somewhat divergent gender patterns in old age. At the same time, without substantial shifts in gender arrangements, inequalities between men and women will persist, although levels and expressions may change.

Generational Differences: Age-Period-Cohort

K W Schaie, The Pennsylvania State University, State College, PA, USA

Glossary

Cohort – Group of persons entering the environment at the same point or range in time.

Cross-Sectional Sequence – Groups of persons assessed once, where at least two age levels are sampled at a minimum of two different measurement occasions.

Longitudinal Sequence – At least two groups of persons assessed at least twice over the same age range.

Introduction

Generational differences are treated in this article from a psychological perspective, although attention

will be called to the historical context of the concept as it evolved in both sociology and psychology. Moreover, generations are differentiated from cohorts, and the article discusses the relevance of the literature on cohort differences to an understanding of generational differences. Methodological issues in the psychological study of generational differences and cohort differences will be considered, including an exposition of the age-cohort-period model. Examples of findings from the literature will draw largely on the Seattle Longitudinal Study, including findings on generational differences in cognitive performance, selected demographic characteristics, and perceptions of family environments.

Sociologists' and Psychologists' Views of Generations

The concept of generational differences received considerable play in the early twentieth century when the sociologist Karl Mannheim called attention to generational conflicts, particularly those between adolescents and young adults and their parents. Indeed, much of the sociological literature on generational differences deals with issues of generational conflicts and transmission of values. Similar early concerns in psychology appear in the work of Charlotte Buehler, centering on conflicts between adolescents and their parents. Among developmental psychologists, hints of concern about possible effects of generational differences can be found in the work of Raymond Kuhlen, who was the first in psychology to call attention to the fact that individuals age within the context of changing societies, implying the possibility that the timing of behavioral change might be important.

In the more recent literature, generational differences began to resurface in the mid-1960s almost simultaneously in both the sociological and developmental psychology literature. Ryder suggested that the notion of cohort progression was an essential concept for the sociological study of change. Riley, Johnson, and Foner further developed this theme in its implication for social gerontology in a seminal volume. At the same time, the author called attention to the fact that aging data obtained from cross-sectional and longitudinal data sets could not correspond, because cross-sectional age differences are confounded with cohort (generational) differences, while longitudinal age changes are confounded with time-of-measurement (period) differences. He specified a general developmental model that examined the formal nature of these relationships, placed them in the framework of quasi-experimental designs in psychology and education, and proposed strategies for collecting and analyzing data that might help obtain better estimates of the age factor.

Attempts to unconfound the age-period-cohort model have been controversial. However, given appropriate limiting assumptions, cohort studies have played an important role in behavioral research, not only in controlling for methodological artifacts that might result in the over- or underestimation of aging effects, but also in examining the contextual variables that affect levels of behavior and expression of personality traits over time. There is still a lack of good understanding of the relationship between macro-societal change and its effects upon age differences and age changes in behavior, but the study of generational differences in behavior has provided an initial attempt to identify those variables most prone to shifts across generations. Many geropsychologists who began prospective studies of aging in the 1960s have therefore included multiple cohort designs of one kind or another to deal with the issue of possible generational differences.

Generation and Cohort

The term generation often denotes successive groups in time in which the second group could (but need not necessarily be) the biological offspring of the first group. By contrast, the term cohort is an arbitrary definition of a point in time or range of time during which members of a group enter the environment (by birth or other temporal entry). Hence the temporal distance between two generations will generally represent a time frame from 20 to 30 years, while cohort differences may and often do cover much shorter periods of time.

Generational and cohort differences are usually studied in the context of groups of people (birth cohorts) entering the environment at the same point (or range) of calendar time. It should nevertheless be stressed that the temporal boundaries for generations could also be characterized by non-calendar definitions. For example, the initial group of workers hired for a new factory or the first faculty of a new educational institution would represent a generation (regardless of the individuals' calendar age), as would the initial membership of a newly formed club, persons called to active duty in the armed forces at the same point in time, or the first-time purchasers of homes in a new residential subdivision.

Methodological Issues

Research Designs for the Study of Generational Differences: The Age-Cohort-Period Model

The age-cohort-period model specifies that any age-related or time-dependent behavior can be assigned

three temporal characteristics, such that

$$b = f(A + C + P),$$

where b (behavior) is observed at the chronological age A, for individuals over the calendar period P who entered the environment as members of cohort C. This relationship is similar to the relationship among the physical variables of volume, pressure, and temperature. Here, also, the third component can always be stated as a function of the other two components. Thus,

$$A = C + P$$
$$C = A + P,$$

and

$$P = A + C.$$

Each of these three components may be of primary interest for some scientific questions in the developmental sciences, and it is therefore useful to be able to estimate the specific contribution attributable to each component. In the behavioral sciences, in particular, we typically want to differentiate effects that change across age (intraindividual change) from those effects that differ across cohorts or generations (interindividual differences). On the other hand, educational researchers might be more interested in differentiating changing educational impact across different periods from the ages of those affected.

Data Collection Strategies

Empirical studies in the developmental sciences involve age and/or cohort comparisons either at one point in time or at successive time intervals. Traditional strategies used for this purpose are represented by cross-sectional, longitudinal, and time-lag designs.

Cross-sectional strategy investigates the hypothesis that there are differences in one or more characteristics for samples drawn from different cohorts but measured at the same point in time. This strategy is most appropriate for the study of interindividual differences. Age differences in behavior at a particular point in historical time may be relevant for policy decisions that lead to differential societal responses regardless of the antecedent conditions responsible for the age differences. Age differences detected in a cross-sectional data set, however, are inextricably confounded with cohort differences. Since cross-sectional subsamples are measured only once, no information is available on intraindividual change. Unless there is independent evidence to suggest that older cohorts performed at the same level as younger cohorts at equivalent ages, it would be most parsimonious to assume, at least in comparisons of adult samples, that cross-sectional age differences represent estimates of cohort differences that may be either inflated or reduced by maturational changes occurring over a specified age range.

Longitudinal strategy investigates whether age-related changes have occurred within the same population cohort measured on two or more occasions. This strategy is appropriate when the investigator wishes to predict age differentiation in behavior that occurs over time. But longitudinal data do not always provide unambiguous estimates of intraindividual change. A single-cohort longitudinal study confounds age-related (maturational) change with period effects that are specific to the particular historical period over which the behavior is monitored. The period effects could either mask or grossly inflate estimates of maturational changes.

Time-lag strategy compares two or more samples of individuals drawn from successive cohorts at successive points in time at the same chronological age. The hypothesis tested is whether there are differences in a given behavior for samples of equal age but drawn at different points in time. This strategy is of interest to social and educational psychologists. It is particularly appropriate when one wishes to study performance of individuals of similar age in successive cohorts (e.g., comparing baby boomers with the preceding generation). The simple time-lag design confounds cohort effect with period effects and may provide inflated or reduced cohort estimates depending on whether the temporal interval between the cohorts represents a period of favorable or adverse environmental influences.

Sequential Strategies

Generational differences were seen as serious confounds in studies of human aging. Consequently, several alternative sequential strategies were introduced that might differentiate effects of maturation characteristic for a particular developmental period from the attainment of different levels of functioning attributable to differences in socialization and/or other life experiences characteristic for successive generations by assessing the behavior of more than one cohort over a given age range.

The term 'sequential' implies that the sampling strategy used to study generational differences must include the acquisition of a sequence of samples taken across several measurement occasions. Perhaps the most widely used sequential strategy is the cross-sequential design, in which two or more cohorts are followed over an identical time period. This

approach permits the direct comparison of longitudinal and cross-sectional data (provided that the calendar time ranges are similar for age and cohort). The advantage of this approach is that only two points in time are needed, hence the early appearance in the literature of studies using this design. For purposes of studying generational differences, however, this approach represents a 'model misspecification' because it does not allow the comparison of each cohort over the same age range.

As indicated previously, geropsychologists and other developmental scientists often find the cohort-sequential design of greatest interest because it explicitly differentiates intraindividual age changes that occur within a generation from interindividual differences between generations. This design also permits a check of the consistency of age functions over successive generations, thereby offering greater external validity than would be provided by a single-cohort longitudinal design. A cohort-sequential study consists of two or more generations (however defined) being followed over two or more similar age levels. The minimum design for such a study involves three measurement points, allowing each of two cohorts to be followed over the same age range.

Repeated Measures and Independent Samples

In a typical longitudinal study, repeated measures are taken of the same research participants at successive times. It is also possible, however, to use the same research design but with independent samples at each age level being measured. In this alternative design, one would draw a new (independent) sample from the same cohort initially tested. The independent sampling approach works well when a large sample is drawn from a large population, and when one is primarily interested in the estimation of population parameters. This approach controls for the effects of non-random dropout, regression to the mean because of fallible measurement instruments, and effects of practice or inadvertent changes in experimental protocols. If small samples are used, it is, of course, necessary to make sure that successive independent samples are matched on factors such as gender, income, and education to avoid possible differences due to selection biases.

Designs for Specific Issues in the Study of Generational Differences

If the primary interest of an investigator is the estimation of magnitudes of generational differences, then the independent samples approach described earlier will suffice. That is, one needs to obtain data from a minimum of two cohorts at the same age in order to estimate the magnitude of the cohort difference. However, it is probably quite problematic to estimate generational differences at only one age level, because of the possibility of age-by-cohort interactions. Hence, one would recommend for this purpose a cross-sectional sequence of sufficient temporal length that each pair of cohorts can be compared at multiple age levels, even though all cohort pairs cannot be compared at every age level of interest. When this is done, one can then set the performance of the earliest-born cohort as a base and cumulate successive cohort differences, in the same manner as life span psychologists estimate age gradients. This approach permits contrasting generational shifts in performance levels over time for distinct behavioral dimensions.

It should be noted that this approach would not suffice for the estimation of generational differences in rates of change. For this purpose it is necessary to follow the same individuals over time in the form of a longitudinal sequence that allows contrasting successive cohorts over the same age range. That approach is essential if one wishes to address the question of whether there have been any changes in the rate of aging for successive generations.

The study of differences in the behavior of successive generations of biologically related individuals requires contrasting parents with their adult offspring. Ideally, data should be available for parents and offspring at the same ages. Barring the availability of such ideal data, designs of studies involving differences within family units must pay attention to the age at which study participants are assessed, as well as to gender differences, when cross-gender parent–offspring pairs are studied. Adjustments for the confounding variables of age and gender must often be used to obtain realistic estimates of generational differences within biologically related family units.

Substantive Findings

The remainder of this article outlines what is currently known of generational differences in intellectual competence, selected demographic characteristics, and perceptions of family environments that may have implications for our understanding of behavioral aging; it relies heavily on findings from the Seattle Longitudinal Study.

Generational Differences in Cognitive Abilities

Generational differences were first studied by means of cohort-sequential designs as part of the analyses conducted for the third cycle of the Seattle Longitudinal Study (SLS). This study began in 1956

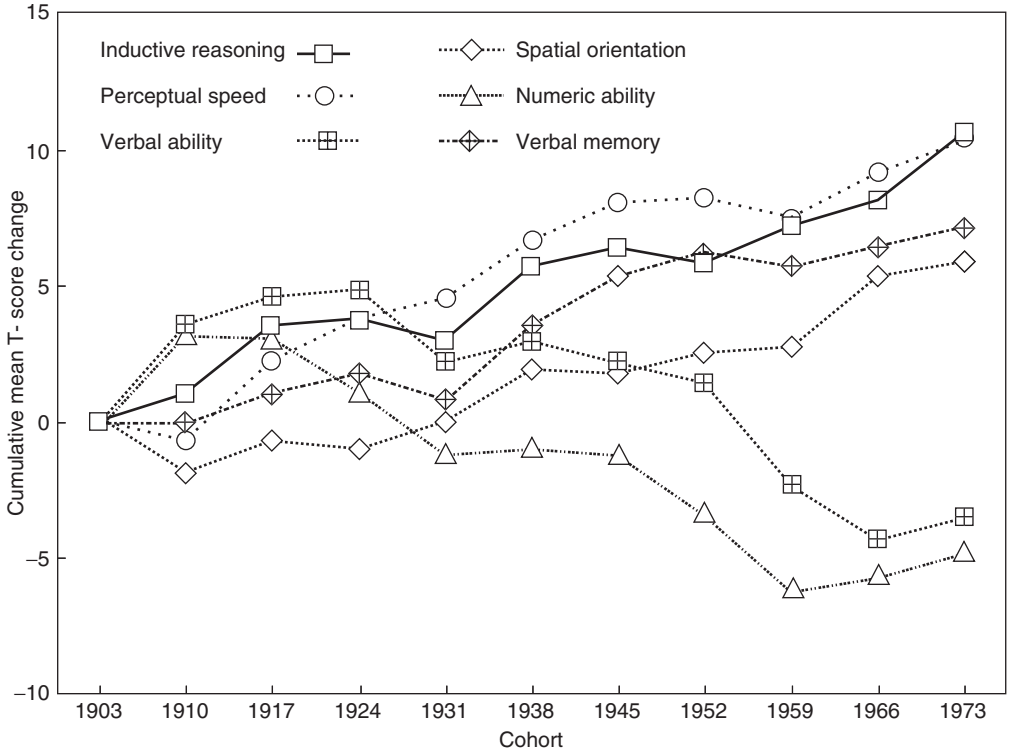

Figure 1 Cumulative generational differences of six mental abilities for birth cohorts in 7-year intervals from 1903 to 1973. From Schaie KW (2005) *Developmental Influences on Adult Cognitive Development: The Seattle Longitudinal Study*. © by Oxford University Press, Inc. Used by permission of Oxford University Press, Inc.

as a cross-sectional inquiry of Thurstone's primary mental abilities over the age range from the 20 s to the 70 s. Longitudinal follow-ups were conducted at six successive time points (7 years apart) in 1963, 1970, 1977, 1984, 1991, and 1998. All study participants were community-dwelling members of a health maintenance organization and represent the upper 75% of the socioeconomic spectrum. **Figure 1** shows cumulated generational differences for birth cohorts from 1903 to 1973 in 7-year intervals for six primary mental abilities: verbal ability (recognition of the meaning of words); inductive reasoning (the ability to abstract rules and principles from reoccurring single instances); spatial orientation (mental rotation of objects in two-dimensional space); numeric ability (skill in simple mathematical operations such as addition, subtraction, and multiplication); perceptual speed (rapid identification or matching of simple objects, or comparison of numbers); and verbal memory (immediate and delayed word recall). All abilities were measured by three or four different tests.

Substantial positive and linear generational differences were observed for inductive reasoning, perceptual speed, and verbal memory. The 70-year gain amounted to approximately 1 standard deviation (SD). This gain is likely to be associated with the substantial increase in educational exposure occurring over this time period. The positive gain across successive generations in inductive reasoning may also be related to changes in educational practice from rote learning to the encouragement of discovery methods. The virtual conquest of childhood diseases and the adoption of more favorable lifestyles in successive birth cohorts may also be implicated. A similar positive, although less steep, difference pattern occurred for spatial orientation. By contrast, verbal and numeric abilities seem to have peaked in the second decade of the twentieth century and have declined somewhat since then, but was stabilizing in the most recently born cohorts. The same changes in educational practices that have been favorable for inductive reasoning may have led to some loss in number manipulation skills as well. The decline in numeric ability across recent cohorts explains the fact that current cross-sectional studies suggest relatively little decline in numeric ability even though substantial decline has been found in longitudinal data. Generational differences of a magnitude similar to the inductive reasoning factor have also been observed for a measure of practical intelligence involving common everyday tasks.

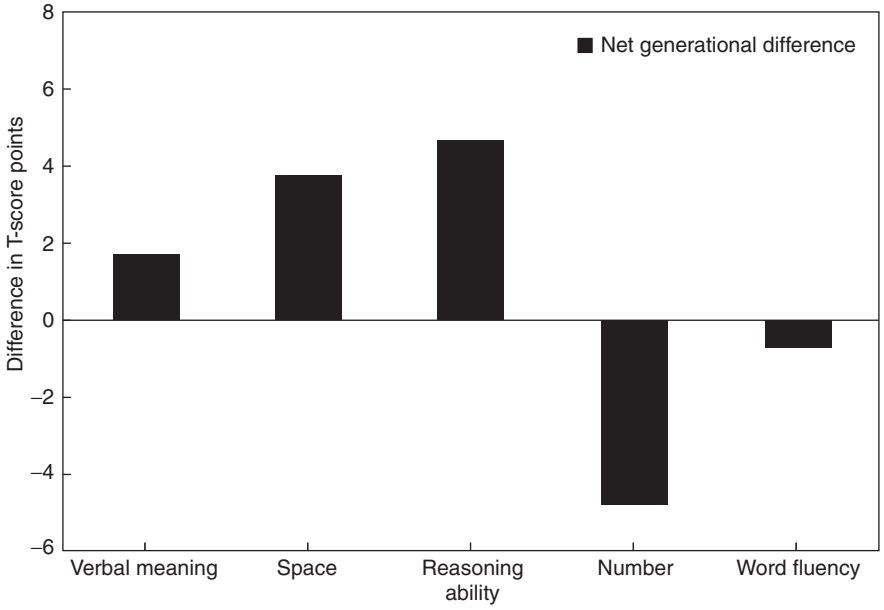

Figure 2 Generational differences in primary mental abilities between parents and their adult offspring. Adapted from Schaie KW (2005) *Developmental Influences on Adult Cognitive Development: The Seattle Longitudinal Study*. © by Oxford University Press, Inc. Used by permission of Oxford University Press, Inc.

Comparisons from family studies of biologically related individuals involving parents and their adult offspring have yielded similar findings on generational differences in cognitive abilities. **Figure 2** shows findings on tests of five primary mental abilities for the difference between parents and their adult offspring. The bars show the net difference, adjusted for age, in a large data set of more than 600 families. If there were no differences between generations, the solid bar would be zero. As can be seen in the figure, there are significant differences that favor the younger (offspring) generation on inductive reasoning, spatial orientation, and verbal ability. On number ability, it is the older generation that is at an advantage, while there is little difference on word fluency.

These findings are supported in extensive analyses by Flynn, who studied differences across generations of young adults from 1932 to 1978 in the United States as well as in 14 different countries and who also reported massive gains in IQ over the past half century.

In addition to studying level of generational differences in cognition, we have also examined generational differences in rate of change over 7 years in parent–offspring dyads at comparable ages. **Figure 3** shows 7-year changes for six abilities from age 60 to age 67. Again, we see higher levels for the second generation for all variables except number. What is most noteworthy, however, is the fact that while the parent generation showed decline over this age range, the offspring over the same age range show stability or modest increment, except for word fluency and number skills, which continue to show relatively early declines.

Generational Differences in Selective Demographic Characteristics

Gerontologists have long been aware that some of the age difference findings reported in the literature are clouded by the non-comparability between the young and the old of a variety of demographic characteristics. Often these differences have been interpreted as inevitable products of the aging process, and investigators have failed to correct for them. Some studies have shown that a number of these demographic differences actually have little to do with the aging process, but rather must be attributed to generational differences. Examples of substantial generational differences in demographic characteristics include educational level, age at first marriage, and age at birth of first child.

Over the range of birth cohorts represented in the SLS (1889 to 1973) there has been a steady increase in years of education, amounting to a difference in education of about 5.5 years between the earliest and latest cohorts studied. As shown in **Figure 4**, the increase has been close to 1 year greater for men than for women. Age at first marriage, as shown in **Figure 5**, declined by approximately 4 years from the earliest cohort to those born in the 1930s (the lowest level for men was reached by those born in 1938 and

for women by those born in 1931). From then on there has been a steady rise, which is most pronounced for women. As for the age of individuals when their first child was born, for women there has been a steady increment that leveled off at those born in 1959, but it has continued to rise for men. On average, parental age at birth of the first child is approximately 5 years older for the most recently born

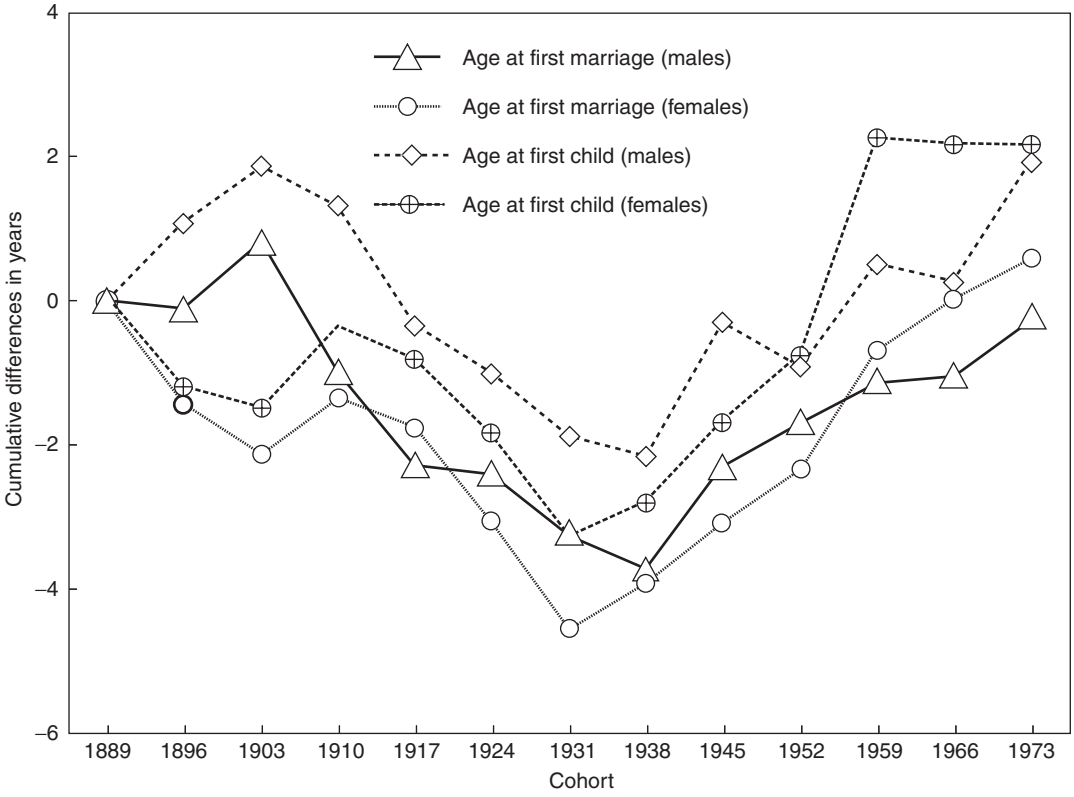

Figure 5 Generational differences in age at first marriage and age at birth of first child, by gender. than for the 1930s cohorts. However, recent adult cohorts did not have their first child significantly later than their grandparents.

Other demographic characteristics that may be important in aging studies include measures of mobility (changes in the location of one's home, changes of job, and changes in occupation). **Figure 6** shows average changes for cohorts born from 1889 to 1973 in the 5 years preceding each reporting date. Note that there is a very modest drop in residential and job mobility from the oldest cohort to that born in 1938; over the same cohort range there are virtually no cohort differences in occupational mobility. But mobility characteristics increase sharply for the baby boomer cohorts for all three measures, with residential and job mobility changes showing the most pronounced generational differences.

Generational Differences in Perceptions of Family Environments

A final set of findings of generational differences in geropsychology comes from the assessment of perceptions of family environments by older parents and their adult children within their current families and their families of origins (the families in which they were raised). Although one must always be careful in accepting the veracity of subjective data, particularly when it is retrospective in nature, there is substantial evidence of the utility of perceptions of behavioral dimensions.

In addition to comparing such perceptions across biologically related generations for large populations, it is also instructive to look at shifts in these relationships for successive birth cohorts, similar to those considered previously for cognitive and demographic variables. For example, it may be asked whether there are differences among parent–offspring pairs when offspring are classified into those born prior to World War II, those born during the war years and immediately thereafter, and those who belong to the baby boomers cohorts.

The relevant data inform us that there is a clear differentiation for parents and offspring in the perceived level of all family dimensions between their family of origin and their current families. Obviously the retrospective distance in time is greater for the parents than for the adult offspring. Nevertheless, shifts in the quality of family environments are reported consistently over persons' own life course. The

current families are seen as more cohesive and expressive but also characterized by more conflict than was reported for the families of origin. There seems to be a shift toward greater openness and engagement in family interactions. More intensive family interactions are also reflected by intellectual-cultural and active-recreational orientation from the family of origin to the current family. Along with these shifts there is the

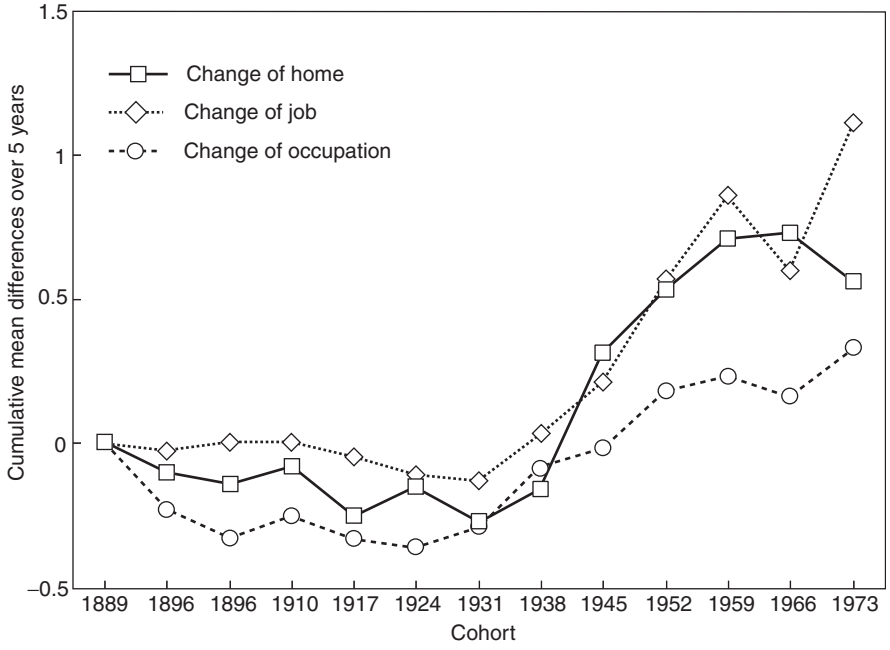

Figure 6 Generational differences in frequency of change of job, occupation, and place of residence. overall perception of lower levels of perceived control, family organization, and achievement orientation (see **Figure 7**). Perhaps these judgments are another way of describing the increasing complexity of modern American families. Combined with continuing reports of ever-lower reported levels of social responsibility, this may well mean that the perceived role of the American family is changing from that of a primary socialization agent (operating on behalf of the larger society) to a more effective support system for the needs of the individual family member.

When the two-generation parent–offspring sample is broken down into four distinct cohort groups, it appears that the shifts in perceived family level occurred primarily for perceptions of the family of origin. Perceptions of the current family are much more similar across birth cohorts. This is reasonable, since judgments of the current family reflect the current societal climate common to most, while perceptions of the family of origin reflect different secular periods for which successive cohorts described their early family experiences.

Substantial correlations between parents' description of their current family environment and their offspring's description of their family of origin provide supporting evidence for the continuity of family values and behaviors. Even though there is a substantial time gap in the period rated, these two ratings do refer to the same parental family unit. This similarity of perceptions across generations was particularly strong for three dimensions most closely reflective of value orientations (achievement, intellectual-cultural, and active-recreational) and for family organization.

It is interesting to note that the magnitude of perceived similarity across generations differs by gender pairing and by specific family environment dimensions. It is not surprising that the strongest similarity of family environment perceptions occurs within mother–daughter pairings, even though frequency of contact between adult mothers and daughters is only slightly greater than that for other relationship combinations. In fact, the intensity (frequency) of contact between parents and offspring seems to have virtually no impact upon the similarity of reported family environments.

Glossary

Allele – One of many particular forms of a gene.

Cellular Senescence – The limited proliferative potential of human somatic cells and of cells of many other species that limits the number of replicative divisions that a cell can undergo; also called replicative senescence.

Gene – The basic unit of inheritance; typically refers to the coding sequence and control regions for a single protein or to a DNA region controlling synthesis of a particular gene product.

Genotype – The entire set of genes and alleles of those genes carried by an individual organism.

Gerontogene – A gene involved in aging; usually refers to genes whose normal function involves a shortening of life.

Heritability – Refers to the fraction of the variability in a population that results from genetic effects rather than from environment or chance.

Longevity Assurance Gene – A gene that normally functions to extend life.

Mutant – An organism carrying a mutation, usually one causing an easily observed change in phenotype.

Mutation – An alteration in the DNA leading to a new allele; typically leads to some observable difference in phenotype.

Phenotype – The visible characteristics of an organism, its appearance.

Segmental Progeroid Diseases – Diseases that mimic aging in that they accelerate some, but not all, physiological processes normally associated with aging.

Introduction

Genetics is both a discipline and a research tool. Genetics as a research tool has allowed the identification and reading of the common thread uniting all life on earth, the DNA molecule. Genetics as a discipline has united the biological and biomedical sciences by providing a common framework and tool kit for exploring the multiple processes of life and by providing a common terminology that allows researchers in numerous disparate fields to share information through the identification of genes and the interpretation of their DNA sequence. All of these meanings of the term genetics come into play in this review. Genetics refers to the underlying genetic elements making up living species as well as to the discipline that analyzes these processes. The current state of knowledge of the genetics of aging in humans will first be reviewed. Next studies in model systems that are beginning to reveal the underlying processes associated with aging will be described; much of this work has relied on life span as an end point in the assessment of aging. Finally, we will review the current state of affairs concerning molecular genetic analyses of aging.

Genetics Studies in Humans

Genetic studies of aging in humans have proceeded through several distinct routes. First has been the study of an *in vitro* model of aging: the limited number of cell divisions observed in most, if not all, non-transformed cells in culture, which we will call cellular senescence. Second has been the study of rare diseases that have been termed segmental progeroid diseases to suggest that in each of these diseases many, but not all, aspects of aging have been accelerated. Examples of these include Hutchinson-Gilford disease and Werner's syndrome. Third, both pedigree analysis and population studies have begun; this work may ultimately reveal genes or, at least chromosomal regions, that are associated with various human diseases and with alterations in length of life. Finally, twin studies and other designs have recently been used to begin to determine what proportion of the variation in age-related function or age at death is genetically determined.

Cellular Senescence

Some 35 years ago it was recognized that human cells could not go on dividing forever in tissue culture. This revolutionary observation, cellular senescence, countered classical observation by giants in the field. The acceptance of this fact was quickly followed by the suggestion that the finite proliferative capacity of tissue culture cells might be a model for, or even the basis of, normal human aging. The 1970s saw careful characterization of the aging phenotype of these cells and the finding that the proliferative capacity of these cells declines in parallel with the age of the donor. This fact together with the observations that cell lines derived from certain 'segmental progeroid diseases' have more limited proliferative potential and that proliferative potential correlates with the maximum life span potential of a species, have led many to accept that cellular senescence is a valid model of human aging. More recent evidence seems to suggest that cellular senescence may well be cellular differentiation; many similarities between cellular senescence, as studied in the fibroblast, and muscle cell differentiation can be made. Although the dispute cannot be resolved at this time, it seems likely that cellular senescence is a model for terminal differentiation and has relevance to some *in vivo* cellular aging phenomena.

The analysis of human tissue culture cells is much easier than is the study of intact organisms, and the study of these cells has allowed significant advances in our understanding of cellular processes. The genes responsible for cellular senescence are being identified, and their role in limiting the proliferative capacity of these cells is being elucidated. A surprising result of genetic studies is that in immortalized cell lines, the immortal phenotype is recessive (i.e., a lack

of some essential protein is probably responsible for immortalization rather than the converse). Immortalization seems to result from mutation of any one of four complementation groups; three of these groups have been localized to individual chromosomes. Two recent developments serve to illustrate these points. A gene, variously termed *SDI1*, *WAF1*, or *CIP1*, has been cloned that seems to be one of the players causing cellular senescence. It has been proposed that p21, the protein product of this gene, is involved in regulating the cell cycle by inhibiting cyclin-dependent kinases, thus serving as a checkpoint regulating entry into the S phase of the cell cycle. A second process has also been tentatively identified as a determinant of cellular senescence: the limited proliferative capacity of the telomeres (chromosome ends). Somatic cells lack telomerase – an enzyme that has an RNA cofactor and is used to get around the potentially deadly problem that the 5′ ends of the chromosome cannot be replicated without priming – an absolute requirement of DNA polymerase. The telomere model then states that, in the absence of telomerase, telomeres continue to shorten until chromosome instability and other problems occur. Most, perhaps all, human tumors have reactivated the telomerase allowing indefinite replication. It could be that the absence of telomerase in normal somatic cells is an additional assurance preventing oncogenesis and tumor formation. In any case, these findings have major therapeutic implications and have served as an important focus for current research into cellular senescence (*see* Cellular Aging: Growth Factors and Cellular Senescence).

Segmental Progeroid Mutations

Several human genetic syndromes that accelerate some, but not all, aspects of aging have been described. None of the many syndromes described accelerates all aspects of aging, and thus these are sometimes collectively termed segmental progeroid syndromes. Generally, mutations are deleterious because they eliminate or modify functional DNA sequences leading to an alteration at the protein level; thus, it is expected that mutations should shorten the life span. Hutchinson-Gilford and Werner's syndrome are two diseases commonly called progeria, but Down's syndrome (trisomy 21) accelerates more of the various aspects of normal aging. Werner's syndrome, a recessive, adult-onset progeroid disease has been shown to be associated with extensive genomic deletions of 20 kb and greater. Werner's has been mapped to chromosome 8 and cloning of the gene is imminent. Another progeroid syndrome that has received much attention in the popular press is Hutchinson-Gilford disease, also called progeria because it is manifested as rapid aging in children who carry this autosomal dominant disease. It remains in doubt whether these progeroid diseases reflect the normal aging process or only 'mimic' it.

Markers Associated with Longevity

In an effort to find human gerontogenes, a number of marker association studies have been undertaken. In these studies longevity is shown to be associated with certain alleles and genes within small regions of the human genome by characterizing genetic markers at certain candidate loci. The *HLA* locus has long been a candidate for determining human longevity and at least two studies have suggested that certain *HLA* haplotypes may be associated with increased longevity in at least some populations; the validity of these marker associations at the *HLA* locus remain to be proven. *ACE* and *APOE* have been tested as candidates and both have been found to be associated, although not consistently in the direction predicted. These findings may not be too surprising because of the strong associations between the alleles studied and their effects on health. For example, *APOE-ε4* has recently been associated with frequency of onset and rate of progression of Alzheimer's disease (AD), and certain alleles of the *HLA* locus have long been associated with susceptibility to or more rapid progress of various human diseases (*see* Markers of Aging).

Diseases Associated with Aging

Huntington's Disease A large number of genetic diseases show age-dependent levels of expression and/or penetrance. These include two diseases that are expressed especially late in life: Huntington's disease (HD) and AD. HD is a disease leading to degeneration of the nervous system. The average age of onset is 35–42 years, and the gene segregates as an autosomal dominant. Despite the fact that HD was the first human gene to be mapped using restriction fragment-length polymorphism (RFLP) mapping (chromosome 4), it was only cloned in 1993. That cloning was based on the supposition that the phenomenon of 'anticipation' (seen in HD as an ever-earlier age of onset in succeeding generations) might result from the expansion of a trinucleotide repeat sequence similar to those that have been implicated in a number of other human neurological diseases. An expanded $(CAG)_n$ longer than the normal range was found in all disease families examined suggesting that this was the HD gene. The coding sequence makes a predicted 348-kDa protein of unknown

function that shows no homology to any other cloned gene.

Alzheimer's Disease The best example, and certainly the best studied, age-related genetic disease in humans is AD. About 2–6% of people over 65 show symptoms of AD; the prevalence of this disease increases strikingly with age, such that by 85 as many as 40% of the population may show symptoms of AD. Pedigree analysis has allowed the localization of three distinct genes that are involved in the specification of familial AD (FAD). Rare mutations in the gene encoding the precursor protein of Alzheimer-associated amyloid on chromosome 21 are associated with FAD, but these account for only 2–3% of the affected individuals. Genes on 14 and 19 are susceptibility loci associated with late-onset (after age 65) and early-onset forms of the disease, respectively. There are still other pedigrees in which the susceptibility to FAD is unlinked to these three loci, which suggests that there are still other loci to be found. Thus FAD is clearly very heterogeneous in origin. A further complication is that the degree to which FAD is genetic is uncertain, with estimates ranging from 10–100%. A marked association with the *APOE* locus on chromosome 14 has been shown and replicated in many studies, such that individuals homozygous for *APOE-ε4* have an almost eightfold increase in the probability of getting AD at almost any age when compared with people carrying other alleles of *APOE* (*see* Dementia).

Heritability of Aging and Life Span

From analysis of parent–offspring correlations in life span and differential life spans of identical and fraternal twins, estimates of the fraction of the variation in life span that is under genetic control (the heritability) can be made. Human heritability studies suggest modest amounts of inheritance of longevity, perhaps on the order of 10–30%. Longitudinal studies of various traits suggest that the heritable proportion may change with age in rather surprising ways; unfortunately, little of this material has been published. An other recent area of inquiry is into the genetics of demography. Clearly genetic variation within and between populations plays a major role in affecting demographic predictions of survival.

Model Systems

Genetic studies of aging and age-associated effects can be most effectively carried out in species other than humans. The most popular model systems have been mice; however, the long life span and high expenses of maintaining rodents have led a number of investigators to study invertebrate models including *Drosophila melanogaster* (a fruit fly), *Caenorhabditis elegans* (a nematode), and several fungi including *Neurospora crassa, Podospora anserina*, and *Saccharomyces cerevisiae*. Advantages of invertebrates include lower expenses, a life span of weeks or months (instead of years), and much more powerful methods for genetic analysis, including selective breeding and the identification of mutants that have altered aging processes. Because many genetic alterations can shorten life span, most genetic studies have involved the study of longer-lived strains. Only in invertebrates have mutations that lengthen life span been found.

Early studies largely focused on proving that genes play a role in determining longevity or rate of aging and on quantitative estimates of this genetic component through estimations of heritability. Genetic studies have used one of three different approaches (polygenic analyses, identification of mutants, and construction of transgenics). Each approach is based on a different level of background knowledge, the different fields of training of the investigators, and the desired level of understanding. The most powerful approach for understanding biological processes – the identification of mutants and the subsequent cloning and molecular dissection of the underlying molecular mechanisms responsible for the phenotypic alterations – have only been pursued in a few species, and only in *C. elegans* has the approach really been pursued in any depth. In the last 10 years a number of studies have begun to yield useful information. A molecular understanding of the basis of extended longevity is beginning (*see* Models of Aging: Invertebrates, Filamentous Fungi, and Yeasts; Models of Aging: Vertebrates).

Polygenic Approaches

Many different alleles for many genes can be found in natural populations. Several approaches have taken advantage of this variation: selective breeding, the analysis of recombinant inbred progeny, and the construction of stocks in which single chromosomes from wild populations have been introgressed into a standard stock. These studies are invariably polygenic in that many genes (sometimes hundreds) can contribute to the differences in phenotype, including differences in life span and other life history traits. Such studies have shown significant genetic components for longevity in mice, in fruit flies, and in the nematode. Typical heritability estimates are in the range of 15–30%. These studies also clearly demonstrate that many genes affect this variation in life span.

Mice Smith and Walford observed that strains congenic for the *H-2* locus (part of the mouse major histocompatibility complex [MHC]) showed significant differences in longevity and that certain *H-2* alleles were associated with increased longevity. These strains were also associated with altered levels of phytohemagglutinin response, DNA repair, free radical scavenging enzymes, and cAMP levels. Affects of the *H-2* locus on age of onset of reproductive cyclicity have also been shown. Frequency of cycle time and age of loss of reproductive potential have also been related to *H-2* genotype. Several other genetic studies have shown that the *H-2* locus or genes near to this locus do have an effect on life span, although the effect of this region may be no more than many other regions of the genome. In crosses between *C57*/DBA F_1 mice and their DBA parents, the largest single-locus effect on average life span was associated with the *B* coat color gene rather than with the *H-2* locus, but if one looked at 90th percentile of survival, the *H-2* locus showed the largest effect. Moreover, there was a small but significant effect of *H-2* heterozygosity, with hybrid strains being slightly longer lived. This study shows that many regions of the genome contain genes with alleles that affect life span and that *H-2* is not unique.

Life spans of 20 BXD (C57BL/6J X DBA/2J) recombinant-inbred strains were determined in an effort to identify the genes (quantitative trait loci [QTLs]) that affect length of life. The mean life spans of most of these strains were very similar with a few extremes (mean life spans of 479 days vs. 904 days). In a simple regression analysis, 43% of the loci had effects on life span. After more appropriate statistical analyses, there were six genetic regions that were significantly associated with length of survival; the *H-2* region on chromosome 17 was not one of them. Again the MHC region was not detected as having major importance in determining length of life.

Lines of mice have been bred for high or low immune responsiveness. These high and low antibody responder lines have mean life spans that are positively correlated with response to antigen ($r = 0.97$). Further quantitative analysis suggested that high responsiveness is almost dominant over low and that the mode of inheritance is polygenic with three to seven independent loci being involved in the response. A major problem with these selective breeding studies is that the low line had a mean life span of only 346 days, significantly less than the typical inbred line. Thus, much of the selective response is in the direction of shorter life span, as expected for mice that have a reduced immune response. Therefore, the alleles selected in this study are likely to be ones specifying lower immunity and consequently a reduced life span. Additional confirmatory selective breeding has recently been undertaken to test these earlier findings, but results of these new studies are not yet available.

Another approach to the genetics of aging has been through the study of senescence-accelerated mice (SAM). These mice were identified as spontaneous isolates in a mouse colony in Kyoto and their exact origin is unknown, but they probably resulted from the mating of two or more distinct strains. These mice have shorter than normal life spans and many aspects of the aging processes have been accelerated. They represent a progeroid model of mouse senescence and are being more widely studied despite the lack of knowledge surrounding their origin. Because certain aspects of senescence seem to be differentially accelerated in one or more SAM strains, they may represent a useful resource, but it remains to be proven that the senescence acceleration reflects normal aging rather than merely mimicing certain aspects of the normal aging processes that have been elicited as a result of one or more mutant alleles in a SAM strain.

Drosophila Despite the failure of selection directly for extended life in fruit flies (*Drosophila melanogaster*), several groups have successfully selected for extended mean and maximum life span by selecting for late age of reproduction. These selections have been performed in outbred populations of fruit flies that had been captured and kept in the laboratory for some time. These selections resulted in an almost twofold increase in longevity and significant increases in late-life reproduction. The increased late fertility was associated with decreased early fertility. Quite surprising is the fact that this increase in life span is not seen in all environments and is dependent on larval density. Under low larval density no differences between selected and control strains were observed. This dependence on growth conditions may explain the earlier negative reports for selection for longer life and also points to the extreme care that must be used in performing selections or other quantitative genetic analyses on life span and probably on other life history traits as well. These environmental effects could also point to important physiological and environmental interactions that could be exploited to determine the molecular basis of this differential longevity.

Longer life is also associated with reduced ovary weight early in life and increased resistance to starvation, desiccation, and other environmental stresses. Indeed, selection for increased desiccation resistance yields longer-lived lines. These responses result from the action of many (even hundreds) of

genes or QTLs. Attempts to dissect the process further have revealed regions of the genome that may be especially rich in QTLs, but further dissection has met with little success, perhaps because so many QTLs are involved. Generally, the results are consistent with a trade-off between early fertility and extended life span as might be predicted by the evolutionary theory of aging. However, these are not critical tests of the theory because so many genes are being selected for simultaneously and thus the trade-off may not be at the level of the individual gene. Moreover, it is bothersome that numerous failures to confirm the theory have been discounted by the proponents of this theory. There has been no clear demonstration in *Drosophila* of the pleiotropic action of a single gene on both life span and some other life history trait, such as development or fertility. Moreover, classical studies by Maynard Smith, although frequently cited as showing such pleiotropy, have not been adequately replicated by modern laboratories studying these processes.

The long-lived strains were also resistant to a variety of environmental stresses including free radicals. Indeed at least two different groups have suggested that the physiological basis of the extended life is increased resistance to reactive oxygen species. A variety of other specific physiological alterations have been implicated in these long-lived strains, but none of these alternative models have been critically tested in these selected lines. At least one attempt to critically test the involvement of superoxide dismutase (SOD) in extended life resulted in a failure to detect a significant effect, but this finding was dismissed post hoc because this locus represented only one of hundreds of genes that were segregating in the population. This apparent lack of ability to refute this model suggests that selective breeding for increased life span in *Drosophila* is not likely to yield additional relevant insights into the molecular and physiological basis of life extension; for that other approaches are needed, as described next.

Nematodes Although several species of nematode have been used to study aging, *Caenorhabditis elegans*, a small, free-living soil nematode that was initially chosen by Sydney Brenner to study development and behavior, has proven to be the nematode of choice for all recent studies because of its excellent genetics. Several thousand genes have now been closed in *C. elegans*, and most of the genome is readily available as an ordered overlapping collection of cosmids and yeast artificial chromosomes (YACs), which greatly facilitates cloning strategies. Procedures for transforming *C. elegans* have been worked out. Hermaphrodites (XX) reproduce by self-fertilization whereas males (XO) occur only rarely but are useful in stock construction. Each hermaphrodite produces about 250 to 300 offspring during her 5-day reproductive period at 20°C. The average life span for an unmated wild-type *C. elegans* hermaphrodite is approximately 3 weeks, which makes this an attractive model system. All somatic tissue in the adult is post-mitotic.

Because *C. elegans* is an inbreeding species, another approach has been used to identify QTLs that specify longer than normal life spans. Several studies have used recombinant inbred strains, which can be generated very easily due to the self-fertilizing mode of reproduction of *C. elegans*, to ask questions about heritability, genetic trade-offs, and number of genes involved in the specification of life span. Reasonable heritability estimates of 15–30% have been reported; estimates suggest that approximately seven QTLs are involved in determining life span. Some trade-offs between early and the late fertility have been identified, but no trade-offs between fertility and life span or rate of development and life span have been found, although more detailed studies are underway.

Two studies have examined crosses between two wild-type strains (N2 and Bergerac) and identified QTLs that are responsible for increased life span. Both studies localized these genes to various chromosomal regions using the Tc1 transposable element to determine map position and strain of origin; polymerase chain reaction (PCR) strategies have been developed that use Tc1 as a molecular marker that can be assayed in individual worms and used to position QTLs. One approach was to examine populations of worms that were segregating these markers and then to see which markers were selectively enriched in older worms, which would indicate that a QTL of interest was nearby. This study found evidence for genes on chromosomes 2, 4, and the X that may be involved in prolonging life and that a number of loci may be selected against in such populations. Nonetheless, this study was not designed in a way that trade-offs between life history traits could be detected. The other study used recombinant-inbred strains and found that QTLs for life span were found on chromosomes 2, 4, and the X and QTLs for fertility on chromosomes 2, 3, and 4. In neither study was there any evidence for the trade-offs between fertility and life span that might be expected from evolutionary theories of aging.

Mutants

Mutational analysis represents the most effective means of identifying genes involved in a biological process. Unfortunately, mutational approaches are

Table 1 Genes shown to be involved in prolongation of life

Gene name	*Species*	*Effect of mutation*
LAG-1	*S. cerevisiae*	Overexpression: increased number cell divisions; other mutations: complex effects
LAG-2	*S. cerevisiae*	Null mutant: decreased number cell divisions; overexpression: increased number cell divisions
SIR-4	*S. cerevisiae*	Semidominant mutation increase of 50% in cell divisions: altered telomere silencing?
age-1, etc.	*N. crassa*	Up to 10 × increase in conidial longevity
i	*P. anserina*	Double mutant *i viv* shows indefinite growth
gr	*P. anserina*	Double mutant *gr viv* shows indefinite growth
viv	*P. anserina*	Double mutant *i viv* or *gr viv* shows indefinite growth
age-1	*C. elegans*	65% increase of mean life span; little effect of fertility; increased resistance to many stresses
spe-26	*C. elegans*	65% increase of mean life span; > 90% reduction in fertility
daf-2	*C. elegans*	Twofold increase of mean life span (shift to 20°C); dauer constitutive (25°C)
daf-12	*C. elegans*	No effect alone; double mutants with *daf-2* increases mean life span fourfold (20°C); dauer constitutive (25°C)
daf-16	*C. elegans*	Blocks action of *daf-2*, *age-1*, and *spe-26*
clk-1	*C. elegans*	Extends timing of development, some neurological events, and life span

difficult to apply to aging because of the difficulty of identifying mutant strains with altered aging processes or longer life span. A list of genes that when mutated affect length of life is given in **Table 1**. In fungi several mutations that affect life span have been identified. A series of mutations affect conidial viability in the fungus *Neurospora crassa* leading to huge extensions of 'shelf-life' in these mutants. Clonal viability is affected by mutations in a series of genes in *Posdospora anserine*, where either *i viv* or *gr viv* double mutants show indefinite ability to grow. Recently, cellular senescence in the yeast *Saccharomyces cerevisiae* has been used as a model for aging, and mutations in two genes that are differentially expressed over the replicative life span (*LAG-1* or *LAG-2*) can prolong the number of cell divisions. Also mutations in four genes have been found to lengthen the replicative life span of yeast; one of these is *SIR-4*, which plays a role in chromosome silencing.

Although a few studies have been carried out in *Drosophila*, all of the interesting work has been performed in the nematode *C. elegans*. The self-fertilizing nature of this species and the lack of inbreeding depression coupled with the existence of the dauer (an alternative larval stage that can remain immature for months and then resume development to a normal adult with a normal life span) make this species especially attractive for such studies. Screens for long-lived mutants were carried out some 15 years ago using a replica-plating strategy. These screens produced several long-lived strains, but only one of them could be studied subsequently; all mutations were in the first gene thus identified, which was named *age-1*.

age-1(*hx546*), the mutant allele most studied, averages a 65% increase in mean life span (25.3 days vs. 15.0 days) and a 110% increase in maximum life span (46.2 days vs. 22.0 days) at 25°C. Long-lived (Age) mutant strains have no change in rate of development, in behavior, or in other life processes and only modest decreases in fertility, if any at all. Some of the most exciting work in *C. elegans* involves the cloning of genes whose protein products are unknown, a process known as 'positional cloning,' and a great deal of effort has so far failed to reveal a clone for *age-1*, largely because of the difficulty associated with the positional cloning of genes affecting length of life.

There are four other published reports of mutations in *C. elegans* that result in longer life. (a) Mutations in *spe-26* dramatically reduce sperm formation and result in life extensions of about 80% for the hermaphrodite and the mated male. (b) *daf-2* mutants cause dauer formation under temperature-sensitive conditions in which dauers are not usually seen and result in a more than twofold extension of mean life span at the permissive temperature; this extension is blocked by the action of *daf-16*. *daf-2* mutations also affect other life history traits marginally in that reproduction can go on at very low levels for weeks. (c) *rad-8* mutant worms exhibit almost 50% longer mean life span than wild type at 16°C and normal oxygen tension. (d) *clk-1* is a mutation that lengthens life 20–50%, depending on the allele, and also affects many other 'timing events' including the length of embryonic and larval development, fertility and the rate of egg production and behavioral timers such as rate of pumping, food ingestion and defecation. Recently published reports suggest that several other dauer-constitutive mutants also affect length of life. *daf-23* doubles the length of the normal adult life span, and *daf-12* mutants interact with *daf-2* to cause an enhancement of the life-prolongation phenotype to an almost fourfold increase in mean life span. The

dominant, dauer-constitutive mutant, *daf-28*, can also prolong life slightly. Other dauer-formation mutants define a signal-transduction pathway in which homologs to mammalian genes involved in signal transduction can be identified, although the roles of the genes defined above remain unclear. *daf-1* codes for a translational product that has homology to a serine-threonine kinase in the *raf* superfamily and which may be a cell-surface receptor. *daf-4* is the nematode homolog of human bone morphogenetic protein (BMP) receptor with the *daf-7* gene encoding BMP. Finally, *daf-12* encodes a transcription factor of the steroid-thyroid hormone receptor superfamily. Note that none of the cloned genes results in life extension.

Our lab has discovered that most, if not all, long-lived mutants of the nematode are more resistant to many environmental stresses. The bases for this statement are twofold. First, four of the long-lived mutants (*age-1*, *daf-2*, *daf-28*, and *spe-26*) are more resistant to two distinct stressors (thermal stress and UV irradiation). Only *age-1* has been shown to be resistant to reactive oxygen species; the *clk-1* mutation has not been tested for any stressors. Second, induction of thermotolerence via non-lethal heat stress results in a longer life span. *age-1* mutants have higher levels of Cu-Zn SOD and catalase at later ages. *age-1* mutants also respond to thermal stress by expressing heat shock protein 16 (*HSP-16*), an α crystalline homolog, at higher levels than does the wild type. Thus, the *age-1* mutation may be uncovering a common genetic pathway that is involved in the mediation of stress response from a variety of environmental stresses.

Transgenics

The ultimate demonstration that a particular process is affected by a particular gene is to show that altering a single gene affects that particular process. The best way to demonstrate this causality is to alter a particular gene and to demonstrate that this affects the phenotype of interest, for instance, life span. Exactly this approach is used in the analysis of transgenic animals (mice, yeast, fruit flies, and nematodes) to demonstrate an effect on aging as a result of alterations in one or a few genes. This approach is just beginning to be applied to a variety of systems to test specific genes for their effects on life span and/or rate of aging.

The best example of the use of transgenics is in *Drosophila*, where transgenic strains that overexpress both Cu-Zn SOD and catalase by 20–50% have been constructed. These transgenic strains had longer life spans and lower rates of mortality than did the wild type. There was also a decrease in the rate of accumulation of oxidized protein and a delay in loss of physical performance. It should be noted that transgenics for both SOD and catalase had life extensions that were much better than the sum of the two single transgenic strains alone. This might be suggested by the involvement of catalase in detoxifying the hydrogen peroxide radical produced by Cu-Zn SOD.

Transgenic strains of *C. elegans* have been produced in an attempt to clone the *age-1* gene by complementation with a normal exogenous gene, but the cloning is still underway. Several transgenic strains of mice have been examined for their effects on aging and life span. Mouse transgenic strains that express the Aβ peptide in neurons show increased neurotoxicity and reduced life spans and probably show an elevation in the level of apoptotic cell death. Mouse strains carrying extra copies of Cu-Zn SOD have shorter life spans and display some of the toxic effects normally associated with Down's syndrome. Other mouse transgenic strains are currently being tested to see what effects loss of different genes might have on life extension and other age-related processes.

Molecular Studies of Genes and Gene Action

DNA Repair and Somatic Mutation

Almost 60 years ago the suggestion was made that mutations in somatic cells could cause aging. The theory has been extensively tested in several invertebrate metazoans and thoroughly disproved in those short-lived insects. It is unclear whether somatic mutation is a general cause of aging or senescence in most mammalian species, although DNA rearrangements have been implicated in many processes during mammalian aging. Three areas of study continue to be actively pursued as possible causes of aging and senescence in mammals: deletion and rearrangements of the mitochondrial DNA, telomere shortening, and somatic mutation as a cause of cancer.

Convincing evidence has been obtained showing that disruption of the mitochondrial genome specifies senescence in a variety of fungal species. In metazoans there is much less direct evidence for a role of these deletions in causing aging and senescence. Mitochondrial DNA deletions have been found in humans, other mammals, and other higher eukaryotes but at low frequencies, prompting proponents of the theory to suggest that the already characterized deletions represent only 'the tip of the iceberg.' The prevalence of several well-characterized

deletions in older people is unclear and is the subject of active investigation by many groups. Deletions of various portions of the mitochondrial genome have been implicated in a variety of human diseases, but there is no direct support for a causal role for mitochondrial deletions in mammalian senescence.

It is clear that chromosomal rearrangements increase dramatically with increasing age, and several human diseases that cause chromosomal instability have some of the attributes that one might expect for an 'accelerated aging' syndrome. For example, Werner's, an adult-onset progeria syndrome, results in a large increase in the frequency of chromosomal aberrations *in vivo*. Cell cultures from Werner's patients have 10- to 500-fold elevations in the rate of new mutations. Much of the age dependence of cancer has been attributed to new mutations and ionizing radiation both *in vitro*, and in studies with Hiroshima survivors it has been shown to cause elevated levels of malignant transformation. There is also an age-related increase in mutation frequency in human lymphocytes. Unfortunately the relationship for other age-related diseases (dementia, arthritis, osteoporosis, etc.) are not so simple, and there is little evidence for the involvement of mutations in these processes.

Telomeres (the ends of chromosomes) have particular problems during DNA replication that led to the hypothesis that telomere loss could cause the finite replicative life span of fibroblast cultures. Telomere loss does appear to be causally linked to cellular senescence in mammals, and telomerase (the enzyme that replicates telomeres) seems to be reactivated in most or all immortal cells. On the other hand, there is no direct support for a causal role for telomere loss in causing aging or senescence in mammals.

Regulation of Gene Action

Altered gene expression has been put forth as a central mechanism for causing aging and senescence for many years. Even evolutionary models for senescence, which are notoriously free of specific mechanistic predictions, suggest that altered regulation of gene expression might be seen in aged animals. Aging is not development, however. Unlike the situation in development where many genes are being up- and down-regulated at a variety of different stages in gene expression, aged organisms express almost the same complement of proteins as do young animals. A variety of attempts to find altered patterns of expression at the protein level have resulted in only few or no detectable alterations. At the RNA level some genes are modulated but few are turned on or off completely. However, again, unlike development, thee seems to be no large-scale alteration in transcription that is coordinately regulated by the synthesis of new batteries of transcriptional regulatory proteins.

Several systems, including senescent tissue culture cells, tissues, or hepatocytes from aged rats, and invertebrate species (fruit flies and nematodes) are deficient in the synthesis of *HSPs* after a variety of inductive events. In rat hepatocytes this defect has been traced to altered heat shock factor that is needed to induce transcription from the *hsp* genes. An exciting hypothesis is that the longer life span of *age-1*, *daf-2*, and perhaps other longevity mutants in *C. elegans* results from an up-regulation of genes that respond to a variety of environmental stresses. There are published reports of increased resistance to both oxidative stress and thermal stress, and unpublished work from our lab shows that all of the mutants so far identified as being gerontogenes may extend life by up-regulating a variety of different pathways, including resistance to UV irradiation.

By far the most complete understanding for the role of gene regulation in specifying aging and senescence comes from studies on tissue culture cells and may not be a model of aging so much as somatic differentiation. Several genes that are necessary for normal cell cycling are not expressed in senescent tissue culture cells. Several of these genes are regulated at the transcriptional level and are not turned on because of a lack of the E2F transcription factor. Senescent cells also differentially express cyclins and cyclin-dependent protein kinases and overexpress several growth inhibitors. The primary regulator of cell senescence still remains to be identified (*see* DNA and Gene Expression).

The Genetic Frontier in Aging Studies

Effective research strategies are underway, which will allow the identification of key genes and regulatory elements causing aging and senescence or limiting the normal life span. Several key systems, but especially senescent fibroblasts and nematodes, have allowed the identification of crucial genes and processes that limit the normal life span. We can look forward to more and more targeted experiments in mice and clinical experiments in humans that will test our understanding while developing pharmacological interventions into one or more aspects of the aging process. Genetic manipulations and technologies will play a crucial role in the coming era.

Gerontechnology

D C Burdick, The Richard Stockton College of New Jersey, Pomona, NJ, USA

Glossary

Gerontechnology (also called Gerotechnology) – The study of technology and aging.

Technologies – Tools or artifacts which when properly designed and utilized make life easier, enhance efficiencies, extend capacities, and/or that lengthen life.

Introduction

The age distribution of our population is undergoing rapid and dramatic changes as the Baby Boom cohort enters old age. Technological advances are likewise occurring at an accelerating rate. The intersection of these trends provides many opportunities and perils. Careful planning, interdisciplinary research, and product development leading to the appropriate use of technological innovations can help to enhance the quality of life for the aged and reduce the potential costs and burdens associated with population aging.

This article discusses key intersections between technology and aging. It begins with definitions and a brief snapshot of the causes for the current enthusiasm about working with technology and aging. It then discusses selected sociological, psychological, and gerontological theories, which assist in understanding current and potential impacts of technological innovations. Next, it reviews several domains in which technology and aging are currently being studied and producing significant results. These include computers and the Internet, assistive devices, rehabilitative devices, environmental modification such as universal or senior-friendly design, and telemedicine. The article ends with a brief sketch of current and historical leaders in this emerging field.

As humans advance in age, predictable changes occur in their biological, psychological, and social functioning. Sensory, perceptual, and cognitive abilities undergo many predictable changes (not all negative). The same is true for physical ability (including declines in strength, stamina, and balance; particularly in the absence of exercise). In short, with advanced age, humans are in many respects less able to respond effectively to a variety of environmental demands.

Yet, contrary to previous beliefs, many older adults maintain and enhance their various capabilities well

into their very late years, most wish to continue to live full and meaningful lives, and many are becoming empowered to take the appropriate steps necessary to make these goals a reality. This is particularly important because the life expectancy at age 65 is currently nearly 20 additional years. Steps must be taken to assist seniors with maintaining well-being mentally, physically, socially, and spiritually. Technologies can assist with this goal in a wide and expanding variety of ways.

As societies advance through technological innovation, they too undergo sometimes-predictable change. Employment, education, leisure, political, social, and spiritual domains may all change. It is the intersection of these two mega trends – aging population and aging individuals with rapidly advancing technology that most interest those who study technology and aging. The impact of cohort membership on this interaction must also be considered because cohort is often a better predictor than age. With increasingly deliberate actions, technologies are being brought to bear on the needs and interests of an aging population.

The study of technology and aging is referred to as either gerontechnology or gerotechnology, often interchangeably. This article uses the former as the preferred term to connote all work involving technology and aging intersections. At a recent professional meeting, Jim Fozard (a longtime leader in this field) noted that "gerontechnology provides a systematic way to organize and understand research and education related to technology and aging." One major genesis of this study comes from within the field of human factors and ergonomics (itself a multidisciplinary endeavor involving psychologists, engineers, architects, etc.). Core concerns of this field include several micro-level interactions of individual persons (or their component systems – sensory, perceptual, cognitive, or motor) with specific technological interventions and interfaces that are part of the environment (*see* Human Factors Engineering and Ergonomics).

Gerontechnology also considers many macro-level and social considerations and involves a wide variety of disciplines. For example, it considers what sorts of useful information seniors can find on the Internet and to what end, while at the same time it considers such issues as why older men have difficulty with double-clicking the mouse and how more useable pointing devices might be developed.

The key point is that by linking advances from the multidisciplinary study of gerontology with work in fields such as rehabilitation engineering, architectural design, human factors and ergonomics, and the computer and telecommunications fields, there is currently a significant increase in the number and nature of successful interactions of aging humans with technology at the micro, mesa, and macro levels. These interactions have begun to positively influence health, well-being, and life satisfaction, and show great promise for reductions of cost associated with long-term care. A wide variety of useful tools for independent and successful aging is being developed, produced, and marketed for consumers at an accelerating pace as the Baby Boomers age.

Technologies are variously defined as tools or artifacts, which, when properly designed and utilized, make life easier, enhance efficiencies, extend capacities, or even lengthen life. Technologies can be classified in several ways, for example, as high, medium, and low, or as hard vs. soft (as in hardware or software). Technologies of all levels and types may have a positive impact on seniors, but negative impacts are as likely if the technologies are not properly designed. What seems to have emerged in recent years is a clear intentionality to promote the former.

Selecting appropriate technologies of any kind involves important decisions regarding cost, ease of use, dependability, and consequences of product failure, safety, and adaptability to changing user needs. The common failure of technologies to produce improvements in the lives of elders is of great concern to those who study technology and aging. In fact, numerous examples from both the distant and recent past show less than optimal attention to seniors' needs, wants, and capacities. In a 2000 congressional briefing on technology and aging sponsored by the American Psychological Society, Wendy Rogers reported that users of a commonly owned blood sugar testing kit made clinically significant errors more than 60% of the time.

At the micro level, Rogers and associates from the multi-campus CREATE Centers (Center for Research and Education on Aging and Technology Enhancement) have done a careful task analysis of many household technologies frequently used by older adults and repeatedly demonstrated that failure of proper use resulted from poor design, poor instructions, or a combination of both. Research at places such as CREATE, Gerontech–The Israeli Center for Assistive Technology and Aging, and SENTHA at the Technical University of Berlin, to name a few, provide exemplars of best practices for sustaining and accelerating groundbreaking applied research in technology and aging.

At the macro level, Lesnoff-Caravaglia and others have turned their attention to moral and ethical issues, which must receive more attention. We must not lose sight of the big picture. It is important to pose these questions now as a cautionary note

because the remainder of this article primarily focuses on the good that may be derived with the use of technology. Questions arise such as the following: Under what circumstances and for who is the sacrifice of privacy worth the benefits of having one's house wired for automated activity tracking and analysis systems? Why do we continue to settle for perhaps 100 000 deaths per year in the United States alone due to medical mistakes, and why have we not applied the successful safety standards and practices of the aviation industry to the use of technologies in health care? What happens to social institutions such as family, work, and retirement if (when) technological advances allow for average life expectancies of 160? How is our perhaps overdependence on technology making it more difficult to emotionally adjust to aging and to understand the immutable fact of limited mortality?

Fitting Together the Puzzle Pieces

Why, at the beginning of the twenty-first century, is there a dramatic acceleration of interest and innovation in technology and aging? Why are products reaching the market as researchers, practitioners, designers, and marketers display heretofore unseen intentionality in linking human aging to technological devices? The most obvious answer is market forces related to the aging of the Baby Boomers in first-world countries. Seventy million strong in the United States alone, they have commanded our attention throughout their lives, and now is no different. Several other pieces of this puzzle are now falling into place:

- A specific sense of urgency associated with the aging of the Baby Boomers based on the specter of a growing burden to society as they get old. Technology is viewed as a potential cost saver
- Aging and technological advance are no longer viewed as independent, unrelated, or incompatible
- Research findings on aging have evolved and demonstrate that although many human capacities decline with advanced age, others hold up quite well or even increase. Many others are amenable to intervention aimed at restoring function or slowing decline
- Thirty years of research on environments and aging provides a solid understanding of the multifaceted influence of various micro and macro environmental factors on human behavior and is being applied with the notions of sustainability, usability, universal and senior-friendly design, and smart house technologies
- A belief in the power of interdisciplinary approaches has gained favor, making gerontology and gerontechnology more valued. Improved collaboration and communication channels between basic researchers, product development, and marketing enterprises have begun to emerge. Examples include work by university research labs such as CREATE, corporate attention by Microsoft, Intel, and Honeywell, and so on
- There is a new optimism, previously unseen, that technological products can be useful for a broad variety of older adults
- Entrepreneurs and venture capitalists are joining the endeavor. While this began in the late 1990s, the dot-com bust of 1999 had created a temporary delay.

Optimism and a shifting belief system about aging probably have had the greatest impact. We are finally moving away from a blame the victim view that considers technology and aging to be somewhat oxymoronic. 'He is too old to program his own VCR; let his grandson do it' is being replaced with 'By providing basic training and consumer choice of control/display interface, a range of older users can effortlessly modify environmental, entertainment, and food preparation controls from touch screen panels strategically located around the house, and remotely from their personal information managers'.

The Technology and Aging Imperative

Technology has been widely touted as a quick fix for the anticipated escalating costs associated with aging Baby Boomers. The notion is that effectively and efficiently deployed technologies can cut cost and reduce the burden of care. A recent example of this enthusiasm was the December 2005 US White House Conference on Aging. This decennial event, charged with developing recommendations for research and action in the field of aging, has been largely responsible for setting the groundwork for the enactment in 1965 of Medicare, Medicaid, and the Older Americans Act. The centerpiece of the 2005 WHCoA Exhibit Hall was the Imagine Pavilion of the Center for Aging Services Technologies (CAST), which touted the promise of emerging technologies to help rein in out-of-control health-care costs, to assist family caregivers, to promote enhanced or prolonged life satisfaction, and to compensate for what Arthur Flemming referred to as the "vagaries and vicissitudes of aging" at the 1995 White House Conference on Aging. Indeed, technology is the

centerpiece of many key systems change initiatives currently being promoted by the US Administration on Aging. Similar government initiatives and encouragement are evident in Canada, Germany, and elsewhere.

Theoretical Contexts for Technology and Aging

Because modern technology will be increasingly counted on for its beneficial role in the lives of older adults, it is incumbent that great care be taken. The application of human factors and ergonomic principles to the design of various technologies, devices, and environments provides the greatest opportunity for using technologies to promote successful aging. Attention to such design principles can yield improved personal function in several important domains: mental and physical health, communication, mobility, independence, safety, job performance, life enrichment, and leisure.

Some of the current explosion of products is the result of careful study in the lab and of user-centered design. Unfortunately, some is not. Because of this, it seems particularly important to provide appropriate theoretical underpinnings, which can help to ensure that technological innovations intended for older adults are more positive than negative, more useful than harmful. Because the issues and concerns span several disciplines, it is necessary to build upon rich theories from several sources, which consider various aspects ranging from the macro to the micro level. These theories are included here for their significant heuristic value – they can guide careful research, encourage new questions, and perhaps encourage many innovative uses of technologies for and by older adults.

Sociological Theory: Modernization and Aging

Modernization and aging theory, proposed by Cowgill and Holmes in 1972, noted that while technological advances during the industrial era led to an increase in average longevity and in the proportion of the population that was old, it also precipitated a rather significant decrease in the overall social status of older adults. Surplus workers and surplus funds led to a formal retirement system, causing the aged to lose valued social roles and income. Non-workers at a time when this society had a strong work ethic were devalued, whatever their age. Rapid technological innovations coupled with a child-centered educational system made it difficult for older adults to keep pace with new technologies and other secular change. In sum, the theory proposes that complex interactive mechanisms operating on major social institutions stripped elders of status and control, left them behind in deteriorating neighborhoods, with less material resources, obsolete skills and knowledge, and the anomie of a forced retirement from a meaningful job and into an undefined role of retired.

These phenomena can be credited, in part, for the development of ageism, a pervasive stigma associated with old age, which was not evident in less developed eras and still is not in third-world regions of the world. It is also responsible in large part for the creation of the generation gap. Therefore, in many respects, technology was harmful to older adults.

The modernization and aging theory is instructive as we consider the influence of today's information technologies upon older populations. Will information age technology continue to marginalize the aged? Yes, unless we intentionally marshel technologies to do otherwise. Heidrun Mollenkopf of the German Centre for Research on Aging at the University of Heidelberg is one of the leading writers in this area. Doug McConatha's theory of e-quality, which systematically discusses the Internet's modern variants of the industrial age's institutions, shows how technologies can be intentionally used to assist the aged and transform the same institutions that previously had harmed elders. For example, accessible distributed education delivered via the Internet is helping to make our educational system less child/youth-centered and to encourage lifelong learning. An intentionality to use technologies to improve the lives of elders is gaining momentum and is readily apparent in research labs, Wall Street, and Madison Avenue.

Premature dependence upon new technologies is not always successful, however, at least initially. For example, in the United States during the first half of 2006, seniors, caregivers, physicians, pharmacists, and other providers are mightily attempting to understand and implement the prescription drug benefit portion of the 2003 Medicare Prescription Drug, Improvement and Modernization Act. A frequent news image is of seniors, with younger helpers, glaring at computer screens trying to decide which of the scores of drug plans best meet their needs. The general idea of making information available on the Internet is perhaps not the main flaw. After all, seniors are the fastest growing segment on the Internet. A more fundamental problem is the limited human cognitive capacity to comprehend and choose the best plan among multiple providers based on a variety of drugs and cost variables, and in the context of conflicting advice and advertising from various providers and advocates.

Other Theories from Other Sciences

Neither gerontology nor the other scholarly disciplines were immune from a negative view of aging exacerbated by industrialization. Research as recent as the 1980s focused primarily on a litany of age-related decline. Thankfully, and with important ramifications for gerontechnology, these disciplines have more recently developed a more balanced view and shifted focus to promoting healthy, successful aging. Influential books from the two eras symbolize the dramatic shift: Robert N. Butler's pessimistic *Why Survive? Growing Old in America,* penned in 1975, won a Pulitzer Prize; John Rowe and Robert Kahn, with substantial funding from John D. and Katherine T. MacArthur Foundation Genius Award countered with the optimistic *Successful Aging* in 1998.

Now a growing body of research and theory on aging from multiple perspectives (biological, psychological, and social) has shed the pessimistic stance and provides a more balanced view of aging. For example, research in geropsychology discusses hold vs. no-hold capacities in cognitive functioning. Sociological theory is more optimistic (e.g., activity and reinvestment theories have replaced disengagement for all but the very old and infirm), and recent biological research on exercise, nutrition, and telomeres, for example, has demonstrated real or potential means of slowing the aging process and compressing morbidity into the latest years.

As noted by Rowe and Kahn, successful aging depends on a wide variety of biopsychosocial processes, capacities, and opportunities. According to Rowe, optimism is perhaps the most important variable. Paul and the late Margret Baltes and colleagues have described the need for selection, optimization, and compensation (SOC) as individuals adjust to aging and disease. SOC provides a very useful roadmap for applying technology to aging.

Psychological Theory: Field Theory and Information Processing

Field Theory Lewin's field theory, first developed in the 1930s, proposes that in order to predict, explain, and control behavior we must understand the characteristics of the person and the environment in which behavior occurs. Simply stated, behaviors result from transactions between persons and their environments ($B = f(P, E)$). While this may seem intuitive today, it was the antithesis to Freud's popular notion that emphasized internal and unconscious drives as determinants of behavior.

As psychological theory and research developed during the twentieth century, theorists such as Klaus Reigel described the complex, interdependent, and dialectic nature of the influences on human behavior, and this led to an extension of Lewin's model ($B = f(P, E, P \times E)$). This expanded model, like its predecessor, has significant heuristic value for gerontechnology. For example, technology can be added to the model as an intervening variable, it can be viewed as part of the environment, or the model could be used to predict technology's behavior as follows: The behavior of technological innovations in the hands of seniors depends on the complex interactions of those humans within their environments. The next section further develops this theme by introducing Lawton and Nahimow's ecological theory and Fozard's further elaboration.

Information Processing The development of the information-processing model in cognitive psychology during the 1960s through 1980s laid the groundwork for significantly improved understanding of how humans acquire, interpret, and respond to environmental stimuli. It encouraged researchers to conduct a systematic task analysis of the successive processes of sensation, perception, and cognition. (Note that this approach is what made Rogers' work, cited in the introduction, so important and effective.) Coupling parallel work in human factors engineering and ergonomics better allows innovators to match a variety of new technologies to the needs of elders. Knowledge of which human capacities decline, which hold up, and which are amenable to restoration or rehabilitation helps gerontechnologists to assist with the selection, optimization, and compensation that Paul and Margret Baltes proposed as necessary for successful aging.

Gerontological Theory: Lawton and Nahimow's Extension of Field Theory: A Human Factor of Aging

Powell Lawton and Lucille Nahimow's ecological theory of aging extends field theory to gerontology and fills in several important details. Working on the micro-level, it brings us closer to understanding the core of gerontechnology: How can/should we design and provide technologies to enhance the lives of older adults?

The model encourages us to better delineate and consider relevant characteristics of the person and environment to better predict the behavioral/affective outcomes of transactions between the two. Undesirable outcomes (labeled negative affect and maladaptive behavior) occur whenever competence (person) and press (environment) are significantly mismatched. This can occur when either one is significantly greater than the other.

The most desirable outcomes of person–environment transactions are most likely when press and competence are reasonably well matched. If competence is slightly greater than environmental press, the outcome is described as maximum comfort. When press is slightly above competence, the outcome is a zone where maximum performance potential occurs. Setting demands slightly above an individual's capabilities often yields improve competence or performance. The track and field exhortation to set the bar high but not too high clearly applies to older adults in environments and with new technologies.

Adding Technology to the Model Lawton and Nahimow's model was not intended to speak directly to issues of technology and aging; however, the implications of the model to this work should be clear. Technological innovation can help to continually stimulate and enrich the lives of older adults, pushing them to stay active and involved. They can also assist seniors in adjusting to age-related or illness-related declines in capacities. With such declines, demands from the environment must be similarly reduced in order to avoid precipitating negative affect or maladaptive behavior. The careful addition of assistive technology and environmental interventions (AT-EI) to senior environments demonstrates the power of the ecological model in planning for and developing various technological interventions.

As in earlier sections, it is important to caution about overassisting through technology. Lawton and Nahimow's theory predicts what happens when environmental press is too low for the capabilities of the person. That is, technologies that greatly mitigate environmental demand relative to individual capacities can sometimes trigger negative outcomes – laziness, learned helplessness, and/or real and measurable declines in capacities. In the 1970s Bob Kahn coined the term excess disabilities as an environmentally induced condition that is worse than what would have been caused by organic change within the individual. There has been some renewed interest in this concept in the context of technology and aging. Unfortunately, our best intentions for serving a proximal individual exigency may lead to negative distal consequences. Careful task analysis and longitudinal research will assist us in better understanding consequences of the utilization of various technologies.

Take the example of an elder with difficulty rising from his or her favorite easy chair. While rising from the chair and mobility is the crucial behavior, the impact of the chosen means of rising should be considered. If a low-tech, minimalist solution is satisfactory (such as putting a board under the cushion to provide slightly more support, or buying another armchair that is somewhat further off the ground and which has firmer arms, allowing the person to gain leverage with his or her arms); then perhaps a higher tech solution should not be selected. A chair that at the push of a button actuates a lifting device that delivers the individual to a standing position may unwittingly contribute to a further weakening of leg and arm muscles needed to rise from other chairs, to maintain balance when standing, etc. Mollenkopf, Lesnoff-Caravaglia, and others have noted that the long-term outcomes of inappropriate technology adoption may be undesirable.

Adding Secular Change to the Model James Fozard adds an important technology-related dimension to Lawton's model by discussing secular change. After reviewing pertinent research by a variety of investigators he has concluded that all cohorts experience technology somewhat differently, based primarily upon their age when each technology was initially introduced. One's cohort rather than one's age may be a better predictor of affinity toward and ability to utilize specific types of technologies and technology interfaces. Consequently, technology innovators will need to continue to consider alterations to appropriate design, based upon the aging of successive cohorts. In other words, cohort-appropriate design is as important as age-appropriate design (**Figure 1**).

An Example of Secular Change In 2006, the notion that old people can't program their VCRs is still a familiar stereotype about today's older cohort held by individuals of roughly age 30 and up. Yet, as Baby Boomers age, most will maintain their ability to program the VCR and to use other familiar technologies. However, secular change – the evolution of video recording from tape to digital – not only renders the VCR obsolete, but also makes this example nearly meaningless to younger persons.

Fozard and associates have provided another very important addition to our understanding of technology and aging by developing a classification matrix of domains in which technological innovations can affect the aged. In a symposium discussion presented at the 2005 Annual Scientific Meeting of the Gerontological Society of America he noted that "we conceive of gerontechnology as relating to five broad areas of human activity: health and self esteem, housing and daily living, mobility and transport, communication and governance, and work and leisure. In each of the five domains the goals for using technology are: prevention or delay of decline, compensation for age-related loss of function, care support

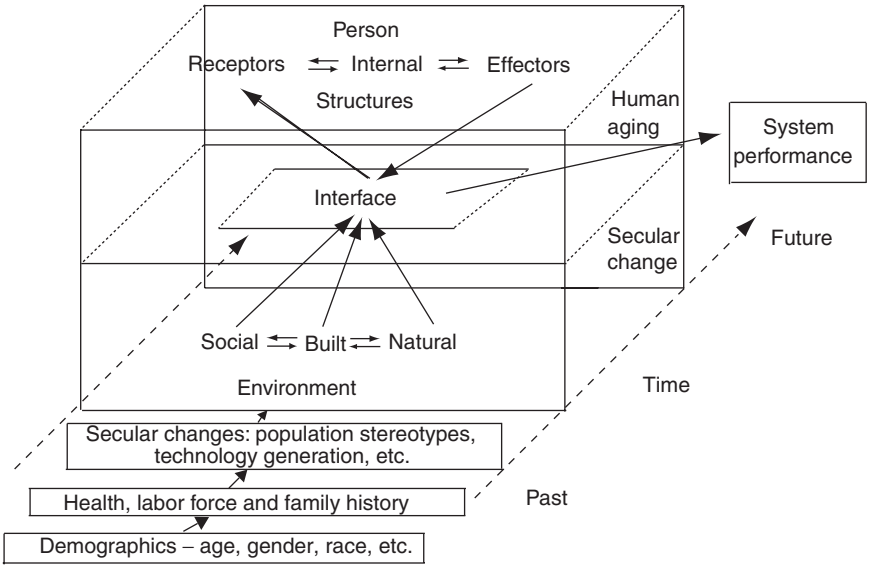

Figure 1 Diagram of dynamics of person–environment interface over time. The interaction of a person and the environment shows the three components of human response to environment that change with age (top half of figure), and the three components of the environment (built, social, physical or natural) that undergo secular change over time (lower half of figure). System performance is indicated by the box to the right of the diagram. Some antecedents contributing to the changing dynamics of the person–environment interface over time are shown in the boxes in the lower part of the figure. Adapted from Burdick D and Kwon S (eds.) (2004) *Gerotechnology: Research and Practice in Technology and Aging*. New York: Springer Publishers.

and organization, and for all of the above, enhancement and satisfaction with respect to quality of life." After briefly reviewing some common age-related changes in capacities, this listing shall serve as our template for considering a variety of uses of technologies for the aged.

Age-Related Changes in Information Processing and Implications for Gerontechnological Interventions

Findings from a growing body of research on age changes in information-processing ability have many implications for technology and aging. These changes are not all negative. With appropriate interventions some age-related declines can be slowed or reversed. The following section seeks to briefly note a few of the more common or problematic changes in sensory, perceptual, and cognitive function and their implications for the design of various technologies (*see* Human Factors Engineering and Ergonomics).

Sensation and Perception

Changes in Vision Several changes in visual sensation and perception occur because of normal aging and/or various age-related disease processes (e.g., cataracts, macular degeneration, diabetic retinopathy, and glaucoma). All have significant implications for environmental design and design of technologies for use by older adults. For example:

- The normal yellowing of the crystalline lens renders colors differently and makes discrimination of short wavelength colors such as violet, blue, and green quite difficult. Video displays, websites, printed advertisements, and so on should avoid requiring discrimination among colors or selection of figure/ground colors in this area of the color spectrum. High color contrast should be maintained.
- The aging lens progressively loses ability to accommodate (change shape) so as to focus in a continuous range from proximal to distal objects. This inevitable presbyopia requires careful prescribing of glasses, contact lenses, and lens implants (in the case of cataract surgery) when sharp acuity is necessary for variable distances. The interaction of age, lens, and distance to and resolution of computer, PDA, or in-vehicle informatics displays must be considered.
- Susceptibility to glare and visual blur increases with age, and visual acuity declines (particularly in the periphery). These changes have several implications for the design of visual displays, signage, etc. Displays with dark background and light text are sometimes preferable.
- Light and dark adaptation takes significantly longer in the advanced years of life. A given scene

or environment appears darker/dimmer for older persons (partly due to smaller pupil openings and partly due to internal neural processing changes). Implications are clear for the need for somewhat brighter ambient and task lighting in restaurants, theaters, etc. Screens on PDAs or cell phones that are carried into environments with dynamic changing ambient lighting should automatically adjust screen brightness to compensate for such changes.

Several researchers have described the implications of the aforementioned changes as well as others (such as attentional deficits) and provide a compelling case for the importance of better understanding the collective impact of these changes upon the functioning of older individuals in dynamic environments. Leading advocates for the application of the preceding knowledge to technologies and environments for the aged include Cynthia Steun and others at Lighthouse International, research sponsored by the SPRY Foundation and conducted by Donald Kline, Chip Scialfa, Frank Scheiber, and others.

Computer hardware (screen size, resolution, brightness, contrast) and software offer many opportunities for users to tailor the screen display to their specific needs and preferences. Successive generations of MS Windows, Office, and other products, as well as the programs of several other vendors, have provided improved user options. Windows, for example, provides a variety of accessibility options and setup wizards for modifying screen characteristics and input device function (keyboard, mouse, etc.) to meet individual needs. Office products include a lengthy tutorial on accessibility features. Unfortunately, work in this area is incomplete, and users sometimes encounter unanticipated barriers when various programs and program settings do not properly work together. Microsoft's Windows vista, due out in 2007, promises to be a significant improvement in usability, particularly for users with impaired vision.

Changes in Audition Changes in auditory function can profoundly effect older adults' interaction with their environments and technological devices. Presbycusis, age-related diminished ability to discriminate high-frequency sounds (e.g., consonants in the spoken language), is the most common age-related hearing loss and makes it difficult for seniors to comprehend speech, particularly when low sound intensities are coupled with noisy environments. Technologies that utilize auditory signals or that transmit spoken information must be cognizant of this fact and be designed accordingly.

A common complaint of young and old alike involves cell phones in which the audible signal of button push success is not loud enough, particularly in noisy environments. Individual needs often conflict with the desire not to disrupt others in the area. More significant a problem is the signal quality provided by cell phones, which is dependent on transmitted signal quality, bandwidth, speaker and microphone design, etc. Another issue is whether cell phones are compatible with hearing aides. The U.S. Federal Communication Commission mandated that wireless phone manufacturers must provide at least two hearing aid-compatible (HAC) digital cell phones by August 2005 and that at least one-half of their phones must be compatible by February 2008.

Changes in Other Senses Age-related changes in gustatory, olfactory, somesthetic (composed of sensitivity to touch, pressure, cold, heat, and pain), vestibular, and kinesthetic senses have all been noted in the literature. As with vision and audition, normal change can be accelerated by, or secondary to, various disease processes. In fact, health status and other variables often exert a greater impact than age alone. Some issues related to technology and environmental designs include the following:

- A combination of weakened musculature and compromised vestibular and kinesthetic sensitivity dramatically increases the likelihood of falls among the very old and/or disabled (*see* Balance, Posture and Gait). Successful environmental design helps to compensate – for example, by minimizing stairs, uneven surfaces, or deep pile/padded carpets and providing handrails and clear visual cues for grade changes and edges. Various technologies have been utilized recently in the assessment and prevention of falls. PERS (personal emergency response systems) such as Lifeline Systems have been developed over the past 20 years that enable users to call for assistance after life-threatening falls have occurred.
- Age-related decrements in sensitivity to heat and cold help to make the aged more susceptible to hypothermia and hyperthermia (heat stroke). Implications for design are clear.

Cognition

Cognition includes processes such as learning, memory, intelligence, attention, creativity, and wisdom (*see* Information Processing/Cognition; Intelligence; Learning; Memory; Memory, Strategies). The inclusion of wisdom in this list is a reminder that

age-related cognitive decline is not universal; for example, the apparent age-related maintenance of crystallized intelligence contrasts to general declines in fluid abilities. Beginning in the 1980s, longitudinal research results have shown that age-related declines occur later and are less severe than what had been documented in cross-sectional studies; many skills hold up quite well in the absence of chronic illness. Significant inter- and intra-individual differences provide implications for design of environments and technological interventions aimed at improving status or function of elders in our society.

Mayhorn *et al*. note that the promise of innovative technology will be unmet unless designers and manufacturers apply user-centered approaches, focusing on needs, capabilities, and limitations of the potential older users. Some important findings and issues include the following:

- Cognitive processes that show age-related decline include working memory and some spatial abilities. Working memory declines are more common as the complexity of the memory task increases and under certain conditions of divided attention. Mayhorn and colleagues provide an interesting example of how this decline can interact with technology in the form of telephone menu systems. The processing demands of a long string of options, coupled with complex semantic meaning, often render these systems ineffective for older adults. The authors recommend careful consideration of delivery speed, ordering from most commonly requested to least, nested/hierarchical menus, etc. Spatial abilities (ability to mentally manipulate objects) undergo consistent age-related change. Such deficits may have an impact upon older adults' ability to efficiently navigate complex websites, utilize informatics displays in automobiles, etc.
- Cognitive processes that hold up or improve with aging include the long-term memory storage of factual information and vocabulary (semantic memory), storage of familiar images (iconic memory), and storage of well-rehearsed procedural memory. Fisk, Mayhorn and others have advocated that the design of technology for older adults should capitalize on these common strengths. This is similar to the strength model of intervention of social work practice – instead of providing interventions that make the care recipient dependent upon a care provider, provide the means by which the individual can utilize his or her capacities in order to stay independent. This relates to Baltes' selection, optimization, and compensation model.
- Some cognitive processes either hold or decline, depending on the specific task. For example time-based prospective memory (remembering to do something in the future) tends to decline, while event-based (remembering a specific event) does not. Time-based tasks can be rendered easier to remember if they are connected to a task (or environmental cue).

Active Domains of Gerontechnology

Previous sections should serve as a roadmap for effective ways to consider and address the intersections of older adults with technology from micro through macro levels. This section briefly provides diverse examples of currently active domains in which technology and aging intersect with increasingly positive outcomes for older adults, their families, others who provide goods and services, and society. These, coupled with examples previously provided, give a good idea of the current state of the field.

Fozard's five areas of influence noted in an earlier section have evolved over several years and are often used in the health promotion literature. They provide the outline here and for each example the primary outcomes of intervention are provided in parentheses.

Health and Self-Esteem

- Health information is increasingly available on the Internet, helping older adults and their caregivers to become informed consumers. The SPRY Foundation (Setting Priorities for Retirement Years) has sponsored several conferences, research projects, and training on improving web design. They also promote health literacy projects so that consumers can assess the quality of online information. (Prevention or delay of decline; compensation for age-related loss of function; care support and organization; and enhancement/satisfaction and quality of life.)
- Several websites of the U.S. Government have become the gold standard for accessibility, comprehensiveness, and usefulness, with information for older adults and their caregivers. Examples include the U.S. Administration on Aging's Eldercare Locator, First Gov for Seniors, information promoting healthy lifestyles, etc. (Prevention or delay of decline; compensation for age-related loss of function; care support and organization; and enhancement/satisfaction and quality of life.)
- The field of telemedicine is expanding rapidly, allowing health-care professional to monitor

patients in their homes on a wide variety of parameters, including body temperature, heart rate and blood pressure, blood oxygen levels, etc.
- A recent technological innovation entitled the Wisdom Circle was profiled on National Public Radio's Morning Edition in February 2006. Two hundred fifty older volunteers from around the United States, including some nursing home residents, provide Internet-based advice, often to younger people. (Enhancement/satisfaction and quality of life.)
- Cognitive well-being can be stimulated by enriched environments. A recent article in *Gerontology Today* describes a growing trend among older Japanese persons to purchase Nintendo Brain Training for Adults games designed to keep mental abilities sharp. More than 3 million units were sold in the first year alone. In the United States, Memory Works, designed and produced by the Practical Memory Institute, is designed to have a similar impact. (Prevention, delay, or restoration of decline; enhancement/satisfaction and quality of life.)

Housing and Daily Living

- Universal design, senior friendly design, smart house with implications for older users have all received significantly increased attention in recent years. Centers leading this work include the Center for Universal Design at North Carolina State University, and SENTHA at the Technical University of Berlin (compensation for age-related loss of function; care support and organization; enhancement/satisfaction and quality of life).
- Technologies designed to help individuals age in place include personal emergency response systems (such as Lifeline), and automated activity track and analysis systems (AATAS) such as Quiet Care (compensation for age-related loss of function; care support and organization; and enhancement/satisfaction and quality of life).
- A wide variety of computer-mediated caregiver support systems have been developed around the country. Some are synchronous, others are asynchronous, and connect caregivers to peers and to professional assistance (care support and organization).
- Anti-wandering devices help to keep patients suffering from senile dementia safe without restraining them or locking down an entire facility (compensation for age-related loss of function; care support and organization; and enhancement/satisfaction and quality of life).
- Assistive technology and environmental interventions include a range of products, services, devices, home modifications, and so on, which for many years have been a mainstay of the fields of rehabilitation and occupational therapy. As these fields turn greater attention to the needs of frail older adults, more positive outcomes are being obtained (compensation for age-related loss of function; care support and organization; and enhancement/satisfaction and quality of life).

Mobility and Transport

- At Johns Hopkins University, George Rebok and associates are bringing together sophisticated simulator technology adapted from NASA and pilot training with neuroimaging technology (fMRIs) in order to develop a better understanding of age-related driver behavior. This work may result in effective means of deciding which older persons should cease or curtail driving. It also can be used to train effective driver skills (prevention or delay of decline; compensation for age-related loss of function).
- At the University of Calgary, Chip Scialfa and associates are working on understanding the characteristics of on-board informatics systems (to assist with way finding, etc.) that are safest and most useful for older drivers (compensation for age-related loss of function).
- The U.S. Department of Transportation has funded diverse research designed to adapt transportation to the needs of a maturing society, including how to make mass transit more user friendly. At the University of Akron, Ronnie and Harvey Sterns are studying ways to improve usability for bus and train timetables (compensation for age-related loss of function and enhancement/satisfaction and quality of life).

Communication and Governance

- Research on the micro environmental level is leading to better understanding of proper design for cell phones and other communication devices. Bill Mann and colleagues at the University of Florida Rehabilitation Engineering Research Center on Technology for Successful Aging have worked with industry to encourage senior-friendly design (compensation for age-related loss of function).
- Modern hearing aides are significantly better than previous generations. Instructions and training help users to adjust and reduce rejection rate (compensation for age-related loss of function and enhancement/satisfaction and quality of life).

Work and Leisure

- At the University of Miami, Sara Czaja and associates are conducting comprehensive studies on tele-work and telecommuting. Based on a growing body of evidence regarding information processing, perceptions and attitudes toward telecommuting, etc., their work is identifying barriers and producing training programs for telecommuting (enhancement/satisfaction and quality of life; prevention or delay of decline; compensation for age-related loss of function).
- There is a wide variety of local and national online learning communities for older adults throughout the world (e.g., Seniornet) (enhancement/satisfaction and quality of life).
- The AARP produces a monthly e-mailed Computers and Technology Newsletter (enhancement/satisfaction and quality of life).

Gerontechnology: Past, Present, and Future

Fozard notes that the early emphasis in the Human Factors and Ergonomics Society (HFES) was on military applications. Gradually in the 1970s and 1980s technical interest groups (TIGs) developed to consider specialized areas of application such as computer operations and vision, or personality and individual difference, rehabilitation, etc. The interest group on aging was slow to develop but now shows robust activity, with a variety of current contributors and contributions.

Other professional/scholarly organizations have sections or groups that focus significant attention to issues of technology and aging. The Gerontological Society of America's Formal Interest Group on Technology and Aging was founded by Gari Lesnoff-Caravaglia in 1987. Today the group has nearly 200 active members and sponsors a listserv and several sessions at GSA's annual meetings. GSA's Formal Interest Group on Physical Environments and Aging (PEA) and on Assisted Living often discusses technological issues. The American Society on Aging's Network on Environments, Services, and Technology (NEST) and Division 20 (Adult Development and Aging) of the American Psychological Association have also demonstrated significant interest in technology issues. (Three prominent gerontechnologists – Neil Charness, Jim Fozard, and Harvey Stearns – have all served as president of APA Division 20.) The Association for Gerontology in Higher Education has recently published a Brief Bibliography on Technology and Aging and a cover story in the AGHExchange on the importance of teaching gerontechnology in diverse courses on aging.

Several other organizations have led the way in the study of technology and aging. The International Society for Gerontechnology was founded in 1997, publishes the journal *Gerontechnology,* and has held four international conferences on gerontechnology. The Center for Aging Services Technology (CAST), founded in 2003, has already become a leading player in the effort to develop and deploy innovative technologies for older adults. It now has over 400 members representing technology companies, government, research universities, and service organizations.

Finally, large corporations such as 3-Com, Cisco Systems, Compaq, Honeywell, Intel, Microsoft, and Sony have gotten involved. Microsoft's Aging and Accessible Technology website provides an excellent summary of the many ways that computers, assistive devices, and environmental modifications are improving the lives of the aged and aging, enhancing the provision of services and health care, and reducing costs associated with population aging. There is, indeed, reason for enthusiasm and optimism in this burgeoning field.

Globalization and Aging

C Phillipson, Keele University, Keele, UK
J Vincent, University of Exeter, Exeter, UK

Glossary

Globalization – Refers to those mechanisms, actors, and institutions that link together individuals and groups across different nation-states.

Introduction

Understanding the future of old age requires an appreciation of the possibilities of life in old age across the whole world and not merely those of people living in the West. The topic of globalization is used here to provide a perspective to social gerontology that is often missing from discussions that focus on national health and welfare policies and that fail to locate people within a wider context. Debates on the theme of globalization became highly influential in the social sciences during the 1990s, notably in sociology and in political science. Subsequently, this work was to broaden out with extensive discussions in social policy as well as social gerontology. Globalization has now become an influential force in the construction of old age, most notably in the framing of social and economic policies designed to manage and regulate population aging. Research on aging must be placed within a broader geopolitical framework, with international organizations (such as the World Bank and International Monetary Fund [IMF]) and cross-border migrations creating new conditions and environments for older people.

The main argument developed in this article is that the phenomenon of globalization raises important new

concerns for social gerontology. In general, the focus on globalization confirms the importance of locating individuals within the orbit of social and economic structures, with these increasingly subject to forces acting beyond the boundaries of the nation-state. At the same time, globalization has been linked to the abandonment of those routines and institutions established in what writers such as Giddens and Beck refer to as the first phase of modernity. The sociological argument here is that we are now living in a post-traditional society, in which, in comparison with the past, there is greater emphasis on developing new lifestyles and making fresh choices about the conduct of daily life. This article explores the various dimensions associated with global aging, viewed from within the theoretical framework provided by globalization as an economic, political, and social process. The discussion is divided into five parts: first, an overview of relevant concepts; second, a summary of the dimensions associated with global aging; third, a discussion of global social policy; fourth, a review of the impact of migration and the role of transnational communities; finally, a summary of future trends associated with globalization and their likely impact on older people.

Globalization and Aging

Globalization, it is argued in this article, will have a major influence on the future of growing old. The term globalization refers to those mechanisms, actors, and institutions that link together individuals and groups across different nation-states. Globalization brings forth a new set of actors and institutions influencing the social construction of public policy for old age. To take one example, the increasing power of global finance and private transnational bodies raises significant issues about the nature of citizenship and associated rights to health and social care, in stages of life such as old age. In the period of welfare state reconstruction, rights were defined and negotiated through various manifestations of nation-state-based social policy. Globalization, however, transfers citizenship issues to a transnational stage, driven by a combination of the power of intergovernmental structures, the influence of multinational corporations, and the pressures of population movement and migration.

Following the analysis developed by sociologists such as Bauman and Beck, it might also be argued that rights, in the period of late modernity, have become more fragmented as well as individualized. At one level, the risks associated with aging – the threat of poverty, the need for long-term care, the likelihood of serious illness – are relatively unchanged. What has changed is that the duty and the necessity to cope with these risks are being transferred to individual families (women carers in particular) and individual older people (notably with respect to financing for old age). The new social construction (and contradiction) of aging is, on the one hand, the focus upon growing old as a global problem and issue, but on the other hand, the individualization of the various risks attached to the life course. The tension between these different elements is likely to set the broad parameters around which global aging is developed over the next decade (*see* Critical Gerontology).

Global Aging

The processes identified previously are important in shaping responses to the global trend of population aging. This development is driven by the move from a demographic regime of high fertility and relatively low mortality to one of low fertility and low mortality. The former is associated with fast-growing young populations, the latter with more stable populations, including a larger proportion of people in the older age groups. With the exception of sub-Saharan Africa, no part of the world has been left untouched by this demographic revolution, and the evidence suggests that a return to patterns of high fertility and mortality is unlikely.

The 2002 United Nations report on World Population Prospects suggests that the median age of the world's population increased from 23.6 years in 1950 to 26.4 years in 2000 and will rise to 36.8 by the year 2050. In the 50-year period from 2000 to 2050, the same source anticipates that the proportion of the population who are 60 or over will rise from 10 to 21.4%, but with regional variations within this overall global picture. The pace of demographic aging is increasing fastest in the developing world. It is most noticeable in countries such as China, where fertility is well below replacement levels and life expectancy is greater than 71 years. Projections suggest that by 2025 China alone will contain more people over 60 than the whole of Europe, with the proportion of older people (65 plus) doubling in the space of just 25 years – from 6.96 to 13.2% over the period 2000 to 2005. In Asia, which contains the bulk of the world's population, median age will increase between 2000 and 2050 from 26.1 to 38.7 years. Europe will age at a slower rate but from an older starting point, with the median age over the same period rising from 37.7 to 47.7 years; Oceania and North America will follow a similar pattern.

The situation in the countries comprising sub-Saharan Africa is more complex, given the continuation of high fertility alongside the impact of HIV/AIDS on the region and the high rates of mortality among younger age groups. Nonetheless, two

consequences follow from this: first, with rapid population growth, the absolute numbers of older people will increase, and second, high mortality among younger people is likely to increase the proportion of older people in the population of many African countries. The number of people aged 65 and over is projected to increase by about 10 million in sub-Saharan Africa between 1999 and 2015. While the overall population size will increase by 47% during this period, the growth in the number of people of 65 years or older will rise by 57%.

Population aging will have a major impact on the less economically developed countries of the world. Already, the majority (61% or 355 million) of the world's population of older people live in poorer countries. This proportion will increase to nearly 70% by 2025. For many countries, however, population aging has been accompanied by reductions in per capita income and declining living standards. Fewer than 20% of people aged over 60 in the developing world receive any formal social protection. Between 1950 and the late 1970s, life expectancy increased by at least 10% in every developing country of the world, or on average by about 15 years. However, at the beginning of the twenty-first century, life expectancy remains lower than 60 years in 41 of the 53 countries comprising sub-Saharan Africa.

Older people in the poorest regions of the world are especially vulnerable to disease and illness. The first deaths in famine are invariably found among the very young and the very old. Despite the problems facing older people in developing countries, they may play a crucial role in providing care within the family. This is clearly illustrated in the increasing role of grandparents providing care to children orphaned by HIV/AIDS. Over 60% of orphaned children live in grandparent-headed households in Namibia, South Africa, and Zimbabwe, and over 50% do so in Botswana, Malawi, and Tanzania. According to UNAIDS estimates, about 11 million children have been orphaned by HIV/AIDS in sub-Saharan Africa. Data from 27 countries in the region show that the extended family takes care of nine out of ten of these orphans. In most cases, responsibility for care falls upon grandparents, usually the grandmother. Given that older people are already one of the poorest groups within developing countries, the impact of HIV/AIDS may further exacerbate the problems they face in managing both their own old age and their caregiving role within the family.

Global Social Policy and Aging

Transnational bodies of different kinds are of increasing importance in shaping policy debates in the field of aging. Of particular importance is the way in which globalization as a social and economic process has created restrictions on the development of social welfare, a significant byproduct of the influence of transnational organizations. Financial globalization, to give one illustration, while not a direct cause of the erosion of welfare states, nonetheless sets significant boundaries around their development (*see* Critical Gerontology). A distinctive feature of the present period, as identified by David Held and others, is the extent to which financial globalization has imposed an external financial discipline on governments that have contributed to both the emergence of a more market-friendly state and a shift in the balance of power between financial markets. In this respect, the political agenda of advanced capitalist states increasingly reflects the constraints of global finance, even though the specific impact of financial globalization will vary greatly among nation-states.

A significant aspect of global aging has been the way in which intergovernmental organizations (IGOs) feed into what has been termed, by Carroll Estes and others, the crisis construction and crisis management of policies for older people. A discourse has emerged among leading global actors about the future of social policy, most notably in areas such as pensions and health and social services. Agencies such as the World Bank and IMF have been at the forefront of attempts to foster a political climate conducive to limiting the scope of state welfare, promoting in its place private and voluntary initiatives. The World Bank report *Averting the Old Age Crisis* was a seminal document in promoting the virtues of multipillar pension systems, and in particular the case for a second pillar built around private, non-redistributive, defined pension contribution plans. The World Bank has also argued for reducing state pay-as-you-go (PAYG) schemes to a minimal role for basic pension provision. This position has influenced both national governments and transnational bodies such as the International Labour Organization (ILO), with the latter now conceding to the World Bank's position with their advocacy of a means-tested first pension, the promotion of an extended role for individualized and capitalized private pensions, and the call for Organisation for Economic Co-operation and Development (OECD) member countries to raise the age of retirement (now being put into effect in many European countries). This debate amounts to a significant global discourse about pension provision and retirement ages, but one that has largely excluded perspectives that might suggest an enlarged role for the state, as well as those that might also question the stability and cost-effectiveness of private pension schemes.

IGOs have also begun to exert an influential role in relation to health and social care services. Increasingly, the social infrastructure of welfare states is being targeted as a major area of opportunity for global investors. The World Trade Organization (WTO) has promoted the idea of a more restricted role for the state in the provision of services with an enlarged role for the private (commercial) sector in health services, together with equal treatment for domestic and foreign health providers. The WTO enforces more than 20 separate international agreements, using international trade tribunals that adjudicate disputes. Such agreements include the General Agreement on Trade in Services (GATS), the first multilateral legally enforceable agreement covering banking, insurance, financial services, and related areas. The WTO has called upon member governments to reconsider the breadth and depth of their commitments to health and social services. This will almost certainly place enormous pressure on countries to move further in the opening-up of public services to competition from global (and especially US) corporate providers.

Global Migration and Aging

Migration and the redistribution of people around the world are products of poverty and prosperity but are also profoundly influenced by war and famine and the dispersal of refugee populations. Different kinds of migration can be linked to globalization, each with different consequences for older people. There is internal migration within states that accompanies relocation of populations during the course of development. This typically includes rural–urban migration. Towns and cities expand rapidly, attracting a young population of migrants leaving the rural areas with increasing numbers of elderly people. This was a common pattern in Europe and North America in the twentieth century and is increasingly common in the developing world. There is also the international migration that accompanies development, with people from poorer parts of the world seeking economic opportunities in richer and more developed areas. This not only has the effect of accelerating aging in rural areas, but also has the effect of spreading cultural diversity and the range of ethnic minorities in metropolitan cities. Some migrants settle in their new locations, but some return to their home community, bringing with them new ideas, resources, and possibilities. Many rural areas in Europe and increasingly across the world have come to benefit from the pensions of returned migrants.

The rich members of the world community also move both internally and externally to their nations. They move to find economic opportunity, but there is an increasing movement of people upon reaching retirement, for example, to resort locations both within and outside their own countries. Some of this migration is seasonal, in which extended summer holidays merge with dual homes and retirement relocation. In other cases, the move is either permanent or at least until late old age, when a return journey home may be made. Migration that is related to early retirement is likely to become visible for the first time in the next decade simply because the early retirees will be Baby Boomers from the cohort born in the years following the ending of the Second World War.

A major aspect of migration concerns the development of what has been defined as transnational communities, that is, the social relationships constructed across space that link migrants with nonmigrants. In this context, if what might be called the first phase of aging (which lasted for much of the twentieth century) was about growing old as a reinforcement of national identity and citizenship, the second phase will involve to a much greater extent the development of hybrid identities. Growing old in the first phase – or aging in the twentieth century – was partly a celebration of community, or of lives lived within particular communities with unique histories. In the second phase, however, which we have now entered, belonging and identity may become detached from association with particular places and locations.

Clearly, there will be losers and winners in this process, but the increasing importance of migration and mobility is raising substantial questions for gerontological research in a global context. A world of greater mobility will in the long term bring a number of benefits associated with cultural diversity. But in the short term, an increase in racism and associated forms of oppression also seems evident and may well create further divisions within the population of older people. This appears especially evident in hard-pressed inner city areas, where pressures on resources and services may produce conflict between the majority population and minority ethnic groups.

The rise of transnational communities is likely to bring major issues for social policy, with the development of groups holding together care tasks or financial responsibilities that may be strung across continents. Moreover, the experience of migration – with people in middle and older age settling into new cultures or bearing the strain of moving from one culture to another – raises questions about the adequacy of support in areas such as housing, income, and social services. On the one hand, migrant groups bring new forms of social capital to hard-pressed urban areas; indeed, they may be said to revitalize such communities in significant respects. On the other hand, they may represent a significant challenge for

traditional models of delivering health and social care. A successful response to the latter will require a more sensitive understanding of the distinctive histories of particular ethnic minority groups, as well as improved mechanisms for incorporating their views on ways of improving the delivery of community care services. A critical task over the next decade will be to respond to the diversity of care needs among the multicultural and multi-ethnic populations generated by the social dynamics of globalization. Moving ethnic minority elders from the margins of service provision will be a central part of the challenge.

Studying Global Aging

Taking a global perspective of the lives of older people will be of increasing importance over the course of the twenty-first century. Increasingly, we will appreciate the extent to which older people both live in and are shaped by a world of social and cultural diversity. Reflecting this point, Dannefer has suggested that a new global geography of the life course has begun to emerge, with contrasting experiences in the less-developed as opposed to the more-developed regions of the world. The typical life course pattern associated with Western industrialized countries (the so-called three boxes of education, work, and retirement) is in fact atypical for much of the world. A global perspective on the life course underlines the importance of encompassing a fuller range of human diversity and lifestyles. In particular, we shall need to understand the factors that contribute to the differential shape of the life course, with factors such as transnational flows of capital, the role of multinational organizations, and labor market opportunities being among the key elements.

Studies of global aging will also need to consider the extent to which older people are themselves active within movements that challenge the power of multinational corporations as well as IGOs. Struggles over low pay, decent living standards, and human rights affect all age groups and need to be fully incorporated into pensioners' movements within and across nation-states. Thus far, older people and their representative organizations can claim only limited influence on the major debates about population aging launched by the World Bank and similar organizations. The case that needs to be made is for an age-sensitive globalization in which older people have greater influence in key international fora. Relevant aspects might include the following:

1. auditing the activities of key IGOs in respect of their activities on aging issues
2. building an age dimension into development policies and strategies
3. promoting aging organizations as major players alongside existing multilateral agencies
4. strengthening the age dimension in human rights legislation
5. encouraging older people's organizations to play a prominent role in the network of groups and fora that comprise global civil society.

This is an important agenda, but one that is being only partially addressed in the United Nations, the WHO, and related bodies. This is illustrated by the Madrid International Plan of Action on Ageing (MIPAA), which arose from the Second World Assembly on Ageing. The ultimate goal of MIPAA is to improve the quality of life of older people on the basis of security, dignity, and participation, while at the same time promoting measures to reconcile aging and development and sustaining supportive formal and informal systems of individual well-being. Although such a goal provides a strong platform for developing a new agenda for population aging, the need to engage with growing income inequality must also be confronted. Incomes across the globe became markedly more unequal in the period from the late 1980s to the early 1990s, with research suggesting that the share of world income going to the poorest 10% of the world's population fell by over a quarter; in contrast, the share of the richest 10% rose by 8% over the same period. More generally, research by Wade and others suggests that globalization as it currently operates is increasing inequality within as well as between countries. Such inequalities are creating new forms of exclusion, notably for women, the working class, and minority ethnic groups. Developments such as these require more positive action from bodies such as the United Nations and WHO. The concern of these organizations to encourage the empowerment of older people and to achieve what has been defined as 'active aging' will almost certainly fail unless national and global inequalities – notably those that reduce the life chances of those older people living in less-developed countries and the poorer communities of the developed world – are tackled in a systematic way. Moreover, bodies such as the UN and WHO will need to confront the power of IGOs such as the IMF and the World Bank to impose social policies that result in reductions in expenditure on services for groups such as older people. This has been a particular feature of economic programs directed at Latin American and East European countries and is in direct conflict with the aspirations of the Madrid plan to build a secure and dignified old age across the global community.

In conclusion, globalization – as one constituent of the risk society – may generate new forms of insecurity, of which anxieties and fears about growing old may represent one significant aspect. But other developments may also take place. Will a new cohort of older people (e.g., the post-war Baby Boom generation) give a different voice and meaning to the nature of growing old? If they do, to what extent will this be determined by social networks that embrace global in addition to national contexts? To what extent will globalization undermine the social, economic, and cultural threads (tenuous at best given the role of class, gender, and ethnicity) linking together people identified only through biological age? Globalization has certainly transformed the world, but it is changing the nature of aging as well – and in equally radical ways. Further study of this important phenomenon will be a major task for gerontology in the years ahead.

Glycation

A T Lee and A Cerami, The Picower Institute for Medical Research, Manhasset, NY, USA

Glossary

Advanced Glycation End Products (AGEs) – Permanent, covalently attached glucose-derived modifications on macromolecules.

Deoxyribonucleic Acid (DNA) – Genetic material responsible for transmitting heritable characteristics.

Non-enzymatic Glycation – The spontaneous reaction of glucose with biological macromolecules usually involving sugar attachment to a primary amino group.

Reducing Sugars – Carbohydrates able to reduce oxidizing agents, typically those possessing an α-hydroxyketone, α-hydroxyaldehyde, hemiketal, or hemi-acetal group, and including all monosaccharides.

Transgenic Mice – Mice containing heritable DNA from another source, which is permanently integrated into the genome of each cell.

Introduction

Non-enzymatic glycation is a term used to describe the permanent post-translational modification of protein amino groups by reducing sugars. Although initially applied to proteins in the context of food chemistry, non-enzymatic glycation has been shown to occur slowly under physiologic conditions *in vivo* and is now known also to occur with certain nucleic acids and lipid molecules. The non-enzymatic reaction of reducing sugars to form permanent modifications with proteins not only alters their physical characteristics, but also impairs their biological function. These types of sugar-derived modifications have been termed advanced glycation end products (AGEs). During the past two decades, the presence and biological relevance of AGE modification has been evaluated for a number of important proteins. These investigations have led to an increasing body of evidence supporting the pivotal role of non-enzymatic glycation in the pathogenic mechanisms leading to complications associated with normal aging and diabetes mellitus. This review will focus on the current understanding of the chemical pathway and the biological consequences of AGE modification, and possible methods of pharmacological intervention.

Chemistry

Non-enzymatic glycation was first described in 1912 by the food chemist Louis C. Maillard to account, in part, for the golden brown color of foods following cooking and for the change in taste and texture of foods during long-term storage. The Maillard reaction, or non-enzymatic glycation, begins with the spontaneous formation of a readily reversible Schiff base between the aldehyde group of a reducing sugar, such as glucose, and a primary amino group of a macromolecule, usually a protein. Within a relatively short time (days), the Schiff base can undergo intramolecular rearrangement and reach equilibrium with a more stable, but still slowly reversible, Amadori product (in the case of glucose). Over several weeks, the Amadori product can undergo a series of further spontaneous reactions including inter- and intramolecular rearrangements, dehydrations, and intermolecular condensations to form a heterogeneous array of irreversible end products that are as a group, fluorescent, yellow-brown in color, and stable inter- and intramolecular cross-links. These end products are collectively referred to as advanced glycation end products (AGEs) (**Figure 1**). The formation of AGEs is entirely non-enzymatic and is not known to require any cofactors. The extent of AGE formation and accumulation depends on a number of variables such as temperature, pH, protein and glucose concentrations, and substrate turnover. Although temperature, pH, and protein concentration remain relatively constant *in vivo*, variability in mean blood glucose levels (glucose concentration) and protein half-life (incubation time) significantly influences the extent and accumulation of AGE-modified proteins. Proteins with half-lives greater than a few weeks, for instance, have the opportunity to accumulate more non-enzymatic glycation end products than those that have a half-life of only a few days. Proteins that are continuously exposed to circulating glucose, such as extracellular and serum proteins, also have an increased vulnerability to non-enzymatic glycation. In addition, diabetes mellitus, an illness characterized by chronic hyperglycemia, directly influences the rate of accumulation of AGE-modified proteins in proportion to the degree of mean blood glucose elevation.

The characterization and structural identification of specific AGEs has been impeded by the inherent diversity of products formed during the spontaneous chemical reactions and rearrangements of the non-enzymatic glycation pathway. Using model reactions, a limited number of specific AGE structures have been determined (**Figure 2**). Because glucose is the major extracellular-reducing sugar in the body, it has been used extensively in model mechanistic studies. However, it is important to note that analogous reactions could occur with other reducing sugars. The first AGE to be isolated was 2-(2-furoyl)-4(5)-(2-furanyl)-1H-imidazole (FFI), which was synthesized by incubating glucose with polylysine or bovine serum albumin. Other AGE structures including pentosidine, carboxymethyl-lysine (CML), and pyrraline have also been identified in model incubations, and their presence has been confirmed *in vivo*. Because the process of AGE formation by nature leads to a markedly heterogeneous spectrum of products, the specific yield of any one product is very limited. For this reason, it was postulated that by inhibiting alternate pathways of the non-enzymatic glycation reaction, one could enrich for specific intermediate compounds. Sulfites have been well recognized by food chemists to inhibit non-enzymatic glycation in foodstuffs and have been used extensively in the food industry as preservatives. The presence of sodium sulfite as an inhibitor in a model reaction of glucose and 6-amino-hexanoic acid led to the identification of an AGE intermediate product, 1-alkyl-2-formyl 3,4-diglycosylpyrrole (AFGP).

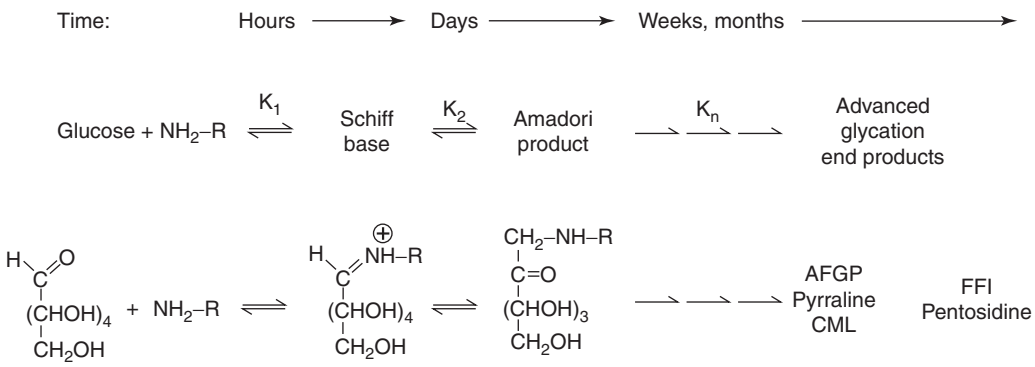

Figure 1 Formation of advanced glycation end products.

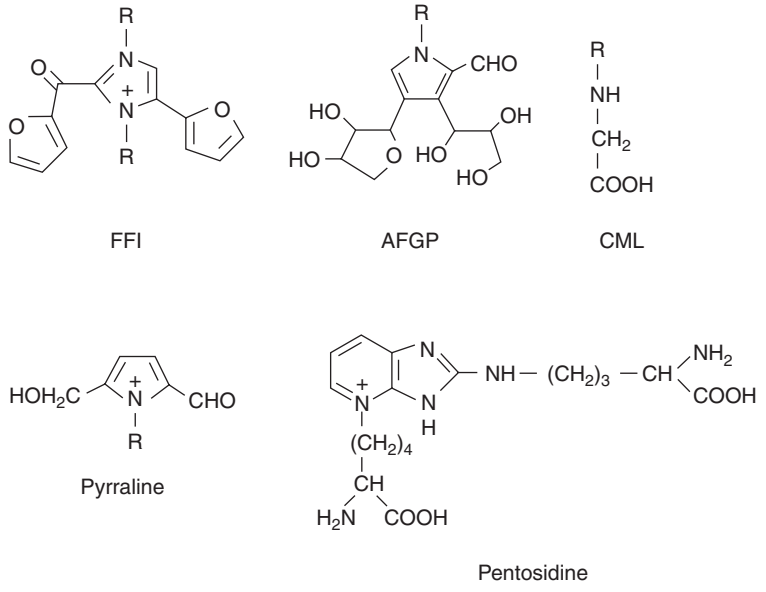

Figure 2 Structures of advanced glycation end products.

Biological Consequences

The formation of AGEs on biological macromolecules alters their structural and functional properties. This type of slow, progressive modification on biologically relevant macromolecules and the accumulation of these modified macromolecules *in vivo* has been implicated in a number of pathologic abnormalities, most prominently the complications associated with normal aging and long-term diabetes. The similarities in the type and development of such complications suggest that the effects of chronic hyperglycemia resemble accelerated aging.

Intracellular Proteins

That non-enzymatic glycation occurred *in vivo* was originally discovered by the presence of a minor hemoglobin species, $A_{1c}(HbA_{1c})$, in erythrocytes. It was later discovered that HbA_{1c} was more prevalent in blood from diabetic individuals compared to nondiabetic. Further biochemical investigations into the origin of HbA_{1c} in blood from diabetic samples demonstrated the presence of a glucose-derived Amadori product covalently linked to the N-terminal valine of the beta-chain of hemoglobin. The clinical measurement of glycosylated hemoglobin in erythrocytes has become an indispensable indicator of circulating mean glucose levels, and is routinely used to assess diabetic control over the 3–4-week period prior to sampling.

Because glucose is found throughout the body, it was hypothesized that other proteins may be sensitive to modification by glucose. Lens proteins were thought to be likely candidates to show the accumulation of AGEs, because these proteins turn over very slowly, if at all. Like hemoglobin in erythrocytes, lens proteins are present in insulin-independent cells; therefore, lens proteins are exposed to glucose levels that directly reflect the extracellular sugar concentrations. In addition, a number of age-related

changes in lens proteins, such as increased aggregation, changes in absorption peaks, and the presence of flurorescent chromophores suggested that non-enzymatic glycation occurred prominently within the lens. In particular, the accumulation of lens protein cross-links contributes to the opacification and cataracts so often observed in aged human lens. *In vitro* studies confirmed that lens proteins could react with glucose or glucose-6-phosphate to result in protein cross-links and lead to changes in absorbance and flurorescence spectra similar to those observed in digests of cataractous lens proteins from aged and diabetic individuals. The observed similarities between lens proteins that were non-enzymatically glycated *in vitro* and lens proteins from aged or diabetic individuals provided the first evidence that non-enzymatic glycation was involved in the development and progression of complications related to normal aging and long-term diabetes.

Extracellular Proteins

The influence of extracellular glucose on the modification of lens proteins provided further impetus to study the significance of non-enzymatic glycation in the pathogenic mechanisms involving other long-lived proteins. Extracellular proteins were considered to be particularly susceptible because, like proteins within insulin-independent cells, non-enzymatic glycation of extracellular proteins would be directly influenced by the concentration of circulating glucose. Collagen is the predominant extracellular protein in the body and the major component of connective tissues, such as skin, tendons, and cartilage. Given its abundance, long half-life, and accessibility by circulating glucose, collagen appeared to have the necessary characteristics for susceptibility to non-enzymatic glycation. Increased collagen stiffness and rigidity is often ascribed to normal symptoms of aging, and this decreased flexibility might be attributed, in part, to AGE-mediated collagen cross-links. The extent of modification of collagen by non-enzymatic glycation has been measured in a number of different collagen-rich tissues including aorta, dura mater, and skin. In each case, the extent to which collagen has become AGE-modified correlates positively with age. Tissue samples from insulin-dependent diabetics show an increase in AGE-modified collagen as a function of chronological age, but the levels observed were comparable to normal individuals twice as old as the diabetic patients. These results reaffirm that the development of some common consequences of normal aging is accelerated in individuals with long-term diabetes.

The presence of AGEs on collagen not only affects its physical and structural characteristics, but AGE modification of collagen can also contribute to atherosclerosis, nephropathy, and peripheral vascular disorders. Studies have shown that AGE-modified collagen can cross-link not only to other collagen molecules, but also to circulating serum proteins. The covalent attachment and immobilization of circulating proteins such as low-density lipoproteins, serum albumin, and immunoglobulins to tissue collagen is thought to contribute to the development of atherosclerotic lesions, thickening of basement membrane in renal tissue, and peripheral vasculature occlusion.

Other Pathologic Consequences

More recent investigations have revealed a potential role of AGE-modified proteins in other age-related pathologies, such as Alzheimer's disease (AD) and brain damage due to stroke. The presence and progressive accumulation of amyloid plaques in brain tissue is a central hallmark of AD, and a great deal of work has centered on the mechanisms leading to the aggregation and deposition of β-amyloid (βA) accumulations in the brain. Recently, amyloid plaques from diseased and normal brain tissues were evaluated for the presence of AGEs. It was found that samples from AD-diseased brains contained almost three times more AGEs per milligram of protein than did age-matched controls. Also, glycation of soluble βA peptides markedly accelerated the formation of insoluble fibrillar βA aggregates in test-tube incubations. These findings suggest that AGEs may be involved in amyloid plaque formation and deposition, and thus contribute to the neuropathologies associated with AD (*see* Dementia).

The exacerbation of another neuropathological disorder by AGEs has recently been observed in a rodent model. Administration of physiological concentrations of AGE-modified proteins to normal rats prior to cerebral artery occlusion caused a significantly larger volume of stroke damage and infarction when compared to non-treated animals. These results suggest that AGEs can initiate potentially neurotoxic processes; however, it is not clear whether AGEs induce damage directly or if they are mediated through one or more secondary pathways.

Nucleic Acids

The identification of non-enzymatic modification by glucose of different classes of biologically relevant macromolecules supports the pervasive nature of this reaction in cells and tissues of the body. A number of years ago it was hypothesized that free amino groups on DNA bases could also participate

in non-enzymatic reactions with glucose, in a manner similar to that of the Maillard reaction with proteins. The non-enzymatic glycation of DNA may contribute to several well-known age-related genetic dysfunctions, such as decreased RNA and protein synthesis, decreased DNA repair and replication, and increased chromosomal aberrations.

Initial *in vitro* studies demonstrated that amino groups of nucleotides, whether free or polymerized in single- or double-stranded DNA, could react with glucose and glucose-6-phosphate. These non-enzymatic reactions generated glycated DNA with altered absorbance and fluorescence spectra, in a time- and sugar-concentration-dependent manner that were directly comparable to the spectral changes observed to accompany the non-enzymatic glycation of proteins. When plasmid DNA, which had been glycated *in vitro* was used to transform bacteria, the glucose-modified DNA had a significantly lower transformation efficiency than control plasmid DNA. This loss in activity correlated with the length of the incubation period and the glucose concentration present in the reaction. Plasmid DNA isolated from some of the transformed colonies was analyzed and found to contain anomalous sequences. These observations supported, for the first time at the molecular level, the hypothesis that non-enzymatic glycation of DNA could have adverse biological effects. Similar results have been observed in other *in vitro* and *in vivo* prokaryotic and eukaryotic model systems, confirming the mutagenic potential of DNA glycation. The effects of DNA glycation can permanently compromise the integrity of the genome and may result in various degrees of impaired cellular function, in extreme cases inducing cell death.

Transgenic mice containing a specific mutagenesis marker gene, *lacI,* were used to determine whether the effects of non-enzymatic glycation extended to the genome in intact animals. By measuring the accumulation of *lacI* mutants as a function of age, it was determined that mutant frequency increased linearly with time. The types of DNA mutations observed were not limited to simple base substitutions, but included large deletions and insertions, suggesting the activity of complex AGE-dependent DNA repair pathways. Given these results over the short life spans of experimental animals, one can also expect that AGE-induced DNA damage and mutations may account for some of the genetic alterations that are observed in elderly humans.

It has been well documented that there is a significantly higher incidence of birth defects in infants born to insulin-dependent diabetic mothers than in those born to their non-diabetic counterparts. Using the same *lacI* transgenic mice, the mutagenic effects of maternal hyperglycemia on developing embryos could be assessed. In fetuses that developed in diabetic dams versus those developing under normal conditions, there was a twofold increase in *lacI* mutant frequency. Molecular analysis of these *lacI* mutants showed a pattern of DNA mutations similar to those observed in aged mice. These similarities suggest a common mechanism of DNA damage and subsequent inefficient repair in normal aging and diabetic pregnancies. This study provided the first potential molecular link between maternal hyperglycemia, DNA damage, and congenital malformations.

Pharmacological Intervention

Specific knowledge of the chemical pathways involved in AGE formation has allowed potential pharmacological inhibitors to be synthesized. The first compound to show promise in this regard has been the small molecule, aminoguanidine. Aminoguanidine can react with a post-Amadori product to form products that do not go on to form AGEs, and is effective in this regard in test tube reactions and in animals. Although still early in the process of clinical assessment, there is encouraging evidence from animal studies that this drug has the therapeutic potential to prevent the development of AGE-related pathologies. It is hoped that better understandings of the chemistry leading to the formation of AGEs will lead to the development of additional anti-AGE approaches with therapeutic potential.

Conclusions

The non-enzymatic reactions initiated by the chemical condensations of reducing sugars with proteins and nucleic acids lead to the formation of irreversible structural modifications, AGEs, which have important biological implications. A number of complications associated with diabetes mellitus and chronic hyperglycemia (e.g., cataracts, collagen stiffening, and atherosclerosis) resemble those characteristics of normal aging, suggesting that the diabetic environment represents a model for accelerated aging. AGEs accumulate slowly in normal aging and more rapidly in the diabetic environment. These molecular modifications appear to account significantly for these similar parthological courses. Therefore, mechanisms that prevent, reduce, or relieve AGE-related diabetic complications can also be expected to improve age-related symptoms. Not only will therapeutic methods of intervention increase the quality of life of millions

of individuals affected by diabetes, but they may also benefit the lives of all older individuals.

Grandparenthood

H Q Kivnick and H M Sinclair, University of Minnesota, Minneapolis, MN, USA

Glossary

Affect – The feelings, moods, and tones expressed in the family.

Extended Family – A group of individuals consisting of the nuclear family, as well as individuals related by ties of consanguinity. Extension of ties exists among parents and their children, grandchildren, and between siblings.

Family – A basic unit of society, characterized as one whose members are economically and emotionally dependent on one another and are responsible for each other's development, stability, and protection. The family serves as the basic unit of socialization to teach cultural values and adaptation to society. Currently, in our society, the traditional definition of the family is undergoing transition because of the emerging prominence of alternative lifestyles.

Generation – A group of individuals constituting a single step in the line of descent from an ancestor.

Instrumental Activity – Behavior that is directed toward a goal.

Intergenerational – Pertaining to or involving individuals in different generations.

Nuclear Family – A family consisting of a husband, a wife, and their immediate children.

Role – A set of behaviors expected on the basis of a particular status. Roles may be ascribed (assigned on the basis of factors over which the individual has no control) or achieved (earned on the basis of individual effort).

Introduction

Grandparenthood is the family role assigned to an individual whose child produces a child. Grandparenthood is also a dyadic relationship involving a grandparent and a grandchild. Grandparenthood has existed for as long as families have included three or more generations. Its associated rights, responsibilities, behaviors, meanings, and satisfactions have varied with factors that are cultural, demographic, social, economic, psychological, and historical in nature. Grandparenthood has been investigated as a role, status, and relationship. Findings have implications for research and practice.

Background

Anthropological Context

Although grandparents have played a role in family life for as long as families have included three or more generations, the nature of this role has varied with a multiplicity of cultural, demographic, social, economic, psychological, and historical factors.

Levels of formality and respect in grandparenthood relationships are directly related to elder power over societal and family structure. In cultures and historical periods where decision making and economic power reside with the old, relations between grandparents and members of other generations are formal and authoritarian, characterized by prerogative and protective care on one side, and by dependence and respect, on the other. Conversely, in cultures and periods in which the old are removed from functional authority, grandparent–grandchild relationships are warmer and more indulgent; they are characterized by a friendly equality that can function to relieve tensions between family generations.

Changing Demography of Intergenerational Relations

Over the course of the twentieth century, changes in mortality and fertility have led to greater life expectancy and to changing rhythms in the family cycle – both of which have dramatically influenced the nature of intergenerational family relations. Reductions in mortality rates, public health advances, and control over once-fatal childhood diseases have combined to increase life expectancies, over the course of that century, from roughly 46 to nearly 80 years. For the first time in history, human beings can expect to live between one-third and one-half of their lives after they have reproduced. Never before have so many individuals lived long enough (and had their children live long enough) to become grandparents. Demographers report that in 1990, 94% of all older adults with children were grandparents, and nearly 50% were great-grandparents. Reciprocally, birth cohorts of children have never before had so many grandparents and great-grandparents.

Extended life expectancies have increased the number of multigenerational families, and have led to an unprecedented emergence of the long-term intergenerational relationships referred to by one family sociologist as 'crescive bonds.' Parent–child bonds may be expected to endure for six or more decades, four of which involve parents and their adult children. Americans today typically become grandparents in midlife; they can expect to spend four or more decades – roughly one half of their lives – in this role. One family historian notes that only since the twentieth century have grandparents and grandchildren enjoyed a meaningful period of overlap in their lives. Contrary to popular misconception, grandparenting has been a phenomenon of middle age for at least the past century. What makes contemporary grandparenthood demographically unique is its duration through both middle and later life.

Twentieth-century America has seen an overall reduction in the number of children per family, and a corresponding contraction in any given family's period of childbearing. These changes have led to an increasing distinction between parenthood and grandparenthood, both as individual life experiences, and as statuses within the family. No longer is it common, in mainstream society, for new grandparents to be actively involved in bearing and rearing their own children. Sociologists point out that when a person becomes a grandparent today, he or she is likely to have fewer family roles competing for personal time and attention than would have been the case in previous generations. Today's competing roles are more likely to be located in the workplace and the community than inside the family. (Increasing life expectancies for the frail elderly may come to replace child care with elder care as a major family responsibility of the middle aged and the young old.)

Socioeconomic Changes

Family historians describe a shift in the family, dating back to the late 1800s, from a corporate unit whose members were bound by lifelong interdependence, to a largely emotional entity whose members stress individual and nuclear independence. This shift in family structure is closely related to society-wide changes in work schedules, retirement, social programs, overall standards of living, transportation, and communication. At the beginning of this period, low wages, unemployment crises, illness, death, and the absence of social welfare programs forced family members to rely on one another for support. Family ties were seen as permanent obligations that took precedence over often transient feelings of affection or its opposite. Over the course of the twentieth century wages and general standards of living have risen, the work week has stabilized at roughly 40 hours, and, in many sectors of society, unemployment crises have diminished. Today's average male can expect to spend 15 years of his adult life retired from the labor force. Control over illness and death have increased. Social welfare and insurance programs have transferred basic financial reponsibility for the elderly, the disabled, and the infirm from kin to society as a whole. Improved transportation and communication technologies facilitate frequent contact across great distances (*see* Economics: Society).

All together, these changes have both permitted and promoted the independence of family generations, nuclear units, and individual members. Obligatory family ties based on need have been replaced with more voluntary bonds based on sentiment and attachment. The family as an institution

governed by strict social mores and laws has given way to what has been described as a 'companionship,' with behavior determined by mutual affection and by membership consensus.

Thus, today's grandparents are likely to have more time and money to spend on their grandchildren than their predecessors did. They are less likely to be raising their own children while actively grandparenting. They are less likely to provide instrumental family services out of need and obligation, and more likely to do so on the basis of desire and affection. Pressures related to work, marriage, education, climate, and security all contribute to the fact that today's grandparents and their grandchildren live at considerable geographic distances from one another. Nonetheless, they are likely to maintain regular telephone contact, and to visit several times a year.

Grandparenthood Research

As discussed above, socioeconomic and demographic trends in the first half of the twentieth century permitted nuclear families to enact the self-reliance and individual independence that constitute this country's most basic social values. It should therefore not be surprising that family researchers in these years all but ignored the grandparent role, which they saw as either ignominiously dependent or anachronistically controlling. Instead, they drew invidious comparisons between the contemporary American nuclear family, rooted in individualism and democracy, and the historical American family, characterized as multigenerational and patriarchal. During this period grandparents appear in social science research, if at all, almost entirely in the work of anthropologists.

By the late 1950s, family theorists began to challenge their earlier neglect of extended family networks. Over the next 15 years scholars began to cite evidence for the modern modality of the American 'modified extended family,' a system of nuclear families bound together by affectional ties, patterns of social activity, and mutual assistance. In addition, family historians of this new period reinterpreted historical data to conclude that harmonious, multigenerational family life had never been common in America. Rather, they asserted, intrafamily cooperation and assistance had always been American norms; along with parents and children, grandparents had always participated in mutual-help networks of kin.

Grandparenthood research in the 1960s and 1970s focused primarily on such singular qualities as love, authority, esteem, and responsibility. Gradually these unidimensional descriptions gave way to more comprehensive typologies. More recent research has attempted to establish causal links between typological categories and a host of demographic, personality, and family variables.

Grandparenthood to Grandparents

Discussions of the grandparent role often confound the components of behavior, meaning, and satisfaction. Perhaps because all three components are difficult to measure, researchers refer to the grandparent role without systematically differentiating among components or investigating their interrelationships. However, although behavior, meaning, and satisfaction are clearly related, they are, just as clearly, conceptually distinct. In addition to these three components, the grandparent role also involves such elements as role ambiguity, career development, timing, and instrumentality.

Behavior

On the basis of interviews with 70 grandparent couples, one study identified five distinct styles of grand-parenting: formal, fun seeker, surrogate parent, reservoir of family wisdom, and distant figure. In a more recent study, 510 grandparents were interviewed to describe three grandparenting styles: remote, companionate, and involved.

Research indicates that most contemporary American grandparent relationships may be described as companionate in style. Leisure and pleasure, rather than labor and responsibility, govern these relationships. Grandparents share fun and games with their grandchildren, enjoying affectionate, informal time together. With respect to matters of discipline, values, and socialization, companionate grandparents say that they hold their tongues and adhere to a widely accepted norm of non-interference across nuclear family boundaries. Some companionate grandparents express regret at having to withhold what they regard as valuable advice, and others want more interaction with the grandchildren, but know they are powerless to get it. Nonetheless, most reconcile themselves to being both connected to and separate from their grandchildren, and they agree that their lack of authority makes grandparenthood relationships uniquely pleasant and comfortable.

The norm of grandparental non-interference is part of what psychiatrist A. Kornhaber disparages as the new social contract, according to which the value of mutual independence supersedes other long-term concerns and short-term needs. Kornhaber reports that after years of heavy family responsibilities, grandparents welcome the opportunity to place their own, individual wishes first. Psychologist

D. Gutmann suggests that more than actually wanting to enact freedom, grandparents want to be seen as embodying societal values of self-sufficiency and independence. Anthropologist C. Johnson maintains that grandparents acquiesce to non-involvement largely because they believe they should not interfere in their children's families. According to this view, grandparents actively pursue interests outside the family essentially to distract themselves from intruding.

Remote grandparenthood relationships are characterized by emotional distance and formal, reserved interactions, as experienced by both grandparent and grandchild. This is the behavioral style most often chosen by today's grandparents to describe their own grandparents, two generations ago. Involved grandparenting entails spending a good deal of time working and playing together. These relationships are both companionable and instrumental. Their ties are based on exchange, on direct action, and on behaviors, concerns, and responsibilities that many companionate grandparents would regard as off limits.

Most grandparents and grandchildren can establish only symbolic bonds unless they see each other regularly. However, although amount of contact is often used in research to operationalize importance of the grandparenthood role, this variable is a prerequisite, not a proxy, for the phenomenon researchers seek to measure. Amount and quality of contact may be influenced by geographical proximity and by grandparent health and competing commitments; research suggests that proximity is the most powerful influence. Serving as 'lineage bridges,' parents can promote or inhibit relationships between the generations on either side. Parents model relationships with older family members, and they provide children with examples of how to relate to grandparents. Parental attitudes toward older people, in general, and their relations with their own parents, in particular, affect the grandparenthood relationships in their own family. Parents serve as gatekeepers to their children. However, despite this acknowledged power in the middle generation, it seems that only rarely do parents deliberately limit grandparenthood contact.

The grandparent role is enacted by means of specific behaviors that are associated with a multiplicity of variables. Age, gender, and marital status influence grandparent behaviors. Older grandparents tend to be more formal, younger grandparents to be more relaxed and playful. In accord with women's 'kinkeeper' role in families, maternal grandmothers tend to be visited more frequently and to be seen as emotionally closer than paternal grandparents. Grandfathers tend to be oriented outside the family, as 'ambassadors,' whereas grandmothers are oriented inward, as 'ministers of the interior.' Widows are more likely to be actively involved with their grandchildren than are remarried older men.

As described in research throughout the social sciences, grandparenthood role enactment is also influenced by variables that may be categorized in terms of family structure (e.g., number of grandchildren; importance of family), socioeconomics (e.g., employment status; educational level; economic resources), social resources (e.g., ethnic and subcultural identification; frequency of interaction with friends; community ties; number and nature of non-family roles), and personal resources (e.g., health; well-being; personality variables). Perhaps the most outspoken contemporary advocate of grandparenthood as a vital intergenerational connection, Kornhaber identifies a somewhat different set of determinants of grandparent role behavior. He points to societal attitude toward grandparenting, and to personality altruism. He also identifies the following earlier-life, intergenerational determinants of grandparent behavior: (a) the individual's experience as a grandchild, and (b) the individual's parents' grandparenting behaviors. These last determinants remind us that as a relationship in which most people participate for most of their lives, grandparenthood rests on a foundation that is established, inalterably, in childhood. A given adult's grandparenthood is determined both by circumstances that are in effect in adulthood, and also by those that were influential during childhood. For better or worse, the grandchildhood experiences of today's children will influence the grandparenthood they are able to enact two generations hence.

Meaning

Attention to behavior alone ignores the meaning and importance of the grandparent role to grandparents. Neugarten and Weinstein used their interview data to specify five categories of grandparenthood meaning: source of biological renewal, opportunity to succeed in a new emotional role, teacher–resource person role, vicarious achievement, and remote role. Examining grandparenthood meaning as a product of social and personal forces, V. Wood and J. Robertson designated four grandparenthood role types, representing high versus low dichotomizations of each dimension. These early typologies share the property of categorization (e.g., a grandparent's style is either formal or fun seeker; the meaning he or she finds in grandparenthood is either vicarious achievement or source of biological renewal).

Based on interviews with 286 grandparents, psychologist H. Kivnick deductively derived five different

dimensions of grandparenthood meaning: centrality, valued elder, indulgence, immortality through clan, and reinvolvement with personal past. Unlike earlier typologies, these dimensions were conceptualized as comprising, all together, the overall meaning a given individual finds in grandparenthood. Rather than being categorized as experiencing grandparenthood in terms of centrality or indulgence, for example, an individual is assumed to experience grandparenthood in terms of all five dimensions; he or she may be scored from high to low on each dimension.

Life cycle theorist E. H. Erikson and his colleagues J. Erikson and H. Kivnick describe the psychosocial theme of generativity and stagnation as comprising the experiences of caring, nurturing, and maintaining. After middle adulthood's direct 'responsibility for the maintenance of the world,' generativity comes to involve more indirect nurturing, to promote the robust senses of caring, generational connectedness, and wisdom that are the goals of middle and later adulthood. An integral part of the generational cycle, grandparenthood offers a valuable opportunity for grandparents to revisit their own capacities to nurture and to care, while, at the same time, enriching the essential generativity received by grandchildren.

Kornhaber and Woodward highlight reciprocity in the ways grandparent and grandchild roles are linked to the developmental needs of both generations. Shared time, shared place, shared activities, commitment to family – all these are crucial in establishing and maintaining a grandparenthood relationship. All are also crucial in accomplishing age-appropriate tasks related to generativity for both grandparent and grandchild. Qualitative exploration of grandparental units provides empirical evidence for the existence of generativity in the grandparenthood relationship. Although interviewed grandparents did not articulate consciously generative goals, enduring positive relations with grandchildren and feelings of success with intergenerational family life were interpreted as indications that grandparenthood facilitates developmental generativity. By maintaining strong affectional ties and mutually acceptable levels of association with grandchildren, grandparents seem to be able to balance their conflicting needs for contact and independence, for family identity and individuality, for personal usefulness and freedom from responsibility.

Role Ambiguity and Grandparenthood Career

Failing to find powerful associations between grandparenthood and diverse measures of grandparent well-being, researchers have long described the grandparent role as a relatively unimportant component of later life. Sociologists L. Burton and V. Bengtson note that grandparenthood conforms to Rosow's definition of a tenuous role (i.e., a definite social position with only vague behavioral guidelines). In the macrosocial structure, grandparenthood cannot be considered a functional role. Its presence or absence is thought to have no definitive effect on whether or not 'society is possible.' It carries no universal expectations governed by Durkheim's 'collective conscience.' It assumes a comparably idiosyncratic character within the microstructure; regardless of family expectations, a grandparent may choose to engage or not to engage in any role behavior.

Like that of parent, the role of grandparent follows a career trajectory, and the course of its interactions changes in predictable ways. The career begins with the news of imminent grandparenthood (i.e., of the imminent acquisition of a new status). This anticipatory stage is structured by expectations that are generally vague but enjoyable. The role at this point is titular. Behaviors include telling the news to friends and other family members, and, in some cases, assisting with preparations. Consistent with Kornhaber's new social contract, anticipatory grandparents speak of waiting to see how these new relationships will develop far more often than they describe assuming an active role in creating or structuring them.

Research suggests that once the grandparenthood bond is established in childhood, it remains fairly stable throughout the rest of the life course. Nonetheless, the grandparent career moves through distinct periods. During the grandchild's preschool and elementary years, grandparents typically enjoy their most frequent contact. As grandparent and grandchild spend time together, the grandparent's role broadens and deepens. These are the years Cherlin and Furstenberg refer to as the 'fat years,' during which grandparents can becoming living ancestors and historians, treasured companions, and role models. During the subsequent 'lean years' of the grandchild's adolescence, contact typically decreases and – if a solid bond has been established in the previous stage – the grandparent typically becomes a source of assistance and advice in times of expressed need. The final period of grandparenthood is the longest, beginning when the grandchild enters adulthood and grandparents, like parents, must learn to let go. Greatgrandparenthood, with its primarily symbolic significance, may be seen as a separate phase in this long final period.

Timing

Neugarten's concept of social time – society's age-grade system for appropriate progression through life's roles – influences the grandparenthood experience.

The significance of grandparenthood timing is particularly important in view of the fact that becoming a grandparent is a countertransition (i.e., a role change dependent on a transition initiated by another family member). The timing of grandparenthood hinges both on the age at which the individual became a parent, and also on the age at which his or her children reproduce for the first time. Grandparents have no control over the timing of this countertransition; they must live with the timing forced upon them.

Normative in middle age, first-time grandparenthood is seen as on time when it occurs between the ages of 42 and 57. Research indicates that assuming the grandmother role significantly early (ages 25–38) may result in 'crisis accumulation,' in which the combined demands of children, grandchildren, work, and other generational family members make a woman vulnerable to 'role overload.' In addition to concrete behavioral demands, early grandmotherhood may precipitate tension in a young woman's view of herself, and it may trigger conflict in the familywide system of cohesion and social support. Defending against all these tensions, some early grandmothers explicitly refuse to engage in the grandparent role. By contrast, research suggests that on-time grandmothers avoid the strains of off-time transitions and feel good about their grandparenthood timing.

Instrumentality

Despite contemporary norms of grandparent noninterference, the role does involve a variety of instrumental expressions. As 'family watchdogs,' grandparents respond to obvious need in the next generations by providing service. Reciprocally, grandparents often receive essential service from intergenerational family members. The last years of the twentieth century witnessed a dramatic shrinkage of societal economic resources, and a corresponding expansion of the demands placed on extended family members. It is therefore not surprising that the bulk of current grandparenthood research concerns instrumental service provision.

Grandparent Caretakers Grandparents provide care for their grandchildren within a range of structures. Some provide regular day care while the parents are at work. Others provide primary care while coresiding with the grandchildren, and, perhaps, with their parent(s), as well. Still others acquire legal custody of the grandchildren (*see* Caregiving and Caring). Traditionally, the Black community has emphasized support within extended kin networks. Indeed, Black children are much more likely than Whites or Latinos to live in grandparents' homes. However, since 1980 it is White children who have been moving into grandparents' homes at the greatest rates.

Although many grandparents function as their grandchildren's sole caregiver, parents of adolescent mothers often share caregiving responsibilities with coresiding daughters who must now balance the demands of parenthood with the developmental tasks of adolescence. As these families' most consistent providers of care and support, grandparents serve as both role models and caregivers to both mother and grandchild. Grandparents play an important role in assessing the mother's competency to care for her child, often taking over when they judge the mother to be incompetent. For young mothers, grandmothers tend to provide the most and highest-quality support when the mother lives with them, and when the grandchild's father is less involved. Young Black mothers are far more likely than Whites to coreside with grandmothers. For older mothers, grandmothers are likely to be most effective caregivers in noncoresidential situaions. Grandmothers seem to experience most caregiver satisfaction when they do not have preschool children of their own, and when they, themselves, receive support from a partner or financial assistance such as Aid to Families with Dependent Children (AFDC).

When grandmothers provide daily child care, the grandchild's mother or father or both are usually working full time. Such grandmothers want to help the parent(s) financially, and they would rather not leave their grandchildren in paid day care or at a sitter's house. In such circumstances, grandparents attempt to support the middle-generation nuclear family and help keep it intact.

Under other circumstances (e.g., child abandonment, neglect, or abuse; parental mental or emotional problems; parental death; parental incarceration; parental drug addiction, particularly to crack cocaine), the middle-generation nuclear family is so badly disintegrated that grandparents intervene both to provide care and, when necessary, to assume legal responsibility for the grandchildren. Some of these negative circumstances may arise without warning, such as a young mother's sudden death or incarceration. Others arise as a result of ongoing parent–grandparent negotiation. Still others develop over time, until the grandparent decides that personal intervention is necessary.

Most caregiving grandparents experience emotional, physical, and financial strains associated with their caregiving roles. If their primary caregiving is to be long term or permanent, grandparents may worry about living long enough to raise their grandchildren

to adulthood. Others are concerned about keeping up with the grandchildren's school, social, and physical activities. Still others are anxious about possible psychological harm to grandchildren who have been abused by their parents.

Parental crack cocaine addiction creates unique concerns for grandparent caregivers. Many fear for their own safety and security, as well as their grandchildren's. Some worry that their addicted children will steal their money or property to buy drugs, perhaps using physical violence to do so. Others experience anxiety about the burglaries, drive-by shootings, and dangerous automobile traffic that pervade neighborhoods beset by drug trafficking. In addition, these grandparents anticipate the financial and emotional drains of having to provide care for multiple kin. With respect to the grandchildren, grandparents worry that despite their best caregiving efforts, the children will inherit their parents' addictions.

Grandparents undergo a variety of life changes when they assume parental responsibility for the grandchildren. Most often reported are the negative changes. Grandparents who quit jobs to become full-time caregivers may miss contact with co-workers; most regret decreased opportunities for socializing with friends and confidantes. Many feel cheated of personal space, privacy, and freedom. Others experience moving backward in their lives. Still others find that renewed caregiving responsibilities strain their once postparental marriages. Negative health-related outcomes may include physical conditions such as heart attacks, strokes, diabetes, and arthritis. Alcoholism, increased smoking, and depression and anxiety have all been reported as negative emotional consequences (*see* Alcohol and Drugs; Depression).

Not all the changes associated with full-time caregiving are negative. Some caregiving grandparents develop new friendships as they identify with other people who share their current situation. Where some experience marital strain, as noted above, others report enhanced marriages or relationships as the grandchildren foster improved communication and increased time together between partners. Although health problems plague some grandparent caregivers, others experience improved health as they adopt more nutritious diets and engage in physical activity with the grandchildren.

Within the family context, grandparent caregivers may experience a variety of important satisfactions. Those who are displeased with the way they raised their own children may welcome what they regard as a second chance at parenting. Others value the opportunity to nurture their family line. Many treasure the gifts of companionship and love they receive from their grandchildren. Most grandparents who provide caregiving in place of ineffective parents are proud to see themselves as actively creating positive change in an otherwise deteriorating family cycle.

Reciprocal Caregiving The relationship between American elders and their families is characterized by a 'generalized reciprocity' across generations. Over the life course, family members exchange affective and instrumental support as needed, effectively making deposits and withdrawals from what T. Antonucci refers to as a lifelong bank of support. Not only do grandparents provide assistance in times of family crises. They receive needed care and support, as well (*see* Social Networks, Support, and Integration).

Although grandparents and their adult grandchildren seem to share expectations of turning to one another for whatever support may be needed, grandparents both expect and receive more emotional than instrumental support from their adult grandchildren. And grandparents generally perceive that they receive more from their adult grandchildren than they currently provide in return. These findings correspond to the literature on relations between adult children and their aging parents. Where instrumental support is provided, it comes most often from female members of the middle generation.

Divorce Middle-generation divorce is one of the major family disruptions against which grandparents are seen as providing continuity. During such times of crisis, older persons' importance to the family may increase significantly. Johnson reports that after a divorce, most grandparents try to provide instrumental assistance (e.g., money, babysitting, and other services) and emotional support to parents and grandchildren. Grandparents may be in a unique position to offer the grandchildren an emotional haven. In some cases, grandparents assume parental responsibility for a number of years, while the biological parent retains or struggles to regain legal custody.

Divorce can precipitate both increases and decreases in grandparents' contact with their grandchildren. Increases typically result when the grandchildren move to a closer geographic location, when grandmothers provide child care for custodial daughters who reenter the workforce, and when hostile parents are removed from the grandchildren's daily lives. Decreased contact typically results from distant geographic moves and from unresolved grandparent–parent conflict in the wake of the divorce.

Particularly after divorce, parents have the power to facilitate or prevent grandparent access to grandchildren. Although all states (excluding the District

of Columbia) have passed grandparent visitation rights statutes, the matter of postdivorce grandparent contact is far from settled. Proponents argue that the grandparent–grandchild bond is uniquely precious, and that it is in the child's best interest for the court to enforce visitation rights. Opponents counter that court-ordered grandparent visitation interferes with appropriate parental authority. Even in the absence of conflict, non-custodial parents may be reluctant to share their child visitation time with grandparents.

In addition to depending on family dynamics, grandparents' roles during and after divorce can vary with grandparent age and lineage. Older grandparents are more likely to experience disabilities that prevent them from offering help and assistance. Even before divorce, younger grandparents tend to be more active and to have more contact with grandchildren. Younger grandparents may also be more tolerant and less judgmental, and they may therefore be more welcome in postdivorce households. Although paternal grandmothers are generally described as having less contact with and providing less assistance to postdivorce grandchildren, many paternal grandmothers make a point of maintaining contact with their former daughters-in-law who, in turn, permit access to the grandchildren.

Grandparent Satisfaction and Well-Being

Research finds that grandparents generally report satisfaction, pride, and pleasure in grandparenthood. No one variable emerges as critical in determining level of satisfaction. Rather, chronological age, timing of role entry, religious affiliation, lineage, and frequency of contact all seem to contribute. Despite expressions of role satisfaction, interviewed grandparents frequently mention disappointment and disapproval in connection with particular relationships. They deny wanting to be more involved with their grandchildren, despite psychologist J. Thomas's finding that grandmothers and grandfathers who experience most satisfaction are those who have most responsibility for helping with grandchildren. These contradictions suggest that in circumstances of perceived interpersonal powerlessness, grandparents may be working hard to make the best of existing situations. They feel they can do little to influence particular relationships. What they can influence is the satisfaction they allow themselves to experience in grandparenthood, as a whole.

Apart from grandparenthood satisfaction, per se, researchers have tried, with little success, to explore the influence of grandparenthood on grandparents' psychosocial well-being. There appears to be some disagreement about whether higher grandparent involvement with grandchildren's families is associated with increased grandparent morale (as a function of providing essential service) or decreased morale (as a result of being the only available helper when a child's family is in trouble). The nature of existing research does not permit investigation of the proposition that grandparent involvement may be associated with increased morale among grandparents who might otherwise be even more depressed and despondent.

Psychologist V. Kivett suggests that the grandparent role may provide an important sense of psychological security for both Black and White grandmothers. Kivnick proposes that grandparenthood offers a valuable opportunity for the grandparent to make progress in the essential psychosocial work of middle and later adulthood. As such, the role should be expected to enhance grandparent well-being. Burton identifies psychological rewards experienced by grandmothers who serve as surrogate parents. Psychologist R. Pruchno proposes an elaborate model for evaluating the psychological well-being of grandparent caregivers, as a function of stressors (e.g., child-care demands; competing role demands; life-event demands), resources (personal; family; social; environmental), and perceptions of relative satisfaction and burden.

Grandparenthood to Younger Generations

Elusive Influence

Research on grandparent influence generally begins with an impression that grandparents are important in the lives of grandchildren, fails to confirm this importance, and concludes with a perflexed unwillingness to dismiss, altogether, the value of grandparents. Scholars have begun to resolve this contradiction by suggesting that grandparents' importance in families may not reside in observable behaviors or in other easily measurable variables. Rather, their importance may be far more elusive, related to a variety of symbolic meanings and influences that are not easily captured with the tools of quantitative social science.

Perhaps, too, grandparents' major influence may blossom over the life cycle and may be all but undetectable during the 'fat years' that are most often studied. For example, research finds little evidence that grandparents' values influence the values of their grandchildren. However, much of this research assesses particular family values, as they exist in grandchildren's minds during childhood. Where do children learn those values that underlie a lifetime of behavior (e.g., commitment to competence at a craft; rootedness in history; commitment to family; understanding generational connectedness)? Perhaps

these values are learned in the context of an ongoing relationship with grandparents. It is not unreasonable to expect that meaningful childhood relations with grandparents contribute to positive adjustment and mental health in adulthood, or to lifelong satisfaction in cross-generational relationships. The fact that these influences are not detected by conventional research methodologies neither confirms nor denies their existence.

Symbolic Influence

Sociologists identify the following symbolic functions of grandparents within families:

1. Stabilize the next generation by providing a buffer against its mortality.
2. Catalyze family cohesion.
3. Moderate intensity of nuclear family life by providing a sounding board and a mediator for both generations.
4. Serve as 'family watchdogs,' maintaining a latent observation and protection service that can become active frontline management when necessary.
5. Symbolize family continuity across generational past, present, and future – particularly during times of family disruption.

Family practitioners agree that grandparents can be crucial to the effective functioning of families in the following ways:

1. Reduce intensity of intergenerational conflicts by prompting maneuvering around touchy issues.
2. Mediate and interpret between two generations.
3. Provide emotional and financial support for parenting.
4. Serve as a nexus of family connections.
5. Relate to parents in a way that facilitates marital adjustment.
6. Support parents during times of marital conflict.
7. Modulate family life experiences on the basis of accumulated wisdom.
8. Expand the age range and number of available role models for family members, modeling adulthood and old age for grandchildren, and modeling grandparenthood itself for both children and their parents.

Developmental Influence

Despite disappointing empirical results, grandparent researchers remain convinced of the importance of grandparents for grandchildren. Emotional attachments between grandparents and grandchildren have been described as uniquely unconditional because of this relationship's exemption from parent–child intensities and responsibilities. Grandparents can serve as constant objects in the child's life, as 'Great Parents' who provide a secure and loving adult–child relationship that is next in emotional power only to the parental bond.

Pastoralists D. Conroy and C. Fahey point out that grandparents have a great deal to do with the initial development of a child's view of life. Kornhaber asserts that children's complete emotional well-being requires a direct, and not merely derived or symbolic, link with their grandparents. In the absence of this relationship children experience a deprivation of nurturance, support, and emotional security. Anthropologist M. Mead maintains that intergenerational family relationships, exemplified by grandparenthood, are absolutely essential to the child's development of his or her own uniqueness, wholeness, and cultural and historical continuity.

Young Adult and Adolescent Grandchildren

If grandchildren's preschool and school years signify grandparenthood's 'fat period' to grandparents, the children's adolescent and young adult years signify increasingly lean periods. How do grandchildren experience these distinct relationship periods? Scholars report that the amount of grandparenthood contact during childhood directly affects the type of relationship grandchildren and grandparents later maintain. They further suggest that when close, intimate grandparenthood relationships are formed during childhood, both grandparent and grandchild continue to nurture the attachment throughout life. Nonetheless, the literature does not consistently support the view that grandparents remain significant throughout grandchildren's adolescent and young adult years.

Secondary data analysis indicates that adolescent children of single mothers benefit from a grandparent's presence in the home. Because adolescents in single-parent homes are especially independent, they are likely to be in particular need of the supervision and control available in an extended household. Furhermore, a grandparent's presence in a family that otherwise tends to be non-hierarchical may reinforce generational boundaries, thus maintaining the benefits of hierarchical structure.

Based on self-report questionnaires, the overall picture of grandparenthood to adolescents seems to be one of frequent, dynamic intergenerational involvement. High school students report viewing their grandparents as confidantes and companions. They say it is enjoyment of contact, rather than

family obligation, that motivates them to maintain these relationships, and they describe brief conversations and important discussions as replacing childhood's largely recreational visits. Young-adult grandchildren describe relationships with grandparents as extremely important; they indicate that contact frequency affects the solidarity, not the importance, of these relationships. However, these findings conflict with longitudinal data indicating that grandchildren's transition from childhood to adolescence prompts a more dramatic change in grandparenthood relationships than any other grandparent or grandchild life transition.

Cross-cultural Grandparents

Relation to Cultural Values

Mainstream Euro-American culture has long been characterized by its overwhelming emphasis on the principles of autonomy and individualism. Under conditions of economic hardship, individual wishes and aspirations are subordinated to the family obligations that ensure survival. But in times of relative security, behavior is governed by individual independence, self-reliance, and freedom from the constraints of commitment. This underlying value system is absolutely consistent with Cherlin and Furstenberg's description of contemporary American grandparents as paying far more attention to preserving independence (their own, their children's, and their grandchildren's) than to promoting long-term or deep-seated emotional well-being.

Little research is available to describe grandparents in diverse American subcultures that are organized around family commitment, group interdependence, or respect for elders. We might expect Native American grandparents, for example, to be more concerned with a given relationship's impact on a grandchild's long-term development than with its momentary enjoyment value. We might expect Hmong-American grandparenting behaviors to be determined more powerfully by their effect on overall group well-being than by their protection of individual freedom.

African-American Grandparents

In view of traditional African emphasis on individual interconnectedness with the group, Kivett's finding that grandparenthood is more salient in the Black community than the White should not be surprising. Black grandparents assume parental responsibility for grandchildren far more often than White grandparents. To a far greater extent than White families, Black families demonstrate regard for older adults, propensities to protect the frail and dependent, and expandable household boundaries as dictated by the needs of kin and significant non-kin. Indeed, 'fictive' or 'pseudo' kin are important members of many Black families. These people are regarded in kinship terms, they are accorded many of kinship's rights and statuses, and they participate fully in informal support networks. Whereas only 8% of Anglos in Bengtson's cross-cultural study report having raised children other than their own biological offspring, nearly half of the Black adults over 60 report having raised fictive children and grandchildren.

Research seems to confirm some stereotypes about Black intergenerational families while failing to confirm others. Burton and Bengtson acknowledge the important tradition represented by Black grandmothers in African-American culture. However, they describe the familiar view that Black women regard children as God's blessing as a holdover from slavery, rather than a cultural tradition. They report that for most of their respondents, off-time grandmotherhood may represent both a symbolic and an instrumental crisis. That is, for these women, too-early accession to this lineage role creates conflicts both in their view of themselves, and also in their family system of cohesion and social support.

African American scholar R. Taylor notes that aged Blacks have significant and varied family roles, maintaining extensive contact with children and grandchildren. Qualitative studies point to the importance and critical nature of the family for the functioning of elderly African Americans and, reciprocally, to the importance of these elderly for the survival of African American families. On many socioeconomic indicators older Blacks represent one of the most severely disadvantaged groups in our society. Their family roles are particularly important, both in view of their special needs for assistance, and also in terms of their unique capacities for contribution.

Latino Grandparents

In Latino culture, elders are esteemed for the wisdom that is reserved for them, alone. Within neighborhoods elders act as part of a grapevine of social control. Within households, their presence helps reduce anxiety resulting from such nuclear family stresses as a child's illness, divorce, or overtime work for parents. Hispanic tradition supports the view that elders are teachers who participate in cooperative efforts. Because their wisdom is valued, physical decline does not diminish the family contributions of aged Latinos as it does among Anglos.

Gerontologist C. Garcia points out that extended Latino families must be viewed in terms of function (interaction and exchange) rather than structure (residence). By and large, Latino grandparents live with a child's family. But because a grandparent has many children and because he or she can only live in one household, most middle-generation households do not structurally include grandparents. Functionally, however, Garcia reports that every household views grandparents as active members.

Studies of Chicano grandparents find that grandmothers play several roles:

1. child rearers
2. participants in family decision making
3. religious advocates and teachers
4. participants in a female network of healers.

Both grandmothers and grandfathers value their caregiving activities, considering themselves equally responsible for child rearing. They view their most important task to be teaching the grandchildren Spanish, traditional customs, and morality. Rather than stressing autonomy, they emphasize interdependence and cooperation with their families.

Latino culture does not regard productive work in one's occupation as life's central task. Cultural tradition also values leisure, and it regards extended family relationships as an important source of personal identity. As a result of the family being so highly valued, aged Latinos do not seem to undergo a dramatic role change upon retirement.

Future Outlook

Research

Grandparenthood has been properly explored within the disciplines of anthropology, sociology, history, family studies, psychology, psychiatry, gerontology, social work, public policy, and cultural studies. Each discipline views the world through its own theoretical lens, focusing on its own issues of concern, utilizing its own research tools, reporting in its own terms. Over the less than 50 years that grandparenthood has been formally studied, historical trends have influenced not only the role and relationship under investigation, but also the goals, foci, and strategies of research within every involved discipline. Accumulated disparate findings are not easily synthesized into a coherent body of knowledge. Thus, after decades of research, our understanding of grandparenthood – family relationship, ascribed status, social role, psychological object, source of personal meaning, and more – remains fragmented. Attempts to integrate risk confounding description, explanation, prediction, and advocacy.

Quantitative research methods have focused our attention on a wide array of measurable demographic, behavioral, and psychological variables. However, because measurable variables are not necessarily valid operationalizations of the concepts under investigation, descriptive findings too often appear superficial and removed from the lives of the real people who are grandparents. Grandparenthood meaning, importance, and influence remain elusive.

Recent qualitative investigations of cross-cultural grandparents have begun to provide valuable insights into grandparenthood's complexity, and to suggest lines of inquiry for mainstream grandparenthood, as well. This work suggests that the values of particular cultures (concerning family, wisdom, work, aging, and more) are integrally related to grandparenthood and must be explored further. It is to be hoped that qualitative research will continue to make progress in identifying, understanding, operationalizing, and quantifying meaningful variables, and in building theoretical concepts that will be amenable to traditional, quantitative social science research.

As a phenomenon that is both intergenerational and lifelong, grandparenthood must be explored with research strategies that are sensitive both to intergenerational and family systems issues, on the one hand, and to life cycle development issues, on the other. Related to both science and practice, grandparenthood research must be conducted with an eye both to building knowledge and also to improving practice and policy. Areas of special current concern include grandparents as caregivers and as recipients of family-care, grandparenthood in the expanding life period of 'old-old' age, and grandparents as part of our society's complex system of racial, ethnic, and cultural relations.

Practice

Discussions of contemporary American grandparenthood fall on a continuum. At one end we are called to return to the 'good old days' of strong family ties. At the other end we are reminded that progress has its costs, and that strong, involved grandparenthood may be one of them. Several important practical issues underlie this entire continuum.

Grandparenthood conflicts and dilemmas may be seen as a metaphor for all family relationships. Every family bond involves a self and an 'other,' whether that other be an individual or a group. Establishing and maintaining bonds requires a constant balancing and rebalancing of concerns for self with concerns for other. In addition, maintaining family bonds over

time requires a balance between perceived well-being now, and anticipated well-being over a life cycle that involves both personal and generational futures. To the extent that we seek to understand or influence grandparenthood, we must do so in the context of these essential balances and their parameters.

American society is constantly evolving. We must remember that just as grandparenthood has changed with past historical shifts, so it will change with the social, economic, and cultural shifts of the present and future. Contemporary grandparenthood may be an understandable reflection of intergenerational affection without interference. But grandparenthood will not necessarily reflect these same values in the future.

Family scholars inform students that maintaining viable intergenerational ties requires considerable care and effort; grandparents have long admonished grandchildren that 'You get out of something what you put into it.' Grandparenthood as an institution may, indeed, reflect sociohistorical developments. But within any given family, people are free to make of this relationship as much or as little as they choose. American societal norms may encourage individualism and non-interference. But individual families and communities are free to balance these values with cooperation and respectful long-term responsibility. Grandparenthood, as a phenomenon, will continue to reflect large-scale societal currents. But individual people and families need not bob, like dinghies on the waves. The participants in any particular grandparenthood relationship can work to make that relationship meet the needs they decide are important.

Glossary

Geriatrics – The practice of care for frail older people and represents the intersection of chronic disease care and gerontology.

Managed Care – Some method by which a fixed sum is paid to cover a person's health care costs for periods of time, and efforts are made to deliver that care as efficiently as possible.

Successful Care – Making someone better and/or slowing the rate of deterioration.

Introduction

Health care for older people involves managing chronic illness. In essence, geriatrics represents the intersection of chronic disease care and gerontology. Diseases present differently in older persons, and their treatment is complicated by the presence of impairments in other domains, such as affect, cognition, and economics. In the United States, older persons are the only group covered by a universal health care insurance system. Nonetheless, there remains substantial geographic variation in access to care. In general, older people still suffer from ageism; decisions about what care they should receive is influenced by beliefs about what is age appropriate.

Dominance of Chronic Illness

The story of health care for older persons is inexorably linked to chronic disease. Indeed, chronic disease is the dominant factor in health care for all ages, but its predominance is especially high for older persons. If for no other reason than because such conditions accumulate with time, older people are disproportionately heavy users of health care, largely because they have a heavier illness burden. **Figure 1** shows the distribution of chronic illness among elderly persons. In the United States, elderly persons are the only demographic group that has virtually universal health coverage, under Medicare.

Addressing chronic care effectively implies drastically changing the current health system, which was developed to address primarily acute problems. The implied reformation addresses a wide range of aspects of care, including the definitions of concepts such as prevention, the role of patients, and even time. Prevention is best thought of in terms of avoiding major catastrophes. In effect, good chronic disease care will handle problems proactively to prevent emergency room visits and hospitalizations.

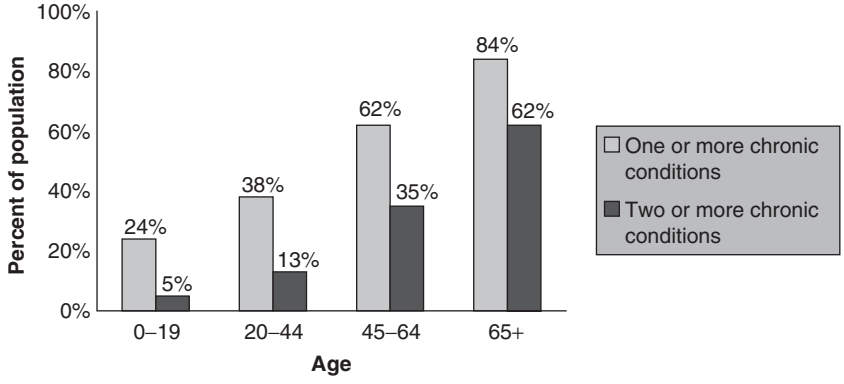

Figure 1 Percent of US population with chronic conditions by age. From Partnership for Solutions (2002).

It is unrealistic to think about managing chronic disease without actively involving patients in their own care. They are the ones who must deal with the disease every day. The challenge lies in determining how to create a productive partnership between patients and their clinicians. Programs designed to give patients a greater sense of empowerment have been promising. Another approach encourages patients to record systematic observations on defined parameters that reflect the clinical course of their diseases and to notify their clinicians when the observed course deviates from what had been expected.

Time too takes on a new meaning, beyond that implied by the term 'chronic.' In effect, chronic care means thinking in terms of investments. One provides active primary care with the expectation of recouping that effort in terms of subsequent care avoided. Focusing attention on high-risk periods, such as immediately after a hospital discharge, can pay dividends. Nurses working with patients in these situations can improve compliance with postdischarge regimens and prevent subsequent readmissions. Scheduling encounters need to be overhauled. Instead of seeing patients on a fixed time schedule based on a loose expectation of when another assessment is needed, visits should be triggered by patients' actual courses. They need to be seen when their condition deviates from the predicted path; then they need to be seen quickly to treat the problem before it becomes serious.

Professionals can be quite varied. Nurse practitioners have been shown to be very effective in managing chronic problems. They can work independently, or they can team with specialists to allow them to address the organ of interest while the nurse attends to the whole person.

Perhaps one of the most difficult issues surrounding chronic illness is the definition of successful care. Because the general course of chronic illness is gradual deterioration, success is not simply making someone better; it may be slowing the rate of deterioration. However, establishing that effect is difficult in the absence of some point of comparison. What would have occurred in the absence of good care? Such comparison groups are rarely available. Instead, we must rely on statistical analyses, but these data are too theoretical to be attractive or convincing. The logical support for chronic care is information technology. Systems that can show changes over time and that can notify clinicians about changes in a patient's condition can play central roles in proactive care. Because many different professionals may be involved in the care of some frail older people, ways to share information should be useful. The utility would be enhanced if the information were available in a structured format that allowed systematic collection.

Care of frail older persons frequently involves coordinating the medical and social components of care. Most older people requiring long-term care have serious underlying medical problems. Attention to these problems will affect functioning and quality of life. However, life consists of more than having good medical care.

The goals of effective chronic disease care can be summarized as follows:

1. Manage the disease as well as possible to reduce the extent and frequency of exacerbations.
2. Prevent (or at least minimize) the transition from impairment to disability, and from disability to handicap.
3. Encourage the patient to play an active role in managing his or her disease but avoid allowing the disease to become the dominant force in the person's life.
4. Provide care in a culturally sensitive manner.
5. Integrate medical care with other aspects of life and care without medicalizing those aspects.

Table 1 summarizes a number of innovative approaches to addressing the problems associated with managing chronic disease. Most have shown at least some benefits. Ironically, the one area that has shown the fewest positive effects is the one most actively embraced, case management. Part of the problem can be traced to the confusing way this term has been used. In fact, there are many different types of case management, often directed at different goals. At least five variants can be identified: eligibility management, care coordination, utilization management, disease management, and chronic care management. **Table 2** contrasts these variations on the case management theme.

Geriatric Paradigm

Geriatrics is the practice of care for frail older people. The epitome of geriatrics is treating multiple interactive problems that cross domains. In essence, geriatrics represents the intersection of chronic disease care and gerontology. Clinicians caring for older persons need to understand that diseases present differently in older persons, and their management is complicated by the presence of other factors. Older people take more medications, and hence are at greater risk of drug interactions. Older people may face problems in other sectors of their lives, such as their social roles, their economic status, their cognition, and their affect, which complicates treatment for specific health problems.

Table 1 Effectiveness of chronic disease care interventions[a]

	Satisfaction	*Function*	*Utilization*	*Costs*	*Mortality*
Interdisciplinary home care	+	+	+	+	
Self management	+	+	+	+	
Group care	+		+	+	
Home hospital	+		+	+	=
Disease management			+	+	
Professional dyads in nursing homes			+		=
Acute care for the elderly hospital wards	+	+	=	=	=
Geriatric evaluation and management	+	+	−	−	=
Transitional care	=	=	+	+	=
Case management		=	=	=	=

[a] +, indicates a superior outcome associated with the experimental form of care; −, indicates a worse outcome associated with the experimental form of care; =, indicates similar outcomes for the experimental and the comparison forms of care; an empty cell indicates that the outcome was not measured.

Table 2 Variations on case management

	Typical provider	*Aims*	*Implications*
Eligibility management	Social worker or nurse	Assessment to see if client reaches threshold for eligibility Care plan Implementations	Cursory monitoring for change in status that would affect eligibility
Care coordination	Social worker or nurse	Structured assessment to indentify needs Care plan addressing each need Arrange services to meet each need Follow up to assure services are delivered Re-assess periodically and adjust care plan	
Utilization management	Usually a nurse	Identify high-volume/high-cost cases Work with high users to change clinical course • Monitor intensively • Counsel to encourage compliance • Seek ways to prevent problems • Flag charts to alert clinicians	
Disease management	Usually a nurse, possibly an MD	Focus on a single disease Provide reminders Counseling Monitoring	Usually not coordinated with primary care
Chronic care management	Nurse or nurse practitioner	Establish expected clinical course Monitor salient parameter for each condition followed • Patients can do most of the monitoring • Communicate with clinicians by phone, web • Intervene when actual course differs from expected course • Indication for active intervention	See clients primarily when their condition changes significantly Can monitor many conditions simultaneously Can address function as well as diseases

Medical problems may manifest differently in older persons than in younger ones for two reasons. First, older people often suffer from multiple diseases. A change in one of these may become lost in the noisy background of others. Whereas in a younger the person the onset of new problems may be distinct, like a mesa in the desert, in an older person an exacerbation, or even a new onset,

may be as hard to detect as a new peak among the Alps.

The second relevant concept is based on the changes associated with aging. In general, age-related physiological changes are most evident in dynamic measures. Older people do not react to stress as well as their younger counterparts. Most of the manifestations of disease, what we call signs and symptoms, are usually not the effects of the disease per se, but the body's reaction to the stress produced by the disease. Little wonder, then, that older people would not show the classic symptoms of a disease, but instead some muted or general response. Whereas a younger person having a heart attack might complain about chest pain, an older person might present with confusion. This same symptom could be caused by pneumonia or a drug reaction. Thus, diagnosing disease in older people is often a much more difficult feat than with younger patients.

Diagnosis is hindered still further by communication problems created by problems with vision, hearing, or dementia. On top of these communication problems, older people often suffer from multiple diseases, making it harder to distinguish the onset or change of a given symptom.

The basic technology of geriatrics is the comprehensive geriatric assessment (CGA). Experience has taught that exposing frail older persons to such an evaluation and then returning them to the same care environment did not sustain the effects. Gradually the concept of geriatric evaluation and management (GEM) evolved, which involved treating the patient for as long as needed to implement and sustain the necessary changes in the regimen. Few other approaches to care have been studied as thoroughly as CGA and GEM. Unfortunately, the results have provided a confusing and often contradictory story. Although meta-analyses imply that CGA is effective, the pattern is not consistent. **Table 3** summarizes the results of several inpatient CGA/GEM randomized trials. **Table 4** offers a comparable summary of outpatient studies. One of the largest and most recent studies was a multisite trial that involved both types of care. Although it was carefully targeted to patients who were deemed likely to benefit, it found scant effects. By contrast, a study that involved a simple home visit by a nurse practitioner to unselected older persons living at home yielded potent benefits, as did a preventive assessment by occupational therapists.

Sites of Care

A basic rule in geriatric care is not to confound the type of care received with the site of delivery. Clinical vocabulary has caused confusion by adopting terminology that defines care by where it is provided. Thus, we speak about inpatient and outpatient care, or nursing home and home care, as if those terms defined some level or type of care. In fact, the same care can be rendered in many settings. It is important to identify the critical elements of care and then ask what environmental supports are needed to provide it. The expansion of technology has meant that much care that formerly was restricted to institutions can now be delivered in outpatient settings or even at home. Laboratory tests that used to require specialized laboratories can now

be performed by patients at home. Monitoring is possible from long distances.

Changing locations can save money. For example, by treating medical conditions of nursing home residents in the nursing home instead of sending them to the hospital emergency room (and likely hospitalization), one managed care organization saved substantial amounts of money and reduced the stress on the residents.

Organization of Care

The way care is organized affects how it is delivered and often what effects it produces. In many ways managed care would seem to be the natural vehicle by which to encourage better chronic care. Managed care implies some method by which a fixed sum is paid to cover a person's health-care costs for periods of time and efforts are made to deliver that care as efficiently as possible. Because the costs are paid up front, there are incentives for not spending money. Ideally, the per capita payment is calculated in an actuarially fair way, which reflects the expected costs of each enrollee based on their prior history and underlying health status. To the extent that good primary care prevents expensive complications, managed care provides a means to generate the capital needed to invest in an infrastructure that can produce better primary care, be it personnel or equipment.

Unfortunately, the promise of capitated care has not lived up to its potential. Given a weak case-mix adjustment payment system, it has proven easier to recruit fewer sick beneficiaries at an average price than to create the more cost-effective approaches of caring for those who need more attention. Indeed, there exists a strong disincentive to become good at chronic care for fear that those with the greatest needs will be attracted to such a program. If the case-mix adjustment is insufficient, the managed care organization may be financially disadvantaged by getting average costs for persons with greater than average needs.

In truth, every public health-care system (e.g., Medicare, the UK's National Health Service) can be viewed as managed care to the extent that it receives a fixed amount for care and is responsible for using the resources to the greatest advantage. In a universally covered system, there is nowhere to hide. Issues of case-mix payments do not apply, at least not in the aggregate, although some subcontractors may still require such a payment approach.

Variation

There is substantial geographic variation in the rates with which medical care is delivered. This variation among Medicare recipients in the United States has been extensively studied, because they have universal

coverage and a good data system. One study showed that both the effects of patient characteristics (e.g., race and ethnicity) and hospital market effects played a role in access to care among Medicare beneficiaries. Data provided by the Organisation for Economic Co-operation and Development (OECD) illustrates the variation across countries. These rates are based on populations, not just older persons, but the patterns can be safely extrapolated. **Table 5** shows the patterns for several surgical procedures. The variation among countries is not consistent across procedures. The United States has the highest rates among all three cardiovascular procedures, but the country with the lowest rate is different in each case (Switzerland for PTCAs, Italy for stents, and France for CABGs). Canada has the highest rate of cholecystectomies and the lowest rate of hip replacements. The United States has the lowest rate of hip replacements and the highest rate of knee replacements. For all procedures, the extent of variation is at least 2-fold; for some conditions, the rate is more than 10-fold (e.g., stenting). The United States is not the most active country in organ transplantation. Given that most of these countries (except the United States) have some form of universal access, the variation seems attributable to both formal and informal practice policies. One might speculate that the variation reflects the underlying rate of disease, but differences across procedures designed to address a similar problem suggest that other factors are in play.

Role of Primary Care

The key to chronic disease management is effective primary care. This level of care implies first contact care. In most developed societies, primary care is delivered by general practitioners (GPs), who care for persons living in the community (and sometimes in institutions, such as nursing homes). They provide the bulk of the care needed, referring to hospital-based specialists only when the case is too complicated for them to manage or when the patient needs more intensive hospital care. In most such situations patients can see a specialist only upon referral by a primary care clinician. The United States differs from most other countries in not having a formal schism between primary and specialty care. Instead, patients can choose whom they want to provide their primary care, who may well be a specialist. The decision is determined by supply and practice style. Such an arrangement creates substantial confusion.

Primary care physicians for adults are usually family practitioners and internists, although some women use their gynecologists in this role. As medicine has become more technologically oriented, fewer new physicians are entering primary care. The gap is being filled by nurse practitioners, nurses who are largely trained at the masters level to provide care to persons requiring primary care. There is substantial evidence suggesting that these nurse practitioners can provide primary care on a level equivalent to that provided by physicians.

Although many still consider geriatrics a specialty, in the United States it has also been proposed as a form of primary care. One problem with this formulation is that it places geriatrics in direct competition with the disciplines from which it would hope to draw referrals.

Changing Nature of Care

Since the 1980s the nature of medical care has undergone a remarkable transition. Various technologies that make the use of surgery less necessary

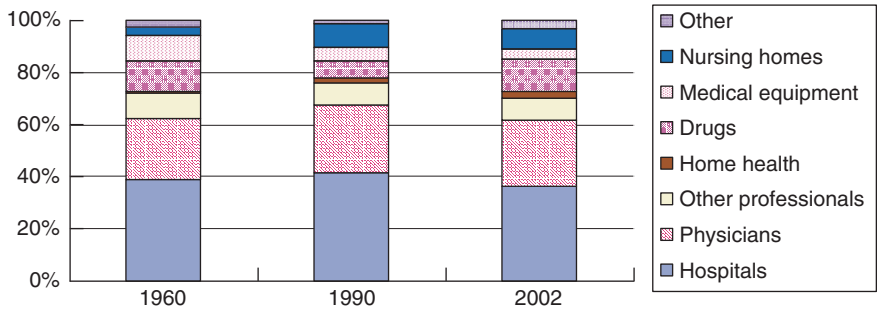

Figure 2 Personal health services expenditures in 1960, 1990, and 2002. Data from Health Care Financing Review, Medicare and Medicaid Statistical Supplement (2003), Table 4.

have evolved. Whether because of intravascular or endoscopic procedures, many surgical operations can now be done simpler and faster, often as outpatient procedures. At the same time, advances in pharmacy have created medications that have displaced hospital care in many situations.

As a result of these changes, the patterns of health-care expenditures have changed. **Figure 2** traces personal health-care expenditures in the United States from 1960 to 2002. Nursing home and home expenditures grew substantially after the passage of Medicaid in 1964. Between 1990 and 2002 hospital care receded and pharmacy advanced. In the United States, the latter shift created special problems because outpatient drugs had not been included in Medicare coverage. Thus, older people were left in an awkward situation: their basic care was covered, but the means of implementing it was not. The cost of medications was a growing concern. The passage of the Medicare Modernization Act of 2004 was designed to provide drug coverage, but its design left many problems.

While access to medications is a central aspect of assuring adequate care for older persons, misuse of medications poses a major problem as well. The rate of inappropriate prescribing varies from country to country, but it is still substantial. One European study estimated that almost 20% of elderly home-care patients were receiving at least one inappropriate medication.

Hospital Use Concerns

Hospitals are generally dangerous places for older persons. Frail older persons are at high risk for iatrogenic events. From that perspective, efforts to reduce hospital stays or to prevent them altogether can be viewed as positive events. On the other hand, denying older persons adequate hospital care may reflect discrimination. Efforts to control the use of hospitals by older persons began in the United States in 1984 with the imposition of a new approach to paying for hospital care, diagnosis-related groups (DRGs). These DRGs were based on the median lengths of stay (LOS) experienced by older persons. These LOS estimates were tied to costs for a set of over 400 DRGs, clusters of diagnoses that shared LOS characteristics, and made some clinical sense. Moving to this sort of prospective payment system completely changed the incentives for hospitals and thus their behavior. Whereas in the past more care had been a source of revenue, it now became an unreimbursed cost once the hospitals were paid a fixed amount per admission. The hospitals' immediate response was to take active steps to shorten stays and reduce the intensity of care. Concerns about 'quicker and sicker' discharges soon surfaced, but an early evaluation suggested that there was little adverse effect on quality of care.

There was, however, a tremendous impact on the use of posthospital care. Services that had been included as benefits under Medicare but had lain virtually dormant now experienced great growth as those discharged from hospital continued to need support in their recuperation. There was a growth in Medicare-covered home health care, nursing home care, and inpatient rehabilitation. This so-called post-acute care (PAC) became an increasingly large part of the Medicare budget. Indeed, it was soon the fastest growing component.

Much of PAC proved to be interchangeable. Depending on supply and practice styles, care for similar individuals could be provided in various settings. However, some settings were more effective than others. In general, patients discharged to nursing homes experienced the poorest outcomes.

The growth in PAC expenditures led to a demand for imposing cost controls using an approach based on that applied to hospitals. Prospective payment systems were created for each of the three major PAC modalities. Each one was independent, re-enforcing the silo approach that had ignored their potential

interchangeability. The prospective payment for nursing homes was based on a daily rate adjusted for case mix. The payments for home health care and rehabilitation were based on per episode costs estimated on the basis of client characteristics using two separate approaches.

The potential for bundling the costs of PAC into a single payment has been discussed but has not been adopted. Such a bundling approach makes sense on several levels. In addition to the observation about interchangeability, many patients actually experience several types of PAC during the course of their post-hospital care. Separate accounting makes it hard to affix responsibility for outcomes or to develop meaningful accountability.

Integrating Medical and Social Care

In many countries, medical and social (or long-term) care are the responsibilities of different programs. Integrating these two elements of care can be a challenge, but some models suggest at least some success. While the coverage of medical care may be universally available, coverage of social care is often treated as part of the welfare system. In the United States this distinction is reflected in coverage under two separate programs. Medicare is a universal health insurance program for older persons, whereas Medicaid is a welfare program available to poor persons at all ages.

Inevitably, some persons are covered by both programs, but the coordination across the programs is poor. These so-called dual eligibles account for a disproportionate share of resources from both programs. Approximately 17% of individuals enrolled in Medicare were also covered by the Medicaid program; they represented 28% of total Medicare expenditures during 1997. Dual eligibles represent approximately 19% of the Medicaid population, and account for 35% of Medicaid expenditures.

Efforts to address the needs of this subgroup have generally relied on some form of managed care as the means to pool funds from both Medicare and Medicaid. In theory, pooling these funds and developing specifically targeted approaches to meeting the needs of these high-risk frail older persons should improve outcomes. Perhaps the best-known program in this context is the Program of All-Inclusive Care of the Elderly (PACE), which targets a specific subset: dually eligible persons who are deemed eligible for nursing home care by virtue of their disability levels but who continue to live in the community. To enroll in PACE, patients must be willing to accept a PACE physician as their medical care provider. In effect, they must be willing to give up their prior medical care. The key to PACE is coordinated care. All of the staff, from van drivers to physicians, are viewed as members of the caregiving team. Medical care in the PACE model closely follows geriatric principles. Active primary care, with an emphasis on comprehensive assessment, addressing both functional as well as medical concerns, is a hallmark. The active effort to avoid institutional use often requires innovative solutions to providing care. In addition to using formal approaches, such as day care and home care, new venues of service have been created. For example, special housing arrangements have been developed whereby patients can be monitored during clinical exacerbations, using PACE personnel or informal caregivers.

PACE also places demands on the informal caregivers. PACE does not attempt to supplant informal care. Rather, such care is central to its mission of avoiding institutionalization. Whenever such care is available, informal caregivers are expected to provide active support. This is usually achieved by some form of social contracting.

The requirements to change physicians and to attend day care have restricted enrollment. Many frail older persons are reluctant to change their physicians if they have had any sustained relationship.

Unfortunately, the evaluation of the PACE program during its demonstration phase was inadequate. Despite the absence of substantial data to document whether PACE has achieved its promise, it appears that PACE did achieve its goal of reducing the use of institutions. Hospital days and hospital admissions for PACE clients were lower than those for fee-for-service Medicare beneficiaries in general for the first 18 months of the evaluation, an impressive statistic considering the frailty of PACE clients. Likewise, PACE clients had fewer nursing nights and admissions through the first year of the evaluation, but the difference dwindled over time. Perhaps commensurately, PACE clients had more ambulatory visits throughout the 24 months of the evaluation. Much less is known about the clinical outcomes of this care. There were few differences between PACE clients and controls in terms of functional status over time. Nor were there many patterns of differences in terms of self-rated health status, quality of life, or satisfaction. Despite the lack of evidence about an overall benefit from PACE care, it has been incorporated into the mainstream of Medicare managed care.

Several PACE programs have begun to experiment with alternative arrangements, more akin to independent practice associations (IPAs). In these situations, private practitioners could contract with the

PACE program to provide necessary primary care medical services. One such program is the Wisconsin Partnership Program (WPP). Unfortunately, easing the restrictions on physician enrollment was associated with poorer control of utilization. One possible contributing factor was the low rate of participation among physicians; each had on average only six WPP clients. Physicians caring for so few people are unlikely to change the practice styles to accommodate the needs of these frail patients.

Another approach to addressing the needs of dual eligibles is the Minnesota Senior Health Options (MSHO). In contrast to PACE, MSHO addresses elders in both the community and nursing homes; the range of disability is thus much larger. The MSHO program has not had a profound effect on the utilization of persons living in the community, nor has there been any substantial benefit in terms of improved functioning.

In contrast, the utilization effect on nursing home residents has been profound. Much of that benefit can be readily attributed to using services from Evercare, a program that was originally developed as a Medicare managed care plan targeted specifically at nursing residents. The Evercare model, which has been emulated by others, makes active use of nurse practitioners, who add to the overall primary care provided to the nursing home residents and who are also effective in communicating with family members. The Evercare model has been shown to dramatically reduce the use of hospitals and emergency rooms. Much of those savings come from shifting the locus of care from the hospital to the nursing home, thereby avoiding transfers, but some benefit also seems to arise from more aggressive primary care.

Another program that has attempted to address the gulf between medical and social care is the Social Health Maintenance Organization (SHMO). SHMOs are basically Medicare-managed care programs that receive a higher payment, which is designed to cover at least a modicum of long-term care. These programs have been viewed as lacking an aggressive stance in geriatrics; an evaluation suggested that they achieved little more than traditional Medicare-managed care plans.

A Canadian approach to integrating care for frail older persons draws from some of the American experience and tries to encourage more active roles for community physicians, while creating incentives to shift the locus of care from hospitals and nursing homes to community care.

The National Health Service (NHS) in the United Kingdom has embarked on a series of reforms designed to improve health care for older persons. In addition to establishing an agenda that addresses selected geriatric issues, the NHS has also created performance incentives for general practitioners to encourage greater adherence to chronic care guidelines. A substantial proportion of their overall payments will come from actively following these guidelines.

Glossary

Presbycusis – Hearing impairment associated with aging.

Tinnitus – Ringing in the ears.

Introduction

The general population in the United States is aging, and the fastest growing age group includes individuals over the age of 65 years. Only 4% of the population was over the age of 65 years in 1900, whereas projections state that over 17% of the population will be over the age of 65 in the year 2020. As the population ages, the number of chronic disabilities, including hearing loss, in that population increases. Communication difficulties related to hearing loss may lead to reduced quality of life, depression, and social isolation in older people. Communication lines begin to break down and frustration increases, which compounds the difficulty in communication. Despite these hardships, hearing loss is often an unrecognized affliction. Older individuals themselves may not recognize the onset of the hearing impairment, deny its existence, or accept it as part of growing old. Unrecognized hearing impairments may go untreated; only a fraction of older people with hearing impairments wear hearing aids, use other assistive listening devices, or receive aural rehabilitation.

Background: Prevalence and Origin of Presbycusis

Hearing impairment associated with aging (presbycusis) is present in older individuals of virtually all societies. Hearing loss is variously estimated to be the third or fourth most common complaint among older people. Tinnitus (ringing in the ears) is related to hearing loss and is the ninth most common complaint of older individuals.

Presbycusis includes both a loss of hearing sensitivity (elevated pure tone thresholds) and a reduced ability to understand speech, especially in noisy or acoustically poor environments. The audiogram (diagram of hearing levels by sound frequency) characteristic of presbycusis indicates a bilateral, symmetrical high-frequency hearing loss that worsens with age. Although men typically have poorer hearing than women, there is no evidence of an intrinsic cause for hearing loss to be determined by gender, and the difference in hearing is generally attributed to lifestyle factors. The rate of deterioration of hearing accelerates with age in both men and women, but men generally show deterioration at more than twice the rate of women. Risk factors for hearing impairment include exposure to noise either on the job or in recreational activities, exposure to ototoxic medications, cardiovascular disease, smoking, high blood pressure, alcohol consumption, and disorders of the hearing mechanism. Studies of normal aging attempt to dissociate disorders from aging, but because these risk factors are pervasive in industrial societies, it may be impossible to determine the amount of hearing loss that is determined by age alone.

Auditory Anatomy and Physiology

External and Middle Ears

A diagram of the external, middle, and inner ears is shown in **Figure 1**. The external ear consists of the auricle (pinna) and the external auditory meatus (ear canal). The pinna is made of a cartilage frame covered in skin, which is continuous with the skin of the external ear canal. The outer one-third to one-half of the ear canal is cartilaginous, and its skin covering bears cerumenous glands and hair follicles. The medial part of the ear canal is osseous and is covered with thin skin. The primary functions of the outer ear are to carry sounds to the middle ear, to assist in sound localization, and to protect the middle ear from the elements. The pinna and ear canal serve as resonators to amplify high-frequency sounds by approximately 10–15 dB. The most common changes with aging are dry and thinning skin, degeneration of collagen, prolapsed ear canals, and an increase in hair growth. The cerumen (ear wax) may become hard and dry and adhere to hairs in the ear canal and cause a conductive hearing loss due to the blocked path of sound into the middle ear. The cerumen may also cause tinnitus, pain, or vertigo (dizziness). Cleaning out the ear canal can be difficult in older individuals, as the thinned skin is easily irritated. Otherwise, the aging changes of the external ear only rarely affect hearing.

The middle ear is an air-filled cavity within the temporal bone that is bounded by the tympanic membrane (ear drum) and the oval window. The middle ear contains three small bones (ossicles) – the malleus, incus, and stapes. The tympanic membrane collects the sound from the external ear canal and delivers it to the ossicular chain, which in turn delivers it to the oval window at the entrance to the fluid-filled cochlea. The area ratio of the tympanic membrane to the oval window and the lever action of the ossicular chain amplify sounds approximately 30 dB to overcome the mismatch of impedance during the conversion of airborne sound waves to fluidborne traveling waves in the cochlea. The Eustachian tube connects the middle ear to the nasopharyanx, and serves to aerate and maintain atmospheric pressure within the middle ear. The

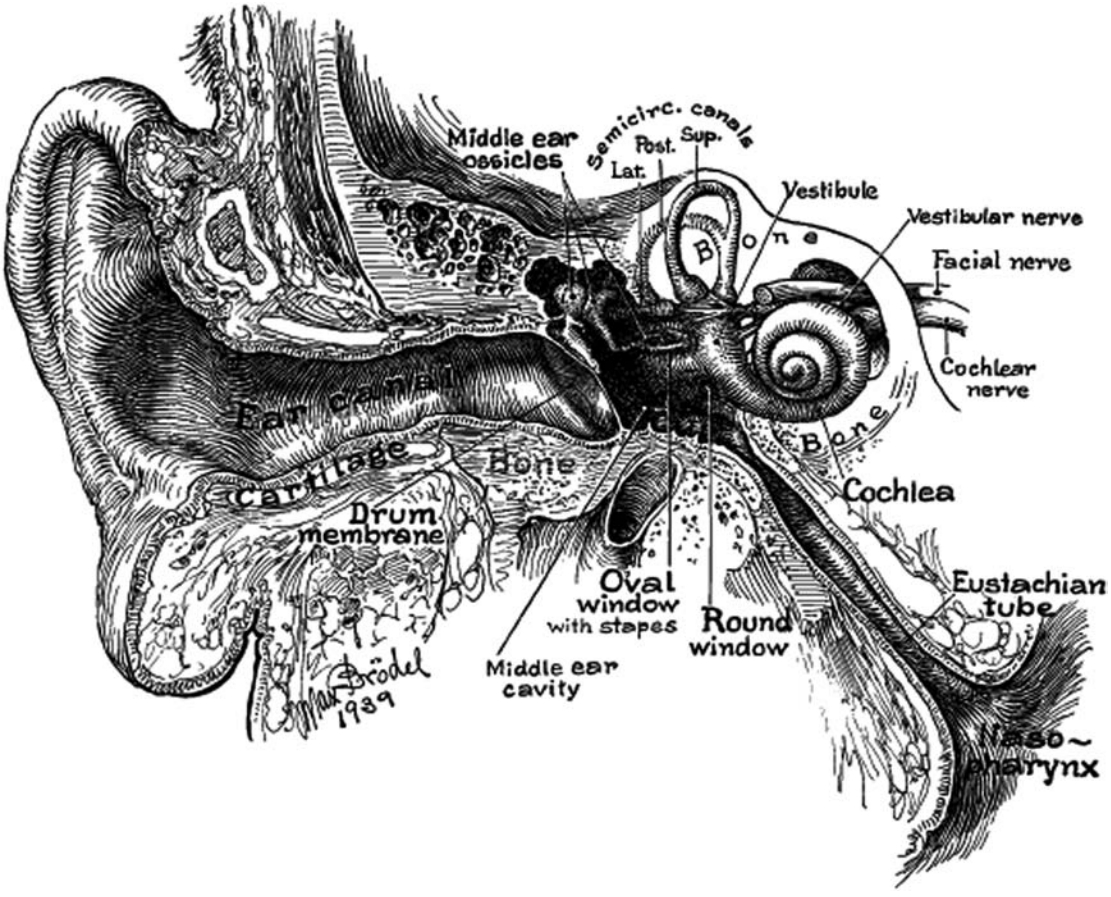

Figure 1 A cross-sectional diagram of the outer, middle, and inner ear, with landmarks labeled. Reprinted with permission from Broedel M (1946) Three unpublished drawings of the anatomy of the human ear. Philadelphia, PA: W. B. Saunders Co.

Eustachian tube is opened by the contraction of three muscles – the tensor veli palatini, levator veli palatini, and salpingopharyngeus. Two muscles, the stapedius and the tensor tympani, contract with loud sounds to reduce low-frequency energy entering the cochlea, thereby protecting it from noise damage.

All of the structures of the middle ear are affected by aging. The tympanic membrane becomes less vascular, thinner, and less elastic. There may be degeneration and arthritic changes in the incudomalleal and incudostapedial joints between the ossicles. The cartilaginous structure of the Eustachian tube may become ossified, and the muscles controlling the opening and closing may atrophy. The fibers of the middle ear muscles degenerate with age. Altogether, these changes may produce little or no effect on functional status of the middle ear and no significant reduction in hearing.

Inner Ear and Auditory Nerve

The inner ear or labyrinth is a bony structure that contains the cochlea of the auditory system for hearing and the vestibule and semicircular canals of the vestibular system for balance. The cochlea is a snail-shaped organ with two and three-quarters turns known as the basal, middle, and apical turns. Within the bony shell is a membranous labyrinth that includes three longitudinal compartments, the scala tympani, scala media, and scala vestibuli. The scalae tympani and vestibuli contain perilymph, a fluid that is high in sodium and similar to cerebral spinal fluid, and the scala media contains endolymph, a fluid high in potassium. The sensory epithelium of the auditory system, the organ of Corti, is situated in the scala media. The organ of Corti, shown in **Figure 2**, consists of the basilar membrane as the floor, supporting cells, tectorial membrane, and two types of hair cells (one row of inner hair cells and three rows of outer hair cells). The lateral wall of the cochlea contains the stria vascularis, which has a rich blood supply and generates the $+80\,\text{mV}$ endocochlear potential that serves as a local source of energy for hair cell function. The footplate of the stapes inserts into the oval window and delivers the mechanical energy to the perilymphatic fluids of the labyrinth. The vibratory motion of the stapes footplate sets up a fluid traveling wave in the cochlea, which propagates down the basilar membrane and stimulates high frequencies at the base and lower frequencies toward

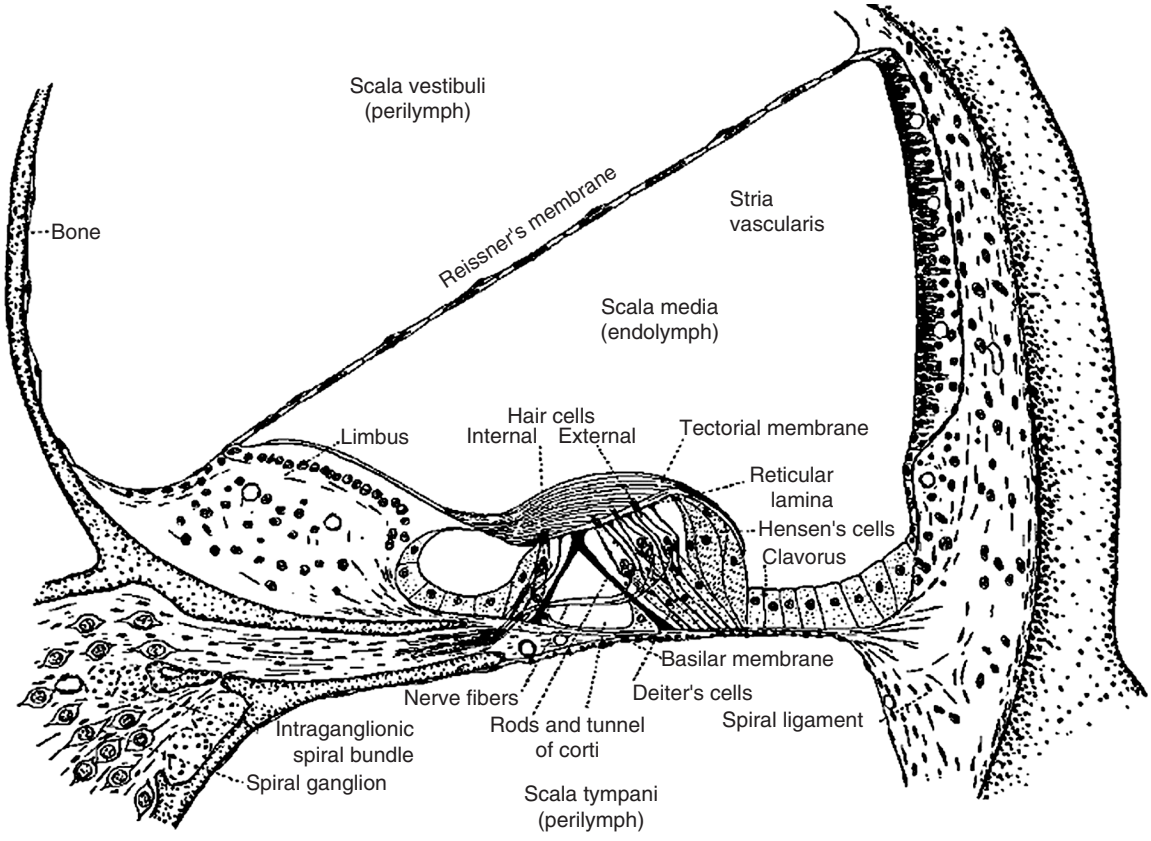

Figure 2 Cross-section diagram through the cochlea showing the organ of Corti. Reprinted with permission from Davis H et al. (1953) Acoustic trauma in the guinea pig. *Journal of the Acoustical Society of America* 25: 1180. Copyright 1953, American Institute of Physics.

the apex. The resultant pressure wave causes mechanical bending of the cilia protruding from the outer hair cells. An active process in the outer hair cells pumps energy into the basilar membrane to sensitize the response of the inner hair cells. The inner hair cells then release neurotransmitters at their base, which diffuse across the synaptic cleft. The chemicals are absorbed by the dendrites of the auditory nerve (cranial nerve VIII) and initiate neural impulses in the fibers of the auditory nerve.

Many age-related changes occur in the cochlea, and in combination they reduce the ability of the cochlea to respond to low-level sounds. Hair cells degenerate, nerve cell bodies in the spiral ganglion degenerate, the endocochlear potential declines, and nerve cells atrophy. Some of these changes result from noise, trauma, and diseases, but some appear to result from the process of aging as well. The basal, or high-frequency, end of the cochlea is the most vulnerable, and the typical result is primarily a high-frequency hearing loss. Primary or secondary loss of neural fibers is thought to result in sensitivity loss and distortion of signal processing, resulting in deficits of speech perception.

Central Auditory Nervous System

The central auditory nervous system (CANS) includes nerve fibers and nuclei (cell bodies) of the brain stem, midbrain, and cortex. The auditory pathways in the brain stem are shown in **Figure 3**. The fiber tracts are both uncrossed and crossed and connect the nuclei on both sides of the brain stem. The function of the CANS is to process signals for recognition of sounds, sound localization, auditory attention, and pattern recognition. With other brain structures, the auditory system controls attention to target sounds in backgrounds of noise and integration of auditory signals

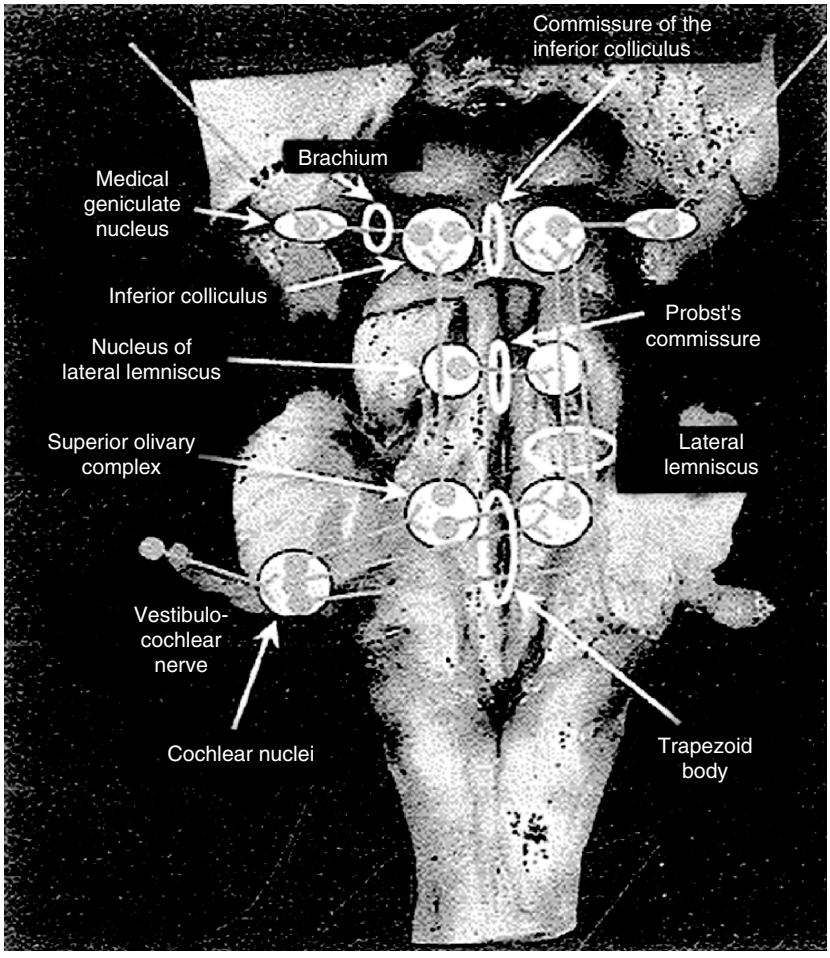

Figure 3 Dorsal view of the brain stem with superimposed schematic organization of subcortical relay stations of the ascending auditory system. Reprinted with permission from Seifritz E et al. (2001) Auditory system: functional magnetic resonance imaging. *Neuroimaging Clinics of North America* 11(2): 276.

with other sensory signals. At the cortical level, recognition and meaning are attached to the sounds.

Aging effects are noted throughout the CANS. Anatomical changes include slower nerve conduction velocity and reduction of synchronous firing due to thinning of axons and loss of myelin. Transmission between neurons may be slowed due to reduced neurotransmitter release and fewer postsynaptic receptors. Efferent feedback may be reduced in efficiency. These CANS changes with aging are more likely to result in central auditory processing deficits as opposed to simple loss of sensitivity and probably contribute to the difficulty older people have in understanding speech in difficult listening environments.

Measures of Auditory Function

Pure Tone Thresholds

Presbycusis presents primarily as poorer hearing for high frequencies compared to low frequencies. A composite audiogram showing auditory thresholds from 730 older individuals is shown in **Figure 4**. On this audiogram, only the thresholds from air-conducted signals are shown. Thresholds are also tested for bone-conducted signals, which bypass the middle ear. A gap between the thresholds from air- and bone-conducted signals would suggest a problem in the outer or middle ears. In older people, the thresholds from air- and bone-conducted signals are typically equal, suggesting that the hearing loss results from a loss of function at the sensory (cochlea) and neural levels of the auditory system.

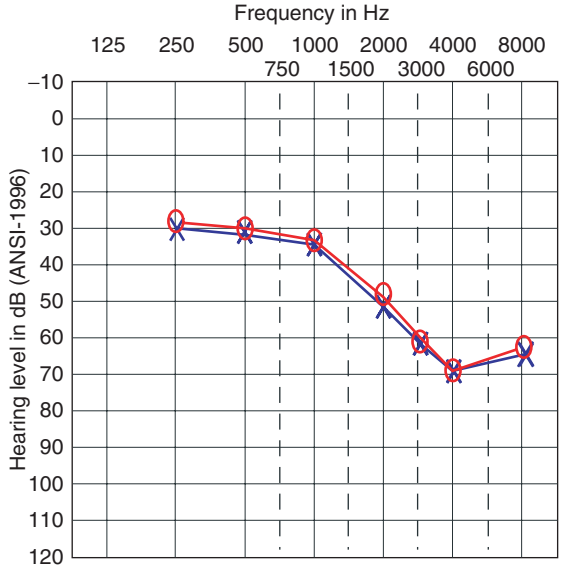

Figure 4 Graph of the average pure-tone thresholds (i.e., audiogram) for the left and right ears of 730 patients 55–88 years of age. Hearing thresholds (ordinate) are represented as a function of test frequency (abscissa). X, left ear; O, right ear. Unpublished data from Richard Wilson, Ph.D.

Audiological evaluations in older adults indicate that hearing loss exists in up to half of the adults over the age of 50 years and up to 90% of the adults over the age of 80 years. Men begin to report a hearing loss in their mid 60s and women report losses about 7 years later. Hearing loss is found four times more often in men than in women, even when risk factors such as education, occupation, and noise exposure are considered. By the age of 70, however, women are just as likely as men to develop hearing loss. After the age of 60, thresholds for pure tone signals decrease at a rate of about 1 dB/year. The rate of decline is initially slower for women than for men, but for many women, the rate of decline accelerates after the age of 70 years.

Presbycusis likely results from a combination of risk factors, including an accumulation of noise exposure from work and leisure activities. Noise exposure has been implicated as a risk factor for hearing loss since studies showed that elders in primitive tribes with minimal noise exposure had significantly less presbycusis than elders in modern industrial societies. In modern societies, individuals who engage in noisy vocational or recreational activities without using ear protection are more likely to suffer from hearing loss than individuals who do not. The hearing loss related to noise exposure interacts with the hearing loss related to aging, such that both appear to share an underlying mechanism. Whereas presbycusis develops with or without noise exposure, aging ears with noise damage initially show accelerated decreases in thresholds compared to aging ears without noise damage, indicating a non-linear addition of hearing loss due to age and noise exposure.

Speech Perception

Older people often complain that they can hear people talking but cannot understand what they are saying. They especially note that understanding speech is difficult in a crowd or a noisy situation where more than one person is talking at the same time. In fact, even if the degree of hearing loss is the same in older and younger individuals, the older persons typically have more difficulty understanding speech in noisy environments.

Speech understanding with aging results from a loss of sensitivity (audibility) as well as a loss of clarity. The hearing loss that most older people have renders inaudible some speech sounds, especially high-frequency consonants that are essential for

distinguishing words. Simply making sounds louder, however, does not completely resolve the problem. The additional loss of clarity in the speech signal may be related to distortion of the message caused by poor auditory processing in the defective cochlea and neural pathways of the auditory system. Because of the combined loss of audibility and clarity, older listeners require speech to be much louder relative to the background noise than younger people do to achieve the same level of understanding.

A variety of speech perception tasks in noise and with degraded speech materials demonstrates the underlying problems of older people. These tasks point to the poor ability of older people to process timing cues in speech and other signals. Older people have difficulty understanding speech that is presented rapidly, compressed, or interrupted with short silent gaps. These difficulties suggest that older people may process speech more slowly than it is presented in some social situations.

Behavioral studies also show auditory perceptual differences between younger and older persons. Older listeners have more difficulty discriminating between continuous and separate events, especially when sounds are soft. Temporal order tasks measure a listener's ability to identify the sequence in which tones are presented. Older adults have difficulty identifying tone sequences that are presented rapidly, again suggesting slowed processing times. General cognitive slowing and a decrease in the speed of perceptual processing may contribute to the poorer temporal processing in older persons.

Cognitive factors clearly can contribute to the speech understanding performance of older persons. When listening to conversations, an individual must be able to switch attention from one talker to another, remember what has been said earlier by one or more speakers, and likely perform both of these tasks in a room with distracting sights and sounds. The cognition required to follow conversations under these circumstances is not trivial. A hearing loss compounds the problem because even a mild hearing loss can be associated with reduced cognition and working (i.e., short-term) memory. Older persons do benefit, however, from contextual cues in the conversation and from a lifetime of experiences. Cognition, therefore, is intricately linked to the ability to understand conversational speech, and any loss in sensory perception is likely to compound the cognitive burden on an older individual.

Auditory Evoked Responses

Otoacoustic emissions (OAEs) are low-level sounds generated by the normal-functioning outer hair cells in the cochlea. The OAEs are generated spontaneously or can be evoked in response to sounds. These sounds are propagated back along the basilar membrane and released into the middle and then external ear, where they are recorded with a sensitive microphone. Two forms of evoked OAEs are recorded clinically: the transient evoked OAEs, which are generated by a click or short tone pip, and the distortion product OAEs, which are generated by an interaction between two pure-tone stimuli close in frequency. If auditory sensitivity is adequately controlled, there appear to be no significant reductions in the amplitudes of either the transient or distortion product OAEs due to age alone.

The auditory brain stem response (ABR) is the neural response to short clicks or tone pips, and is composed of five major waves that are named with Roman numerals. These waves occur within the first 10 ms after stimulus presentation and are recorded via electrodes taped to the scalp. Waves I and II arise from the cranial nerve VIII and the rest are from the auditory brain stem through the level of the lateral lemniscus. The ABRs from older persons typically show longer latencies and smaller amplitudes than the ABRs from younger persons. An example of ABRs of a younger and an older rhesus monkey that demonstrate these changes is shown in **Figure 5**. Specific effects of age are difficult to determine given the interaction between hearing loss and age, both of which may increase the latencies of the waves. Age

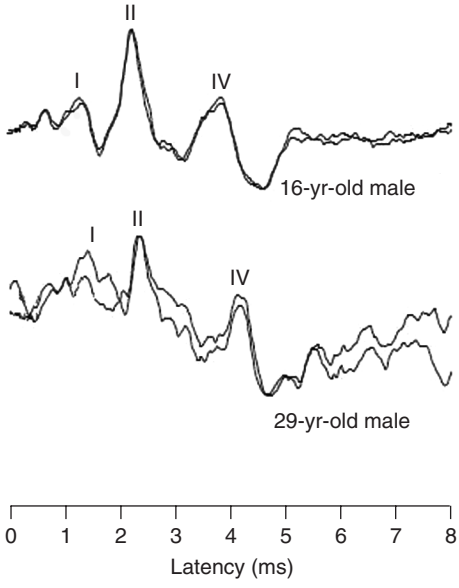

Figure 5 ABR waveforms recorded from a younger rhesus monkey (upper waveform) and an older rhesus monkey (lower waveform), showing the longer latencies and smaller amplitudes of the waveforms in the older monkey.

alone, however, probably contributes less than 0.2 ms to the latency prolongation. Interaction of signals from both ears may be evaluated with the binaural interaction component. The ABR from left ear stimulation is added to the ABR from right ear stimulation, and the binaural response is subtracted from that summation. The binaural interaction component is noted as a difference potential about the latency of wave V. At the brain stem level, the binaural interaction does not appear to be different in younger and older people.

The auditory middle latency responses (AMLRs) appear from 10 to 50 ms after sound stimulation and arise from the upper brain stem and primary auditory cortex. Most studies report that with age, latencies of the peaks Na and Pa are prolonged, and the amplitude of Pa may be enhanced. Although the cause of the enhancement is not certain, some believe that it is related to a reduction of inhibitory input from higher centers. Some hemispheric asymmetries are noted in older individuals when electrodes are placed over the temporal lobes, but these differences have not been correlated with behavioral responses. The binaural interaction component recorded with the AMLR appears to be reduced or absent in some older people.

The auditory long latency responses (ALLRs) include both stimulus-generated and cognitive potentials. These potentials are generated 50–500 ms following presentation of the stimuli. The sources are complex and include the primary auditory cortex, and the electrical activity is spread widely over the scalp. P2, the largest of the stimulus-generated potentials, is significantly smaller in amplitude and longer in latency in older people than in younger people. The amplitude difference between younger and older people for P2 amplitude is greater for activity recorded at the frontal area than at the top of the scalp. This change in the distribution of the electrical activity suggests a change in the underlying generators with age.

The P3 wave is one of many endogenous or cognitive responses that can be recorded using cognitive tasks. Typically a person is asked to note the difference between signals in an oddball paradigm in which a rare signal is randomly interspersed in a sequence of frequent signals. If the listener can distinguish the two signals, a positive response to the rare signals is generated at a latency of approximately 300 ms. The P3 has its shortest latency in early adulthood, and the latency progressively lengthens 1–1.5 ms/year as a person ages into the 90s.

The P3 can be used to demonstrate brain activation that corresponds to behavioral responses. It has been known for quite some time that when words are presented dichotically (different words to both ears simultaneously), a person understands the words presented to the right ear better than words presented to the left ear. This phenomenon is known as the right ear advantage for speech and is attributed to the shorter neural pathway from the right ear across the brain stem to the left hemisphere, the site for speech processing. By contrast, the left ear is at a disadvantage because the neural pathway crosses the brain stem to the right hemisphere and then crosses over the corpus callosum to the left hemisphere for speech processing. The advantage is reversed for non-verbal or tonal signals, which are processed in the right hemisphere and show a left ear advantage. The right ear advantage for speech develops in childhood, reaches a minimum difference in young adulthood, and then appears to increase again with aging.

The P3 can be elicited with both verbal and non-verbal signals and with signals presented dichotically or monotically (each ear separately). Use of these types of signals reveals the distribution of electrical activity in the cortex associated with the right ear advantage for speech and the left ear advantage for non-speech signals. In older adults, in contrast to young adults, the P3 hemispheric activation is asymmetrical for dichotic signals. As shown in **Figure 6A**, for dichotic verbal signals, the right ear produces significantly more P3 hemispheric activation than the left ear, and the opposite situation is seen for dichotic non-verbal signals. As shown in **Figure 6B**, with monotic stimuli, the P3 hemispheric activation is relatively symmetrical when there is no competition for the hemispheric processing centers. This pattern of activation may suggest underlying cortical changes that coincide with the difficulty that many older people have in separating speech from background noise and may lead to predictions regarding which older people will be successful users of binaural hearing aids.

Impact of Presbycusis

Hearing loss can affect all aspects of the life of an older person. The impact of the hearing loss, however, depends on the degree and configuration of the hearing loss, the ability to understand speech, and individual factors, including lifestyle, personality, and general health. A common assessment tool for the impact of the hearing impairment on an individual is the Hearing Handicap Inventory for the Elderly (HHIE) or the screening version, the HHIE-S. These scales consist of questions about the person's perception of the social and emotional impact of the hearing loss in various situations. These scales have only a moderate correlation with actual degree of hearing impairment and underscore the necessity to explore the impact of even mild hearing impairments

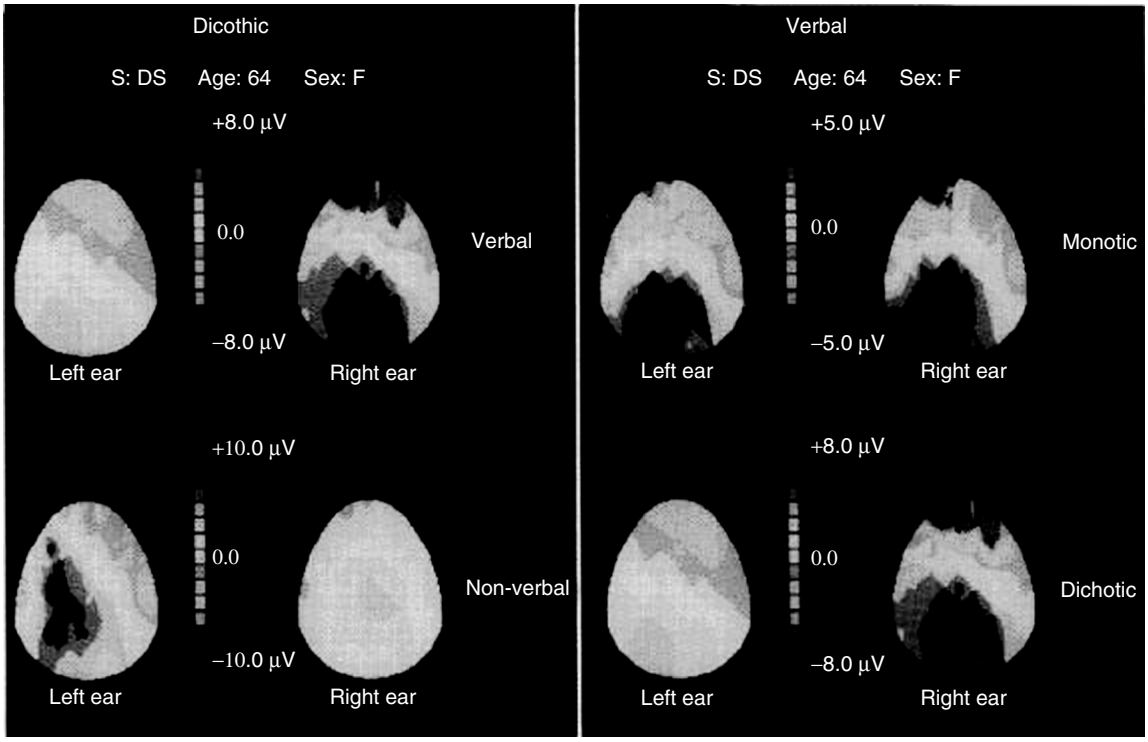

Figure 6 Topographic brain maps of peak P300 waveform in subject DS, a 64-year-old woman with presbycusis who also complained of trouble understanding speech in background noise. Darkest areas reflect greatest positivity. (A) Verbal and non-verbal tasks. (B) Verbal task presented monotically (top) and dichotically (bottom). Reprinted with permission from Jerger J (1997) Functional asymmetries in the auditory system. *The Annals of Otology, Rhinology, and Laryngology* 106(5): 23–30.

on the individual. Because older people may minimize or deny hearing impairment as they do with other chronic disorders, the use of these screening measures may be necessary to reveal an underlying problem that will not be revealed in a quick case history. Only after the problem is evident can a treatment plan be considered.

Older people with hearing impairments may experience depression, anxiety, and social isolation as a result of the difficulty they experience in communication. They may become frustrated, anxious, and less sure of themselves, which causes them to withdraw from their former activities and social contacts. People with hearing impairments are more likely to have other health problems, including high blood pressure, cardiac disease, and poor balance. An association exists between cognitive decline and hearing loss; even a mild hearing loss can result in memory deficits, and the risk of dementia increases with increasing hearing loss. Hospitalized older people in unfamiliar surroundings and without their hearing aids may become disoriented and appear demented.

A significant number of older individuals have vision loss in addition to hearing loss, which compounds the resulting communication handicaps. Estimates of older people experiencing this dual sensory loss range from 6% of community-dwelling elders to 70% of those in assisted living situations. Vision normally supplements hearing by allowing individuals to take advantage of the non-verbal aspects of communication, including speech reading, facial expressions, and gestures. With both hearing and vision impaired, people are less secure in social interactions and experience frustration, fatigue, and embarrassment. Eventually they withdraw from social interactions and activities and experience boredom, loneliness, and inactivity.

Some mitigating factors relate to hearing impairment in older people. Treatment for hearing impairments can significantly reduce the perceived handicap. Women are more likely to seek treatment than men. Older people report less handicap from their hearing loss than younger people with the same degree of hearing loss. Reasons for this difference may include fewer communicative demands placed on older people, less pressure from work, more acceptance of the hearing impairment, and a history of dealing with adversity. Acceptance of the hearing impairment, however, may also prevent older people from seeking treatments and lead to social withdrawal.

Remediation

The best remedy to date for hearing loss is amplification. Hearing aids can be programmed to meet the specific audibility needs of each person based on pure-tone thresholds and speech perception measures. Hearing aids available today include those that are completely digital and programmable and thus are superior to devices available only a decade ago. Recent advances in technology have produced microphones that take advantage of the spatial separation of the speech source and the noise source in the environment. In addition, noise reduction algorithms make use of the spectral and temporal differences between the speech signal and the background noise. The directional microphone technology creates a more advantageous listening environment for the individual hearing aid user by reducing background noise and enhancing the speech signal. Despite these improvements, the most significant problem faced by hearing aid users today remains the difficulty of separating speech from background noise. The enhancement of speech understanding in a background of noise and improvement of listening comfort in noise remain at the forefront of hearing aid research.

Despite the improvements in hearing aids and the customized approach to remediation, fewer than 20% of older persons who are candidates for hearing aids actually wear them. Several factors other than hearing loss influence an individual's motivation to wear a hearing aid. These factors include self-perception of communication problems, the number and quality of conversations experienced by the person, the availability of communication partners, physical health, the perception of hearing aid users as being old, cost of the hearing aid, and belief that hearing aids cannot help.

Several factors are important to consider when selecting a hearing aid for the older person. Possible dexterity problems can inhibit the patient from physically manipulating a small device, but specific modifications on the hearing aids can minimize this problem. Certain cognitive limitations may require more sophisticated devices since hearing aids can be programmed to switch automatically to optimize speech in a quiet environment, a noisy environment, or over the telephone. Finally, the single most important factor in successful hearing aid use is the motivation of the patient.

An individual's perception of his or her hearing problem is an important factor for success in remediation with hearing aids. Older people in general, and older men in particular, report their own hearing loss as less problematic than their communication partner does. Whereas this discrepancy may relate to the stoicism of older individuals who have faced many challenges in their lives, it also reveals the frustration and stress of the partner who tries to communicate with that individual. An individual who minimizes the hearing loss may be more resistant to treatment. Counseling the individual with the hearing impairment and the communication partner is essential to assure a successful hearing aid fitting. Both must understand the advantages and limitations of the hearing aid and must use additional strategies to enhance the communication between them.

For those who cannot wear hearing aids or require supplemental assistance in addition to hearing aids, a variety of assistive listening devices are available to help with communication in general or in specific situations. FM systems, which require the speaker to use a microphone that transmits to a receiver in the ear of the listener, raise the level of the message above the background noise for that listener. These devices are often available in public spaces such as theaters, lectures, and places of worship. Individual ear phones can be attached to the television to allow amplified sound to reach an individual without disturbing other members of the household. Telecommunication devices for the deaf (TDD) can be used for visual transmission of messages. Flashing devices can be attached to the doorbell, telephone, or alarm clock to provide a visual signal to replace or supplement the auditory signal. Pocket talkers are convenient for individuals who are cognitively impaired or otherwise unable to handle hearing aids and rely on others to maintain and manage their amplification devices. Assistive listening devices are relatively inexpensive and are appropriate for those who are unable to afford expensive hearing aids.

Prevention of Presbycusis

Prevention of presbycusis primarily deals with reduction of risk factors for hearing loss. Some sources opine that hearing impairments that accompany aging are due equally to environment and genetics, including interactions of the two. Environmental impact on the development of presbycusis has been studied for over 50 years. Studies beginning in the 1960s noted that members of primitive tribes who live in relatively noise-free environments do develop presbycusis, but the degree of hearing loss is significantly less than that seen in individuals living in modern industrial societies. Public awareness of the damaging effect of noise and its role in the development of hearing loss can help reduce the contribution of noise damage to the development of presbycusis. Noise levels are monitored in many workplaces, and

ear protection may be required for people in work environments that exceed damage risk criteria. Wearing ear protection is urged for people who engage in noisy recreation, including hunting and rock concerts. Noise damage to the hearing mechanism accumulates throughout life and interacts with other causes of hearing impairment to produce serious impairments that increase with aging. Protective measures may reduce the amount of hearing impairment due to this ubiquitous factor in the aging population.

A number of individual risk factors for hearing loss also exist, and some are amenable to control by the individual. Health factors such as hypertension, hyperlipidemia, cardiovascular disease, diabetes, and otologic disease can contribute to hearing loss. Smoking and excessive alcohol consumption have been implicated in hearing loss. These issues suggest that maintaining good general health can minimize hearing loss. Diets deficient in magnesium, vitamin B_{12}, and folate have been noted in hearing impairments in some elderly people, suggesting that some vitamin and mineral supplements may protect against the development of presbycusis. A diet rich in antioxidants has been demonstrated to mitigate the development of presbycusis in some laboratory animals. Calorie-restricted diets, which cut caloric intake but maintain nutrients, increase longevity in many animal models. In many of these animals, the calorie-restricted diet may reduce or postpone the development of presbycusis, but there is no evidence to date that this approach will apply to humans. The fact that all animals, or even all strains of a given animal, do not benefit from these dietary manipulations suggests a role for genes.

The field of genetics is expanding rapidly and includes the identification and understanding of genes that contribute to hearing impairments. An estimated 10% of all genes contribute to the structure and function of the hearing mechanism, and a mutation of a single gene can result in a hearing impairment. Although no specific genes that cause presbycusis have been identified yet, the genes causing nonsyndromic hearing loss have been implicated as likely candidates. Because genes affect mechanisms throughout the body, genetic mutations may produce multiple disorders in addition to the hearing impairment, such as kidney disease, diabetes, and dermatological disorders. Gene expression occurs into adult life, suggesting a continuing role for genes in hearing function. Mutations in mitochondrial genes have been associated with hearing impairments and may lead to disorders in adulthood because numerous cell divisions are required for cells to accumulate enough mutations to cause symptoms. Some genetic mutations interact with environmental factors, such as noise and ototoxic medications, to increase the likelihood of hearing impairment.

W B Ershler, Institute for Advanced Studies in Aging and Geriatric Medicine, Washington, DC, and National Institute on Aging, Baltimore, MD, USA

Glossary

Anemia – Lower than normal range of haemoglobin concentration: 13 g/dl for men and 12 g/dl for women.

Erythrocytes – Red blood cells.

Hematology – The study of blood and the disorders that affect blood.

Leukemia – A malignant transformation of white blood cell precursors and an accumulation of these transformed cells.

Leukocytes – White blood cells that are critical element sin the body's protection against infection and tumors.

Serum – Plasma that is devoid of coagulation factors.

Thrombocytes (also called platelets) – Cellular fragments of bone marrow megakaryocytes that are central to the control of bleeding.

Introduction

Hematology is the study of blood and the disorders that affect blood. Blood is composed of cellular elements and plasma, which itself is composed of proteins, fats, hormones, and other organic and inorganic chemicals. Plasma devoid of coagulation factors is termed serum.

Most circulating cells are derived from a single hematopoietic stem cell. The life span of blood cells is genetically predetermined. Therefore, hematopoiesis is a lifelong continuous process. Stem cells lack the surface molecules, which are associated with differentiation (maturation), but they do express the CD34 molecule on their surface, a feature that has proven to have important clinical implications. Hematopoietic stem cells give rise to unipotent progenitor cells, which then divide and differentiate into cells of a specific lineage. This differentiation process is considered to be random. Once a specific cell line is determined (e.g., leukocyte, erythrocyte), the progenitor cells go through further differentiation to manifest their ultimate predestined phenotype. This is accomplished by up-regulation of specific receptors under the influence of multiple cytokines and growth factors. Some of these cytokines, for example, erythropoietin and granulocyte-colony stimulating factor, have, in recent years, become important clinical tools.

With aging there is a notable reduction in the capacity to produce new blood cells. Yet, unless there is substantial physiological stress, the number of circulating cells remains fairly constant. Quantitative deficiencies are only apparent when stress produces a demand that exceeds reserve proliferative capacity. Such a demand might occur during an acute infection or after cytotoxic chemotherapy. Significant qualitative deficiencies in blood cell function are not thought to be a consequence of aging, but may be associated with age-associated chronic diseases.

The three major types of blood cells are erythrocytes, leukocytes, and platelets. Deficiency or overproduction of each of these cell types can lead to major clinical consequences.

Erythrocytes

The major role of erythrocytes or red blood cells is to transport oxygen. This is accomplished by a complex interaction of oxygen with the primary erythrocyte protein, hemoglobin. The average life span of red cells is 120 days. Therefore, to maintain steady state, approximately 0.8 to 1% of the total circulating red blood cells need to be replaced each day. If they are not, the red cell volume will decline and a condition termed anemia will develop.

Anemia

The lower limit of the normal range for hemoglobin concentration in blood, established by the World Health Organization, is 13 g/dl for men and 12 g/dl for women. Anemia occurs when there is a persistent decline in the hemoglobin concentration from the normal range accepted for a particular group. Hemoglobin levels tend to be lower in women and in certain racial groups, but the reasons for this are not fully understood.

Anemia is the most frequently encountered hematologic problem in the elderly. Hemoglobin concentration begins to show a steady decline in the sixth decade and beyond. It remains controversial whether aging results in anemia, but the current prevalent opinion is that the age-associated increase is the

result of coexisting disease or nutritional deficiencies and is not a consequence of aging itself.

Anemia may be characterized in a number of ways. One useful approach is classification on the basis of erythrocyte size. Accordingly, there are three major categories: microcytic, normocytic, and macrocytic anemia.

Microcytic Anemia Microcytic anemias are characterized by red blood cells with a mean corpuscular volume of less than 80 fl. The major causes of microcytic anemia in adults are iron deficiency, inflammatory disease, and thalassemia.

The most common cause of microcytic anemia is iron deficiency. This can occur due to inadequate nutritional intake, which is commonly observed in older people due to a change in dietary habits, dental problems, or malabsorption. However, the major cause of iron deficiency is blood loss, primarily through the gastrointestinal (GI) tract. It is very important to survey the GI tract in any case of otherwise unexplained iron deficiency, as iron deficiency anemia is one of the most common presentations of GI malignancy. Uterine or vaginal bleeding can also be the result of a developing cancer and a gynecological exam is warranted in women who present with iron deficiency.

Iron deficiency anemia is usually detected during routine laboratory testing. Although the serum ferritin is considered to be the most useful test in the diagnosis, it can sometimes be misleading, as this protein is also an acute phase reactant and can be elevated in inflammatory states. The measurement of the soluble transferrin receptor appears to be a more sensitive test, but it has yet to gain widespread clinical use.

Once iron deficiency is identified and a cause established, the most effective therapy is reversal of the identified cause (e.g., removal of colonic polyp) and the administration of iron supplementation. Usually, this can be accomplished with oral iron preparations. The treatment phase usually takes about 6 months. Oral iron is often not well tolerated, particularly by older patients, primarily because it is associated with constipation. Thus, lack of compliance with treatment recommendations becomes an issue and should be considered if the laboratory indicators do not reflect improvement within 2 months. Absorption may be erratic and, as mentioned, oral preparations may be intolerable for some patients. For these, parenteral preparations are now available, and many physicians are currently prepared to administer these either in their office or at an infusion clinic.

Other causes of microcytic anemia include thalassemia and inflammation. Many chronic diseases are associated with microcytic anemia (e.g., cancer, arthritis, infection, and even atherosclerosis and diabetes). Although some patients will also have iron deficiency, most will have laboratory evidence for adequate total body iron stores. Typically, such patients will have microcytic anemia, a clinically apparent inflammatory or chronic disease, and an elevated erythrocyte sedimentation rate (ESR). The mechanism of inflammation-associated anemia is not completely understood, but likely involves proinflammatory cytokines such as interleukin-6 and the newly described liver peptide hepcidin.

Normocytic Anemia Normocytic anemias are characterized by red blood cells that have mean corpuscular volumes of 80 to 100 fl.

Acute blood loss is the most common cause of normocytic anemia. In the absence of acute blood loss, other causes include hemolysis; early nutritional deficiency of iron, vitamin B_{12}, or folic acid; or erythropoietin deficiency secondary to kidney impairment.

Hemolytic anemia can be further defined as either intravascular (red blood cell destruction within blood vessels) or extravascular (red blood cell destruction within the spleen or liver). These conditions can be acute, subacute, or chronic and are diagnosed by laboratory tests, e.g., elevated levels of lactate dehydrogenase (LDH), indirect bilirubin, carbon monoxide, and urinary urobilinogen. The reticulocyte count is usually elevated, as the body attempts to compensate for the acute blood loss. Examination of the peripheral blood smear is crucial to help determine the cause of hemolysis. Often, the cause is secondary to an antibody, which either specifically or non-specifically binds to the red blood cell surface, causing direct (intravascular) or indirect (extravascular) hemolysis. The cause of such antibodies is sometimes associated with drugs (e.g., penicillin) or infection (e.g., *Mycoplasma pneumoniae*). Drugs may also result in hemolytic anemia directly, without producing antibodies. An offending drug or infectious agent is frequently not uncovered in a condition termed autoimmune hemolytic anemia. Treatment is geared toward stabilization of the underlying disease process, and transfusions are potentially dangerous because of the potential for exaggerating the hemolytic process.

Macrocytic Anemia Macrocytic anemias are characterized by red blood cells that have mean corpuscular volumes of greater than 100 fl. The three most common causes of macrocytic anemia are substance abuse, drug toxicity, and nutritional deficiency.

Substance abuse Both alcohol and tobacco abuse can lead to a macrocytic anemia.

Drug toxicity Drugs that commonly lead to macrocytic anemia are hydroxyurea, methotrexate, trimethoprim, and most cytotoxic chemotherapeutic agents.

Nutritional deficiency Vitamin B_{12} and folic acid deficiency are the two most common nutritional causes of macrocytosis. Folate deficiency is usually manifest by decreased folate levels in the serum or red blood cells. However, the most practical way to assess for folic acid deficiency is to measure serum homocysteine levels. Folic acid is required to convert homocysteine to methionine, and when it is deficient, homocysteine levels rise. High homocysteine levels can lead to more serious cardiovascular consequences.

B_{12} deficiency is typically discovered by low serum B_{12} levels. In the elderly, however, serum levels may be inaccurate. Measurement of the serum methylmalonic acid is a more accurate way to assess for B_{12} deficiency. B_{12} is a required cofactor in the conversion of methylmalonyl coenzyme A to succinyl coenzyme A. Therefore, in true B_{12}-deficient states, the levels of methylmalonyl coenzyme A would be expected to rise.

B_{12} deficiency can result from an inadequate nutritional intake of vitamin B_{12} or an inability to absorb vitamin B_{12} from the GI tract. This is often caused by atrophic gastritis or the unavailability of the intrinsic factor that is required to absorb B_{12} from the gut, resulting in pernicious anemia.

B_{12} deficiency can have a profound effect on DNA synthesis throughout the body, particularly in the central nervous system. In severe cases, permanent motor neuron injury and dementia (megaloblastic madness) can result. Thus, a comprehensive effort to establish the cause and implement correction of B_{12} deficiency is warranted in any patient with macrocytic anemia.

Other causes of macrocytosis can be liver disease and hypothyroidism.

Hemoglobinopathies

Hemoglobinopathies represent the most common genetic disorder in humans. Sickle cell anemia and thalassemia are genetic disorders that result in abnormal hemoglobin synthesis. It has been postulated that there is an evolutionary advantage in preserving these genetic mutations in certain regions of the world, as their presence has provided protection against malarial death.

Polycythemia Vera (PV)

Erythrocytosis (or polycythemia) is an increase in the hemoglobin concentration of the blood. This can result from an increase in the number of red blood cells or a decrease in the plasma volume that gives the appearance of a relative increase in red cells. Thus, polycythemia can occur as a result of reduced plasma volume (dehydration) or as a consequence of cigarette smoking, other lung disease, or living at high altitudes. In these situations, the red cell mass has been expanded by a compensatory mechanism to overcome chronic hypoxia. In contrast, polycythemia vera (PV) is a specific myeloproliferative disorder in which the red cell mass is expanded inappropriately. This disease occurs with a greater frequency in people over the age of 60 years, and there is a slight increase in prevalence in men versus women. Clinical manifestations result from whole blood hyperviscosity and associated decrease in oxygen delivery to tissues. Clinical signs and symptoms include headaches, dizziness, dyspnea, blurred vision, facial plethora, and paresthesias. Splenomegaly is common; this produces abdominal discomfort, weight loss, and night sweats. For unknown reasons, pruritus is common.

The diagnosis is suspected when there is an increased red cell mass (hemoglobin greater than 20 g/dl) with low serum erythropoietin levels in the absence of secondary causes. The diagnosis can be confirmed by determination of red cell mass by isotope dilution and cytogenetic studies. This is a chronic disease with a median survival of 15 years at time of diagnosis. People with this diagnosis need to be monitored closely for cardiovascular complications arising from whole blood hyperviscosity and also for progression to acute leukemia or myelofibrosis. Treatment involves routine phlebotomy. Hydroxyurea should be considered for patients over 70 years old and those with a history of thrombosis or thrombocytosis.

Leukocytes

Leukocytes or white blood cells are critical elements in the body's protection against infection and tumors. There are three major types of leukocytes: monocytes, lymphocytes, and granulocytes, the latter of which are further classified by staining characteristics as neutrophils, basophils, or eosinophils.

Neutropenia

Neutropenia, or low neutrophil count, can be genetic or acquired. Adults presenting with new-onset neutropenia most often have an acquired neutropenia due to reduced production, peripheral destruction, or

improper storage leading to a reduced number of these cells in the peripheral circulation.

The most common cause of neutropenia is reduced production secondary to drug toxicity. Although neutropenia will most often develop within a few weeks of initial exposure to the offending drug, it can potentially develop at any time, even after prolonged exposure to a particular medication. Older persons are particularly at risk for developing drug-induced neutropenia. The most common offending agents are cancer chemotherapeutic drugs and antibiotics, especially of the penicillin, cephalosporin, and sulfa classes. Other medications that have been known to cause neutropenia are thyroid-suppressing agents, anti-arrhythmic drugs, and non-steroidal anti-inflammatory agents. Any drug can potentially cause this problem and should be suspected when temporally related to the development of neutropenia.

Infections, especially viral infections, are also a major cause of neutropenia. If this is suspected as the cause and the patient is otherwise stable, the blood counts should be repeated to ensure that the white blood cell count is within the normal range. Bacterial infection, particularly when overwhelming (sepsis), is associated with a drop in white count, a finding with negative prognostic implications.

Cyclic Neutropenia Cyclic neutropenia is a genetic disorder that is often not diagnosed until adulthood. It is characterized by low white blood cell count associated with episodes of malaise, fatigue, oral ulcers, and cervical lymph node enlargement lasting 3 to 4 days occurring every 3 to 4 weeks. If this diagnosis is suspected, the white blood cell count should be checked regularly (two times a week for 2 months) to establish a consistent pattern.

Benign Familial Neutropenia Benign familial neutropenia is a condition that involves a slightly decreased white blood cell count without any other clinical evidence of disease. The bone marrow exam reveals normal cellularity with normal red blood cell and platelet counts. This finding is more common within certain ethnic groups, including African Americans, West Indians, and Yemenite Jews.

No treatment is required, and standard of care involves routine surveillance of the white blood cell count.

Leukemia

Leukemia results from a malignant transformation of white blood cell precursors and an accumulation of these transformed cells. Leukemias can be divided into acute or chronic based on the maturation level of the cells that are affected.

Acute Leukemia Acute leukemia results from a malignant transformation of white blood cells occurring in immature hematopoietic cells that progresses rapidly to death if untreated. A combination of genetic and environmental factors has been implicated in the development of acute leukemia. There is an increased incidence in individuals of Eastern European Jewish descent, in people with first-degree relatives with leukemia, particularly identical twins, and also in those with other genetic disorders such as Down's syndrome, Fanconi's anemia, Bloom syndrome, and ataxia telangiectasia. Environmental factors include ionizing radiation from an atomic bomb or nuclear plant accidents, benzene petroleum products, and antineoplastic agents, especially alkylating agents.

Acute leukemia was initially classified into myelocytic and lymphocytic subtypes. In the 1970s, a group of French, American, and British pathologists devised the FAB system of classification, which has become the universally accepted system of classifying acute leukemias. This system incorporates morphology, cytochemistry, cytogenetics, and immunophenotype.

Acute lymphocytic leukemia (ALL) Based on the FAB system, acute lymphocytic leukemia (ALL) can be subclassified into four subtypes: early pre-B, pre-B, B cell, and T cell. Although ALL can occur at any age, ALL is most commonly diagnosed in young children.

Children are reported to have very high cure rates, from 70 to 90%, with aggressive chemotherapy. Older people, unfortunately, do not fare as well. The recurrence-free rate 5 years after treatment is reported to be 35 to 40%.

Treatment involves aggressive chemotherapy that is often quite toxic in the elderly. Yet older patients (over the age of 65 years) have treatment responses similar to younger adults (unlike the situation for acute myelogenous leukemia, as noted below). The use of autologous bone marrow or stem cell transplant is being explored for the treatment of older patients, but the results to date are inconclusive.

Acute myelogenous leukemia (AML) In contrast to ALL, most cases of acute myelogenous leukemia (AML) occur in adults, and the frequency increases with advancing age. The FAB classification system breaks this type of leukemia into seven subtypes of AML (M1 to M7). The median age at diagnosis is 60 years.

Remission rates for adults with AML are higher than those with ALL, but long-term survival is comparable. Approximately 65% of those treated respond to initial induction therapy that typically consists of a combination of cytosine arabinoside and

an anthracycline. Allogeneic or autologous bone marrow transplant can be considered for patients in first or second remission, although the value of such an approach has yet to be established for those over the age of 60 years.

It has been said that older patients (over the age of 70 years) with many forms of cancer (e.g., breast cancer) have more indolent tumor growth and spread. Investigations have led to several features of senescent tissues that may account for this. However, the experience with AML is in stark contrast. Older patients with this disorder are less likely to achieve a complete remission, and survival is considerably shorter for the oldest patients with this disease.

Chronic Leukemia In contrast to acute leukemia, chronic leukemia results from a malignant transformation of mature leukocytes, and this disease usually has a more indolent course.

Chronic lymphocytic leukemia (CLL) Chronic lymphocytic leukemia (CLL) makes up more than 90% of the chronic lymphoid leukemias and is the most prevalent form of leukemia in the Western world. It mostly occurs in adults and is very rare in children. The prevalence is greater in men and in Caucasians. The classification system used for this leukemia is the Rai system, which is a clinical staging system based on absolute lymphocyte count and presence of lymphadenopathy, splenomegaly, anemia, and thrombocytopenia.

Typically, CLL is an indolent disease. Adults with low-stage disease with white blood counts less than 30 000/UL do not have any change in life expectancy when compared to age-matched controls without CLL. However, those with more advanced stage disease do not fare as well. Treatment is indicated for only those with symptomatic disease at any stage. Several chemotherapeutic agents are effective against CLL, but fludarabine is currently considered first-line therapy. As with acute leukemia, autologous bone marrow and peripheral blood stem cell transplantation are currently being explored.

Chronic myelogenous leukemia (CML) Chronic myelogenous leukemia (CML) results from a clonal expansion of a hematopoietic stem cell. The disease is characterized by a cytogenetic abnormality (Philadelphia chromosome) that heralds a reciprocal translocation between chromosomes 9 and 22. This change approximates a cellular oncogene (abl) from chromosome 9 close to the bcr gene of chromosome 22, resulting in the fusion gene (bcr/abl) that is oncogenic. CML occurs early in life but increases in incidence, occurring most commonly in the sixth and seventh decades.

Most patients are asymptomatic at presentation, with diagnosis typically made by routine blood analysis. The chronic phase is indolent for several years but may be associated with fatigue, weight loss, splenomegaly, and thrombocytosis. Untreated, the disease progresses from the initial chronic phase to blast crisis with an intermediate accelerated phase. Although interferon, hydroxyurea, and busulfan are all active, the introduction of imatinib (Gleevec) has dramatically improved the outlook for CML patients. This agent causes inhibition of the bcr-abl tyrosine kinase resulting in suppression of the CML clone. Imatinib is now considered to be first-line therapy, and overall survival, which had been measured in months, is now well over a decade.

Multiple Myeloma

Multiple myeloma results from a malignant proliferation of a single clone of plasma cells. This is a common disorder and represents approximately 10% of the hematologic malignancies in Western countries. The median age of diagnosis is 65 years, and the incidence is slightly higher in males and in those of African descent.

Clinical manifestations include bone pain, weakness, and fatigue. Initial laboratory findings may be non-specific but include anemia, hypercalcemia, hyperproteinemia, proteinuria, and renal insufficiency. Because of the non-specific nature of the presenting symptoms (bone pain, fatigue), delays in diagnosis are typically 6 months or more. If the diagnosis is suspected based on the clinical presentation and initial laboratory data, a serum protein electrophoresis should be done, which will show a localized band in approximately 80% of people with the disease. The diagnosis can be confirmed by a bone marrow biopsy.

Monoclonal protein may present in serum without myeloma or malignant disease. Thus, the presence of an abnormal protein electrophoresis should be considered in the context of the patient and the presence or absence of bone or kidney disease, hypercalcemia, or anemia. Bone marrow aspiration may reveal unusual-appearing plasma cells typical of myeloma, but not always. The presence of benign monoclonal proteins (paraproteinemia) increases with each advancing decade. Thus, the presence of a monoclonal protein in the blood of an older patient warrants special attention. Although it is likely to be a benign condition, it can reflect early multiple myeloma. A reasonable approach for a patient without other signs of myeloma (bone or kidney disease) is to

follow the level of paraprotein at regular intervals (e.g., every 3 months). Benign paraproteinemia will remain stable. If early myeloma is present, paraprotein levels will increase.

Thrombocytes

Thrombocytes (platelets) are cellular fragments of bone marrow megakaryocytes. These small elements (approximately 1–3 μm in diameter) are central to the control of bleeding (hemostasis). When the numbers are low (thrombocytopenia) or function is impaired, spontaneous hemorrhage can result. The normal platelet count in peripheral blood ranges from 150×10^6 to 400×10^6/l.

Thrombocytopenia

Low platelet counts can result from decreased bone marrow production, increased splenic sequestration, or intravascular destruction. In general, spontaneous bleeding due to thrombocytopenia is uncommon unless the platelet count falls below 20×10^6/l.

Non-immune-Mediated Thrombocytopenia Platelet destruction can be caused by immune and non-immune-mediated mechanisms. Non-immune-mediated mechanisms include vasculitis, hemolytic uremic syndrome (HUS), thrombotic thrombocytopenic purpura (TTP), and disseminated intravascular coagulation (DIC). HUS and TTP are characterized by small blood vessel red blood cell damage or destruction (microangiopathic hemolytic anemia), thrombocytopenia, neurologic symptoms, fever, and renal insufficiency.

TTP and HUS are medical emergencies requiring prompt hospitalization and the implementation of medical therapy. For TTP, the immediate implementation of plasma exchange (plasmapheresis) can be life saving.

DIC is also a medical emergency and is usually associated with systemic illness, such as sepsis. Treatment involves supportive therapy, with cryoprecipitate for fibrinogen levels below 100 mg/dl, fresh frozen plasma if a deficiency of coagulation factors has resulted in a prolonged prothrombin time (PT), and platelet transfusion if the platelet count falls below 10×10^6/l or even with higher levels if there is evidence of acute bleeding.

Immune-Mediated Thrombocytopenia (ITP) ITP can be acute or chronic and may be the result of an unusual response to common drugs or infections. Alternatively, the disorder may develop without associated drug or infection (idiopathic thrombocytopenia purpura). Of the many drugs that can lead to thrombocytopenia, heparin is the most common cause of drug-induced thrombocytopenia in hospitalized patients.

Treatment of ITP involves removal of the offending agent or appropriate treatment with antibiotics. Additional therapies have included corticosteroids, intravenous gamma globulins, cytotoxic chemotherapy (e.g., cyclophosphamide), androgens, and, most recently, rituximab (a monoclonal antibody to a subset of B lymphocytes). Refractory patients may benefit from splenectomy.

Thrombocytosis

Thrombocytosis or platelet overproduction is most commonly observed with acute or chronic inflammation or iron deficiency. Most typically, patients with reactive thrombocytosis have platelet counts between 400×10^6 and 900×10^6/l; counts over 1000×10^6/l are very uncommon. The treatment for reactive thrombocytosis should focus on the cause.

Thrombocytosis may also be the result of another myeloproliferative disorder, essential thrombocythemia (ET). This disorder is characterized by platelet counts greater than 1000×10^6/l associated with moderate leukocytosis, splenomegaly, and either excessive clotting or bleeding.

Treatment of ET depends upon the overall clinical picture. Those with a history of recent thrombosis, age greater than 60 years, cardiovascular or cerebrovascular disease, or counts in excess of 1000×10^6/l are candidates for treatment with hydroxyurea, interferon, or agrylin. As is the case with other myeloproliferative disorders (chronic myelogenous leukemia, polycythemia vera myelofibrosis, and agnogenic myeloid metaplasia), a percentage of ET patients will have their disease evolve to acute leukemia or to marrow fibrosis. However, the majority of patients under medical management survive without complications for a decade or more.

Disorders of the Clotting System

Disorders of the clotting system can result in excessive bleeding or pathological blood clots.

Bleeding Disorders

Bleeding disorders can be inherited or acquired. They result from an inadequate amount or functional impairment of platelets or clotting factors.

Inherited Bleeding Disorders Inherited bleeding disorders, such as von Williebrand's disease or hemophilia, are infrequently observed in geriatric medicine.

von Willebrand's disease (VWD) The most common inherited bleeding disorder is von Willebrand's disease (VWD); in certain populations, its prevalence can be as high as 1 to 2%. von Willebrand's factor (VWF) is a plasma glycoprotein produced by platelets and vascular endothelial cells. VWF aids in platelet adhesion to other platelets as well as to vascular endothelium. It also serves as a transport protein for factor VIII. VWD is subdivided into three different subtypes based on the quantity and quality of VWF present in the circulation. With the exception of type III disease, all other forms are inherited as autosomal dominant traits. Bleeding time is prolonged in all three types. The PT is usually within normal limits, but the partial thromboplastin time (PTT) may be prolonged if the VWF levels fall low enough to have an impact on the factor VIII levels.

Treatment is indicated for bleeding or as prophylaxis prior to surgery. Treatment options include DDAVP, antifibrinolytic agents, and plasma. DDAVP promotes release of VWF from endothelial cells and increases factor VIII levels. Antifibrinolytic agents include aminocaproic acid and tranexamic acid both of which inhibit clot lysis. In addition, recombinant clotting factor concentrates are under investigation for future use in the treatment of this disease.

Hemophilia Hemophilia is a congenital bleeding disorder that results from a deficiency of clotting factors. Hemophilia A results from a factor VIII deficiency, and B results from a factor IX deficiency. Hemophilia A and B are X linked recessive disorders. Hemophilia C results from a factor XI deficiency that follows an autosomal dominant inheritance pattern.

The clinical manifestations depend on the severity of the disease, and these disorders are rarely seen in geriatric medicine. Patients with mild disease have increased bruising and bleeding after trauma or surgery. Those with more severe forms of the disease can have spontaneous bleeding. The soft tissues and joints are the typical bleeding sites for hemophiliacs, although bleeding can occur anywhere in the body.

Treatment includes DDAVP, antifibrinolytic agents, plasma-derived clotting factor concentrates, and recombinant clotting factor concentrates.

Acquired Bleeding Disorders The acquired bleeding disorders include inhibitors to plasma coagulation factors such as inhibitors to factor VIII. The clinical manifestations and treatment options are similar to those for hemophilia, but this disorder usually occurs in people over 60 years of age and shows an equal distribution between the sexes.

There is also a form of acquired VWD that most often occurs in conjunction with other disease processes such as autoimmune disease, myeloproliferative disorder, lymphoproliferative disease, dysproteinemia, multiple myeloma, and hypothyroidism. Clinical manifestations and treatment are similar to those of the congenital form of the disease.

Thrombotic Disorders

There are many factors that predispose certain individuals to develop blood clots. Thrombosis can occur in the arterial or venous systems. Venous thrombi typically are composed of red cells and large amounts of fibrin. In contrast, arterial clots are composed primarily of platelets with only a small amount of fibrin deposition. The human body employs a variety of mechanisms to prevent spontaneous thrombus formation and subsequent occlusion of blood vessels. Both the vascular endothelium and plasma have naturally occurring anticoagulants that serve to neutralize or inactivate procoagulants. Under steady-state conditions, the anticoagulants prevail and blood remains liquid. However, when exposed to tissue injury, procoagulants predominate and a clot is formed. If there is a congenital (e.g., protein C or protein S) deficiency of anticoagulants or an acquired increase in procoagulant activity (e.g., with certain cancers), the patient may develop a hypercoagulable state characterized by spontaneous deep vein thrombus formation and possibly pulmonary embolus.

Inherited Thrombotic Disorders The most commonly inherited abnormalities include deficiencies of antithrombin III, protein S, or protein C or mutations in factor II (prothrombin) or factor V (factor V Leiden). Any of these abnormalities may lead to increased clot development. People who have a venous thromboembolism in the presence of one of these defects should be considered for long-term anticoagulation therapy.

Acquired Thrombotic Disorders The acquired thrombotic disorders include the antiphospholipid antibody syndromes, including lupus anticoagulant and anticardiolipin antibody. Treatment with chronic anticoagulation therapy is dependent on the clinical history. Those people who do not have a history of venous thromboembolism do not necessarily require chronic anticoagulation therapy.

Hyperhomocysteinemia Hyperhomocysteinemia can be inherited or acquired. Elevated homocysteine levels are thought to inhibit the expression of thrombomodulin from the vascular endothelium.

Elevations of homocysteine can be found with B_6, B_{12}, and folic acid deficiency as well as with renal insuffiency and hypothyroidism. Hyperhomocysteinemia may also result from mutation of the methylene tetrahydrofolate reductase (MTHFR) gene. Treatment should be geared toward the underlying disease process and nutritional support, especially with folic acid supplementation. Patients with a homozygous MTHFR gene mutation who develop deep vein thrombosis should be considered for lifelong anticoagulation.

Bone Marrow Failure

Bone marrow failure results in an inability of the bone marrow to manufacture one or multiple cell lines. Included in this category of hematologic illness is myelodysplasia (common) and aplastic anemia (uncommon).

Myelodysplasia (MDS)

Myelodysplasia (MDS) results from a clonal disorder of the hematopoietic stem cells, which results in cytopenias secondary to ineffective hematopoiesis. This usually occurs in older people, and the median age at diagnosis is approximately 70 years. The incidence is higher in men. MDS has been subdivided into five different categories by the FAB cooperative group based on the presence or absence of ringed sideroblasts, the degree of dysplastic features in the marrow aspirate, and the percentage of myeloblasts.

The clinical presentation often involves refractory anemia, neutropenia, and thrombocytopenia. Patients frequently seek medical attention for chronic infections of the lower respiratory tract and skin abscesses. Diagnosis is made by bone marrow biopsy and cytogenetic studies.

The natural history of the disease ranges from chronic anemia to rapidly progressive acute leukemia. Until recently, treatment has been primarily supportive. MDS patients are often dependent on blood transfusions and may require iron chelation therapy as a result of transfusion-related iron overload. Cytoreductive chemotherapy has been disappointing. However, recently 5′ azacytidine and thalidomide (or thalidomide analog) have been shown to induce meaningful responses in MDS patients.

When acute leukemia develops in patients who have had prior MDS, the leukemia has been commonly refractory to typical antileukemia regimens. In elderly patients with MDS-associated acute leukemia, many experts have advocated supportive management alone.

Aplastic Anemia

Aplastic anemia results from complete bone marrow failure with absence of stem cells resulting in severe decline of all cell lines. The disease is characterized by severe neutropenia, anemia, and thrombocytopenia, and the diagnosis is confirmed by bone marrow biopsy revealing a paucity of cellular elements.

Treatment is based on the degree of cytopenias, with blood product support and antibiotics if there is evidence of infection. Immunosuppressive therapy has helped to reduce transfusion requirements. Transfusions should be minimized and specifically avoided from family members to prevent alloimmunization in potential transplant candidates. Bone marrow transplant should be considered for all patients, although the published experience in older patients is limited and this approach is currently under active investigation.

History of Aging

W A Achenbaum, University of Houston, Houston, TX, USA

Glossary

Gerousia – A council of men who were at least 60 years old.

Stem Families – Domestic units where young or old relatives would move into a middle-aged householder's residence.

Introduction

Old age embraces age-old, universal, diverse phenomena. While every culture past and present has deployed comparable terms or phrases to demarcate the life course's beginning and end, images and realities associated with the last stage of life have differed everywhere. Any historical generalization must take account of the influence of gender, class, race, ethnicity, and age. Growing older and becoming old thus have varied greatly from place to place over historical time. The range of meanings ascribed to old age and the conditions experienced by older people at any given time and place diverge enormously.

While historians can safely attest to the diversity in international historical perspectives on aging, it should be noted that scholars possess more cultural data than information about other aspects of aging. Except in mythology, no investigator has discovered evidence of a golden age in which older men and women lived in a bucolic Elysium. Yet our knowledge of the global history of aging is fragmentary. Not much is known about the socioeconomic conditions of the elderly, particularly those living below the equator and especially prior to the nineteenth century. We only have begun to describe and explain the plethora of positive, negative, contradictory, ambivalent, and ambiguous images and relationships that form the matrix of late-life opportunities and exigencies.

International historical perspectives on aging, moreover, do not always capture the full context that shaped senescence's voices and realities. Generational factors – whether the eldest son marries early or late and whether that affects inheritance patterns and living arrangements – influenced cohorts as they navigated the life course. Furthermore, the meanings and experiences of late life often are byproducts arising from political, social, economic, cultural, and demographic factors that shape a particular society at a specific historical moment. Far earlier in pre-industrial time than was once believed, older people in England maintained nuclear households until economic and physical necessity required coresidence. In Eastern Europe during the same period, however, stem families and complex housing arrangements prevailed.

Researchers, it must be added, have sometimes misread historical and cross-cultural evidence. Three decades ago, modernization theory was the template used by many gerontologists to describe and explain the pathways of aging. It was taken for granted that older people lived better in rural than in urban settings and that industrialization destroyed the extended household structures and reduced work opportunities for the aged. Dualisms characterized the international history of old age: before–after, good–bad, networks–autonomy. And insofar as developing nations were expected to follow, or at least emulate, the historical trajectory of North America and Western Europe, similar trends were presumed to obtain in due course. Recent scholarship has undermined historical patterns once limned as unidirectional or inevitable. Household structures and familial obligations have never been as monolithic in Asia and South Asia as was once thought: they depend on labor force patterns and the impact of public old-age relief, among other things. Indigenous traits matter; this makes the interpretation of the fragments of the past such a daunting task.

The Decline of the Aging Body: The Foundation for Perspectives on Historical Gerontology

With such caveats in mind, let us begin with the physical signs of aging and old age. The oldest known document referring to aging is a description by the philosopher and poet Ptah-hotep, writing in Egypt in 2500 BCE: "How hard and painful are the last days of an aged man! He grows weaker every day." (Gunn BG, trans., *The Instruction of Ptah-Hotep*, http://www.kensemedia.com/encyclopedia/ppp/instructions_ptah_hotep.htm (accessed 28 March 2006)). This characterization challenges notions that the elderly in primordial times lived healthily and happily. Ptah-hotep characterized physical aging as bodily decline, a universally recurring but not ubiquitous a theme in the history of global aging.

Men over 50, for example, thrived in Eastern households during ancient times. Confucius described moral development chronologically: "At forty I no longer had doubts; at sixty there was nothing on earth that could shake me; at seventy I could follow the dictates of my heart without disobeying the moral law." Maturity, declared Eastern sages, deepened an elder's affinity to family ancestors. So critical was age in the Confucian world view that older women prevailed over their sons and daughters.

Similar conditions existed elsewhere in the region. According to the Taoist tradition, extreme longevity was proof of sainthood. According to Brahaman canons, a few elderly hermits attained so much wisdom that their bodies were transubstantiated into immortality. Religious traditions, passed down from generation to generation, were thought to bind the old in a safety net. Yet in postwar Asia, most dramatically in Japan, demographic pressures and public policies have undermined the favorable status of late life.

Such respect for old age was not enduring in early Western cultures. Following Aristotle's lead as well as findings by physicians in the fifth century BCE, the ancient Greeks deplored late life's lamentable nature: they characterized older people's bodies as abnormally cold and dry, and their bile black, thus making death the natural consequence of aging. The ancient Greeks believed that specific diseases afflicted the last stage of life. Hippocrates catalogued old-age maladies – such as cataracts, nephritis, vertigo, apoplexy, and poor mental health – in his *Aphorisms* (400 BCE). Thus, Hippocrates anticipated the observation by Seneca (4 BCE–AD 65) that *senectus morbidus est* – "old age is a disease."

Greek images of old age were not resolutely negative. (Shades of gray color virtually all meanings and experiences attributed to aging in global history.) Sparta beginning in the seventh century BCE was ruled by a *gerousia*, a council of men who were at least 60 years old. Elderly leaders, selected for their wisdom, were expected to exercise authority conservatively. Yet abuse of power by the *gerousia* prompted satire by Aristophanes in the fifth century.

Like the Greeks, the Romans portrayed old age in contrasting hews. At one extreme, Virgil (70–19 BCE) in the *Georgics* and Juvenal (60–130 AD) in his *Satires* bemoaned its infirmities. Cicero (106–43 BCE), on the other hand, argued in *De Senectute* that years of experience more than compensated for the physical decline that came with advancing years: "Old age is usually not only poorer, but is even richer…old age, so far from being feeble and inactive, is ever busy and doing and effecting something."

Hebrew scripture provides another variegated treasure trove of late-life images and stories. "A hoary head is a crown of glory; it is gained in a righteous life," according to Proverbs (16:31). The fifth commandment not only demanded respect for elders, but also implied that children would be punished if they disobeyed their parents. According to the Pentateuch, longevity was the Lord's reward for faithful service. That Sarah and Ruth enjoyed the fruits of ripeness suggested that even in patriarchal societies, the advantages of age could accrue to women through God's graciousness. Other passages in Hebrew scripture, however, paint a gruesome portrait of physical decline, fear of rejection, and increasing vulnerability with advancing years that anticipated the contrasts secular writers made between a green old age and second childhood, as well as the more recent distinction that Bernice Neugarten posited between the young-old and old-old. Because living too long was risky business, prophets urged the children of Israel to care for helpless, decrepit widows.

This modest gloss on texts suffices to establish an important generalization: the physical aspects of senescence, sometimes linked to chronological age, lay the foundation for a perception, both international and historical, that people who attained old age declined in the process. Interpretations of this perceived reality varied. In the Koran, senescence meant "neither more nor less than one more sign" of Allah's power. In most traditions, people of all ages presumed that diminished capacity inexorably led to disease, dependency, and death. As Jonathan Swift observed, "every man desires to live; but no man would be old."

Folk artists between the fourteenth and nineteenth centuries designed graphic renditions of the steps of ages, wherein toddlers traversed up stairs and then adults descended another set of stairs to death. *Lebbenstreppe* were especially popular in central Europe. The number of steps ranged from four to thirteen. Icons differed for men and women, though some life stairs featured partners. Children played with toys. Boys carried books while girls learned to spin. Men in their prime were soldiers; women, mothers. Artists made their aged subjects stooped; the elderly were assigned sedentary duties. At 70 or 80 the old ones were confined to their beds, dependent on others while awaiting Father Time to turn his sickle (a symbol of fertility) into an instrument of destruction. The message was clear: youth rose in due course to displace the control wielded by their elders.

Diverse depictions of the physical manifestations of old age have passed down to the contemporary era, filtered through broader cultural and historical lenses. There has been no dramatic or sudden shift in

old-age imagery, although revolutionary situations tend to undermine prevailing images of old age. For instance, young Chinese intellectuals in the early twentieth century assaulted the centuries-old respect for age as part of their sweeping attack on Confucianism. "Youth is like the early spring," wrote a leader of the May 4th movement. "What is the struggle [of youth]? It is to exert one's intellect, discard resolutely the old and the rotten." Modern Chinese revolutionaries rejected longstanding deference paid to the old on account of their advanced age.

Sometimes physicians' clinical gaze validated popular perceptions of the elderly. Nobel Laureate Elie Metchnikoff in 1905 diagnosed old age as "an infectious, chronic disease which is manifested by a degeneration, or an enfeebling of the noble elements." Four decades later a different prognosis was offered by geriatricians: "Senescence is not all decline....With planned cultivation of these compensatory capacities, the increments can very nearly balance the decrements." Alchemists' attempts at prolongevity have proved ephemeral throughout the ages; nowadays public health, pharmacology, and modern science offer genuine hope that many vicissitudes of age might be controlled, if not eliminated. Indeed, some scientists go a step further, contending that anti-aging interventions can prolong healthful longevity, thus expanding the human life span.

One final, essential point on the physical ravages of age: although not articulated fully in the historical literature, since women for much of world history have been invisible in texts and missing from public records, a gender bias persists over time and across space in characterizing senescence. Ageism has affected older women more than men, in part because the latter possess resources that compensate for losing good looks. There are exceptions: while females typically play a subordinate role in the Muslim world, older women wield power and authority in Hausa sectors of urban Nigeria. And the derogatory term hag ironically comes from *hagia*, Greek for a holy woman. Still, contemporary culture by and large marginalizes older women, who comprise the majority in both developing and advanced industrial societies.

Demographic Patterns in International Historical Perspective

Just as the physical attributes of old age represent salient traits of the last stage of life, so too do the demographic realities of human longevity put numbers to its diverse dimensions. Anthropological and historical research suggests four generalizations about demographic patterns of aging:

1. Old people have existed throughout most of recorded history, but they have constituted a very small percentage of the total population in any given time or place – less than 2% of the total, usually far less. Reaching old age was a rare event when the odds of surviving to age 1 were poor. Only one in three babies survived their first birthday in Bombay at the beginning of the twentieth century. If a person reached the age of 20, then his or her chances of surviving to age 40 and beyond were significantly improved.
2. Since at least 1700, written records in Europe and North America (such as laws, diaries, and encyclopedias) have loosely placed the onset of chronological old age around 65, give or take 15 years. There is little evidence indicating that chronological old age occurred before age 40, though ethnographies of contemporary Sri Lanka report age-related decrements at that age. Men and women who controlled physical and economic resources, and who gained favorable status through the tasks that they performed, were considered to be in their prime. The Chimu kingdom in Peru at the time of the Spanish conquest, for instance, considered warriors between the ages of 50 and 60 to be 'half old.' After 60, individuals paid no tribute and were exempt from military service.
3. The greatest increases in life expectancy at birth and in life expectancy at age 40 have occurred in the twentieth century. Since 1950 there have been modest gains in life expectancy at age 60. Three-quarters of all gains in longevity have been attained since 1900. Since the end of World War II, sharp declines in fertility rates have been a major factor increasing the proportion of old people in a given population.
4. Along with gains in adult longevity has been the aging of population structures themselves. Rates of societal aging vary among and between mature and developing nations. Thus, Japan, which as late as 1950 had only 5% of its population over 65 now has the greatest percentage of elders in its midst, surpassing even Sweden. Life expectancy in Japan rose from 50 to 78 for men, and from 55 to 83 for women from 1947 to 1995. "From a historical perspective population ageing represents a human success story," contended a National Research Council report (2001). "At the same time, the sustained shift in population age structures poses an array of challenges to policy makers."

These generalizations affect in at least two ways how people around the world have perceived aging and how older people have interacted with younger persons. Consider first that, until recently, few human beings attained old age. The paucity of elders consigned them to the role of strangers in the land of the young – and even to themselves. "Old age is the most unexpected of all things that happen to a man," declared Lev Trotsky, age 56, in 1935. Dubiety has historically made for ambiguity in human interactions. Strangers can pass unnoticed in crowds. In rural settings they can get by if local residents are hospitable and helpful. Where norms and mores associate a healthful manner of living with the virtues of a ripe old age, elderly men and women are presumed to be assets unless their actions suggest otherwise. Some elders put a spin on this idea, writing their own scripts: Thomas Jefferson, arguably America's greatest sage, and Maggie Kuhn, the founder of the Gray Panthers 150 years later, both exulted in their 80s about the pleasure of outliving their opponents, thus having the last word.

Yet even healthful longevity is a double-edged sword. Viewing the aged as strangers has lent itself to a less sanguine interpretation of aging over time – one of wariness, even fear. Just as many people treat aliens with suspicion, projections and fears cause older persons to be viewed as potential witches or burdens on the community. Legends and case studies indicate that parricide has occurred in places with scarce resources. Portraits of age drawn by elders can be as gloomy as the ones younger people imagine. John Burroughs, shortly before his death at age 84, wrote: "The octogenarian has no alternative but to live in the past. He lives with the dead, and they pull him down." Survivorship amid frailty and poverty without a sufficient support network brings the risk of rejection and dependency.

Second, it is worth noting that old age's prescribed span of years has always been perceived as longer than the boundaries of any other stage of life. Infancy lasts no more than 2 years; adolescence nowadays rarely stretches more than two decades. But the benchmarks of late life encompass much of the life course. In some countries people can qualify for old-age privileges at 50. Alternatively, some elders are successful in denying that they are old: after reaching 80, Bernard Baruch persistently claimed that old age began at his current age plus 15 years. Elastic thresholds make old age the most heterogeneous stage of life. In part this explains why past generations of elders differ in physical, mental, psychological, and social capabilities. Two people at the same age in the same place and historical moment may share no other common attribute than the number of years they have lived. Such diversity has always existed across cohorts. Some people mature fruitfully as they grow older; others decline slowly; still others are victims of an unexpected mishap. Many older people try to maintain lifestyles that they adapted in middle age. Others opt, by choice or circumstance, for radical changes in what they think, feel, live, or do. Some move on; others become stuck in helplessness.

The heterogeneity that inheres in late life may have grown richer in recent decades. A subtle revolution is in the making, which results from societal aging. With the years added to adult life expectancies since the mid-nineteenth century, age-based differences within elderly populations everywhere have widened. When the aged were few in number, their problems were manageable. It mattered little if the potential contributions of the aged were squandered. Now that the elderly are an increasingly larger subset of the population, their wants, desires, and needs can no longer be discounted. Senior citizens represent a potent voting bloc, one entitled to governmental support. People during the past century came to believe that they would reach the age of 65. They considered a good retirement a right. These demographic and economic expectations alone justify the hypothesis that the great watershed in the history of aging, particularly in developed countries, occurred during the twentieth century.

Family Ties

Regardless of historical moment or geographic location, family members have always been the primary line of defense in situations of old-age dependency. Structures diverge notably over time and by setting. In western European nations and North America, the elderly (usually men) have traditionally wished to remain heads of their own household as long as possible. This generalization requires at least two qualifications. First, in the early modern period, some domestic units (temporarily in Western Europe, longer in Eastern Europe) became 'stem families' – young or old relatives would move into a middle-aged householder's residence – an arrangement that typically lasted for a short duration. Second, more emphasis has been placed lately on the autonomy than on the independence of family elders. Nuclear families typify the Western model: older people maintain their residences as long as possible.

Elsewhere, very different arrangements obtain. In Africa and parts of Asia, elderly women often headed family units. Daughters-in-law either resided in the abodes of their mothers-in-law or they lived in close

proximity in order to conform to her domestic plans; women who lived in their husband's village viewed the arrangement as a temporary enclave. Deference to elders animated pre-industrial Japanese families, where permanent members ranked ahead of temporary residents, men ahead of women. Aborigines in Australia opted for more open arrangements, so fathers might be fictive kin, and middle-aged persons might be elders since they controlled local matters energetically.

Whatever the domestic arrangements, women have been more likely than men in virtually every historical setting around the world to be the primary caregivers for older people. In some places the responsibility fell to the youngest daughter. Sometimes aunts or female cousins fulfilled the tasks of cooking food, bathing, or cared for an infirm elder. In rural Japan, public and private rituals of concern traditionally have been gendered. Men typically participated in domestic matters only when there was no alternative.

Some safety nets develop holes. Estrangements and divorce can disrupt caregiving plans. Designated caregivers may move with their spouse out of their community to a place too far away to be able to serve. Poverty strains resources. Death breaks bonds. In such situations, neighbors and friends take over on an informal basis. In modern times, compensatory arrangements exist. New modes of transportation and communication have enabled siblings and children to remain in touch with their elder kin even if they are not in physical contact daily.

Societal aging has disrupted traditional familial patterns in at least three other ways. In the East, skyrocketing real estate prices have made it impossible for family members to cohabit in commodious space. Elders in Japan and China now make hard choices about residency like their contemporaries in the West. Second, many women are unwilling or unable to serve as primary caregivers for elders because they are gainfully employed outside the household. Finally, the traditional pyramidal family structure has, with multigenerational survivors, come to resemble a bean pole. There are now more elders available to assist with caring for the chronically impaired or very old, but divorce, relocations, or the caregiver's own failing health may preclude the ability to assist.

Economic Patterns

Agricultural pursuits, which have been the most prevalent mode of economic activity everywhere throughout recorded history, generally provide favorable opportunities for elderly men and women. Farming is hard work, especially at harvest time. Nonetheless, there are many tasks entailed in keeping a farm running that can be accomplished by people with diminished capacities – if they have the requisite expertise. For example, the aged can supervise the work of others and keep records. The insights accrued over a lifetime of observing nature's bounty and brutality have historically solidified the popular perception of the elderly as veterans of productivity.

Control of the land, moreover, assured older people a measure of economic security. Children worked the land for their parents or grandparents with the expectation that in due course they would gain title to the family property. Elders wisely transferred property only after making due provisions for themselves in their declining years or for a spouse's widowhood. Studies of inheritance patterns and the provisions made for widows, however, require case-by-case analysis, for we still know far too little about the roles of kin networks in property transfer. Nor do we have more than anecdotal evidence about the ability of the aged to assure their well-being through other means. Healing powers and the magic of Shamanistic rituals accorded the aged prestige in Native American tribes, but more work must be done before a historical generalization is warranted.

After the Industrial Revolution, the economic status of older people changed, for better and for worse, especially insofar as new modes of production and consumption altered prevailing ways of doing business. Economies of scale made hand-made goods a luxury. In a world dominated by bureaucratic procedures rather than personal or familial connections, it became more difficult for elders to adapt to the changing marketplace. Many old workers became obsolescent. At the same time, however, men over 60 who managed or owned railroads, steel mills, or other profitable corporations controlled a disproportionate share of the nation's wealth. And home purchases in late life indicate that members of the working class benefited from the new order.

In the initial phases of industrialization it was common for workers and manager to treat the aged as if they were disabled. Superannuated workers joined the lame and blind in begging for money at the factory gate or in the saloon. By the middle of the nineteenth century, progressive banks in Britain and transportation companies in the United States began to offer pensions based on an employee's age and years of service. Retirement became both a reward for faithful service and a tool for getting rid of worn-out workers. Corporate pensions were deemed gratuities in the boardroom; only after the governments established their own Social Security measures did the financing of corporate and union pensions become regularized and regulated.

It has always been possible for older people to retrain themselves for new positions in a changing marketplace. Various private organizations, beginning in the mid-eighteenth century, established lyceums and adult education programs to teach older people new skills or to enrich their days with learning opportunities they did not have earlier in life. Such programs may become increasingly significant in the future, but their success in reintegrating older workers into the marketplace thus far has been modest.

A dramatic change in late-life economic patterns over the past 50 years has been a consequence of women's growing participation in the paid workforce. Traditionally, young women worked before they married; widows became bartenders, inn keepers, or laundresses to make ends meet. Career women, like men, now seek part-time or seasonal employment in their later years. Continuing to work is not always a desideratum: women work by necessity because they live longer on average than men; sex discrimination compounded by ageism impedes their career opportunities and salary potentials.

Indeed, the plight of older women workers is simply the latest phase of a general economic late-life pattern. People have always expected the aged to make provisions for their old age. Generally, this has meant that the old had to work until they were disabled or dead. Pensions, public and private, have made it possible for people to look forward to a sunny retirement. But for most humans internationally and historically, the dream of genuine economic security has not been realized. A majority of older persons have lived at subsistence levels, rarely confident that they could or would outlive their resources.

Political Developments

We have already noted that the elderly everywhere throughout history have held many important leadership positions – in African and Southeast Asian tribes, in the papacy and episcopacy, and in democratically elected offices. The aged putatively have the requisite experience, having risen through the ranks, and the wisdom, having dealt with all sorts of situations and personalities. Despite the gradual aging of most populations, however, there has been no universal preference for making older persons leaders. That said, age discrimination is not rampant. Experience counts in heated contests.

The most important political old-age development has been in the area of social welfare. States provide for those aged considered deserving and/or needy. Public old-age relief typically began in the local community. Institutions such as a religious organization or charity set aside funds (thereby supplementing resources provided by family, friends, and neighbors) to shelter, feed, or provide medical care to elderly indigents. Over time, local entities – the country, a city, a state, a district – made allocations, sometimes also erecting facilities to house the old. State governments or regional polities provided a third layer of non-familial support; municipalities granted pensions to their employees, and smaller government units gave assistance to the elderly poor who met stringent eligibility requirements.

Military or veteran's pensions have been important sources of old-age relief. The precedent for giving loyal bureaucrats retainers so that they might become superannuated dates back to twelfth-century China and fifteenth-century France. By the 1800s, poor, aging veterans began to qualify for stipends or land grants comparable to those awarded to wounded soldiers and sailors. Allocations were not insignificant: by 1913, for instance, pensions to northern Civil War veterans represented 18% of the US federal budget.

In the twentieth century, virtually every nation has enacted some sort of old-age assistance program to deal with dependency and launched old-age insurance plans to enable workers to prepare for their later years. The introduction of old-age pensions in Ireland and elsewhere did not affect residential patterns, though it did bolster family wealth. The historical timing and scope of such schemes depended on the country's population structure, the ideology of the ruling party willing to enact such provisions, and the treasury's current and anticipated funds. The growth of old-age interest groups ensured the liberalization of public benefits. Until very recently, Social Security measures in the United States and Western Europe enjoyed widespread popularity. With population aging and the staggering cost of elder care, however, many nations (rich and poor) are rethinking the entitlements that government officials feel that they can afford to contribute to the well-being of elderly citizens.

Cultural Aspects

This article began by emphasizing how images of bodily decline generated unfavorable perceptions of old age; it ends with a brief overview of how cultural traditions have sometimes enhanced the status of old age historically and internationally. Late-life wisdom and experience count in agricultural settings, in certain political milieu, and in religious institutions. Kin ties often improved work opportunities in urban settings. The elderly, especially men, have retained and increased their power as long as they remained vital. Some, like the Ayatollah Khomeini, dominate revolutions.

The young have typically respected the value of aged mentors. They count on the stories that elderly men and women tell to help them to clarify options and to identify pitfalls that lie ahead. Customs are transferred from generation to generation. The historical record suggests that senior professors, elderly clergy, and retired military sometimes have been recruited in times of crisis to assist younger leaders.

Postmodern cultures of consumption have attempted to manufacture perceptions of a good old age in order to capitalize on the wealth of growing numbers of older men and women in aging societies. Confectioners and card makers have tried to commercialize Grandparent's Day as successfully as Mother's Day or Father's Day. So far such efforts to tap the gray market have not borne much fruit. Advertisers do not know how to reach their intended target. The most memorable media images, in fact, are those depicting 'greedy geezers,' well-off, narcissistic, elders squandering resources that rightly should go to rising generations. Robert Butler coined the term ageism to identify a prejudice comparable to sexism and racism. Contemporary ageism is not the same as Ptah-hotep's, but it serves to remind us that humans everywhere tend to value those (again, there is a gender bias) who demonstrably contribute to other people's well-being. People of all ages tend to disesteem those whose vulnerabilities cannot be masked by a sunny disposition, good health, and economic well-being.

We are entering a new phase in the history of aging, shaped by a long past of cultural and structural lags in integrating the old into communities. Cross-domain relationships – between health and retirement decisions and between family structure and well-being in older age – have always mattered. History provides a baseline to imagine our future selves, but the lessons of the past are apt to be conflicted and unsettling.

History of Gerontology

J E Birren, University of California, Los Angeles, CA, USA

Glossary

Aging – The process of change or transformation of the young to the old organism. The term refers to the patterns of change that occur with age in genetically representative organisms living under representative environmental conditions.

Apologism – The conviction that the study and manipulation of the body to produce greater longevity is a violation of the natural or cosmic order.

Geriatrics – A branch of medicine specialized in the care and treatment of the diseases and health problems of older persons.

Gerontology – The study of the phenomena of aging from a research and scholarly perspective. It embraces studies from the biological, behavioral, and social sciences.

Senescence – The biological process of growing old associated with an increasing probability of dying and susceptibility to disease.

Introduction

Gerontology is an ancient subject but a recent science. In the earliest recorded histories there is evidence that humankind speculated about aging and the association of infirmities and death with advanced age. The processes of aging are complex, and combined with the uncertainties about death, a fertile ground for myth, fantasy, and wishful thinking has always existed. These speculations have given rise to myths about the prolongation of life and the nature of death, Some elements of these myths have been displaced by information provided by scientific research but many still remain as part of our cultural inheritance.

The word gerontology was introduced in 1903 by Nobel Laureate, Elie Metchnikoff (1845–1915), professor at the Pasteur Institute of Paris. Although the word gerontology is of relatively recent origin, there were many early scholars who published their observations and thoughts about why the human organism changed in appearance and in function, and the likelihood of death with advancing chronological age. Gerontology refers to the study of aging, research, and scholarship in all its aspects. The word is derived from the Greek word for an old man, *geront* or *gerontos*; plus the suffix logy, which refers to a branch of knowledge or science. The term *geriatrics* refers to a branch of medicine that specializes in the care and treatment of the diseases and health problems of older persons.

From archeological studies of the careful entombment of persons in preliterate times it is apparent that in many cultures a great deal of thought was given to the transition from life to death and to prospects for life after death. In those cultures, care was taken in the manner of burial and in providing accompanying articles that might be useful in a future existence. Although one can only speculate about what our preliterate ancestors thought about old age and aging, their ideas were undoubtedly carried over into many of the earliest written material.

Gerontology and its background may be divided into several periods: (1) the mythic period from prehistory to the Greco-Roman era; (2) the philosophical period, from Greco-Roman days to the Renaissance; (3) the Renaissance; (4) the early scientific period, from about 1600–1800; (5) the expansion of empirical research, from 1800 to about 1930; and (6) modern gerontology. These eras are not sharply demarcated and it might be argued, for example, that the period of modern gerontology begins somewhat later than 1930 when gerontological societies were formed. For example, the Gerontological Society was founded in 1945, later renamed the Gerontological Society of America, and the International Association of Gerontology about 3 years later. Such dates might be used to mark the beginnings of the modern era, although, as will be pointed out later, activities in the 1930s provided the background for this emergence.

The Mythic Period

From very early writings it may be concluded that humankind has always speculated about the causes of events and offered explanations that attributed causality to mythical forces. Aging is no exception. Gruman prepared a useful history of thoughts about aging and longevity and compiled an extensive bibliography of the mythology of aging with descriptions of the flow of ideas from ancient times to 1800. One of the earliest writings that discussed aging is the epic of Gilgamesh that Gruman dates to around 3000 BC. The hero of this Babylonia poem, Gilgamesh, becomes obsessed with the thought of immortal life and of finding the secret to it.

As ancient people saw others grow old and die and observed changes in themselves they wondered how they might avoid death. One mythic explanation is that humans once had the gift of immortality but lost it in a fall from grace by offending the gods or God. This led people to attempt to regain immortality by pleasing the gods, offering sacrifices, praying, or doing heroic deeds in accord with the customs of their culture.

Other myths were that people living in remote parts of the world still retained the secret of very long life or that somewhere there were healing waters, and bathing in them would restore youth if not bestow immortality. Throughout the ages, such myths have led to geographic explorations to find fountains of youth, though these have never yielded the sought-after secret cure or reversal of aging.

Gruman divided the myths about aging and mortality into three main types: (1) antediluvian, which hold that in the past people lived much longer; (2) hyperborean, in which it is believed that people live much longer in some remote part of the world; and (3) the fountain type, in which healing waters or substances are thought to exist somewhere. Gruman also uses the word prolongevity to refer to the myths and legends in which longevity is extended by means other than those under humans' control.

Myths about longevity have usually been linked with a belief in an 'Abode of the Blessed,' where the pure have extended life. Elements of this pattern have been widespread, appearing in Persian, Teutonic, Japanese, Hebrew, Hindu, and Chinese myths.

Alexander the Great (356–323 BC) is described as having had an encounter with a fountain of life and

Ponce de Leon (1460–1521) purportedly discovered Florida while looking for a fountain that the North American Indians believed was rejuvenating to those who drank or bathed in its waters. It is surprising how many cultures have passed on legends that describe rejuvenating waters that flowed out of an earthly paradise or described mysterious substances that have the power of prolonging life. Myth and magic and wishful thinking about longevity and death apparently pervaded all societies in prescientific eras.

Today these myths may still underlie the popularity of healing spas, diets, exercise programs, and vitamins of special potency. This comment is not meant to express an evaluation of the validity of ways of modifying the course of aging but to express a link between these high contemporary interests and the underlying fear of old age and dying that must have preoccupied some of our preliterate ancestors and still are important to our contemporaries.

Less available to Western scholars have been the East Indian legends, myths, and perspectives on old age and death. A review of East Indian perspectives on aging and the meaning of life has been provided by Ram-Prasad, in which the ideal life pattern is described as consisting of four stages: studenthood, householder, forest dweller, and renouncer. Codification of what students needed to learn began relatively early, from 1500 to 500 BC. By the beginning of the Christian era an Indian system of belief had evolved that encouraged conformity to these four stages of the life course. Individuals were expected to fit into a cosmic order, *dharma*. Ram-Prasad describes dharma as being an overall entity that reflects the regulation of all aspects of the cosmos. The law book of ancient India is the Code of Manu. It is of interest that early phases of life include pleasures and increasing wealth, but later phases require detachment or renunciation. Meaningfulness in later life is attained by a transcendental detachment from the requirements of daily living. As an alternative to the transcendental detachment in the later years, one may attempt to derive meaning from world-directed acts; however, in the classical East Indian view of life, in the final stage of life, old age, the individual transcends and renounces the world.

In Hinduism and Buddhism, there is the tenet that the force developed by an individual's actions, *karma*, provides the energy for the series of rebirths and deaths until the individual achieves spiritual liberation. Reincarnation in a different body form represents the transmission or embodiment of the soul into a new structure. The reincarnated form would be an outcome of the individual's actions during a previous life.

East Indian thought about old age and death accepts the idea of a preordained cosmic order in which the individual lives through stages en route to some ultimate transcendental state. Thus the background for Indian thought is a mixture of philosophy, religion, and the mythology of a long-existing culture.

There has been some filtration into the West of the idea of reincarnation, though the West has been influenced by the Christian view that the individual is ultimately resurrected for eternal life. Both Hinduism and Christianity regard the conditions of future existence as being a consequence of present moral behavior.

Greco-Roman Philosophers

The Greek and Roman philosophers dealt with questions about the nature of aging and death. The contributions of philosophy and the beginnings of science derived their strength from the rigor of the reasoning and its logic but not data. Underlying their views is the realization from personal observations that there is a pattern to changes in life marked by stages, cycles, or seasons of a life. Increasingly, in the Greco-Roman views of life there was a separation of the physical or physiological aspects from the moral or religious points of view.

In the fourth century BC the Greek philosopher, Epicurus (341?–270 BC) thought that if people developed the right attitude about the end of life and death, they lost their fear of them and lived a more peaceful life. According to Gruman, Epicurus thought that a short life could be just as happy as a long one so that prolongation of life was not important. Aristotle (384–322 BC) was more interested in the natural phenomena of old age and thought that the old body was cold and dry leading to death. He had a rather fixed view of cosmic relationships and avoided the idea of humankind's rebelling against nature or attempting to ameliorate the course of aging.

Cicero (106–42 BC) thought that death was a blessing because it freed our immortal souls from their bodily prisons, and he attempted to rebut major objections to old age, including the one that old age interferes with the enjoyment of sensual pleasures. He expressed the opinion that this is a good loss because it permits the older person to concentrate on the promotion of virtue and reason. According to Cole, the Greco-Roman philosophers' worldview of old age was that it was inexorable.

> Beginning at conception, the physiological process of drying out and growing old, continued inexorably until death. The stages of life were nature's milestones, marking the diminution of natural heat and increased desecration.

> Each change dictated its own behavior pattern. This approach to aging and the life cycle took shape in an intellectual world without boundaries between science and philosophy; hence it combined the physical and the moral, interpreting behavioral signs in the light of physiology as well as individual character. (Cole, 1988: 49).

In addition to the philosophers of the era, physicians also contributed their observations about the course of life and the afflictions of the body. The most significant of these was Galen (129–199), who became a model for physicians and for medicine. He believed, like others of his time, that the body dried out as it grew old. Although this suggests that the adding of moisture to the body might extend life, he did not attempt to interfere with what were regarded as the inevitable changes in the body's balance of heat and cold and the drying out of tissues. Two elements in early thought about aging led to the position that attempting to modify the course of life is undesirable. The first of these is that it is against the will of God, the second is that it is against the law of nature. Gruman said that "Galen's writings are dominated by teleological arguments, which emphasize that nature always acts for the best. To the question whether old age is a disease, Galen replied that, 'it is not a disease because it is not contrary to nature'" (p. 17).

In the late Middle Ages, Galen's interpretation of the biology of life was shared by an Arabic philosopher and physician, Avicenna (980–1037). He believed that the drying-out process began in the embryo and continued as a beneficial influence until growth and development ceased at about the age of 30. It was further thought that as the innate moisture of the body dries up, its innate heat decreases, and the aging body becomes cold and dry. This led to a pessimistic outlook about the capacity of medicine to interfere in the decline of function of an aging body. It was thought that extending the life was not a legitimate medical goal, because each individual had a predetermined fixed term of life.

All societies and cultures have been impressed with cycles of the life span and its conclusion with death, although the interpretations or attributions of the forces behind patterns of change have varied. The Greeks and Romans and the Hindus believed that death was part of a natural cosmic order. In Christianity, a different causal attribution was made, that because of sin humankind had fallen from a state of grace in the Garden of Eden and lost immortality and was destined to live a life on this earth plagued by many problems. Eternal life could come only after death and after a life lived according to religious tenets. For many centuries religion and the practice of medicine shared similar views of the preordained character and length of human life.

The religious and theological underpinnings of Western medieval life encouraged the view that one should not tamper with God's will. This position not only discouraged attempts to modify the course of life but also discouraged science generally because its attempts to understand nature were intrusions into the organization of the cosmos as designed and desired by God. Although both the Old and the New Testaments project the view of the fall of humankind and the loss of immortality due to sinfulness, the resurrection of the righteous for eternity is emphasized in Christianity and the New Testament. This views the human body and its afflictions as of little importance in comparison with the soul, which is eternal. Victory over death was achieved by resurrection and eternity by God for the righteous. Translated into the attitudes of educated persons, this discouraged experimentation and explanations cast in terms of natural causes. If one attributes the downfall of humankind from Eden as based on pride, then pride is the paramount sin of the scientist because scientists presume to be able to ascertain causal relationships and thereby God's purposes.

Gruman contrasted apologism and prolongevity. The position of the apologist is essentially that study and manipulation of the body to produce longevity is a violation of the natural order. If humankind became mortal and died because of sin, attempts to modify the course of life are not only likely to be unproductive but they are presumably sinful in and of themselves. By extension, old age and death are beneficial in that it brings us closer to resurrection and eternal life with God. The apologist's position not only deterred the development of science, but it also discouraged the transmission of earlier myths about eternal life that had been passed on in the folklore of many cultures. Just below the surface of medieval society, however, there was evidence that early myths still persisted about eternal life and legendary places in the world where long life was attained. Columbus, for example, in 1498 reported that on his third voyage he located a terrestrial paradise in Venezuela. A relatively recent novel, the *Lost Horizon*, by James Hilton, deals with the myth of Shangri-la. This was the name of a place in the Himalayas where people reportedly lived a very long time.

Medieval theology did not stamp out the desire to believe and perpetuate myths of eternal life on earth or an interest in finding pathways to increase longevity. It did, however, discourage the study and gathering of systematic data on the conditions of life that might lead to life extensions.

In the sixteenth and seventeenth centuries in France and Austria, the Huguenots, a Protestant sect, were expelled and persecuted for their beliefs that encouraged a look at the natural sources of conditions of human life. At that time, the Roman Catholic Church, which dominated Christianity, did not favor the collection and examination of data on the length of human life and its variations in different places and conditions. As recently as the eighteenth and nineteenth centuries, there was evidence that the dominant theology of the West discouraged an empirical approach to demography and epidemiology that could ascribe the length of life to natural phenomena.

Unlike the mythic period, the Greek and later philosophers entered into disputations about their conceptions of aging. Lacking evidence from empirical science, it was the tightness of their logic or elegance of their reasoning that were translated into proof of the validity of their opinions. This was a marked advance in understanding because it brought the circumstances of aging into normal discourse and its causes into disputation rather than leaving them in the hands of temple priests who assigned causes to deistic power or offenses. The philosophers coupled their everyday observations with their abstractions in attempting to weigh evidence before arriving at conclusions. One of the early observations was that in death the body is cold. Hence the loss of heat became an early focus. Aristotle regarded old age as the time when our heat is diminished. Much later this same idea was expressed by Benjamin Franklin (1706–1790), who thought he could rejuvenate a dead chicken by exposing it to a spark of lightning (i.e., heat).

The Renaissance

The fourteenth century was the beginning of a revival of literature, learning, and art in Western Europe. Stimulated by the prosperity of the Italian economy and its culture many new expressions were spawned in art, literature, architecture, and science. In the sixteenth century, the Renaissance was joined by a Reformation movement in which Protestant churches separated from the Roman Catholic church. The Reformation brought with it a new freedom of thought but also new tensions about social controls, religious beliefs, and desirable life activities, though it still carried with it an emphasis on doing good works during one's lifetime.

There are many exceptions to this simple view of the evolution of Western ideas about aging and death. Medieval alchemists thought about prolongevity and apparently had done things to lengthen life. In China, there was no theological resistance to the exploration of natural experiments, and their alchemists also attempted to modify the course of life by using various natural substances.

In the Old Testament of the Bible, there is an account of the attempt to rejuvenate the aging King David (c. 1000–762 BC) by placing a young virgin in his bed. There had long been an assumption that inhaling the breath of a young maiden was a stimulus to longevity. This practice, called *gerokomy*, was recommended by a seventeenth-century Dutch physician who suggested that an aging burgomeister lie between two young virgins, presumably so that he would obtain maximum benefit, to restore his vitality.

The influence of the Renaissance and the Reformation freed investigators to pursue the gathering of data. Data or information could then be used for sorting out valid from invalid views of the causes of natural events. The use of data probably distinguishes more than anything else the approach to present-day thinking in contrast to that of the Greeks and Romans (i.e., it is not only logic and richness of thought that matters but the availability of data on which to revise thought). It also differs from classical East Indian thought about old age and death, which is based on the assumption that there is a preordained cosmic order in which each individual lives through stages en route to some ultimate transcendental state. Thus, the background for Indian thought is a mixture of philosophy, religion, and the practices of a long existing culture, although it did not stimulate scientific research on aging.

In Great Britain, the views of Francis Bacon (1561–1626) encouraged the growth of natural sciences and serious inquiry into the processes of aging. In Italy in 1558, Cornaro (1284–1367) published his *Discourses*, which was very influential in Western Europe. Cornaro believed that longevity could be extended by simple reforms of an individual's life habits. He believed that some very simple hygienic practices would influence the length of life and the condition of a person's health. This view has its counterparts today, that personal dietary habits, exercise, and activity patterns, exposure to noxious environmental influences, and stress influence how long and how well we live. The Renaissance and Reformation permitted a shift in attitudes that supported the growth of natural science and the gathering of systematic data. Although the observations of Galileo (1564–1642) on the organization of the planetary system led to a conflict with the Roman Catholic Church, later observers were able to interpret the organization of the planetary system with impunity and freedom from persecution.

The Scientific Era

As learned scholars began to make systematic observations in areas other than astronomy, a burgeoning period of science ultimately reached the subject matter of aging. In England, Isaac Newton (1642–1727), a member of then-religiously dominated Trinity College, Cambridge, explored physics and developed laws about the force of gravity. His life exemplified both the quest for understanding in natural terms and the conviction that relationships can be expressed lawfully. Scholars believed that every event or act is the inevitable outcome of its antecedents. The successes of astronomy and the physical sciences in explaining natural phenomena encouraged the growth of science in new directions in biology and medicine. Scientists had the conviction that everything was knowable, all things were deterministic and lawful. This encouraged the growth of new perspectives on the issues of aging, longevity, and death.

The expansion of mathematics and sciences occurred rapidly after the seventeenth century. European universities added many faculty members whose expertise and commitment were to science. This expansion originated in the physical sciences. It was followed by biology and then by psychology and the social sciences, although some remaining unease was experienced in the relationships between philosophy, theology, and by the growth of the behavioral and social sciences. As late as 1937, philosophers at Oxford University stated there could never be a science of the mind and voted down the creation of a department of psychology. Less threatening to the belief structure of organized religion was the study of mathematics, chemistry, and physics than was the study of human behavior.

The studies of British biologist Charles Darwin (1809–1882) perhaps epitomize the weakening of philosophical and religious presuppositions in characterizing the status of humankind in the universe. Through his observations of various species, Darwin concluded that there had been an evolution of species from simple early forms to later more complex species, including human. Although this did give humans a superior position in the sense that it was a late evolved species, it clearly broke with the creationist tradition, which regarded humankind as a unique and immediate purposive product of a Divine Being (*see* Evolution and Comparative Biology).

In 1825 Gompertz published his paper on the lawfulness of human mortality and age. He described the relationship between age and death rates, now often referred to as Gompertz' law. He pointed out that death rates fall from birth to about age 10 and then rise and accelerate until the end of the life span. His quantitative description of the life course of mortality was a lasting contribution to the study of aging. It should be remembered, however, that the quantitative description of the course of death rates over the life span does not in itself reveal the causes of mortality.

The expansive period of science in the nineteenth century was based upon the conviction that all phenomena of nature are lawful and that these laws can be determined through scientific investigation. The first application of this point of view in the study of aging was done by a Belgian scientist, mathematician, statistician, and astronomer Adolphe Quetelet (1796–1874). He published his views with supporting data in Paris in 1835. The translated title of his book is *On Man and the Development of his Faculties*. The determinist point of view is clearly expressed in his provocative opening: "Man is born, grows up, and dies, according to certain laws which have never been properly investigated, either as a whole or in the mode of their mutual reactions," (Quetelet, 1842, Edinburgh translation). Quetelet was a distinguished scientist of his day, and he visited and corresponded widely with other leaders in science in Western Europe. It is of interest to note that it is difficult to classify him in terms of contemporary science. He wrote and studied at a time before there were few formal university departments in many of the disciplines. He could be regarded as one of the earliest quantitative workers in the field of exact social science, but he also dealt with issues of mortality and functional capacities. Trained as a mathematician, he developed the concept of "the average man" around which were distributed measurements according to the law of accidental causes. In this he anticipated the work of Gauss, whose work on the binomial distribution, which is commonly known as the normal or bell-shaped curve. Quetelet reviewed mortality data in relation to age, sex, urban, rural, and national differences. He was convinced that little is beyond knowing if one attends to observation and to describing statistical and mathematical relationships. He clearly adopted a deterministic and organismic perspective about human development and aging. In commenting about previous work he said

> But they have neglected to put forward, with sufficient prominence, the study of his physical development, and they have neglected to mark by numbers how individual man increases with respect to weight and height – how, in short, his forces are developed, the sensibility of his organs, and his other physical faculties. They have not determined the age at which his faculties reach their maximum or highest energy, nor the time when they commence to decline. Neither have they determined the

> relative value of his faculties at different epochs or periods of his life, nor the mode according to which they mutually influence each other, nor the modifying causes. In like manner, the progressive development of moral and intellectual man has scarcely occupied their attention: nor have they noted how the facilities of his mind are at every age influenced by those of the body, nor how his faculties mutually react.

His perspectives on aging as resulting from ecological interactions of heredity, behavior, and the environment are congruent with late twentieth-century thinking.

Quetelet had been in contact with Charles Darwin's cousin Francis Galton (1822–1911), another outstanding intellectual pioneer of the nineteenth century. It is of interest to note that both of them were interested in quantifying the relationship of functional aspects of organisms with the age of the organism. Galton like Quetelet had broad interests. He was originally trained in medicine and mathematics and later studied geography, anthropology, and psychology. He became increasingly interested in anthropometric measurements and, like Quetelet, included measurements of physical and mental functions in his research.

An Englishman, Galton sponsored an exhibition of health in London in the 1880s and gathered considerable data on such things as the upper limits of hearing and changes that occur with advancing age. Galton used the term human machine, which undoubtedly reflects his earlier background in physiology. He was interested in fitting the facts of both development and aging in human beings into a broader framework of human evolution and science. One of his major contributions to the study of aging was his gathering of data at the International Health Exhibition of London of 1884. Over 9337 males and females aged 5–80 years were measured on 17 different functions. Because of his exposure to large masses of data, Galton developed an index of correlation to measure the degree of association of two variables (e.g., age and strength). This was a large step forward because it enabled scholars to separate factors according to the degree to which they were related to age or to some purported causal factor of aging.

Galton was very impressed with the power of biometrics and left his personal fortune to create the first university chair of biometrics. Karl Pearson (1857–1936) was its first occupant who extended the statistical methods for the analysis of research data, including the development of a quantitative correlation measure whose limits of error could be specified. Galton's interests later turned away from the study of development and aging to the application of Darwin's ideas of evolution. He attempted to develop principles of eugenics for application in the population at large. He wanted to encourage selective breeding of the population so that persons with high intelligence levels would have more offspring. In the nineteenth century, studies of aging were carried out by men like Galton and Quetelet who had high social status and who had the personal funds to finance them. There were no major organized laboratories that conducted research on aging for significant periods of time. Shortly after Gallon's work, a physician at Cambridge University, Humphrey, conducted a major survey of the health of older adults. The work, although admirably pioneering and comprehensive, lacked the quantitative synthesis provided by Quetelet and Galton.

In America, the statesman Benjamin Franklin (1706–1790) had earlier stimulated considerable speculation about reviving organisms that were showing no signs of life but might still be resurrected. Because of his involvement with the discovery of the lightning rod and thereby controlling the flow of electrical discharge, he thought that the loss of electricity or the loss of vitality might be the cause of aging. This example underscores many uncertainties in the field of gerontology. That is, it is uncertain whether a particular characteristic of the organism associated with advancing age is the cause of general aging or is a result of it. This dilemma is seen, for example, in the earlier emphasis on heat and the body, which led to the assumption that loss of heat was the cause of aging and if heat were replaced, aging would be stopped or reversed. In a similar way because sexual intercourse seems to decline with age, it was thought that stimulating increased sexual activity might fend off the more general effects of aging.

At the beginning of the twentieth century, a number of biologists began to write prolifically about aging. Their underlying theme was the identification of causes of aging or the transformations that occur with age in the human species. The writing of the day was surrounded by a great deal of optimism about the potency of science. No problem appeared to be beyond its understanding and perhaps even the extension of the human life span was potentially under humans' control. There was considerable public interest in prolonging life and even bringing back to life persons who had died.

But serious scholars were becoming more cautious in their expectations that life extension or rejuvenation would be easy or within immediate reach. The Nobel Laureate in physiology, Minot, stated both his optimism and his passion with regard to growing old, which he called senescence.

> We should, indeed, like to have some principle given to us which would retard the rate of senescence and leave us for a longer period the enjoyment of our mature faculties. ... I can venture to suggest to you that in the future deeper insight into these mysteries probably awaits us and there may indeed come a time when we can somewhat regulate these matters. (Minot, 1908: 248)

The views of Minot deeply influenced the earliest American psychologist G. S. Hall (1844–1924), president of Clark University. As a developmental psychologist, Hall is credited with initiating research on adolescence. Near the end of his life, Hall (1922) reviewed much of the available information and the then contemporary thinking about aging in his book *Senescence: the Second Half of Life*. Senescence was a term that he adopted from his reading of biologists of his time. He also included his personal psychological interpretations. "As a psychologist I am convinced that the psychic states of old people have great significance. Senescence, like adolescence, has its own feeling, thought, and will, as well as its own psychology and the regime is important, as well as that of the body. Individual differences here are probably greater than in youth" (Hall, 1922: 100). In this statement Hall anticipated many later psychologists who also pointed to an increase in individual differences that can occur in many traits with advancing age.

In Russia in the 1920s, the Nobel laureate in physiology, Ivan Pavlov (1849–1936), and his colleagues had observed that older animals learn differently and develop conditioned reflexes differently from young animals. They thought that the process of inhibition was more vulnerable to age than was facilitation. This would be reflected in the fact that old habits would be more difficult to eliminate than recent ones. They anticipated somewhat a later development in interpreting the slowness of speed of behavior with advancing age by pointing out that when a nerve process is slowed or delayed, remaining traces of each stimulus overly influence succeeding stimuli.

Pavlov's views about aging were not shared by American researchers. He and his followers believed that the role of the central nervous system (CNS) is important in governing the process of aging of the organism. American physiologists had tended to regard aging of the CNS as resulting from the aging of other organs and the circulatory system rather than its being a primary manifestation of the decline in the regulatory capacity of the CNS itself. More recently the CNS has come to be regarded as an important organ in the aging of primates (*see* Brain and Central Nervous System).

The Beginning of the Modern Period of Gerontology

One of the first laboratories for the systematic study of aging was established in 1928 in the psychology department at Stanford University under the direction of Walter R. Miles (1885–1978); it was supported by the Carnegie Foundation of New York. The motivations behind the establishment of The Stanford Later Maturity Study were many, but an important influence was that in California men over the age of 40 at that time were having difficulties finding work because it was assumed that they were too old. The Stanford laboratory produced about eight doctoral dissertations on various aspects of aging, including such topics as the relations of age to creativity, learning, extinction of learned responses, and motor skills (*see* Creativity; Learning; Motor Control).

In the 1930s new support for the systematic study of aging came through the activities of the Josiah Macy, Jr. Foundation of New York. The Foundation had supported studies of degenerative diseases related to aging, but the director, Dr. Ludwig Kast, believed that degenerative diseases were part of a manifestation of the process of aging. With this in mind he encouraged scholarship and research on aging. The study of aging was encouraged as a parallel to the already vigorous areas of research on childhood growth and development.

E. V. Cowdry, a cytologist at Washington University in St. Louis, was urged by the Macy Foundation to organize the publication of a major integrative volume of the information on aging. He was encouraged to enlarge his initial conception of the book, which dealt primarily with biomedical aspects of aging, to include environmental influences and social, psychological, and psychiatric issues as well. This encouragement led to a subsequent multidisciplinary scientific conference and to the collation of the literature on aging from the various sciences in the pioneering volume *Problems of Ageing*, edited by Cowdry in 1939. (It is of interest that the book uses the English spelling of the word ageing rather than the standard American aging.)

At the time Cowdry's book on aging was published, there was a developing concern about the increased role of chronic diseases as a public health problem. Although earlier, infectious diseases were the major influences on mortality in America, heart disease and cancer were increasing as common causes of death.

The developments in the study of aging that had occurred during the 1930s resulted in the desire to create an organization to promote research on aging.

A guest researcher at the Department of Anatomy at Oxford University, Korenchevsky, visited New York and requested that the Macy Foundation sponsor the organization of a Club for Research on Aging. Similar clubs were being organized in Europe. It was thought that such a club would be an organization where men could discuss and dispute aspects of aging as gentleman scholars and researchers. There was established The Club for Research on Aging in New York, which evolved into a conference series on aging supported by the Macy Foundation both before and after 1940.

By 1940 thinking about aging had become more sophisticated and systematic. Both the Public Health Service and the Josiah Macy, Jr. Foundation regarded the processes of aging as multidisciplinary in character. That emphasis has been continued into the present, although many scientists in the various disciplines find it difficult to adopt a multidisciplinary orientation and to regard aging as a multifactorial process having both genetic and environmental basis. Earlier views of aging frequently adopted the medical model, which held that aging is the product of disease. The current view is that manifestations of aging involve many factors that interact to modulate mortality and morbidity.

In 1941 the United States Public Health Service had organized a conference on mental health aspects of aging. At about the same time the Surgeon General of the U.S. Public Health Service negotiated the establishment of a Section on Aging within the National Institutes of Health. In 1941 Dr. Nathan W. Shock was recruited to head the unit. His efforts to initiate research on aging were delayed by America's entry into World War II, which occurred at the same time the research unit was to begin its work.

Contemporary Gerontology

Shortly after World War II ended in 1945, activities in gerontology began to accelerate. Medicine's increasing interest in the age-associated degenerative diseases, the increase of an older population which portended an older society, and general scientific advances made new methods of study available to students of aging. One of the leaders in the Macy Foundation's efforts to develop research on aging was Lawrence K. Frank. He was one of five sponsors involved with the founding of the Gerontological Society in New York in 1945. About the same time the American Geriatric Society was founded with both organizations publishing journals. These societies have shown continuing development in their membership and in the scope of annual meetings. The International Association of Gerontology was founded shortly thereafter with its first meeting in Liege, Belgium, in 1948 and its second Congress in St. Louis in 1951. The first Pan American Congress of Gerontology was held in Mexico City in 1956. These organized efforts in gerontology stimulated research, teaching, and service.

The publication rate of scientific articles in aging has been growing exponentially. The various constituent sciences and professions are beginning to create their own specialized divisions and they publish their own specialized journals. Also, the professional or applied aspects of aging are growing in significance, and leaders in these fields are encouraging opportunities to exchange ideas about conditions that will benefit the lives of older people more immediately. Interest in the process of aging is being expressed both within the disciplines and between the disciplines.

In many countries, longitudinal studies of aging are being developed that depend upon the collaboration of scientists from many fields. Understanding the aging of organisms requires the collaboration of many disciplines and needs to be accompanied by a complex orientation that will undoubtedly require new and more sophisticated models. Of great importance to the longevity, health, well-being, and quality of life of older persons is the development of increasingly sophisticated theory and research on aging. An interest has already been expressed in the encouragement of such models (*see* Models of Aging: Invertebrates, Filamentous Fungi, and Yeasts; Models of Aging: Vertebrates; Theories of Aging: Biological).

In universities, research units on aging are now common and special degree programs in gerontology are offered in at the baccalaureate, master's, and doctoral levels. Assisting in the growth of teaching is the availability of specialized volumes on aging that provide not only current research findings but also historical background in special areas. New works on the humanities, religion, and aging show a trend in collaboration not previously seen, suggesting that there has been initiated a new phase of scholarship and human service in the field of aging.

Because of the importance of knowledge and research on aging for the well-being of present and future generations, there seems little doubt that gerontology will remain a high priority in academic and professional settings.

Summary

Gerontology, the study of aging, has roots that extend far back in history. Humankind has apparently always speculated about the duration of life and the nature of death. In many early cultures myths were

created about longevity and death that were passed as legends that explained humankind's mortality. These legends also were presented in religious teachings (e.g., that humankind at one point had immortality but through weakness and sin was reduced to mortal existence).

Gerontology appears to be on an expanding growth course for both scientific and practical reasons. There has been increasing scientific interest in understanding processes of aging from molecular biological processes through behavioral, social, and humanitarian factors. Developing and developed societies show increasingly larger numbers of older persons who have changing interests and needs. Serving older populations brings with it concerns about increasing standards and efficiency based upon scientific knowledge.

Understanding and explaining the processes of aging has proven to be complex. Aging may be one of the most complex topics undertaken for research in the life sciences. Perhaps in reaction to the complexity of the subject, investigators have increasingly studied limited aspects of aging. Thus, recent gerontology has been characterized as having many aspect studies and aspect theories. It may also be said that gerontology is a field that is data rich and theory poor. Aided by developments in statistical modeling and analysis, subsystems of the organism may be characterized in terms of causal complexes or subgroups of intereacting variables. The interrelationships of these aspects or causal complexes may lead to an interaction with the models developed in physics dealing with chaotic processes and events.

The increase in initiation of longitudinal studies of human populations that embrace genetic, behavioral, social, and other influences may lead to a more organismic approach to aging in place of the present aspect specialization. The duration of humankind's life increasingly seems to be placed in an ecological context that embraces explanations arising from species and unique individual genetic background together with influences from behavioral and social processes and physical and social environments. It is foolhardy to predict the precise character of gerontology in the twenty-first century, but it seems highly likely that it will show increasing activity and intellectual and scientific sophistication that will provide the basis for significant advances in humankind's quality of life.

Homeostasis, Homeodynamics and Aging

S I S Rattan, University of Aarhus, Aarhus, Denmark

Glossary

Allostasis – Stability through change.

Essential Life Span (also called Natural Life Span) – The time required to fulfil the Darwinian purpose of life, namely successful reproduction for the continuation of generations.

Homeodynamics – Concept that the internal milieu of complex biological systems is not permanently fixed, is not at equilibrium, and is a dynamic regulation and interaction among various levels of organization.

Homeostasis – The ability to respond, counteract, and adapt to the external and internal sources of disturbances.

Hormesis – Beneficial effects resulting from the cellular responses to mild repeated stress that challenges and stimulates homeodynamic machinery.

Introduction

All living systems, in contrast to the non-living systems, have the intrinsic ability to respond, counteract, and adapt to the external and internal sources of disturbance. The traditional conceptual model to describe this property is homeostasis, which has dominated biology, physiology, and medicine since the 1930s. However, tremendous advances in our understanding of the processes of biological growth, development, maturation, reproduction, and, finally, aging, senescence, and death have led to the realization that the homeostasis model as an explanation is seriously incomplete. The main reason for the incompleteness of the homeostasis model is its defining principle of stability through constancy, which does not take into account the new themes, such as cybernetics, control theory, catastrophe theory, chaos theory, and information and interaction networks, that comprise and underline the modern biology of complexity.

Since the 1990s, the term homeodynamics, introduced by F. E. Yates in 1994, has been increasingly used – though it has not yet fully succeeded in replacing homeostasis. The concept of homeodynamics accounts for the fact that the internal milieu of complex biological systems is not permanently fixed, is not at equilibrium, and is a dynamic regulation and interaction among various levels of organization.

Almost in parallel with the development of the concept of homeodynamics, the term allostasis, coined and introduced by Peter Sterling and J. Eyer in 1988, has been gaining recognition and use. According to the allostasis model, stability through change is the most realistic situation for living biological systems. The allostasis model also takes into account characteristics such as reciprocal tradeoffs between various cells, tissues, and organs, accommodative sensing and prediction with respect to the severity of a potential stressor, and the final cost of making a response and readjustment to bring about the necessary change. Every act of allostasis adds to the allostatic load in terms of, for example, unrepaired molecular damage, reduced energy deposits, and progressively less efficient or less stable structural and functional components. Aging, senescence, and death are the final manifestations of unsuccessful homeodynamics or failure of allostasis.

Components of the Homeodynamic Machinery

Of the numerous biochemical and physiological pathways and processes operating in cells, tissues, organs, and systems in any organism, the key pathways and processes that can be considered to be quintessential components of the homeodynamic machinery are the following:

1. The multiple pathways of nuclear and mitochondrial DNA repair, including those for maintaining the accuracy of the information transfer from DNA to RNA to proteins and those for the removal of spontaneous lesions in DNA.
2. The processes for sensing and responding to intra- and extracellular stressors, such as heat shock response, hemeoxygenase response, stress hormones, and ionic fluxes.
3. The pathways for protein repair, such as the renaturation of proteins by chaperones, and the enzymic reversal of the oxidization of amino acids.
4. The pathways for the removal and turnover of defective proteins by proteasomes and lysosomes.
5. The antioxidative and enzymic defenses against reactive oxygen species.
6. The processes for the detoxification of harmful chemicals in the diet.

7. The cellular and humoral immune responses against pathogens and parasites, including massive apoptosis (programmed cell death) after the completion of the cellular immune response.
8. The processes of wound healing, blood clotting, and tissue/organ regeneration.

In addition to these main categories of pathways and processes comprising the homeodynamic machinery, some other physiological processes include temperature control, the epigenetic stability of differentiated cells, and fat storage and energy utilization.

Of course, all these processes involve genes whose gene products and their interactions give rise to a homeodynamic space, which is the ultimate determinant of an individual's chance and ability to survive and maintain a healthy state. At present, our knowledge about the number of genes and their variants and their multiple interactions and consequences is too meager to identify, define, and manipulate the homeodynamic machinery in any sensible way. In the case of human beings and other social animals, determining the role of psychosocial factors as integral components of the homeodynamic machinery is one of the biggest challenges.

Homeodynamic Space and Longevity

Why members of different species have different life spans and what determines the life span potential of an organism are challenging evolutionary questions. The natural life span of a species has also been termed essential life span (ELS) by Suresh Rattan, or the warranty period of a species by Bruce Carnes and S. Jay Olshansky. ELS is defined as the time required to fulfill the Darwinian purpose of life, that is, successful reproduction for the continuation of generations. Species undergoing fast maturation and early onset of reproduction with large reproductive potential generally have a short ELS. In contrast, slow maturation, late onset of reproduction, and small reproductive potential of a species is concurrent with its long ELS. For example, the ELS of *Drosophila* is less than 1 week as compared with the ELS of *Homo sapiens* of less than 50 years, even though in protected environments (laboratories and modern societies), a large proportion of populations of both species can and do live for much longer than that.

Since the 1980s, Robin Holliday and Tom Kirkwood have been developing arguments based on the allocation of energy and metabolic resources (EMR) as the determinants of an organism's longevity and survival potential. According to their ideas, available EMR must be divided among three fundamental features of life: (1) basic metabolism, which includes biochemical synthesis, respiration, cell turnover, movement, feeding, digestion, and excretion; (2) reproduction; and (3) maintenance through homeodynamic machinery as described previously.

Whereas basic metabolism is essential for all animals, the extent of investment in reproduction and maintenance can vary between species. This is the trade-off, known as the disposable soma theory of aging, between investment in maintenance and investment in reproduction, which are related inversely. The evolved balance between the two depends on the life history strategy and ecological niche of the species. Several comparative studies have reported positive correlations between life span and the ability to repair DNA, detoxify reactive oxygen molecules, respond to and counteract stress, and replace worn-out cells. In addition, negative correlation has been demonstrated between longevity and the rate of damage accumulation, including mutations, epimutations, macromolecular oxidation, and aggregation of metabolic by-products.

Although the reasons for the longevity differences among the species can be explained by the disposable soma theory, significant differences among individuals within a species are much harder to explain. Genes, milieu (environment), and chance factors are thought to be the determinants of individual life span. Of these factors, some understanding is emerging about genes and their associations with survival and longevity. In human beings, association studies on gene polymorphism and longevity have identified numerous genes that function in a variety of biochemical pathways, such as cytokines, cholesterol metabolism, DNA repair, and heat shock response. Such studies will ultimately lead to the elucidation of the nature and number of genes involved in comprising the homeodynamic space of an individual, which may be the basis for its modulation and intervention.

Aging as the Failure of Homeodynamics

The evolved nature of the homeodynamic machinery, in accordance with the life history traits of different species, sets an intrinsic genetic limit on the ELS as described previously. Therefore, aging is considered as an emergent phenomenon seen primarily in protected environments that allow survival beyond the natural life span in the wild. No real genes for aging (gerontogenes) are thought to exist, and the genes in aging were defined by Suresh Rattan in 1995 as being virtual gerontogenes owing to their indirect effects on aging and longevity.

Based on a large body of descriptive data, gleaned during a period of more than 50 years in the field of biogerontology, Robin Holliday has defined aging as the progressive failure of homeodynamics. Collectively, biogerontological data characterize aging as a progressive accumulation of molecular damage in nucleic acids, proteins, and lipids. Since the occurrence and accumulation of molecular damage are mainly stochastic, aging is manifested differently in different species, in individuals within a species, organs, tissues, cells, and subcellular components within an individual. The main cause of age-related accumulation of molecular damage and its consequences is the inefficiency and failure of maintenance, repair, and turnover pathways that constitute the genetically determined homeodynamic machinery.

A generalized definition of aging as the failure of homeodynamics still requires a mechanistic explanation as to why such a failure occurs in the first place and what controls the rate of failure in different species. Over the last 50 years, researchers have proposed a large number of hypotheses that attempt to explain how the observed age-related changes in macromolecules, cells, tissues, organs, and systems may occur. The main examples of such hypotheses include altered gene regulation, somatic mutation accumulation, protein errors and modifications, reactive oxygen species and free radicals, immune remodeling, and neuroendocrine dysfunctioning. At the cellular level, the so-called telomere loss theory and the epimutation theory of progressive loss of DNA methylation are other examples of mechanistic explanations for the loss of proliferative potential of normal, differentiated, and diploid cells *in vitro* and *in vivo*.

These and other related hypotheses that provide a variety of explanations for understanding the observed age-related alterations at a specific level can be quite useful within their area of focus. However, in order to answer the question of why the occurrence of detrimental and eventually lethal changes cannot be avoided completely, one has to appeal to the evolutionary theories of aging and longevity, as discussed previously.

Several theoretical and mathematical models are being developed in order to understand the interactive nature of the biological networks and trade-offs. Recently, the reliability theory of aging and longevity proposed by Leonard Gavrilov, about the inevitable failure of complex systems such as cells and organisms, has reiterated the principle that no process can be 100% accurate 100% of the time; and it is the interactive nature of genes, milieu, and chance that effectively determines how long homeodynamic ability can keep a biological system alive.

Homeodynamics and Aging Intervention, Prevention, and Therapies

According to the homeodynamics-based explanations for aging and longevity described previously, the bodies that we have developed after millions of years of evolution, the occurrence of aging in the period beyond ELS, and the onset of one or more diseases before eventual death appear to be the normal sequence of events. This viewpoint makes modulation of aging different from the treatment of one or more specific diseases. In the case of a disease, such as a cancer of any specific kind, its therapy will, ideally, mean the removal and elimination of the cancer cells and restoration of the affected organ or tissue to its original, disease-free state. What, then, will be the treatment of aging and to what original age-free stage would one hope to be restored? Considering aging as a disease and then trying to cure that disease is unscientific and misguided. Similarly, although piecemeal replacement of non-functional or half-functional body parts with natural or synthetic parts made of more durable material may provide a temporary solution to the problems of age-related impairments, it does not modulate the underlying aging process as such.

Scientific and rational anti-aging strategies aim to slow down aging, to prevent and/or delay the physiological decline, and to regain lost functional abilities. Strengthening, improving, or enlarging the homeodynamic space at the level of all genes comprising the homeodynamic machinery of an individual may be the ideal anti-aging solution. However, such a gene therapy approach for gerontomodulation requires redesigning the blueprint for structural and functional units of the body at the level of genes, gene products, macromolecular interactions, molecular milieu interactions, and so on. Considering how little information and knowledge we have at present about the interacting variants of genes, molecules, milieu, and chance, it is not clear what this approach means in practical and achievable terms.

Improving the milieu in which the homeodynamic machinery operates is the other strategy that is being followed by most of the so-called anti-aging experts. Some of the main approaches include supplementation with hormones including growth hormone, dehydroepiandrosterone (DHEA), melatonin, and estrogen, and nutritional supplementation with synthetic and natural antioxidants in purified form or in extracts prepared from plant and animal sources. Although certain of these approaches have been shown to have clinical benefit in the treatment of some diseases in the elderly, none really modulate the

aging process itself. Furthermore, claims for the benefits of intake of high doses of vitamins and various antioxidants and their supposed anti-aging and life-prolonging effects have very little scientific evidence to back them.

In contrast, nutritional modulation through caloric restriction (CR) has been shown to be an effective anti-aging and longevity-extending approach in rodents and monkeys, with possible applications to human beings. However, this is a highly debatable issue at present both in terms of the practicalities of defining CR and in terms of applying CR to human beings in physiological and evolutionary contexts.

Homeodynamics and Hormesis as an Aging Modulator

In a more realistic and near-future scenario, a promising approach in aging intervention and prevention is based on making use of an organism's intrinsic homeodynamic property of self-maintenance and repair. Since aging is characterized by a decrease in adaptive abilities due to progressive failure of homeodynamics, it has been hypothesized that if cells and organisms are exposed to brief periods of stress so that their stress response-induced gene expression is upregulated and the related pathways of maintenance and repair are stimulated, one should observe anti-aging and longevity-promoting effects. Such a phenomenon, in which stimulatory responses to low doses of otherwise harmful conditions improve health and enhance life span, is known as hormesis. (Although the term hormesis was coined in the 1930s, its revival and wide use are accredited to Edward Calabrese.)

The phenomenon of hormesis has been defined in various ways depending on the context. For example, in toxicology, pharmacology, and radiation biology, hormesis is defined by non-linear U-shaped or reverse U-shaped dose–response curves. In biogerontology, hormesis is characterized by the beneficial effects resulting from the cellular responses to mild repeated stress that challenges and stimulates homeodynamic machinery. The paradigm of hormesis in aging is moderate exercise, which is well known to have numerous beneficial effects despite or because of it being a generator of free radicals, acids, and other damaging effects.

Mild stresses that have been reported to delay aging and prolong longevity in various systems (for example, yeast, *Drosophila,* nematodes, rodents, and human cells) include temperature shock, irradiation (UV, gamma, and X-rays), heavy metals, pro-oxidants, acetaldehyde, alcohols, hypergravity, exercise, and food restriction. Hormesis-like beneficial effects of chronic but mild undernutrition have been reported for human beings. Intermittent fasting has been reported to have beneficial effects on glucose metabolism and neuronal resistance to injury.

Although at present there are only a few studies performed that utilize mild stress as a modulator of aging and longevity, hormesis can be a useful experimental approach in biogerontology. However, there are several issues that remain to be resolved before mild stress can be used as a tool to modulate aging and prevent the onset of age-related impairments and pathologies by improving the homeodynamic space of an individual. Some of the issues in the applicability of hormesis as a homeodynamic stimulator are the following:

1. establishing biochemical and molecular criteria for determining the hormetic levels of different stresses;
2. identifying differences and similarities in stress response pathways initiated by different stressors;
3. quantifying the extent of various stress responses;
4. determining the interactive and pleiotropic effects of various stress response pathways;
5. adjusting the levels of mild stress for age-related changes in the sensitivity to stress;
6. determining the biological and evolutionary costs of repeated exposure to stress; and
7. determining the biological significance of relatively small hormetic effects, which may or may not have large beneficial effects during the entire life span.

Resolution of these issues requires much more research on hormesis than is being carried out at present. The proof of the hormetic principle has now been provided by experiments with a wide variety of biological systems and by using a range of physical, chemical, and biological stressors. Two of the main lifestyle interventions, exercise and reduced food intake, both of which bring their beneficial and anti-aging effects through hormesis, are being widely recognized and increasingly practiced as an effective means of achieving a healthy old age. In the consideration of irradiation as a hormetic agent, epidemiological studies of the public, medical cohorts, and occupational workers confirm that low doses of radiation are associated with reduced mortality from all causes, decreased cancer mortality, and reduced mutation load observed in aging and cancer. Increasing use of low-dose total body irradiation as an immunotherapy for cancer also has its basis in hormesis. However, in order that this approach could be developed into a safe and preventive strategy against a variety of age-related diseases, certain issues, for example, those related to radiation load

versus mortality curve, bystander effects, and the nature of energetic particles, need to be resolved.

Hormesis through mental challenge and through mind-concentrating meditational techniques may be useful in stimulating inter- and intracellular debris removal processes, thus preventing the neuronal loss that leads to the onset of age-related neurodegenerative diseases. One can also expect the availability of certain nutriceutical and pharmacological hormetic agents to mimic mild stress as a challenge for the homeodynamic machinery. Plant components such as resveratrol, celastrol, and curcumin are among the potential hormetic molecules identified so far.

Recapitulation

Living systems survive by virtue of a set of defensive maintenance and repair systems that comprise their homeodynamic ability. A large number of interacting genes and genetic networks constitute this machinery, the exact details of which are yet to be unraveled. Successful homeodynamics is crucial for the growth, development, and maturation of an organism until the reproduction and continuation of generations are assured. Homeodynamics is thus a longevity assurance mechanism, whose strength, efficiency, and range have evolved in accordance with the evolutionary history of the species. Survival beyond the required essential life span of a species is necessarily accompanied by the progressive accumulation of random molecular damage. The progressive failure of homeodynamics leads to the physiological malfunctioning manifested as a general functional decline, diseases, and ultimate death. Rational strategies to slow down aging or to prevent the onset of age-related frailty and diseases require the stimulating and strengthening of the homeodynamics of individuals.

Glossary

Hospice – A philosophy of caring for dying patients and their families while emphasizing quality of life.

Introduction

Hospice is a philosophy of caring for dying patients and their families while emphasizing quality of life. Care is provided by an interdisciplinary team to meet the patient's and family's needs throughout the dying process as well as after death. Bereavement care is a key component of hospice, setting it apart from other forms of institutional care provided to dying persons. All hospices share certain characteristics that set them apart from other forms of health care for terminally ill persons: (1) the dying person and family

are the unit of care, (2) the interdisciplinary team serves both the dying person and the family, (3) care focuses on the physical, psychosocial, socioeconomic, and spiritual aspects of dying, (4) services are available on a 24 hour a day, 7 days a week basis, (5) inpatient and home care services are available, and (6) bereavement counseling and support (both prior to and after the individual's death) are available to the dying person and/or the family. Many, if not all, of these issues are reflected in dying persons' perceptions of what is important to them at the end of life. Many hospices are dealing with the financial realities of caring for persons whose resources are limited, and are finding themselves thrust into debates about physician-assisted suicide, euthanasia, and end-of-life care.

The Hospice Philosophy

Hospice is a philosophy of care for people who have terminal illnesses as well as for their families, emphasizing the quality over the quantity of life. Via the active involvement of an interdisciplinary team, a coordinated, individualized plan of care is developed for each patient-family unit. The focus of such care is on pain management and symptom control in the context of maintaining quality of life for the dying patient and his or her family. Death in the hospital (or in the nursing home) is often depersonalized and hidden from public view, in contrast to the deaths of persons in hospice, which are more real, human, and meaningful. Rather than viewed as the end of life, deaths in hospice are better thought of as 'spiritual transformations' from this life to the next. This redefined notion of death in hospice is predicated on the basis of the fact that death need not be accompanied by suffering, i.e., that such care is palliative, and that the patient's and family's wishes will be identified and honored. In effect, death and dying in hospice is a natural event, in contrast to dying in an institution. While hospital care has been characterized as 'event oriented' (focused on the prevention of the event of death), hospice care is 'process oriented' – dying is its focus.

The many problems linked to institutional dying are being addressed by societal and professional efforts to humanize dying by defining the rights of dying persons and by making recommendations about how end-of-life care might be improved. Such efforts were stimulated by the failure of project SUPPORT (Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatment), which attempted to enhance the quality of life for dying patients by improving the communication skills of health-care professionals (i.e., physicians).

In North America, five models of hospice care exist: (1) home-based care, often provided by community-based professionals and volunteers (90% of hospice care is provided in patients' homes), (2) home-based care provided by home health-care agencies or Visiting Nurse Associations (VNA), (3) free-standing, full-service, autonomous hospice facilities, (4) separate hospital-based palliative (pain-reducing) care units, and (5) hospital-based subacute units, emphasizing continuum of care. While many do not differentiate hospice care and palliative care, a distinction between the two is increasingly more commonplace, wherein the latter is typically broader than the former.

Some hospices have begun to explore the concept of adult hospice day care, and moreover, pediatric hospice programs are also becoming more common. Approximately half of all hospices are hospital based, while the balance are operated by home health-care agencies. Most (nearly 80%) are nonprofit in nature, while approximately 15% are for-profit. A third are free-standing facilities. Perhaps reflecting the impact of the hospice philosophy or the dissatisfaction with institutionalized care, nursing homes and assisted-living communities are now providing hospice care, underscoring the continuum of care provided to persons who at one time had been in better health. While most hospice patients have cancer (over half of persons who die of cancer receive hospice care), persons being cared for by hospice also die of AIDS, end-stage heart, lung, or renal disease, dementia (e.g., Alzheimer's disease), and cardiovascular illness. While many such hospice patients are older, hospices care for persons of all ages. Some have greater degrees of community support than do others, and while some still operate on a not-for-profit basis, others that are for-profit in nature are often owned by larger corporations. Approximately 25% of all persons who die will have received hospice care, and the vast majority of hospice patients die at home. The average length of time persons receive hospice care is approximately 50 days.

Regardless of the model of hospice care, all hospices share certain characteristics that set them apart from other forms of health care: (1) the dying person and family are the unit of care, (2) the interdisciplinary team serves both the dying person and the family, (3) care focuses on both the physical and psychosocial aspects of dying, (4) services are available on a 24 hour a day, 7 days a week basis, (5) inpatient and home care services are available, and (6) bereavement counseling and support (both prior to and after the individual's death) are available to the dying person and/or the family. Many, if not all of these issues, are reflected in dying persons' perceptions of what is important to them at the end of life.

These characteristics reflect some very basic ideas about life and death: (1) dying is a natural experience; life and death are equally important and meaningful aspects of our existence; (2) dying persons and their families are important in themselves: the dying person's welfare comes first; (3) dying persons should be able to continue to make decisions for themselves until they are unable or unwilling to do so; (4) it is not demeaning to depend on and be cared for by others; and (5) our relationships with those who have died continue to be important influences on our lives.

Reflecting the continued impact on the lives of patients' families after the patients' death, bereavement researchers are now exploring, more broadly, notions of 'a good death,' with an eye to potential effects on bereaved survivors. Attention is focused on such factors as the dying person's acceptance of and peace with death, alleviating pain, the quality of family relationships, place of death (home, hospice, hospital), and the timeliness of the death. More time in the home setting, in particular, is viewed as allowing the family greater opportunities for meaningful communication and the completion of 'unfinished business,' a meaningful trade-off for many with respect to having to endure pain and emotional distress.

The essential one-on-one aspect of the hospice care philosophy has historically stood in contrast to the cure orientation of conventional hospital oncology care or the maintenance mentality of the nursing home. Hospice patients are less likely to receive intensive medical interventions such as chemotherapy or surgery as well as diagnostic tests (blood tests, X-rays) in the weeks prior to death than those in conventional hospital oncology units. Moreover, while analgesics are more likely to be regularly prescribed for pain on a fixed schedule in conventional health care, pain medication is prescribed on an as-needed basis in hospice.

Origins of Hospice Care

The primary stimulus for hospice in the United States came from the St. Christopher's hospice in London, founded by Dr. Cecily Saunders in 1967, though hospices had existed for many years in Europe. Since then, prompted by the opening of a home-based care hospice, Hospice Inc., in New Haven, Connecticut in 1974, nearly 3300 hospices have been founded in North America. Changes in attitudes toward death, legal decisions and legislation affirming the right of the individual to refuse life-sustaining treatment, and the development of the Medicare Hospice Benefit have also encouraged the expansion of hospice in the United States. Other events important to the development of hospice are the founding of the first hospital-based hospice in North America – the palliative care unit at the Royal Victoria Hospital in Montreal – and the formation of the National Hospice Organization (NHO) in 1977 (now known as the National Hospice and Palliative Care Organization [NHPCO]). In 1992, the principal fund-raising arm of the NHPCO, the National Hospice Foundation (NHF) was founded. NHPCO has been effective in educating the public about hospice and in formulating standards for quality hospice care critical for their accreditation, which makes hospice a viable alternative to institutional care for terminally ill persons and their families.

Who Pays for Hospice Care?

Hospice care became a recognized benefit under Medicare in 1983, and approximately 90% of all hospice programs are Medicare certified. As 28% of all Medicare costs go to persons in their last year of life, and 50% of such costs are expended during the last 2 months of life, hospice can indeed be viewed as an alternative to more expensive and lengthy hospitalizations. While there is an upper limit to what Medicare will reimburse, patients cannot legally be discharged from services if their Medicare ceiling has been reached. Typically, assuming this ceiling is not reached, 6 months' worth of care is covered, unless the dying person's prognosis is recertified by the hospice medical director. For low-income persons, hospice services are also qualified under Medicaid in most states.

Studies have shown that while dying persons represented only a small percentage (1%) of all Medicare beneficiaries at any given time, such persons were consuming a disproportionate share of all Medicare expenditures. Thus, 3 years after hospice care was made reimbursable under Medicare, legislation was passed permitting state Medicaid programs the option of covering hospice. The hospice benefit under Medicare requires that core professional services – physician, nursing, counseling, and medical social work services – be directly provided by the hospice. However, it does not require that hospices directly operate home care or inpatient care facilities. Rather, Medicare simply requires that the hospice staff maintain responsibility for all services regardless of their location and that they guarantee access to such services on a 24-hour basis. Hospices receive a specified amount for each day that regular home care is provided to a patient, and all funds paid to the hospice indeed go directly to the hospice program. The same concerns regarding the costs of acute care for dying persons

that convinced Congress to establish a Medicare benefit have prompted private health insurance companies to move toward hospice coverage. Even when covered by Medicare, hospice costs are sometimes unnecessarily paid by patients and families because questions about private health insurance coverage were not asked.

Case Management in Hospice

Case management ensures that quality care is available to, and continuous for, each patient and family. This is especially important because patients and families often know little about caregiving and may have difficulty in dealing with other agencies. The coordination of care within the interdisciplinary team as well as with other professionals outside of hospice is an essential component of the case management mold in hospice. Case management matches each unique patient-family unit with whatever services they may need, as well as monitoring changes in their needs for such services. Case management also helps patients and families arrange for insurance coverage, plan for emergencies, and if necessary, arrange for services from other agencies. In hospice, case management is often carried out by the primary care nurse or by the social worker.

The care plan for the patient and family is implemented with the patient's and family's needs in mind. It is a process that the dying patient and family actively participate in. Information about the patient's needs is often gathered via interactions with patient and family. This information is utilized by the interdisciplinary team in formulating a care plan. The team also arranges to coordinate and deliver hospice services, monitors the effectiveness of these services, and if necessary, reevaluates the care plan if the patient's physical or emotional status changes. Numerous decisions regarding everyday changes in the dying person's energy level, emotional state, functional (decision-making, self-care) skills, and needs for pain medication must be made by the team, yet must be balanced against the quality of the dying person's life as well as against the demands on the family of work, school, raising children, housecleaning, cooking, and bill paying. Additionally, changes in the family's needs for support and information are likely. For example, the patient and family may initially ask about insurance coverage, the nature of the illness, its progression and treatment, or what the family can do to help care for a dying loved one. They may also want to know about the side effects of pain-relieving medications. As the patient's condition worsens, needs for reassurance and support may surface, and concerns about planning a funeral, writing a will, or living without a loved one may be shared. When their loved one is near death, the family may be less verbal about their needs, and emotional support from a staff member or volunteer may be all that they require. Rather than 'doing something,' hospice personnel may meet this need by simply 'being there.' Indeed, perhaps the greatest lesson that hospice teaches us is that persons can grow spiritually and emotionally by being with a loved one at a very sad and emotionally difficult time of life. Hospice staff and volunteers simply do what they can to make this growth possible.

Legal and Ethical Aspects of Hospice Care

NHCPO does not support either suicide or euthanasia in hospice; indeed, they are infrequent among hospice patients. However, there is the occasional individual for whom 'rational' suicide and/or euthanasia may be perceived as an alternative to living in pain or dying an undignified death. While such statements may mean that the patient's needs are not being met by the hospice, they may also reflect family difficulties, resulting in the dying person's feeling rejected and unloved. Suicidal thoughts may be shared openly or may be unexpressed. Such persons may have a hard time sleeping or eating, refuse medications or visitors, or suddenly change a will.

A wish to commit suicide may also reflect an individual's particular moral values about the quality versus quantity of life. If such concerns do surface, the caregiver should explore whether they are shared by family members, and if they are not, or if the family are unaware of them, the caregiver must make a choice regarding whether to discuss these concerns with the family. In most cases, however, it is preferable that the patient's wishes to discuss suicide or euthanasia with his or her family be respected. Many hospices have adopted a policy against active euthanasia, and feel the same way regarding the acceptability of suicide. What death and dying mean to each person should be explored so that the dying patients can understand and clarify their feelings as to why suicide or euthanasia might be preferable to living, and so that the caregiver can more fully understand the dying person. Not discussing such topics or making them seem unimportant suggests communication difficulties that must be remedied quickly.

The Interdisciplinary Team

Hospice uses an interdisciplinary team to tend to the well-being of dying persons and their families, and

have been demonstrated to be effective in this respect. The term interdisciplinary reflects the variety of skills that professionals, paraprofessionals, and volunteers all contribute in meeting the complex and changing physical, psychosocial, and spiritual needs of the patient and family. In this regard, the team functions to ensure that the dying patient and family function as well as possible given the burden of facing a terminal illness and the realities of daily life: maintaining a household, holding a job, and raising children. The patient's medical needs are given priority, but the patient's and family's needs for intimacy, privacy, and support from relatives, friends, or neighbors must also be met. As the essential component of hospice, the team functions to evaluate and meet the special requirements of each patient-family unit. Within the plan of care that has been developed for the patient and family, the patient care coordinator, who is often the social worker or nurse, brings together each member of the team to assure continuity of care. Not only is this vitally important during the period of time the patient is actually receiving hospice services, but it is also essential to providing effective bereavement support. Such support is especially critical if the staff sense that the family wishes to disengage from them after the death.

Ideally, the team is composed of persons with a mix of professional expertise and background, i.e., nurses, social workers, clergy, physicians, counselors/psychologists, dietitians, physical therapists, pharmacists, and volunteers. For the most part, direct patient hospice care is managed and carried out by nurses in either inpatient or outpatient settings, under the direction of the hospice medical director in concert with the patient's physician. Important roles are also played by clergy, social workers, and especially volunteers. In most cases, teams meet on a weekly or semi-weekly basis to review each case and to discuss problems encountered in carrying out the plan of care, as well as to discuss problems within the patient-family unit itself. As noted previously, the care plan may need to be modified for any number of reasons.

Physicians have direct input into the delivery of care and are primarily responsible for the direction of the medical care that encompasses ongoing, daily, and emergency care. Physicians formulate a medical regimen of pain and symptom control using an array of narcotic and non-narcotic analgesics (pain-relieving drugs). In hospice, however, the physician's role is best defined in the context of the entire team, and likely varies a great deal from hospice to hospice. In rare cases, the role of the physician may be minimal, and the physician may not actively function as the medical director or as a participating member of the team. Relative to the more traditional physician, hospice physicians are more likely to play a less authoritarian role in the delivery of care. They are more patient-family oriented and more strongly emphasize clear, effective, and empathic communication with both patient and family as well as with other hospice staff. Perhaps the physician's most important role, other than in prescribing pain medication, is to serve as a liaison between the hospice and physicians in the community as well as with the patient's personal physician, from whom referrals often originate, and whose attitudes about hospice are critical.

Nurses in hospice often make an initial assessment visit with the family and, because they see the dying person most often, frequently oversee the coordination of direct patient care among the team. In an initial visit, the nurse learns about the history of the illness from the point of view of both the dying person and the family and assesses their needs to help the hospice care team to design a care plan. The nurse is equally attentive to the emotional needs and physical well-being of the patient and family. Relieving pain promptly, as pain often but not always accompanies a terminal illness, as well as keeping the patient as pain-free as possible, is vitally important. Listening and 'normalizing' everyday life are also very important aspects of the role that the hospice nurse plays.

While nurses often provide most of the direct, hands-on skilled care, the social worker may also serve as a case manager. The social worker often conducts the initial psychosocial assessment of the patient-family unit, dealing with such issues as insurance coverage, pensions, wills, and funeral planning. While medical social workers may function similarly to the nurse regarding the family's well-being, they usually assume primary responsibility for tending to the financial and/or legal aspects of terminal care with the family and in helping the family obtain outside assistance with home care, meal planning, or meeting transportation needs. The social worker also often oversees the follow-up bereavement care of the family. In many hospices, a social worker's importance to the welfare of the dying patient and his or her family rivals that of the nurse.

Most hospices could not exist without a viable force of volunteers. The roles of many volunteers are extensions of their professional lives, while those of others are not. Some tend to clerical work, while others work more directly with patients and families. The volunteer can assist the patient and family in a variety of ways on either a continuing or an as-needed basis. Volunteers can, by simply listening and observing, monitor the family's physical and emotional status so that a crisis of caregiving can be

avoided. Volunteers can also help in the provision of care itself: turning patients in bed, providing personal grooming and hygiene assistance, helping with household chores, picking up children from school, or, most importantly, simply being present. Volunteers are an absolutely essential component of the hospice team and should function as such. In most hospices, a volunteer coordinator helps match and assign volunteers to patients and families, and may assist in coordinating and delivering volunteer training. By accompanying the nurse or social worker on an initial visit, the volunteer coordinator can learn about each family's background, interests, and unique needs that influence hospice care, as well as form an impression of each family member as a person.

The role of the clergy is usually more subtle. The clergy often function only on an on-demand basis in hospice, though it is difficult to generalize about the extent of their involvement. Clergy are involved in the team to shed light on the spiritual needs of the patient and, if the patient has no religious affiliation, to minister to the patient and family. Rather than promoting a particular religious philosophy, the chaplain sees to the patient's spiritual well-being by being a link to the religious community. The chaplain often assists in bereavement follow-up as well as in the training of volunteers. The chaplain can also function as counselor, listener, problem-solver, mediator, or friend, as can the hospice administrator, depending on his or her training, over and above the overseeing of personnel and reimbursement issues within the hospice.

Few hospices actually have a psychologist as a paid staff member or a volunteer, though this is changing as the patient-family unit's emotional well-being is being recognized as an even more important influence on the health of the dying person and his or her family. The role of the psychologist or counselor is key in that hospice staff spend more time offering counseling to patients and families than any other activity other than providing direct nursing care. The psychologist or counselor, for the most part, plays a supportive role in consulting with the team regarding the psychosocial functioning of the patient or family. The expertise of counselors or psychologists may be sought regarding family conflicts associated with the stress of terminal care, or long-standing difficulties that are brought to the surface via the dying of a family member. Such conflicts often interfere with either the delivery of care or the patient's or caregiver's well-being. Counselors and psychologists can also help hospice staff cope with the physical, emotional, and even the spiritual demands of their work.

Burnout and Attrition in Hospice

Stress among hospice workers is unique in that uncertainty about whether one's efforts are effective, the duration of time spent with patients, and the importance attached to one's work are all high. Working with dying patients and their families ensures that the staff will have to cope with the deaths of persons to whom they have grown quite close. This, for some persons, takes an enormous emotional toll. While individuals vary in their ability to appraise and respond to stress, the unique commitment hospice staff have to their work and the demanding nature of working with dying persons make them especially prone to stress and burnout. Most hospices now recognize that some form of regular, timely staff support is critical for lessening stress and minimizing staff turnover, though this has not always been so. Staff with little family support who work in home-care-based hospice situations seem to be at greater risk for job stress and burnout. Younger or less mature caregivers also seem to be more prone to dysfunctional stress reactions due to a lack of emotional preparation, as do persons who are more anxious about death or who are trying to cope with the loss of a loved one by immersing themselves in hospice.

Given that burnout predicts the long-term attrition of hospice staff, perhaps most important in minimizing burnout is the selection of hospice staff. Excluding persons who have experienced recent personal losses as well as those with a great deal of anxiety or concern about their own deaths or about being around dying persons is important. Over and above the issue of selection of team members, the team members must have time to be alone with one another to discuss technical and creative issues, as well as to express their feelings and provide emotional support to each other regarding their work. Taking care of oneself is central to lessening hospice team stress and burnout. Moreover, opportunities for continued training and cross-disciplinary sharing outside of hospice are essential for minimizing attrition.

Patient-Family Dynamics in Hospice

While the needs of the dying person are an important focus of hospice, that person is embedded in a matrix of relationships and interactions with other family members. Death may disrupt patterns of communication, role responsibilities, decision making, and assertions of power or dominance within the family. The very identity of the family and of the individuals in that family may be threatened by death. Each family's reaction to the diagnosis of a terminal illness, its management of a loved one's dying, and its

postdeath functioning are all determined by previous family styles and patterns of coping. The impact of death also varies according to whether a parent or a child dies, and with what stage of the family life cycle the family is in.

When hospice care is provided by the family at home, caring for a dying loved one can present an additional burden the family may see as impossible to cope with. The family must believe that home care is both possible and desirable, and they must have access to professional assistance as well as specialized equipment that is often essential to quality terminal care. The family must also have the nursing skills to make physical care possible. Moreover, knowing when death is imminent, what to do at the moment of death, and what to do immediately after death are important skills and knowledge that are important factors in choosing home care. Families report that changes in the dying person's mental status (inability to communicate, confusion, seizures) and changes in his or her ability to care for him- or herself are the most troublesome, as are administering medications and dealing with the loss of bladder or bowel control. Putting personal and career goals on hold, having little 'alone time,' being isolated from others, feeling guilty, and neglecting one's own health are also sources of stress among caregiving families.

Findings suggest that families who have a loved one dying of AIDS face even greater difficulties. Such families express more difficulty in sharing their feelings, report more stress, are less trusting, and have more illness anxiety than families coping with other terminal illnesses. Hospice staff can help in the performance of many needed tasks through education of the family and through the provision of psychological and spiritual support. In most cases, details that seem unmanageable, horrid, or repulsive become less so with a bit of 'hands-on' teaching and knowledge. Because hospice care extends beyond the death of the patient, it is also important to observe how both the patient and family deal with their grief, as this influences the postdeath adjustment of the survivors. Opening up lines of communication may help families face the reality of a loved one's death, particularly if they have had little recent contact with the dying person or if there are long-standing family difficulties.

In evaluating the patient-family unit, the focus is likely to be on the woman's well-being, health, and extent of social support from others, as female spouses tend to experience more family caregiver burden than both men and children. Indeed, psychosocial and emotional support given to the primary caregivers by family is critical. It is also helpful to explore the extent to which family caregivers are depressed, whether they have used social services in the past, and their explanations for the dying person's behavior, as these factors have also been found to predict caregiver burden and may constitute adjustment difficulties in themselves. Such insight may require several visits to achieve, and may necessitate an assessment by more than one hospice staff member. An evaluation of the family's support system is also critical to understanding how they will cope with the illness – do they have extended family, friends, neighbors, or co-workers available? What local support agencies have they contacted (e.g., nursing home, home health-care services)? Do they have savings or private insurance? How much of the cost of care is Medicare likely to cover? Has a will been written? Have funeral arrangements been made? Do they attend or are they members of a church? Would a visit from the hospice clergy be helpful? Through all of this, the family should sense this active support and interest in their welfare and functioning by hospice staff. In cases in which significant family dysfunctional patterns are interfering with care, more formal family therapeutic interventions may be necessary.

Grief and Bereavement in Hospice Care

Bereavement follow-up is a primary characteristic of hospice, and it sets hospice apart from other types of health care for dying persons and their families. In many respects, the job of the formal caregiver has just begun when the patient dies. The family must be sustained and cared for well beyond the death of a loved one, and bereavement care facilitates the expression of grief before death and thereby lessens its severity after death. The same personnel are encouraged to stay in contact with the family to ensure continuity of care. Different staff, however, may be involved to encourage the family to develop new relationships.

The major objectives of hospice bereavement care are for the family to (1) accept the reality of the loss of a loved one, (2) experience the pain of grief, (3) adjust to an environment without the deceased family member, and (4) re-invest energy into other relationships. Research from the National Hospice Study suggests that while hospice bereavement programs can be very beneficial, objective evidence supporting their efficacy is sparse, though the odds of a surviving spouse dying within 18 months of his or her spouse's death are greater if hospice is not used. In addition, better postdeath adjustment has been found among spousal survivors who used hospice.

Bereavement care is often carried out by social workers, nurses, or volunteers. Bereavement care

often focuses on those whose grief is pathological, or on those persons who might have later difficulties in coping. A variety of diverse bereavement services are offered by hospices, including attending the funeral, providing individual or group counseling, sending postcards, making telephone calls, and holding memorial services and other social events. The intensity of involvement by individual hospice staff or by the interdisciplinary team varies, as does the formality of objective bereavement follow-up. Counseling, companionship, and assessment are the prime reasons reported by staff for bereavement visits, and persons in home-based hospices typically receive more bereavement support and counseling than those in hospital-based hospices.

Related to such bereavement support is the fact that persons in home-based hospices are more emotionally distressed and experience more caregiver burden prior to death than those in hospital-based hospices. Because hospice care places a special burden on those family caring for a loved one at home, individuals who have suffered more due to the demands of caregiving may fare more poorly after death. Those survivors who experience greater caregiver burden before the death also experience higher levels of depression and more problems with self-care. After the death, however, their symptoms appear to decline to the levels of non-burdened caregivers. This may reflect a sense of relief as the patient's suffering comes to an end. It may also indicate that during a stressful period of caregiving, family and social support networks would have had sufficient time to prepare to be helpful to bereaved persons. It may also indicate that the consequences of caregiving and bereavement are not additive. Indeed, for many persons, a successful experience with the process and responsibility for caregiving might be expected to result in the development of new coping skills and a sense of mastery and accomplishment.

In home-based hospice settings, especially, caregivers may be at risk for trauma, in addition to caregiver burden. They are required during hands-on caregiving (e.g., for a late-stage cancer patient) to witness a family member in severe distress, which may involve intense pain, choking, vomiting, inability to eat, dehydration, confusion, falling, and so on. The intensity of these experiences with a loved one makes it more likely that the caregiver will experience symptom levels associated with major depression and complicated grief (which reflects a trauma component).

Research evidence, however, is mixed regarding the efficacy of counseling interventions for bereavement (informal or professional). The majority of bereavements tend to be relatively uncomplicated with respect to impact on survivors, and in this context, most individuals are able to adapt and to come to terms with their loss without formal intervention. For these persons, emotional and physical distress abates with time, and they are able to access natural support resources from among family and friends or through their religious affiliations. While social support received prior to the death appears not to buffer against consequences of the loss, support from others received after the death may be associated with lower distress.

While formal interventions have not generally been found to be effective in a preventive sense for uncomplicated bereavements, they do appear useful for individuals at increased risk or for those who may be suffering symptoms of especially high intensity or duration. A related concern is that in providing formal outreach services to bereaved persons, hospice personnel may inadvertently discourage family and informal support efforts. Consequently, it is important to understand bereaved family members as individuals, who may or may not want or need the bereavement support that hospice staff may provide. Moreover, theoretical developments in our understanding of grief may render stage-based approaches to bereavement adjustment less meaningful, in contrast to an approach that stresses the individualized and often unpredictable nature of grief. This revised notion of grief suggests that hospice staff may need to be ever vigilant of problems in everyday functioning or emotional adjustment to loss that bereaved persons may experience, irrespective of time or their apparent risk in experiencing such difficulties.

Emerging Issues in Hospice Care

Hospice is in a sense a movement. Its driving influences are spiritual, social, and political, as well as medical in nature. It has grown quickly in many countries, and in the United States, service providers represent several types of entities, within an evolving regulatory environment. In spite of its growth, and the perception that hospice represents a more commonly seen alternative to institutional death, there have been reports of problems with some hospice agencies, and an active consumer advocacy movement has emerged in response to such concerns. It is our sense that a majority of providers, and the major national hospice associations are responsible, compassionate, and competent. That said, it is prudent for patients and their families to explore the consumer advocacy issues raised by their predecessors.

Driven by the increasing numbers of persons who are suffering from AIDS or Alzheimer's disease, hospice staff are likely to become more involved with

medical professionals and specialists (e.g., geriatric psychiatrists, social workers) who may come to function informally as a member of the interdisciplinary team even before the patient enters hospice care. Such involvement is also likely to alter the training that many types of health professionals receive in light of hospice as a viable alternative to institutional care. Likewise, given the attention to issues surrounding end-of-life care (e.g., the use of advanced directives), discussion of numerous moral and ethical dilemmas is likely to be more commonplace among hospice staff. Hospice will also likely need to become more common in rural areas and more available to those dying in prisons, and the unique nature of providing culturally sensitive care to persons of differing races and ethnicities will likely need to be stressed to a greater extent in the future. In addition, greater attention to enrolling patients earlier may be a key element in maintaining quality of life for them, as well as alleviating the depression that often accompanies a terminal illness. Whether hospices are willing or able to admit patients who will not forego hospitalization and who are receiving parenteral nutrition, tube feedings, radiation, or chemotherapy is also emerging as a controversial issue in hospice admission policy. Cost-effectiveness and other forms of accountability (e.g., improved psychosocial and physical functioning in bereavement, documenting increases in quality of life or pain reduction at the end of life, greater attention to the retention and welfare of hospice staff) are also likely to emerge as salient issues confronting many hospices in the future as alternatives to hospice care emerge.

Housing

J Pynoos and C M Nishita, University of Southern California, Los Angeles, CA, USA
H Kendig, University of Sydney, Lidcombe, NSW, Australia

Glossary

Aging in Place – The desire and tendency of older persons to stay in their current dwelling units for as long as possible.

Assisted Living – A residential setting, usually licensed, that provides private apartments (often efficiencies), a full range of supportive services (e.g., meals, personal care), social activities, and continuous protective oversight (24-hour on-site supervision).

Congregate Housing – Semi-independent multi-unit living arrangement that generally provides group meals to residents.

Continuum of Housing – A range of housing options that are differentiated by their complement of services, physically supportive features, and the age or competency level to which they are targeted.

Elder-Friendly Communities – Supportive and accessible communities with design features such as safe sidewalks and legible signs to maintain older adults' independence and access to transportation and services.

Environmental Press – The demands that environmental settings make on residents' physical and mental competencies.

Home Modifications – Adaptations to home environments intended to make it easier and safer for functionally impaired individuals to carry out activities such as bathing, cooking, walking, navigating steps, and opening doors.

Household – A group of individuals or an individual who lives in a dwelling unit.

Naturally Occurring Retirement Communities (NORCs) – Housing complexes or neighborhoods that were not planned for the elderly but that, due to aging in place and in-movement of new elderly residents, contain high concentrations of older persons.

Supportive Housing – Housing complexes in which the owner or manager coordinates a range of supportive services, many of which are provided by third parties, for residents who typically live in their own apartment units. Most do not provide continuous protective oversight and are unlicensed.

Universal Design – A concept promoting homes and communities that are accessible, adaptable, and usable to the greatest extent possible by persons of all ages and abilities.

Visitability – A small set of key accessibility features that enable persons with disabilities to access the main level of single-family homes.

Introduction

The vast majority of older persons live independently in single-family homes or apartments; the importance of their housing extends far beyond the shelter provided by bricks and mortar. The home is the primary base for daily living, and it can represent a lifetime of memories and provide a sense of security for the future. For older homeowners, it is usually their most valuable asset. For older renters on a limited and fixed income, housing is often their largest monthly expenditure. The features of the neighborhood in which housing is located are crucial to community life and accessibility of shopping, social services, medical care, leisure activities, and recreation.

Especially over recent decades, housing for older persons has been viewed as involving much more than conventional shelter. A larger number of people are reaching advanced ages during which they are likely to have chronic diseases, become frail, and experience losses of family and friends. For these vulnerable individuals, housing and related services can be critical to quality of life. They often are the key factor in enabling a frail older person to stay in a residential setting rather than move to a nursing home.

This overview of housing for older people discusses key concepts, perspectives, living arrangements, and the relationship among household tenure, income, and wealth. It also discusses housing types and problems, followed by an analysis of housing policies and programs that have been developed to improve the housing situation of older persons. Although the major focus of this article is the United States, it includes references to experiences in other industrialized countries. It covers the features of housing for older people living in general housing, supportive housing, and links between housing and services. Unless otherwise mentioned, older people refers to those aged 65 years or over.

Perspectives

Housing and gerontology are multidisciplinary fields that draw on a variety of conceptual perspectives. This section reviews three of the main paradigms that have been applied to developing the present knowledge base about housing the elderly: environmental psychology, the housing market approach, and the political analysis of policies and programs.

A major influence on the field of elderly housing has been environmental psychology. Environmental press, the central concept, refers to the match between individuals' functional capacities and the demands of their environments. A good environmental fit will stimulate and support an individual and enhance his or her functioning and well-being. An overly supportive environment can atrophy an individual's capacities, whereas an overly stressful environment risks a breakdown of capacities and distress. As individuals grow older and their needs and capabilities change, it is important to adapt existing environments or ensure appropriate moves to new environments.

The environmental psychology approach is often termed a microperspective because it emphasizes how individuals relate to their residential environments. Starting in the 1960s, the public and private sectors sponsored research that has applied the microperspective to a wide range of important topics. The emphasis has been on how vulnerable older people adapt to specially built accommodations, such as homes for the elderly, public housing, and nursing homes. This research has shown that sensitive and careful design of building layouts, pedestrian walkways, and other features can assist older persons who would have difficulty in conventional housing settings. Until recently, the microtradition has devoted little attention to housing for the majority of older people who are capable and live in single-family houses and neighborhoods.

Since the 1980s, increasing attention has been directed to older persons in the broader housing market. Sociological analyses have focused on the household characteristics of the elderly, whereas economics analyses have focused on their housing characteristics. This macro work has been greatly stimulated by improved census and survey data on the housing types, conditions, and costs for people of all ages. The information reflects increasing policy attention to identifying the needs of special groups in the housing market and maintaining the quality and best use of housing resources. The available data provide a picture of the housing of various age groups and the housing of older people by their race, martial status, income, and location.

An understanding is emerging of how the processes of individual and population aging relate to the changing composition and use of the housing stock. The concept of the life span has been applied to studying housing careers, that is, the succession of dwellings occupied over a lifetime and how these careers interweave with employment and family careers. Housing demography has provided analytical tools that show how the supply and use of housing changes in periods of history, on aging of individuals and cohorts, and with the succession of new cohorts, people, and dwellings. Change in people's use of housing occurs as a result of complex markets for housing, land, and labor as well as public regulations and subsidies.

A final perspective concerns the politics of public intervention in housing markets and the impacts of housing programs. The political economy perspective emphasizes how government policies toward housing are influenced by interest groups, ideological struggles, and economic considerations. Many actions of government – such as subsidies and tax concessions for home ownership – are not age specific but can have significant impacts when people reach old age. Age-specific policies have risen out of concern for the special needs of older persons, a perception of older persons as the deserving poor, and the growth of older people and the industries that serve them as political constituencies. The political agendas of governments also influence the funding of housing evaluations and studies, which in turn shape the availability of information and assessments of program and policy effectiveness. In addition, as housing encompasses more than shelter, it inevitably has to cross agency boundaries and must confront sometimes conflicting goals, guidelines, and methods of operation.

Before turning to the present knowledge base, it needs to be acknowledged that research on aging and housing requires more development. The complex processes of individual and historical change in housing patterns stand in sharp contrast with available evidence based mainly on cross-sectional surveys and aggregated analyses of trends. It is difficult to compare studies because they can apply different definitions of even basic terms such as households, dwellings, and housing types. Findings differ significantly depending on units of analysis, for example, between individuals and households. Even more problematic are cross-cultural comparisons. Conceptual advances will depend heavily on designing better investigations that take more account of the complexity of the field.

Living Arrangements

A household, the basic unit of housing demand, is made up of an individual who lives alone or a group of people who live together. The composition of households has a major bearing on individuals' cost of living, responsibility for household duties, and proximity of social support. Relatively few older people move immediately after retirement, widowhood, or the onset of disability. The vast majority of them experience personal or household changes while remaining in the established home. Although some older people choose to move to more appropriate housing, most prefer to make housing adjustments through aging in place.

In the United States in the late 1990s, 90% of older people lived in conventional housing, consisting primarily of single-family houses and apartments. Approximately 5% of older persons at any one time live in nursing homes, and another 5% live in other forms of housing that have congregate facilities or services, such as meals. The proportion of older individuals in special housing rises with advancing age, yet represents only slightly more than 25% even for those aged 85 years and older. Those who are most likely to live in government-assisted housing are poor, frail, and not presently married. Overall, the proportion of older persons in non-private housing (not in a private household) in the United States has remained relatively stable over the last few decades. These figures are broadly comparable to those of Australia, the United Kingdom, and other Western countries at similar levels of economic development.

Over the post-World War II era, older people have become much more likely to live alone or live only with their spouse. The explanations are rising real incomes, programs of Social Security, relief of housing shortages, and continuing preference for independent living. At present, approximately half of older Americans live only with their spouse, a third live alone, and the remainder live with others (mainly relatives). Living with someone other than a spouse is much more common among older people who are Black, Hispanic, poor, or disabled. Many of the most vulnerable older people, in terms of income and functional capacities, are overwhelmingly widows who only over recent decades have lived in separate households.

As a result of their generally small households, older people have a disproportionately large presence in the housing stock. Approximately 40% of all American dwellings are headed by a person aged 55 years or older. The head of household is the person who holds the title for an owner-occupied home or who signs the lease for a rented dwelling. The household head is the most common unit for housing analyses relating the characteristic of a dwelling to the personal characteristics of the occupants.

A small proportion of the elderly population can be considered homeless. Homeless people by definition do not live in households, and they are virtually invisible in available databases and the housing literature. Other older persons, unable to afford their own homes, live with relatives, unrelated individuals, or in single rooms. The few studies available on these groups highlight their intense difficulties, which can result from a lifelong combination of personal problems and social and economic exclusion.

Housing Tenure, Income, and Wealth

Housing tenure is one of the most significant economic divides among people in old age. If the entry

costs to home ownership can be met earlier in adult life, savings from the years of peak income are likely to be stored in the home, and this wealth increases through appreciation of house prices. In old age, outright home ownership can provide security of occupancy, relatively low cash outlays for shelter, the means to buy into other accommodations, and even a source of cash through programs such as reverse mortgages. Government-subsidized tenants have fewer financial advantages, usually in the form of low rent. Private tenants (in the absence of government protection) face rising market rents and have little security of occupancy.

Older Americans have largely been successful in achieving home ownership. More than eight in ten adults aged 45 and older own their homes. While the rate of homeownership decreases with advanced age, the majority (78%) of older adults over age 75 still own their own home. Only 5% of older Americans receive direct housing assistance from the federal government. Those who rent in old age overwhelmingly live in non-subsidized housing, and they generally have faced lifelong economic disadvantages that restricted capacities to ever buy homes. Permanent tenants include disproportionately large numbers of Blacks, Hispanics, residents of large cities, and people who have never married or had divorced (especially women). The vast majority of older Americans with middle or higher incomes are homeowners, whereas a small minority of those with low incomes are owners.

People who are now in old age have had relatively high lifelong access to home ownership. Those born since the 1920s, who reached old age since the 1980s, were in their prime home-buying years during the economic and housing boom of the 1950s and 1960s. They were assisted by subsidized and regulated housing finance and income tax concessions on interest payments and capital gains. Housing trajectories set during the affluent postwar era are leading to continuing high rates of home ownership for people entering old age during the early years of the twenty-first century.

People who enter old age as homeowners generally remain so for the remainder of their lives. The relatively small numbers who move out of home ownership for the most part are very old widows who are likely to have experienced economic or health-related functional difficulties. This pattern of stability suggests that age differences found in housing markets at any time reflect strong cohort effects as well as aging effects. It also suggests that housing adjustments in old age (when they take place at all) usually occur in the last several years of life.

Owning a home outright is very important in enabling older people to maintain an adequate standard of living on a retirement income. Older renters, however, generally live near poverty levels and are three times more likely to have severe housing costs. Fifty-seven percent of all renters have moderately to severely high housing costs. In comparison, approximately 25% of all older homeowners spend more than a quarter of their income on housing. Excessive housing costs, according to the definition set by the federal government (over 30% of income), are highly concentrated among older persons with low incomes, especially older women and minorities. Such costs make it difficult for older persons to afford other necessities of life such as health care and transportation.

With rising real costs of buying over recent decades, lifelong access to home ownership is likely to be reduced for those reaching old age during the next century. There is likely to be a historic watershed in which fewer older people will have outright home ownership to cushion the effects of low retirement incomes. To sharpen the social divides further, the present cohort of older owners will be bequeathing their housing assets to adult children who also are likely to be owners and who will themselves be on the verge of old age.

The housing tenure of older people and its distributional consequences varies considerably among countries. Although Australia has ownership rates comparable to those in the United States, more people live in public housing in old age and more private tenants have rent assistance. In Britain, only half of older people are homeowners, with 40% in public housing and most of the remainder in protected private tenancies. The distributional consequences of housing have followed very different patterns in European and Scandinavian countries that encourage non-profit housing cooperatives and have fewer policies subsidizing entry to home ownership.

Housing Types and Problems

The vast majority of people enter old age living in homes selected for their appropriateness in midlife when they were in the paid workforce and typically had larger households. For the cohort of people aged 60–69 years in 1960, there were extremely low increases of apartment living over the following 20 years (virtually none among owners and from 11 to 16% among tenants). Thus, with the boom in building detached dwellings in the 1950s and 1960s, four out of every five older people now live in some form of single-family housing. They are no more

likely than younger people to live in apartments or medium-density housing.

The residential stability of older persons, combined with declining household size, has raised concerns about the underutilization of housing resources. In fact, some analysts contend that over 5 million older American households are overhoused because they live in dwelling units in which bedrooms outnumber household members by more than one. However, studies suggest that very few older people consider their homes too large for them. They report making extensive use of spare rooms for family visits, leisure, and other lifestyle activities centered on the home. Moreover, if older people own their homes outright, there is relatively little financial pressure to change housing. The available evidence suggests that older people are unlikely to be induced into smaller dwellings unless financial and other barriers are lessened and attractive alternatives are available in nearby areas.

The condition of housing occupied by older persons has improved substantially over the last several decades. Fewer than 1% of older people live in overcrowded housing, defined as households with more than one person per room. Almost all older persons now live in housing with hot and cold running water, private bathing and toilet facilities, and a sound physical structure. However, nearly 1.5 million older American households live in substandard housing that is in severe need of physical repairs related to inadequately functioning housing systems such as plumbing and heating. As with high housing cost, these problems are highly concentrated among older persons with low incomes, especially older women and minorities. Overall, the extent of housing problems by these measures is roughly comparable among younger and older Americans.

These summary statistics on housing problems require careful consideration. On the one hand, many older people, especially those with functional limitations, have difficulties in the use of their dwelling units even when they are in good condition. The consequences of housing problems can fall particularly severely on a frail older person who is right on the edge of maintaining functional competency. The apparently small percentage (i.e., 8%) living in substandard dwellings still amounts to a very large number of people (more than 1 million).

On the other hand, the majority of older persons are satisfied with their housing, even when it is technically substandard by the preceding measures. They are unlikely to rate housing as a major area of hardship – certainly less so than younger people. These paradoxes may arise because perceptions are highly specific to individual interpretation. In the case of disadvantaged older persons, apparent satisfaction can reflect low expectations that anything can be done to improve their situation.

A long-standing assumption in the field of housing has been that as persons become more frail, they will have to move from one housing setting to another. While many frail older people eventually move to more supportive accommodations, most wish to continue at home for some time. Of the many needs of frail older people at home, the most common are assistance with gardening, home repairs, home modifications (e.g., addition of grab bars, ramps), and transportation.

The idea of a continuum in the supportiveness of housing is important because it recognizes that housing options can be differentiated by the amount and type of services offered; the supportiveness of the physical setting in terms of accessibility, features, and design; and the age-competency level to which the housing setting is targeted. **Figure 1** indicates how different housing options, including single-family housing, apartments, board and care homes, and skilled nursing homes, generally meet the needs of older persons who are categorized as independent, semidependent, and dependent, respectively. Although semidependent and even dependent older persons can be found throughout the continuum, independent older persons are very unlikely to be found in housing types such as assisted living specially designed and equipped for frail older persons. Nevertheless, frail older persons can be found across the housing spectrum, indicating considerable elasticity of different housing types to support them.

Some housing types serve specific subgroups of the population. For example, several types of purpose-built housing for semi-independent older persons have evolved over the last decade. These options are variously referred to in the United States by such labels as board and care, residential care facilities, and assisted living. In Australia, similar types of housing are called hostels; the Scandinavian versions are generally known as service houses. These types of complexes generally serve persons who need more assistance than other supportive housing options can offer.

Board and care homes – providing meals, supervision, and limited assistance in daily activities – number over 30 000 in the United States, more than double the number of nursing homes. However, most of them have only 5 to 20 units and therefore house only about one-fourth the number of residents (about 400 000 persons) in nursing homes; half of their residents are under 62 years of age. Although most board and care homes are privately run, many residents receive state government subsides as well as

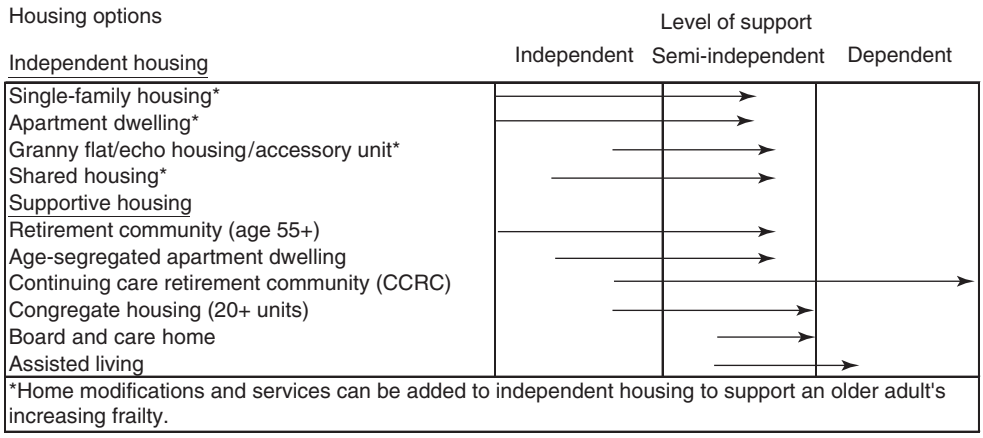

Figure 1 The continuum of housing. Independent: living arrangements designed for individuals and couples capable of handling their own housekeeping, cooking, and personal care needs. Semi-independent: living arrangements designed for those with some chronic limitations. Residents are self-sufficient and capable of self-care, but may rely on the facility for meals, housekeeping, and transportation. Dependent: living arrangements that provide 24-hour supervision, intermittent services, and nursing care for severely impaired individuals. Reproduced from Evashwick, C. J. (2005). *The continuum of long-term care*, 3rd edn. Delmar Learning, a division of Thomson Learning: www.thomsonrights.com.

Supplemental Security Income (SSI). Most board and care homes are very modest in nature and require that residents share rooms. State governments regulate these homes, but many of the smaller ones are unlicensed and enforcement can be lax.

Assisted living, a rapidly growing form of housing in the United States, generally provides independent apartment units (usually including private bathrooms and sometimes kitchens), professional management, and a full range of personal care services, including dispensing medications. The attractiveness of assisted living for older persons and their families is attributable to its homelike design, the desire to maximize privacy and autonomy within the dwelling unit, and the availability of more personal care services such as dressing and bathing assistance. Very frail individuals, including those who are incontinent and those with Alzheimer's disease, view assisted living as an alternative to the hospital-like environment of the typical nursing home. Currently, assisted living in the United States is primarily available to middle- and upper-income older persons who can afford it.

Location

The location of housing can have a major impact on the lives of older persons. It is particularly important for older people to have safe neighborhoods with a range of public and private facilities and good public transportation. Older persons can be especially vulnerable to urban change when they are frail, strongly attached to their homes, and possibly locked in by low home prices or inability to afford higher rents. Older persons report less satisfaction with their neighborhoods than with their housing. In rural locations, older people can be isolated from essential services and social contact, particularly if they cannot drive a car.

Markets and government policies have substantially restructured US cities over the last generation. As new cohorts of individuals in the middle classes moved outward from the central cities, established homeowners have grown old in neighborhoods undergoing major changes in environmental amenities and racial composition. Private tenants have faced rising rents, public or private redevelopment, and conversion of apartments to condominiums. Owners in deteriorating areas may be trapped by falling house prices. In revitalizing areas, owners may be presented with opportunities to cash in on rising property values and move elsewhere.

A recently recognized phenomenon is the concentration of older persons in areas that attracted them but were not intentionally planned for them. Twenty-seven percent of older people live in a building or neighborhood where more than 50% of the residents are over age 60. In many of these buildings and neighborhoods, older persons have aged in place, having moved into them when they were in their 40s, 50s, and 60s. In some situations, the mutual support and security of living with one's age peers have drawn older persons to these settings from other places. In other places, the out-movement of younger cohorts in search of employment has resulted in an increasing percentage of older persons. Referred to as naturally occurring retirement community (NORCs), these communities do not generally offer the social

and health services that older persons need as they age. NORCs provide the opportunity to take advantage of potential economies of scale by clustering services, developing new facilities (e.g., senior centers), and linking housing with services.

Over the last decades, increasing numbers of people have been aging in place in single-family homes built in post-war suburban areas. These areas were designed for travel by car and thus have relatively poor public transport and access to private and public facilities. Compared to older inner city areas, the suburbs can present major spatial barriers to people who do not drive cars and may have difficulty walking. They also have a limited range of housing types, sizes, and costs for those who wish to move to more appropriate housing in a nearby area. These potential difficulties could be minimized by land use policies that ensure a mix of land uses and housing types in new as well as established areas of cities.

Housing Policies and Programs

Since World War II, almost all Western industrialized countries, including the United States, have taken some responsibility to ensure that their citizens have access to decent and affordable housing. Because they are mixed economies and the private sector plays an important role, many of the policies have attempted to provide a stable economic climate so that the private housing industry, a major sector of the economy, can produce an adequate quantity of housing and employment in the building industries. In the United States, national housing policy has consisted of federal mortgage guarantee programs, the establishment of a secondary mortgage market, and tax incentives for home ownership. These policies have had strong political support, especially among builders and realtors, who are powerful interest groups at all levels of government. The elderly, with the highest rates of home ownership, have been major beneficiaries of these overall housing policies.

Governments have also sought to provide housing specifically for vulnerable groups that are not well served by the private sector. In order to simulate production of housing for the poor, governments have either built complexes themselves or provided subsidies to profit and/or non-profit developers for the construction of rental housing. Some countries such as the United States and Britain have developed a substantial stock of housing for low- and moderate-income older persons, using supply-type programs. The early supply-oriented programs for the elderly have initially emphasized the shelter and low-cost aspects of housing. In response to the growing number of very frail older persons, more recent approaches have stressed the inclusion of services.

Demand-oriented strategies include programs that provide housing allowances or vouchers so consumers can pay more for better housing. Demand-side approaches tend to be more acceptable to conservative political parties, which resist direct government efforts to increase the supply of public or welfare housing. The following discussion analyzes four housing programs that illustrate supply-and-demand strategies governments have used to improve the housing situation of the elderly.

Age-Specific Housing for Independent Older Persons

Governments in many countries provided subsidized, age-specific housing for independent older persons only after the most severe post-war housing shortages had been relieved in the 1950s by housing supply programs focused on meeting the needs of young families. As home ownership became possible for families with even modest incomes, subsidy programs in the United States were viewed as permanent housing for low-income families, many of whom were minorities. In 1956, the eligibility requirements were changed to allow single older persons to live in public housing. Increasing numbers of older people began to be served by these programs for three basic reasons: (1) elderly tenants had lower incomes, fewer assets, and poorer housing conditions than younger renters; (2) long-term residents of subsidized housing programs began to age in place; and (3) the elderly were viewed as the deserving poor and were considered less problematic as tenants than younger adults with children.

As older single persons began to move into projects that had previously housed only families, concerns were raised about their safety and potential alienation. At the same time, experts in the emerging field of gerontology began to advocate for age-specific housing for the elderly that would have specific design features (e.g., emergency call buttons, few or no stairs), common space for socialization, and services such as meals. Psychologists and social scientists were concerned about older persons' ability to adapt to such a radical new lifestyle and the potential isolation of large groups of older persons living in age-segregated high-rise buildings. These fears were put to rest, however, by studies finding that residents of age-specific housing, compared with tenants in the community, reported greater morale and life satisfaction, increased friendship formations, increased social interaction, and better perception of health status. By the early 1990s, 37% of public housing

units were occupied by the elderly, with more than 300 000 older persons residing in projects exclusively for the elderly and disabled and a comparable number of older persons living in family projects.

A step up in quality from public housing in the United States is housing for the elderly provided under Section 202 of the National Housing Act of 1959. As originally enacted, Section 202 provided direct, low-interest loans to non-profit sponsors (mostly religious organizations) to provide housing for moderate-income elderly tenants ineligible for public housing. Although these projects generally had more amenities than public housing (e.g., some provide congregate meals), they were also intended for independent elderly. Early advocates of the program did not want the housing to resemble homes for the aged. Consequently, the program did not fund services, and it permitted managers to bar applicants who could not live independently. This approach was consistent with the philosophy of the federal housing agency, which considered its responsibility bricks and mortar and not services. More than 250 000 units of Section 202 housing had been built by 1995.

Other advanced countries have also built government-subsidized housing specifically for older people. For example, in 1962, Peter Townsend, a leading academic, succeeded in urging the British government to develop sheltered housing as a non-institutional form of care. The term sheltered refers to purpose-built apartments with services ranging from an on-site manager to communal dining and homemaker services. Very sheltered housing, a somewhat later development, is similar to congregate housing models in the United States and provides extra wardens or domiciliary assistance to residents. Great Britain, Denmark, and Sweden have constructed purpose-built dwellings in small clusters with supportive design features and on-site managers. However, most European countries have provided for relatively independent older people mainly though public housing for all age groups.

Various forms of age-specific congregate housing have been sought after by older persons. They have also been popular with government officials, who acknowledge that, in contrast to many family projects, housing for the elderly has had few problems and has been well managed. Nevertheless, during the late 1980s, in the United States and other countries, these programs began to experience reduced government funding for new complexes. They have been viewed as relatively costly compared to other housing subsidy approaches, such as vouchers, and have lost favor with conservative governments. There has also been a growing perception that other groups have more pressing needs and that housing for independent older persons has failed to address the problems of very frail older persons. By the mid-1990s, governments in Europe, North America, and Australia were reducing housing programs for independent older persons or adapting them to serve frail older persons.

Supportive Housing and Assisted Living

By the early 1990s, many residents of housing for the elderly had aged in place and were in their late 70s or 80s with accompanying greater needs for physically supportive features and services. For the most part, these housing complexes and their managers were ill equipped to meet changing resident needs. At the same time, government concern with housing the elderly was shifting from independent housing to service-enriched housing. This emerging trend had been driven by the search for cost-effective alternatives to expensive nursing homes and the desire of frail older persons to live in residential rather than institutional settings. Consequently, in the last two decades, programs have been created to develop supportive housing that is physically accessible, contains special features, and has a range of services. Two basic strategies have been used to develop housing for very frail older persons: adapting existing housing originally intended for independent elderly and developing new forms of very supportive housing.

One approach to developing supportive housing in the United States has been to adapt government-assisted housing for independent elderly by better equipping it to serve frail older persons. Although concern about cost-effectiveness has limited the growth of service-enriched programs, such projects have nonetheless demonstrated that existing multi-unit housing complexes can be adapted to improve the quality of life of frail older persons and assist them in aging in place. With these goals in mind, Congress in the early 1990s allocated funds for service coordinators in a wide variety of government-assisted housing complexes for the elderly. Similarly, several years later Australia adopted an aging in place strategy that has emphasized keeping older people as long as possible in senior housing complexes such as hostels.

The difficulty of adapting existing housing and meeting the needs of very frail older persons for ongoing supervision has led to a very rapid growth in assisted living. Although it can serve very impaired older persons including those with Alzheimer's disease, assisted living has not been generally affordable for low-income persons. Wider availability requires melding income streams from diverse housing,

health, and income programs to pay for costs related to shelter and services. Over recent years, some states have utilized Medicaid to reimburse service costs through coverage under the Medicaid state plan or under a Home and Community-Based Services (HCBS) waiver. These waivers provide flexibility to states to develop innovative residential alternatives for Medicaid-eligible individuals who would otherwise need institutional care. As of 2000, 38 states had used Medicaid state plans or waivers to cover services in either assisted living or board and care facilities.

The US Department of Housing and Urban Development (HUD) has appropriated funds for the conversion and retrofitting of entire buildings or floors of Section 202 and other federally assisted housing projects for the elderly into assisted living facilities under the Assisted Living Conversion Program. The experience of this strategy indicates that it increases residents' access to services and provides a residential environment. In some cases, however, buildings were difficult and expensive to retrofit, especially to accommodate persons with Alzheimer's disease. Maintaining a residential atmosphere requires appropriate state regulations that stress privacy and autonomy as well as recognizing that there may be trade-offs in terms of safety. The enactment of such regulations depends on evaluations concerning quality of life considerations and cost savings relative to nursing home expenditures. The latter benefit has not yet been proven, and some groups have argued that because assisted living serves a population with impairments similar to those of residents of nursing homes, it should also be strictly regulated. The danger is that these regulations could shift assisted living away from a social model to a medicalized approach.

In Australia and the United Kingdom, there is increasing interest in unbundling the accommodation and care components of residential care. This means that older people could have high levels of care in a wide variety of housing circumstances – including their own homes and private retirement homes – rather than have to move to nursing homes. This widens the accommodation choices for individuals and shifts capital costs out of government aged care budgets. However, with shortfalls in provision of public housing, there is increasing concern over the affordability of housing and the availability of community-based services.

Home Equity Conversion Mortgages

With the erosion of the government safety net, increasing attention has been directed to ways in which older homeowners can access the equity in their homes without having to sell and move. Reverse mortgages allow older persons to draw out money based on their home equity and repay it after they move or die. The complications and risks of these loans, for both lenders and homeowners, have been reduced by federal insurance for home equity conversion mortgages (HECMs), which provide increased financial protection and security of occupancy for older persons. Nevertheless, the uptake for reverse mortgages has been relatively small, in part due to the high closing costs, the reluctance of older people to tap into a resource that they have saved for many years, and the security that home ownership provides. Over recent years there have been small increases in the number of HECMs due to such factors as reduced retirement income from bonds and dividends. Proposals have been floated to encourage or even require older people to draw down on their equity to pay for long-term care services or insurance, home repairs, and home modifications, thereby reducing government outlays. Such proposals, however, are unlikely to win support from older people themselves. Nevertheless, HECMs have been used for a variety of purposes by older persons such as paying off debts to avoid foreclosure, home repairs and modification, medical expenses, and long-term care. Continued expansion of this option for older persons will depend upon ongoing participation by the federal government in providing insurance, lower closing costs, and a more active involvement of the secondary mortgage market.

Home Modifications and Repairs

Since the early 1980s, governments have increasingly recognized the preference of older persons to remain in their own homes as long as possible. Policymakers have also begun to examine ways to make more efficient use of existing housing resources with emphasis on single-family homes. Based on the realization that many older persons lived in homes with an extra vacant bedroom, a movement developed to share homes. At the same time, there was increasing evidence that many frail older persons had homes that needed repair and modifications to help prevent accidents, make caregiving easier, and substitute for costly personal care services. Several studies suggested that home modifications were being held back by inadequate funding, enormous gaps in services, fragmented service delivery, and a low level of awareness concerning the efficacy of home modifications among consumers and professionals.

In the United States, home modification programs are highly reliant on programs such as Community

Development Block Grants and the Older Americans Act. Neither of these programs earmarks funds for modifications nor necessarily sets it as a high priority. In order to enhance the ability to age in place, a number of countries – such as Britain, the Netherlands, Canada, and Australia – have launched home repair and modifications programs that focus on upgrading individual units, as well as adding features such as ramps, grab bars, and roll-in showers. Inherent in the design of such programs are policy dilemmas concerning the extent to which payment for such changes should rely on loans, grants, or out-of-pocket expenses. A more fundamental approach taken in Australia and Europe is to require that all new dwellings – not just those for older people – meet age-friendly standards of universal design.

Policy and Research Directions

There are mixed prospects for the adequacy of housing for older people in the future. On the one hand, Baby Boomers entering old age over the next decade will have relatively high rates of home ownership that will cushion the financial adjustments to living on a fixed income. On the other hand, many older people will continue as lifelong tenants with few private options for accommodation or services. Major challenges for meeting housing and related needs include the increasing number of people reaching very advanced ages, accessibility difficulties for those growing older in post-war suburbs, and continuing severe restrictions on public expenditures. Although pronounced in the United States, these social and economic trends are also found in other industrialized nations.

The housing of older people in the future will be deeply affected by a wide range of government policies extending to taxation, income support, and regulation of property and land use. While housing situations and policies vary greatly among countries, several broad international directions are apparent. One approach is to provide integrated community care, which enables frail older people to remain in their own homes and limits the use of costly residential care. In many ways, the home itself becomes the care center. A second approach is to encourage older people who have the money to pay for their own housing and related services, whether purchased from the public or the private sector.

Directions in supportive housing for older persons have emphasized consumer-controlled services and new models of accommodation. Many of these initiatives require increased government flexibility, private–public partnerships, and innovative approaches. Their success depends on government involvement through developing and funding housing and services, providing information and technical assistance, and establishing a regulatory framework that protects the right of frail older persons and other consumers. The new directions aim to break down barriers between programs and to include housing as an integral part of the long-term care system. Moreover, understanding the needs of the older person requires a wider examination of the environmental settings in which older adults live. The creation of elder-friendly communities, which consider the location of stores, churches, or parks, the adequacy of sidewalks, and the legibility of signage as important determinants to maintaining independence, has received increasing attention in the United States. Future planning and policy initiatives must recognize the environmental context as key to helping older adults remain mobile and connected. In Australia and Europe, there is increasing recognition of the importance of land use planning in ensuring that neighborhoods provide people of all ages with a range of housing types and land uses near their existing homes.

A number of initiatives have promise to attract public support and yield major benefits for frail older people:

1. *Develop a consumer-controlled voucher system* that would enable older people to choose combinations of housing and services that fit their individual needs and preferences. By unbundling housing and services, portable services would provide a broader set of choices of where to live.
2. *Create innovative models of housing,* such as small-scale places for persons with Alzheimer's disease that are integrated into the community, and provide elderly with access to community facilities and intergenerational contact. New models of senior housing also need to address changing living arrangements, such as the growing trend of grandparents raising grandchildren. Policy changes are required because the majority of government-assisted housing for the elderly has been developed for their exclusive occupancy and does not allow children.
3. *Develop new forms of supportive housing* that provide very frail older people with increased privacy, autonomy, and choice. Assisted living and other home- and community-based long-term care options should be explored as potential substitutes for nursing home care. In addition, policy directions should emphasize the diversion of persons from nursing homes and the transition of nursing home residents to the community.

4. *Incorporate new technology* that can make it easier for frail older persons to summon assistance, access information, and carry out tasks independently. Home modifications, assistive technology, and smart home technology may be cost effective in their ability to delay institutionalization and prevent injuries.
5. *Encourage visitability and universal design*, which promote accessibility in newly constructed housing. Visitability refers to basic accessibility on the first floor of new housing through such features as a zero-step entrance, doors and corridors wide enough to accommodate a wheelchair or walker, an accessible bathroom, and an area in which a person can sleep. Universal design is a broader concept that promotes the use of housing and communities by all persons regardless of size, age, or disability. In addition to visitability features, it includes such features as accessibility from the front and back of the house, countertops of varying heights, controllable light switches at appropriate heights, and access to all parts of the house.

These directions involve many aspects of housing, including financing, housing and building codes, regulations, legal rights, modifying and retrofitting environments, and philosophies of management and care. Advances are already being driven by those who can pay for services such as home modifications or moves to a new setting such as assisted living. The choices for low- and moderate-income older persons, however, are much more constrained. Although a new system with greater consumer choice may create flexibility and new solutions, the magnitude of government support remains in doubt in the United States and other countries as housing subsidies are either capped or reduced. Many older persons continue to pay excessive amounts of their income for housing, live in deficient units, and are at risk of moving unnecessarily to more institutional settings.

Action to improve housing for older people needs to be based on sound knowledge. More research can reveal how life experiences, housing markets, and public policies influence people's housing on entry to old age and transitions through the course of old age. The impact of housing on older people's lives needs to be identified in terms of their standards of living, health, independence, and well-being. Rigorous analysis of housing programs can enhance their cost-effectiveness and increase their political attractiveness. Such a knowledge base requires a strong emphasis on housing as an important area for applied, multidisciplinary research.

R L Shehab, University of Oklahoma, Norman, OK, USA

Glossary

Anthropometry – Measurement of the physical dimensions of the human body.

Biomechanics – The study of the forces and motions involved in human movement.

Human Factors Engineering (also called Ergonomics) – The discipline of scientific and technical endeavor aimed at optimizing the fit between people, their environments, their tools, and the tasks they perform.

Job Design – The consideration of contextual factors such as worker experience, task characteristics, and the method of assessment used to evaluate job performance.

Macroergonomics – The systematic analysis of organizational needs and how these are supported by the abilities of personnel within the contexts of the work environment.

Introduction

Human factors engineering, also referred to as ergonomics and hereafter referred to as HF/E, is a discipline of scientific and technical endeavor aimed at optimizing the fit between people, their environments, their tools, and the tasks they perform. HF/E is necessarily a broad field, covering the extent of human activity. Examples of HF/E work include designing a kitchen counter or industrial workbench for the height of the user, evaluating the physical strain of a lifting task (whether it be groceries into a car trunk or packages onto an industrial conveyor belt), designing a roadway sign so it can be seen at an adequate distance by drivers, creating warning labels that are effective deterrents to risky user behavior, and creating user-friendly controls and displays for computer software and consumer products such as cell phones, televisions, and dishwashers. There is a natural overlap between HF/E and gerontology. Much of gerontology is aimed at maintaining the functioning and independence of older adults, and there are active groups of HF/E researchers and professional practitioners who find the challenge of working for the benefit of older adults particularly challenging and rewarding. This article attempts to provide an overview of the field of HF/E for gerontologists engaged in research and professional practice.

This article is organized as follows: first, we provide an account of the history and background of HF/E, including a discussion of related fields, the primary sources for HF/E professional development, and HF/E research and development publications. Next, we provide an inventory of the many age-related changes and differences that HF/E professionals should bear in mind when designing for older adults, and how that information is considered from an HF/E perspective. Next, we consider some specific results of research and development in applications in areas of importance to older adults. Finally, we conclude with some trends that will be important for both gerontologist and HF/E professionals to consider for the future intersection of gerontology and HF/E.

Human Factors Engineering and Ergonomics – The Profession

It is commonly agreed among practitioners and academics in the field that HF/E has its roots in World War II. Seminal work in the field came from attempts to design better aircraft controls and displays, radar screens to best suit the cognitive and perceptual capabilities of operators, and other military applications. Tracing the roots of the discipline back further into history, one can see linkages to early industrial revolution era 'scientific management' practices promulgated by Frederick W. Taylor, Frank and Lillian Gilbreth, and their contemporaries. The word 'ergonomics' was coined from the Greek words for work (*ergo*) and law (*nomos*) by the Polish scientist Wojciech B. Jastrzebowski, in his 1857 work entitled 'An outline of ergonomics, or, the science of work based upon the truths drawn from the science of nature.'

Being inherently interdisciplinary, HF/E has natural overlaps with other fields of inquiry (see **Figure 1**). From the psychological sciences, the field draws on knowledge of fundamental processes and mechanisms of psychophysics, perception, cognitive psychology (including memory, attention, language processing, and decision making). From engineering and computer science, HF/E overlaps with and draws on areas such as artificial intelligence, software engineering and requirements analysis, signal processing, control systems

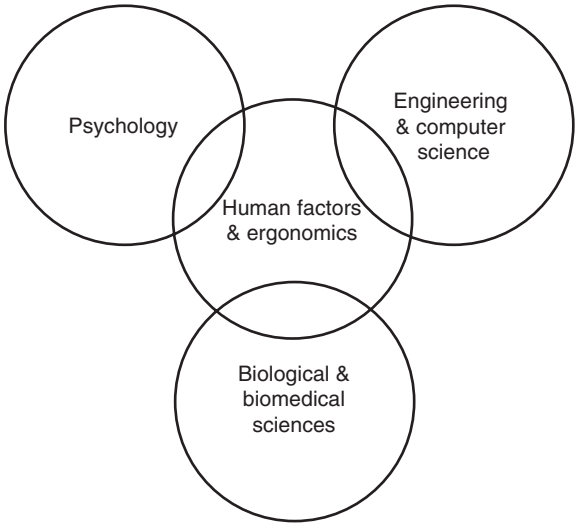

Figure 1 Interdisciplinary overlap of human factors and ergonomics with related fields.

engineering, biomechanics and other aspects of mechanical engineering, traffic engineering, and safety engineering. Finally, HF/E overlaps with the biological and biomedical sciences in areas such as exercise physiology, occupational medicine, and industrial hygiene.

Professional development in HF/E is supported by numerous professional societies, opportunities for certification, and professional publications. The largest and most renowned HF/E societies include the US-based Human Factors and Ergonomics Society and the International Ergonomics Association. Professional certification is handled by the Board of Certification in Professional Ergonomics. Major journals in the field include *Human Factors*, *Ergonomics in Design*, *Ergonomics*, *Applied Ergonomics*, *International Journal of Human–Computer Interaction*, *International Journal of Industrial Ergonomics*, and *Human Factors and Ergonomics in Manufacturing*.

Normal Aging and Human Factors

What does it mean when someone refers to a person as an older adult? Are they merely describing their chronological age or are they referring to underlying changes in a person's functioning? This question is much more complex than it seems. While chronological age is the marker used by most of society to define when a person becomes 'old,' this provides little useful information toward understanding the older person's capabilities and limitations.

There are a number of changes associated with the aging process. Some of these changes are considered to be 'normal' aging, while others are typically associated with age-related disease. This article is concerned with those changes that occur in the absence of pathology. The impact of age-related impairment can be quite severe and can limit a person's ability to work, recreate, and live independently. Human factors specialists are interested in changes that functionally affect ability and, consequently, human performance. This article examines such changes to the sensory system, changes in cognitive function, physical changes, and the impact of skill and expertise.

Visual and Auditory Perception

There are many changes that occur in the aging visual system. One of the most common visual problems experienced by older adults is change in the ability to focus. There are several visual characteristics that relate to the ability to focus on an object. First is the change in visual acuity, or the ability to perceive the finest details of an object. By 80 years of age, acuity experiences a 50% decline on average. In addition, older adults experience problems with accommodation, the ability to focus on objects at different distances. Primarily, the point of resting accommodation and the near point recede, causing an increase in the distance required to accurately view a visual target. There are also more instances of hyperopia (farsightedness) and fewer instances of myopia (nearsightedness) in the elderly population. These functional changes limit human visual performance in many tasks. Often, the older adult is unable to read signs, labels, warnings, and instructions, and consequently may be inadvertently placed at risk. Many designers advocate the use of large fonts for older adults.

Other visual changes observed in older adults are related to illumination. There is a decrease in the amount of light that reaches the retina, implying a need for higher source illumination. However, the slowing in the rate of accommodation creates heightened susceptibility to glare and longer times for adaptation to and recovery from glare sources. It is important to balance the needs for sufficient illumination and glare avoidance in order to promote effective visual performance. Some basic recommendations include providing multiple light sources of lower intensity, shielding the light sources, locating the light sources outside of the visual field, and making sure that illumination levels do not fluctuate.

These visual changes impact the performance of work-related tasks. In laboratory tasks involving visual attention and visual search, older adults exhibit difficulty in ignoring irrelevant information. Mead and Fisk suggested that the use of visual features to draw attention (color in this specific case) may not be

sufficient unless the older adult is trained to look for those features. In vigilance tasks, older adults show little difference from younger adults, unless the visual image is degraded.

Auditory impairments due to aging are hard to identify. There is an inherent conflict between age effects and exposure effects. However, some consistent patterns do emerge. Older adults exhibit decreased sensitivity to higher frequency tones, known as presbycusis, and have difficulty with speech perception in noisy or highly resonant environments. Older adults are also negatively affected by time compressed auditory information. The implications of these impairments are most significant in public environments. Many environments, such as workplaces, shopping centers, and restaurants, are quite noisy and have had little design effort put into damping the noise sources. On the job, this can mean difficulty communicating with co-workers and difficulty detecting auditory warnings and signals. Important auditory information should be presented in both auditory and visual modalities to minimize any risk for misinterpretation of the information.

Memory

It is well acknowledged in the aging literature that memory deficits occur with age. Theories describing the source of these deficits can be categorized as resource-, stage-, or systems-based. While the theories provide insight into the underlying constructs, human factors is concerned with the functional limitations caused by age-related memory impairments.

Much of the research on memory and aging has stemmed from resource theories. Older adults have a diminished working memory capacity that is primarily limited by the processing demands of the task. As tasks require higher levels of processing, older adults exhibit reliable deficits in performance. Some researchers link these age-related deficits in working memory to the slowing of perceptual speed, particularly as task complexity increases. Retrieval, a component of stage theories, has also been shown to be more difficult for older adults by observed performance deficits during free recall tasks. However, a potential conflict exists in sorting out the source of the deficit, be it processing or retrieval. Additional evidence of age-related retrieval problems is the tip-of-the-tongue phenomenon whereby older adults experience greater trouble retrieving familiar words or names. Spatial memory is also susceptible to age-related deficits. Research has typically demonstrated that older adults have difficulty in spatial memory tasks that involve remembering where an item was located within a given spatial context.

The implications of memory impairment can be quite severe for older adults who wish to continue working and living independently. In highly dynamic work environments, an older adult may be required to manage several tasks or projects at a given time and may be under time pressure to complete those projects before deadline. The research on working memory and perceptual speed suggests that these requirements would place a much higher burden on the older worker than the young worker. In addition, older worker performance may suffer if it is necessary for the worker to recall detailed information without the aid of context. In the home, these same deficits can make independent living more difficult. However, the older adult may have the opportunity to use strategies to simplify the performance of home tasks. For example, the older adult may choose to attend to only one task at a time (e.g., cooking) and may identify fixed locations for valuable items (e.g., keys).

Attention

Multiple task performance refers to the ability to simultaneously perform two or more tasks, with competing demands on perception, processing resources, and response. The multiple task performance of older adults is particularly impaired and is represented by small sequential responses of perception–processing–response. The attentional demands of multiple tasks often lead to delays in perception of new stimuli and performance of the response as well as missing other information or stimuli due to fixation with the multiple tasks. The most significant impairments in divided attention are found in tasks of greater complexity. However, the type of tasks used in the multi-task paradigm is critical to understanding the performance impairments. Older adults suffer larger performance deficits for tasks that combine unrelated processing requirements, while no age-related differences are identifiable for tasks that use meaningful speech. Similar results have been shown for auditory information. Shadowing tasks revealed age-related differences when information presented to different ears was in conflict. An age-related deficit was also noted in the time to switch attentional focus between ears.

Attention deficits can be damaging in the workplace and the home environment. If the task demands are overwhelming to the older adult, there is a risk of missing information that can be critical to production or safety. It is important to recognize what Tun and Wingfield called the threshold of functional adequacy. This threshold is situation dependent and separates adequate performance from inadequate

performance. For example, if the difficulty of a given task increases (such as adding additional attentional demands), the decrement in performance may or may not be equivalent for the older person and for the younger person. It is not this interaction between age and difficulty that is critical, but the absolute performance level of the individual that dictates if performance is still functionally adequate. Thus, whether or not an older individual is differentially impaired relative to a younger person, their performance may be lower overall, causing them to go below the threshold of functional adequacy.

Anthropometry and Biomechanics

The goal of human factors specialists is to design to accommodate human characteristics. One application that is driven by this principle is the area of anthropometry. Anthropometry is the measurement of the physical dimensions of the human body. Large-scale databases exist that describe many of the human physical dimensions. However, these databases were developed from measurements of US military personnel and do not necessarily reflect the general population, particularly the older population. Within a narrowly defined age cohort, there tends to be large interindividual variability due to factors such as body type and bone structure. There is also a high level of intraindividual variability due to many health-related factors and moderated by age as well. Age-related changes become most pronounced after the age of 60; however, height begins to decline as early as age 30 at a rate of about 1 cm/decade. The magnitude of change of most physical characteristics is still relatively unestablished. It is commonly observed that as men age, they lose weight, and as women age, they gain weight. However, little scientific data have been collected on older adults. The data that do exist generally are from small sample sizes, cover large age ranges, and are often averaged across males and females. This lack of data, combined with the knowledge that variability increases with age, means that the human factors designer has little information to apply to the design of physical spaces for older adults.

The design of the workplace and the home environment also requires consideration of human strength capabilities. The study of biomechanics is concerned with describing the forces and motions that are involved in human movement. Strength is one aspect of biomechanics that has been demonstrated to decrease as a function of age. In particular, measures of isometric maximal force productions indicate that strength peaks at about 30 years and then declines across most muscle groups. Even though certain neuromuscular changes can be linked to these declines, there are questions about the role played by inactivity and muscle disuse. While it is clear that maximal strength decreases, submaximal work shows little effects due to age. This can perhaps again be related to the concept of functional adequacy, but evidence also exists that older individuals employ compensatory mechanisms that minimize the functional deficits. It is only in the later decades of life that these deficits can not be overcome.

Motor Control

Age-related declines in motor control can be summarized as a slowing of behavior. In particular, this slowing is apparent as increasing reaction times and increasing movement times. While a moderate effect has been noted for simple reaction times (a single stimulus is anticipated and the appropriate response is known), this effect is amplified when the problem becomes more complex, as is the case in choice reaction times (an element of uncertainty is added, with multiple stimuli and/or multiple response choices). As the task uncertainty increases, the stimulus–response compatibility decreases, and as the response modality becomes more difficult (manual rather than vocal), predictable increases in reaction time are observed.

Movement time also suffers age-related declines that are related to the uncertainty and complexity of the motion. Older adults tend to make movements that are slower, less smooth, and less coordinated. Continuous movements are also more problematic; it has been observed that older adults will modify the continuous movement task into a sequence of discrete movements in order to simplify the motor control requirements. In addition, older adults have difficulty if a task requires precise control and force modulation. These deficits can be attenuated with physical activity and training. Connelly *et al.* demonstrated improved smoothness of motion, a decrease in time taken to reverse motion direction, and less deviation from criterion in the motion pattern after just six training sessions using isokinetic ankle movements.

The observed trends in reaction time and movement time suggest that requirements for quick responses may be problematic as one ages. However, the threshold of functional adequacy must again be examined in this context. While most tasks do not demand such limiting thresholds, it is possible that reaction and movement time could be critical if the task involved prevention or recovery from an accident. For example, can the older person respond to an alarm in sufficient time to minimize damage and injury? Can the older person move fast enough to get

out of the way of automatic machinery? These response limitations must be examined in context.

Skill and Expertise

The effects of aging on performance are typically represented by declining function. However, these declines can be moderated to some degree by skill and expertise such that the functional difference between young and old is negligible. Skill is directly linked to practice, whereby practice is the process of skill acquisition. There is evidence that practice can mediate age differences for some tasks such that older adults can attain performance levels comparable to younger adults. In particular, practice reduces the age by complexity effect and reduces the variability in motor control tasks. Practice may provide older users with the opportunity to develop alternative strategies of performance for tasks that have become more difficult. However, acquisition of new skills should build on existing knowledge to compensate for the declining cognitive and motor resources of older adults.

On the other hand, expertise incorporates an element of experience obtained by repeatedly utilizing a skill over time. Morrow and Leirer proposed that the age-related decline in cognitive resources is offset by the increased knowledge and experience acquired with age. Experts compensate for their declining abilities by finding new ways to perform old tasks. This usually involves the development of strategies, such as keeping appointment books and performing collaborative work. Experts also develop accommodation strategies whereby they redefine how to accomplish a given task in order to avoid task requirements that cause them difficulty. For example, many older adults choose to drive at off-peak times in order to avoid traffic congestion.

Human factors specialists should take advantage of the positive impact of skill and practice. It is critical that older workers maintain proficiency through continual application of skills. Regular training sessions may also benefit older workers by allowing them the opportunity to develop alternative performance strategies or by reinforcing the skill set already possessed. However, one should use caution when assigning an older worker to a new task. There should be some thread of continuity between tasks such that the worker's skills can be directly applied in the new context.

HF/E Applications and the Older Adult

Detailed knowledge of the physical, cognitive, and perceptual changes that occur with age has been utilized to address the needs of older adults in a number of areas. To achieve goals such as enhanced safety and life satisfaction, HF/E professionals act to ensure that the demands of daily tasks are commensurate with the abilities of older adults. Task demands are often defined in terms of activities of daily living (ADLs) and instrumental activities of daily living (IADLs). While both ADLs (e.g., bathing, dressing) and IADLs (e.g., money management, using the telephone,) are required for health maintenance and continued autonomy, IADLs are more complex and have traditionally been targeted for intervention. While an exhaustive review of the different areas of HF/E application is beyond the scope of this article, topics covered here include areas that address safety, increased independence, and work in later life.

Safety

Within the domain of safety, HF/E professionals have made numerous contributions such as tailoring warnings to facilitate older adults' comprehension of general hazards as well as collaborating with medical professionals to improve medication adherence and home medical device design.

Warnings One approach to preventing personal injury or property damage is to use warnings to inform those at risk about potential hazards and to promote safe behavior. Because warning comprehension is dependent on a number of perceptual and cognitive abilities, older adults have specialized needs that should be considered by warning designers. For instance, an older adult with visual impairment might not notice a written warning presented using small type size and thus be more susceptible to injury than younger adults. Likewise, age-related cognitive declines tend to place older adults at a significant disadvantage when they encounter pictorial warnings (e.g., a cigarette with a slash negation sign used to indicate 'no smoking' while pumping gasoline) that require the use of inferences to comprehend the nature of a hazard. In general, HF/E interventions to facilitate safety within the warnings domain have focused on designing age-appropriate warnings that attract attention and minimize dependence on inference. One area where such age-specific interventions have focused is the design of medication labels for the purpose of improving medication adherence.

Medication Adherence Medication adherence is defined as taking a medication at the correct times and at the indicated dosage, and following any special instructions as directed by a physician. A large percentage of non-adherence is due to under-use of the

medication, in large part due to forgetfulness. Factors such as complexity of schedule, number of prescribing physicians, and number of medications all tend to correlate with non-adherence. HF/E interventions designed to increase medication adherence have included the use of voicemail reminders, attempts to improve doctor–patient communication, and designing individualized pill organizers using different instructional formats. While each method has met with varying degrees of success, an understanding of how age interacts with the cognitive requirements of the task was most valuable in terms of guiding design of future technology interventions that are not yet in widespread use. One new application area for technological intervention is home medical device design.

Home Medical Devices Relatively recent changes in the health-care system have forced older adults to take a more active role in their personal health care. On a daily basis, older adult patients and caregivers must interact with devices such as blood glucose monitors and flow meters that were not designed for use by laypersons in a non-clinical setting. Evidence suggests that older adults are at risk and demonstrate an increased likelihood of making clinically significant errors when using home medical devices due to insufficient training and poor device interface design. HF/E contributions have focused on identifying age-related sources of error (e.g., device menu navigation, tactile insensitivity) and improving safe device usage by developing effective training programs that teach skills that can be retained over time.

Increased Independence While safety is a basic concern for people of all ages, older adults are also motivated to maintain an independent lifestyle. To remain independent, older adults must find solutions to transportation and communications problems that limit their ability to interact with others.

Transportation Barriers to mobility comprise one of the most profound constraints on older adults' independence. Consider the difficulty of accomplishing daily tasks such as going to the doctor or buying groceries without an effective means of transportation. Potential HF/E interventions have been investigated for a number of transportation issues such as difficulties experienced while using public transit systems and driving. For instance, motor control and related strength limitations might impair an older adult's ability to board a public bus, take a seat, and then exit at the intended destination. Design solutions to public buses might include lower stairs to facilitate boarding and exiting the vehicle, long-handled grab bars to assist balance, and ergonomic chairs that ease egress. Other public transportation issues that have been investigated are the cognitive difficulties associated with wayfinding. Many older adults report difficulties in determining which bus or subway train to take, when it arrives and departs, and how to navigate effectively to the intended destination. Solutions such as sign and map improvement promise to address these problems in public transportation as well as driving.

Although the tasks of driving and using public transportation share many of the same barriers to mobility, these barriers are amplified during driving. Estimates indicate that older drivers have higher crash rates per vehicle per mile driven and that they have higher fatality rates than younger drivers when accidents occur. These data have been attributed to age-related declines in visual search, attention, and slower reaction times. Attempts to reduce older adult traffic fatalities have included HF/E signage interventions that have focused on using redundant signs, reducing clutter from competing signs, and manipulating the physical characteristics of signs to make them salient and noticeable. Increasingly, advances in technology have also been adopted to reduce accidents. For instance, vehicles with proximity sensors should help older drivers to avoid accidents, whereas onboard navigation systems can provide cognitive support to assist with route or destination tracking.

Communication While transportation difficulties can physically limit the ability of older adults to interact with others, communication difficulties can result in social isolation. To effectively communicate with others and function in today's society, older adults are faced with the challenge of using a variety of technologies ranging from telephones to the Internet. Although few older adults report problems using their familiar household telephones, the ubiquity of these devices has been used to enhance their functionality by linking them to new technologies such as automated voice menu systems. Whether an older adult uses the telephone to purchase airline tickets, refill a prescription, or pay the electric bill, the likelihood of encountering an automated voice menu system is quite high. Given the cognitive and auditory demands of using such a system, older adults are at a disadvantage when they encounter them. HF/E interventions to improve automated menu systems have focused on decreasing the speed of presentation and providing cognitive support in the form of visual aids that promote navigational efficiency.

Another trend in communication technology is the adoption of cellular telephones. Cognitive difficulties

with menu navigation are accompanied by perceptual limitations when older adults use these devices. Because cellular telephone designers continue to follow the miniaturization principle by making their products smaller and smaller, older adults are increasingly being placed at a functional disadvantage. Given the number of documented age-related perceptual and motor control difficulties, it is not surprising that older adults report difficulty seeing the small numbers on a cellular display or having difficulty dialing via the small keypad. HF/E interventions have begun to address these usability issues by investigating how age impacts the characteristics of cellular telephone interfaces.

Perhaps the largest growth in new communication technology use by older adults has been their increasing willingness to use computers and the Internet. Older adults 65 and older report that they use computers to interact with friends and family as well as to find information about health care and increase job productivity. Because all of these activities are related to maintaining independence, HF/E researchers and practitioners have focused on making computer systems as accessible and usable as possible for older adults. Efforts to facilitate human–computer interaction (HCI) have ranged from improving the acquisition of basic computer skills (e.g., mouse control, desktop navigation) to the design of elder-friendly Web sites that provide perceptual (e.g., text in large type size sans serif font) and cognitive support (e.g., intuitive menu labeling and organization) to older adults. Basic HCI research has encompassed a large number of areas such as the ability of older adults to use various input devices and displays and system navigation issues. These findings have been applied as HF/E interventions to enhance functionality with a wide variety of devices such as automatic teller machines and library search engines in an effort to improve older adults' quality of life.

Work in Later Life

For a variety of reasons such as financial and esteem needs associated with job satisfaction, older adults are remaining in the workforce longer and the retirement age is steadily increasing. HF/E as a profession has focused on adapting the work environment to the abilities of the worker. Thus, the goal of using HF/E interventions to improve older adults' experiences in the workplace can be achieved through macroergonomics as well as adapting the workplace through training and job design.

Macroergonomics Macroergonomics is defined as the systematic analysis of organizational needs and how these are supported by the abilities of personnel within the context of the work environment. To this end, the goals of the organization must be identified and the structure of the organization must be evaluated in terms of how technology, personnel, and environmental variables interact to influence productivity. If, for instance, an organization's goals are expressed as a raw measure of output per unit worker in a physically demanding factory environment, the likelihood that an older adult will be viewed as competitive with younger co-workers is low. Thus, the effectiveness of an organization as a whole is evaluated at the macroergonomic level, whereas analysis at the level of individual workers and teams of workers is considered to be the microergonomic level. Training and job design are two HF/E methods used to tailor the work environment to meet the needs of older workers.

Training Rapid technological changes in the workplace such as hardware and software upgrades often necessitate the need for an older worker to update his or her skills through training. Thus, to meet the demands of a job, older workers must be able to update their skills, knowledge, and abilities. Given current knowledge of age-related changes in cognition, the need for age-appropriate training programs is essential. HF/E recommendations to develop training programs for older adults often include guidelines such as taking advantage of their experience and introducing new ideas in the context of familiar cues while minimizing the introduction of irrelevant or distracting instructional materials.

Job Design Job design refers to the consideration of contextual factors such as worker experience, task characteristics, and the method of assessment used to evaluate job performance. One method for matching task characteristics with the abilities of the older worker is to compare the knowledge, skills, and abilities (KSAs) necessary for a job to those possessed by an employee. The relative weighting of KSAs may be different for different ages. For example, investigations of cognitive tasks indicate that older workers may rely more heavily on their past experience and accumulated task-relevant skill set to solve problems, whereas younger workers may be more likely to rely on reasoning and general problem-solving skills. Likewise, age-related differences in perceptual and physical characteristics of workers must be considered. HF/E interventions have traditionally focused on reducing age-related difficulties through proper workplace/tool design, reorganization of procedures, and the provision of work aids such as power-assisted lift devices to offset strength

limitations in material handling. An example of workplace modification might include the use of a screen magnifier on a computer screen to offset age-related declines in visual acuity. Procedural manipulations that might allow employers to further maximize work output include assigning tasks based on KSAs rather than worker availability and providing breaks to workers of all ages.

Philosophical Issues and Emerging Trends in Human Factors and Aging

There are some significant philosophical issues and emerging trends that will need to be addressed by those who are working at the intersection of gerontology and human factors engineering. The first issue is the common misconception that the intersection of gerontology and HF/E is 'design for the elderly.' A second issue, related somewhat to the first, is that the population in general, and in particular the population of the oldest-old, is changing dramatically and rapidly.

Consider the depiction of HF/E with respect to gerontology as 'design for the elderly.' The very idea of 'design for …' is manifest in stigmatizing designs that point out the weakness and vulnerability that can come with advanced age, and can signify a paternalistic approach taken by designers. Marketing agencies and popular media are aware of this pitfall – images we see in magazines and television advertisements for products aimed at older consumers typically depict vibrant, healthy-looking, slightly graying-at-the-temples users of their products to hint at the intended market. The essence of a good design is that it will work well for the broadest range of users possible. An emerging field, universal design, which has its roots in the civil rights movement of people with disabilities, is advocating this approach. The 'design for …' idea has been decried and countered in the ergonomics-related research of participatory design (PD). The PD approach focuses on gaining an in-depth understanding of the group of intended beneficiaries of the HF/E intervention, focusing on building teamwork between all participants, and coming up with a solution that is sensitive to the social and emotional needs and concerns of the users, rather than just focusing on functional requirements derived from engineering models of the user-environment system. For HF/E interventions to reach their full potential, they will need the full participation of older adults and gerontologists, rather than just a blunt targeting of a vaguely or even inappropriately defined audience. This brings us to the next point.

The notion of 'design for the elderly' is, further, a drastic oversimplification exemplified by the difficulty in answering the following question – who are 'the elderly'? As gerontologists are commonly aware, population heterogeneity increases with population age. While it is true, as described in the earlier section on age-related changes, that there are reliable shifts in the mean on any given measure of functioning, it is also true that population variance increases dramatically, even on 'normally aging' population characteristics. HF/E has traditionally concerned itself with younger adults and 'normal' population characteristics. For example, the standard anthropometric envelope to target for accommodation has been from the 5th percentile to the 95th percentile of the population. The incredible diversity of the older adult population should challenge our notions of normal aging-related changes in function and encourage a closer look at meaningful ways to distinguish subgroups from each other, such as distinguishing otherwise healthy 'young-old' adults in their 60s from chronically impaired 'old-old' people in their 90s. The balancing act for HF/E theorists will be to continue to search for universals in human experience with tools, tasks, and environments, with which predictive and generalizable models of human performance can be constructed, while at the same time properly focusing and defining the subject matter of the proposed HF/E intervention and being sensitive to the intended beneficiary.

Humor

R J Manheimer, University of North Carolina, Asheville, NC, USA

Glossary

Humor – Disposition or attitude, expressed physically through laughter, caused by the painless resolution of a contradiction or synthesis of contraries, especially those concerned with topics and experiences capable of provoking anxiety, self-repression, or negative emotions.

Introduction

Humor can be understood as a disposition or attitude, expressed physically through laughter, caused by the painless resolution of a contradiction or synthesis of contraries, especially those concerned with topics and experiences capable of provoking anxiety, self-repression, or negative emotions.

Since the facts of human aging and the omnipresence of older adults are commonly, if erroneously, associated with decline, disability, and death, it is not surprising that the elderly have often been the brunt of jokes, even ones told by same-age peers. Negative humor about aging and the elderly focuses on subjects such as sexual impotence, physical changes and disabilities, and fear of death. Humor is used as a safety valve or distancing mechanism for suppressed fears and anxieties about human mortality. But there are positive forms of humor about aging, often produced by the elderly themselves. These reflect humility and acceptance of limitations associated with growing old as well as some of the advantages and strengths that come with age and experience. Wisdom may be expressed through humor because many of life's most profound lessons arrive in the form of paradoxes that can best be expressed through a sigh, jest, witticism, or knowing smile.

Humor may be thought of as a stimulus, mood, attitude, disposition, or way of looking at the world. Humor shows itself in images of the elderly, as a set of therapeutic techniques, and as an aspect of cognitive and affective development.

Concept of Humor

The Word Humor

The English word 'humor' has a revealing history. It comes from the Latin *humere*, meaning 'to be moist.' Ancient and medieval treatises on physiology postulated that the human body had four fluids, or 'humors': bile, phlegm, choler, and blood. The relative proportion or balance among these humors would determine a person's health and temperament or disposition. Medieval medical authorities thought that increasing dryness and cooling off characterized aging. Hence, a lack of humor (moistness) was associated with aging and the elderly. The characterization of an older person as 'dried-up' may have its origins in this early medical speculation.

Modern views of humor transform the medieval material concept of fluids into metaphorical ones. The description of having a good sense of humor, an aspect of happiness, continues to suggest the idea of a well-balanced person who experiences the world with a certain degree of equanimity. Ironically, the mechanics of humor are often related to imbalances, as when we are thrown off guard, surprised by a joke, witticism, irony, double entendre, sight gag, mime, or pratfall. Humor is the resulting disposition of a specific form of the comical. So to understand humor and its connection to aging and the elderly, it would help to understand the structure of comedy.

Aristotle's Concept of Comedy

Aristotle, in *The Poetics*, distinguished the dramatic form of comedy from tragedy. Both forms involve a collision of will – usually that of a prominent public leader such as a king, queen, or general – with larger social and cosmic forces such as tribal taboos, family allegiances, wars, and injustice. In tragedy, flaws of human character result in pain: disgrace, downfall, and death. The cosmic realm asserts its dominion over human desires. But in a comedic drama, according to Aristotle, the individual escapes this destiny, rising triumphant over obstacles and counterforces through tricks, guile, or subterfuge, surviving humiliation, failure, and degradation. What might stand as a flaw of personality (e.g., excessive pride, foolishness, naiveté, impulsiveness) becomes, through inversion, a redeeming quality that turns the tide.

Ancient tragedy and comedy have their origins in religious rituals and, like rituals, have the function of releasing emotions of awe, fear, and pity. The dramas inculcate moral lessons by producing experiences in audience members that, through sublimation in the form of tears or laughter, bring their lives back into harmony with the social order or cause them to reflect on the need to adapt to radical changes taking place in that order.

The laugh of humor can express many things but, as Aristotle's delineation of comedy shows, humor depends on both a cognitive and affective process; it concerns topics of great seriousness; contraries or contradictions are involved as deviations from the expected, producing both surprise and insight. Humor has both 'low' and 'high' forms, the former based on making fun at someone else's expense (an individual or group), the latter pointing to features of the shared human plight. Although humor can be revelatory, it can also be escapist.

Negative and Positive Humor about the Elderly

Negative Humor about the Elderly

In a 2003 study, researcher Alan Bowd found that of 4200 jokes examined, 102 employed a predominant stereotype of older persons. These included the impotent male, the unattractive female, the vain and virile male, the disinterested female, the innocence of second childhood, the insatiable female, the forgetful old person, and the infirm old person. A single example illustrates the typology.

An old man, perhaps in his 80s, is walking down the street when he hears a voice crying, "Pick me up, pick me up." Looking around and finding no source for the voice, he walks on. But then the voice returns, and he spots a large green frog, its mouth forming the words. He picks up the frog and holds it in his palm as the frog explains: "I am a beautiful young woman, turned into a frog by a wicked witch. But a kiss from you will restore me. Do this, and I will be yours to fulfill your deepest desires and sexual fantasies." Having listened, the old man puts the frog in his pocket and walks on. After a few minutes the frog calls out, "So why didn't you kiss me?" The old man replies, "At my age, I'd rather have a talking frog."

In recent years with high-profile media attention given to erectile dysfunction drugs, full body makeovers, anti-aging creams, and memory disorder documentaries (especially those dealing with Alzheimer's disease), an overabundance of jokes have entered the social mainstream, most perpetuating an age-related stereotype. Consider the scene in the 2003 movie

Something's Gotta Give in which actor Jack Nicholson, playing an aging music industry exec with a fondness for young women, has a heart attack while in bed with his trophy girlfriend, Marin, played by Amanda Peet. He is rushed to the hospital and is about to receive a vasodilator drug. When he is asked whether he is taking Viagra, he shakes his head, but when told that the drug interaction could kill him, earnestly shouts, "Yes!"

Positive Humor of the Elderly

Countering the myriad negative jokes about older people, a rising genre of positive humor employed by older people themselves is exemplified in the story told by humor researcher Lucille Nahemow in an important collection of essays, *Humor and Aging*. Nahemow recounts a conversation with a resident of a nursing home who is diligently hemming a square of cloth. Nahemow, out of politeness, complements the woman's work, which, in fact, is rather poorly done. To this the woman replies that she has been a tailor for 60 years. She's just trying to humor an activity director who thinks she is teaching her the art of stitchery.

Certain famous actors have become icons of humor that is expressive of the wit and wisdom of the elderly. Hume Cronin and Jessica Tandy, now both deceased, played elderly characters in numerous films who overcame the prejudices of the young and middle-aged, showing their pluck and capacity for empathy over the ignorant and feckless who saw little value in history, tradition, or its bearers.

Ambivalent Humor about Aging

The 1984 film *Cocoon* captures in its humorous plot certain ambiguous and ambivalent meanings of aging that surface in a growing body of films, novels, and dramas. *Cocoon*'s cast of famous actors play residents of a Florida life-care community who inadvertently stumble on cocoon-like pods resting at the bottom of a swimming pool on an abandoned estate. As the story unfolds, viewers learn that the pods are designed to restore a number of extraterrestrials left on earth from an expedition thousands of years earlier. By swimming in the pool's 'fountain of youth' waters, the human elders' aging process is reversed. Through a series of mishaps, the earthlings are invited to experience eternal life and health if they choose to return with the extraterrestrials to their planet. Despite social conventions that would mitigate against abandoning grandchildren and adult children and foregoing their earthbound responsibilities and the traditional piety of accepting the inevitability of death, the cluster of friends choose literal immortality and head off toward other galaxies. The film is a lightly veiled allegory of the mixed blessings of the powers of life-sustaining medical technologies, uncertainties about the promised resurrection of the body and afterlife of the soul promised by mainstream religions, and fantasies of prolongevity sometimes prophesized by geneticists and molecular biologists.

Four Contemporary Aspects of Humor and Aging

Four important aspects of aging-related humor have emerged since the 1970s: (1) a new image of the elderly in popular culture, (2) humor therapy, (3) humor scholarship, and (4) developmental approaches to humor and aging.

Older People in Popular Media

We have already cited several films in which mature adults serve as protagonists. To these we may add a host of films characterized by a theme that film scholar Charles Nicholas calls the 'elderquest.' Movies such as *The Trip to Bountiful* (1985), *The Straight Story* (1999), and *About Schmidt* (2003) center on an older person's metaphorical and literal journey, whether to a childhood hometown, a sick brother's house, or cross country in a recreational vehicle to a daughter's wedding. Each journey is a personal saga, a search for resolution of some long-simmering conflict, a search for authenticity. The elderquest genre goes back at least to Ingmar Bergman's 1957 classic, *Wild Strawberries*, in which the septuagenarian physician, Isaac Borg, tries to come to terms with painful elements of his past while on a car trip in Sweden to attend an honorary ceremony at the University of Lund.

This motif of return and reconciliation in later life fits well with Erik Erikson's 'eighth stage' of life, in which themes of despair and despondency are juxtaposed with self-acceptance and self-integration, a struggle in which the ideal result is wisdom. Because most of the films have poignant and more or less happy endings, with the protagonist rising above limitations, burdens, and barriers, they qualify as comedic.

Not all films related to later life fit the elderquest theme. The comedy *Grumpy Old Men* (1993), with its curmudgeonly heroes, is meant to be funny, if not plain silly, while the now-classic *Fried Green Tomatoes* (1991; another Jessica Tandy film) adds a feminist angle to lessons of aging passed down to a younger, midlife generation embodied by the dowdy, downtrodden housewife played by Kathy Bates.

Television sitcoms such as *The Golden Girls*, *The Jeffersons*, and even the animated *The Simpsons,* with its nursing home-bound father and grandfather, Abraham Simpson, frequently at the heart of the plot, testify to the prominence of older characters who retain their distinct individuality, eccentricity, and dignity. American newspapers feature numerous elders in comic strips such as *For Better or Worse, Shoe,* and *Lola*. They are sometimes portrayed stereotypically as grumpy, intrusive, disabled, or dithery, but just as often are portrayed as brave, caring, insightful, and wise.

Humor as Therapy

Ever since Norman Cousin's 1976 book, *Anatomy of an Illness*, told the story about how *I Love Lucy* TV episodes and Three Stooges and Marx Brothers films helped the well-known author and journalist recover from a crippling disease, humor's therapeutic value has captured the popular imagination. Countless humor workshops attract people from the corporate world to hospice centers, eager to discover how mirth as an emotional response can help heal, soothe, relieve, strengthen, or motivate. In a 2001 article, Johns Hopkins University School of Nursing professor Ronald Berk summarized eight psychological benefits of humor based on available research: reducing anxiety, reducing tension, reducing stress, reducing depression, improving self-esteem, restoring hope, restoring energy, and providing a sense of empowerment. To this list he added physical benefits such as improving respiration, stimulating circulation, decreasing stress hormones, increasing the immune system, and increasing the production of endorphins, which help to decrease pain by producing a sense of euphoria.

Humor therapeutics have been used in nursing homes to offset depression and even with patients recovering from cataract surgery to speed up the healing process. Humor is also used as a teaching device to communicate with students about sensitive topics such as death, dying, grieving, and suicide.

Humor Scholarship

While one cannot obtain a doctorate in humor, the academic study of humor has proliferated at universities in the United States and abroad through specialized courses, international humor research associations, and journals such as *HUMOR: International Journal of Humor Research*. Further testimony to the productivity of humor scholars are the numerous encyclopedias on American humor, humor in eighteenth, nineteenth, and twentieth century British literature, and humor in Irish literature. There have been numerous academic conferences on humor and aging covering topics ranging from the physiology of laughter to aging comic characters in the late novels of American writers Saul Bellow and Philip Roth.

Humor Viewed Developmentally

Humor is not just a mood, asserted language philosopher Ludwig Wittgenstein, it is a way of looking at the world. Other scholars concur that a person's ability to catch the drift of humorous tales or situations reflects both moral and cognitive developmental stages. Researchers at the University of Toronto's Department of Psychology argued in a 2003 article that they found a clear correlation between cognitive functioning and humor comprehension. This, the authors argued, is important since "affective responsiveness may underlie the success in using humor as a coping mechanism in the elderly."

Curiously, the capacity for producing humorous remarks is observed even in those with mild to moderate dementia. A gerontologist observed the meeting between a cognitively intact sister-in-law and her Alzheimer's disease-afflicted brother-in-law. The woman, reaching out to the brother-in-law from her wheel chair, started to cry. Whereupon the brother-in-law quipped, "Don't cry, Marion. We're still here. Aren't we?"

Countless incidents of ironic humor reflected in mature adults' acceptance of mortality are embodied in this account from another gerontologist observing a committee meeting at a senior center. A tall, tweed-jacketed gentleman rises to give his report on behalf of the long-range planning committee. He clears his throat and announces: "For me, long-range planning means what I'm going to have for breakfast." Such humorous remarks might be classified under the adage 'I don't buy green bananas.'

Although it might not be possible, as gerontologist Mildred Seltzer observed, to convert the humorless of any age, appreciation for humor does seem to deepen and grow more complex as some people age. Greater tolerance of ambiguity and the ability to handle multiple viewpoints and paradoxical life experiences may make one a better humor follower. Those with a great sense of timing may become skilled initiators of humor.

Sigmund Freud recognized humor's positive contribution to mental health. Laughter, Freud asserted, using the early twentieth-century metaphor of the steam engine, is an outlet for psychic or nervous energy. Like a system of pressures, the release valve, laughter, could go off when a person felt that the need to suppress anger or sexual feelings might not be necessary. The energy no longer needed to repress

unruly emotions or unacceptable thoughts would be discharged in the form of laughter. This could be accomplished, Freud said, in three ways: through jokes or witticisms, by means of the comic, or through humor. Jokes are usually made at someone else's expense. The comic often involves our pleasure at watching someone who we perceive as inferior, such as the 'tramp' Chaplin, the trio of Stooges, or the *schlemiel* so often portrayed in Woody Allen films. Sometimes we enjoy our sense of superiority over the fool or bumbling character. Sometimes we identify with these characters when they triumph over the attempted domination of the snobbish, intimidating, or authoritarian.

For Freud, the third form, humor, is a different sort because it has a liberating element that makes it both "fine and elevating." Humor is a way of looking at ourselves that expresses the "triumph of narcissism, the ego's victorious assertion of its own invulnerability." To Freud, humor is not a statement of resignation, but a bolt of rebelliousness. Humor rejects the necessity of suffering and, through a shift of perspective, enables one to attain or retain a sense of personal dignity.

Freud's account of jokes or wit, the comic, and humor suggests a developmental hierarchy: the individual moves from a simpler to a more complex expression of laughter, from the slapstick antics of Larry, Moe, and Curly to the profound irony of the Biblical Sarah's laugh. Does capacity for a humorous perspective on life increase with maturation, or is sense of humor a gift that comes with certain personalities? Freud does not comment, but nineteenth-century Danish philosopher Søren Kierkegaard thought humor was an achieved perspective. He made humor one of his "stages on life's way."

Kierkegaard proposed three 'spheres of existence': the aesthetic, the ethical, and the religious. Each of these 'life attitudes' is shaped by subjectively and qualitatively different experiences of time. Two additional, transitional stages, irony and humor, complete Kierkegaard's developmental theory.

The aesthetic-oriented person, whom Kierkegaard portrays as a young poet or bon vivant, delights in sensuous beauty and the enjoyment of what, today, one might call 'peak' experiences. But such timeless moments are fleeting and lead to disappointment: peaks are exactly that, they lead to valleys. Sobered by such truths, the ironist, an older, wiser, and perhaps slightly jaded individual, steps back from life, adopting an aloof, defensive posture. He or she is not going to be taken in by false hopes and ephemeral thrills. The ironist pretends to be above it all, but that is a lonely position, one that brings despair over the prospect of further development. Eventually, though not always, the ironist accepts life's incongruities and the emptiness of living for shear possibility, and matures into the ethical individual, embracing the enduring value of friendships, marriage, and career. The ethicist, portrayed in Kierkegaard's *Either/Or* by the figure of a judge, is the product of the exhortation 'choose yourself,' and belong to what Kant called the "universally human." While the aesthete dwells in spontaneity and immediacy, the ethicist values reflection and permanence.

Kierkegaard's ethical stage sounds like the achievement of autonomy, frequently regarded as the end stage of moral development. But Kierkegaard argues that the ethical is no stopping point, because people still find an inner urgency caused by the irreconcilability of a yearning for the infinite or eternal while constrained by the finitude of human existence. Kierkegaard is a master of analyzing the condition of despair. In modern popular parlance, a symptom of this longing is commonly expressed by the midlife complaint: "Is this all there is to life?"

Awareness of one's mortality stirs, in some, a spiritual need, the desire to view oneself in a larger context of meaning related to nature, the divine, and the cosmological. The dawning of the religious search is to be at one with the divine. Heralding the transition between the ethical and religious stages, Kierkegaard identifies the intermediate stage of humor, which is a certain type of philosophical outlook characterized by detachment from, yet empathy toward, one's fellow creatures; appreciation for, rather than distress over, the irreconcilable aspects of life; and the realization that the search for meaning will never end, nor will the quest for an illusive sense of completeness.

Kierkegaard insisted that the fulfillment of human development belongs to the religious stage, and not just any religion, but his highly individualistic version of Protestant salvation. Leaving that terminus aside, we note that Kierkegaard was one of the great nineteenth-century thinkers to understand human development as a dialectical process operating well into adulthood. He did not seek to match up the stages of life with specific chronological intervals, but the characters he created to represent these stages suggest that the ethical stage and beyond belong to midlife.

While perhaps not a perfect fit for Kierkegaard's more theological interpretation, still the words of psychologist Florida Scott-Maxwell capture this elevated humor perspective. Writing autobiographically in *The Measure of My Day*, she says: "When a new disability arrives I look about to see if death has come, and I call quietly, 'Death, is that you? Are you there?' So far the disability has answered, 'Don't be silly, it's me.'" Scott-Maxwell shows how the pain of physical decline can be blunted by an attitude of comedic detachment.

Humor, Aging, and Creativity

Koestler on Humor and Creativity

Adding to the appreciation of humor, Arthur Koestler, in *Act of Creation*, saw remarkable similarities between humor and creativity. Scientific discoveries and jokes both involve holding incongruous facts and ideas together in such a way that a new insight may be born. Koestler termed the common element of humor and creativity 'bisociation.' When Einstein climbed aboard a trolley and discovered the analogy he had been seeking for the theory of relativity, one could imagine that Einstein's "aha!" was quickly followed by "ha, ha." Indeed, the laugh of creativity goes back to the Bible.

Biblical Humor and an Elderly Couple

An ancient laugh reaches us from the book of *Genesis*. The primal parents of the Jewish people, Abraham and Sarah, are dwelling in desert tents when three nomadic visitors who are heavenly messengers suddenly show up. Sarah is sitting discretely behind the flap of her tent as one of the messengers tells Abraham that Sarah will soon be with child. This is a remarkable prophecy, since Sarah is a childless 90-year-old and Abraham is nearly 100. A divine voice had already promised Abraham that not only a child but also a whole people would descend from the couple. On that occasion, Abraham had "laughed in his heart." But now, Sarah laughs out loud. The messengers point an accusing finger. How dare she laugh? Sarah denies it, though her doubts are certainly reasonable. Nevertheless, it turns out the angels are right. A few sentences later, the proud parents are naming the child Yitzchak (Isaac), from the Hebrew root meaning 'to laugh.'

For centuries, biblical scholars have argued over Sarah's laugh. Some hear in it the laugh of sarcasm, others that of doubt, ridicule, or incredulity. These interpretations fail to grasp the mythical quality of the story. Through an imaginative leap, the tale links the listener to the story of how God created the world. Sarah and Abraham's laughs echo the creation story: how a world comes forth out of emptiness. The birth of Isaac is a human parallel to the surprise of divine creativity. Sarah's becomes the laugh of joy.

Humor and Wisdom

From the biblical Sarah to the veteran actress Jessica Tandy, the laughter and humor of older people deal with some of the most serious and difficult of subjects: fertility, sexuality, birth, family, aging, death, and wisdom. Seniors' humor teaches us that laughter is a basic human response and humor a natural way of coping.

The first century Jewish historian Philo grasped the connection. "If someone has experienced the wisdom that can only be heard from oneself, learned from oneself, and created from oneself, he does not merely participate in laughter: he becomes laughter itself." Achieving enlightened laughter may not be possible for everyone, but when one hears the laugh of the wisely old, one can at least listen and search for smiles of his or her own.

Images of Aging

M Featherstone, Nottingham Trent University, Nottingham, UK
M Hepworth, University of Aberdeen, Aberdeen, UK

Published 2007 by Elsevier Inc.

Glossary

Ageism – Discrimination against individuals or groups because of their age.

Consumer Culture – The culture of the consumer society with its images of youth, fitness, and beauty.

Images – Visual representations of the external appearance of the human body.

Mask of Aging – The experience of a disjunction between the aging body and the 'ageless' self.

Social Constructionism – The view that aging is not a biological given, but is constructed by society.

Stereotypes – Oversimplified public images that are often stigmatizing.

Introduction

Gerontological interest in the analysis of visual images of the aging body and the role images play in constructing the meaning of the aging process is of comparatively recent origin. It can be traced back to the mid-1960s, when it emerged as the result of two major social developments. The first was the belief that one of the most urgent problems facing societies with increasing numbers of older people was that of ageism, a term that refers to the widespread existence of negative attitudes toward people simply because they are biologically older. Analyses of the images of old age in, for example, greeting cards, comic strips, and the movies showed that older people were consistently represented in a negative manner. The second development was the greater awareness of the key role played by visual images in the construction of social life. It is often observed that contemporary Western societies are consumer societies and that the construction and dissemination of visual images is a central feature of consumer culture. Technological innovations in the means of producing and communicating visual images have resulted in a massive expansion in the volume and realistic quality of visual images that can be communicated to audiences. Recurrent themes in consumer culture imagery are youthfulness and beauty alongside a negative depiction of aging and old age.

It is now widely accepted that the quality of life of the increasing population of older people will be considerably enhanced by the elimination of negative images or stereotypes of the aging body as a body in decline and their replacement with positive images of old age as an extended phase of active life. This quest is built on the assumption that the images that circulate in public work in two ways. First, public images are considered to both reflect and shape social attitudes toward older people and the treatment they receive. Second, public images influence individual perceptions of the self and the construction of personal identity in later life. The personal meanings of old age are the result of the reflection by each individual upon the public images of later life with which he or she becomes familiar. Public images are a key resource for making sense of the biological processes of aging which are exposed to public scrutiny because they are evident on the external surfaces of the human body. Wrinkles on the face may, for example, be interpreted either positively – as signs of a life experienced to the full – or negatively – as signs of failure and regret.

It is now, therefore, accepted that images operate in flexible ways: their meanings exist on several levels and they are always open to a wide variety of interpretations, especially in contemporary Western societies. This perception arises from recent developments in the study of culture and mass communications that have shown that the relationship between image and audience is essentially a dynamic one: audiences can no longer be seen as made up of 'cultural dopes' who can be easily manipulated by the image makers. Mass communications may best be understood as performances, resulting from

processes of interaction between image and audience whereby viewers respond to the images (e.g., television or movies) before them according to their specific interests and cultural allegiances. For this reason, gerontologists are becoming aware of the diversity of images of aging that circulate in multicultural societies. They are also becoming aware of the ways in which images of aging are being actively transformed as the result of technological innovations in communication systems (photography, movies, television, video, and computing).

The images of aging now emerging in contemporary Western cultures are, therefore, becoming much more complex and fluid. Good examples of the development of new images alongside older stereotypes can be found in advertisements for goods and services for the expanding section of the population in the 50 plus age group. Advertisers are coming to appreciate the value of associating images of these consumer products (fashions for the over 50s, cosmetics, retirement homes, vacations, educational opportunities, labor-saving devices) with images of youthful bodies in middle and later life. Biological aging is thus constructed as a period of continuing physical health and activity in opposition to the stereotyped image of middle and later life as a period of diminishing energy and disengagement. Associations between the body in a state of physical decline and rocking chairs, slippers, and drowsiness are replaced with images of continuing bodily activity and vigorous social encounters. What is interesting is that these new images, designed to revise and even revolutionize middle and later life, are also images of age-related retirement and leisure and, given this essential ambiguity, open to a more flexible range of interpretations than the comparatively more rigid older representations of life after 50 as inevitably a one-way status passage to old age and death.

The Role of Images in Social Life

Background

From the moment of birth human bodies are biologically programmed to age and die. The effects of this program are visibly displayed on the human face and body. This means that every time one looks at a human being, or an image of a human being in, for example, a painting or a photograph, one perceives an individual who can be identified in terms of his or her age. In biographical accounts of the lives of famous people, paintings or photographs of these individuals when they are older are often identified with the words in old age or as an old man/woman. Because all humans are part of a process of biological growth and decline, and this process is visibly displayed on the face and body, every image of the human face and body is necessarily an image of aging. But human beings do not only exist in a biological lifetime, running from birth to death; they also exist in historical and cultural time. Images of the body are constructed out of the visual images and language available at any particular time in history and in any particular culture. It is because human beings use images, both visual and verbal, to construct social life and give it meaning that they are more than simply biological bodies. But it is also important to note that the relationship between images of the body and the personal experience of the body is complex and is determined by people's lived experience in a variety of cultural contexts. The meanings of images of the aging body, whether they are found in drawings, paintings, photographs, movies, TV programs, or videos, are culturally coded and yet at the same time open to a wide variety of interpretations depending upon the situations in which they are encountered. In some cultures, for example, the wrinkles on an old person's face are viewed with ridicule or disgust, whereas in other cultures they may go unnoticed or even be seen as a sign of higher status. Images of the aging body, therefore, can be used to convey either positive or negative messages, and these messages can powerfully influence the ways in which younger people relate to older people and older people relate to each other.

Although visual images have emerged as the most influential form of mass communication, it must be remembered that they can never be completely separated from language. When looking at a visual image (a caricature of an old person, a photograph of an older man or woman in a biography or in a family photograph album) the understanding of its meaning is necessarily in terms of the categories or typifications made available through language: for example, the language category 'old man' or 'old woman.' Yet at the same time, images are never wholly reducible to language, and it should be recognized that much of social life (and this has been increasingly the case since the development of consumer culture in the nineteenth century) takes place within the visual field. The study of visual images of aging, therefore, requires an acknowledgment of the dynamic relationship between visual representations and language.

Definitions

In everyday terminology, an image is often regarded as an accurate representation of an object or person. As far as images of human beings are concerned there is a tendency to see the body as something that because of its material (embodied) existence can easily be copied or represented. The notion of copying and

producing an accurate likeness of an original in a variety of media (the sculpted portrait bust of Benjamin Franklin is another good example) is one of the key meanings of the term image which can be traced back to the original Latin meaning of the *imago*.

But the term image also has an important second meaning, and this is derived from associations with the role of the imagination and the imaginary. In this second meaning, the emphasis is not on the accurate representation of an independently existing objective reality, but on the power of the imagination to construct and shape an image of reality. There is an interdependency between the image as it is recorded and the imagination of the viewer. From this perspective, images are regarded as playing an active role in the social construction of reality. Reality is understood to be more of an imaginative projection than an object existing independently of the viewer or society. Just as images have an important part to play in the construction of the body, they are also seen as making a significant contribution to the social construction of the self. The self, grounded as it is in the body – or embodied – is thus a product of social interaction. A good example can again be taken from the use of photography. Debates about the accuracy of photographs of family members are a commonplace feature of everyday life, and people often have some difficulty in recognizing their own photographs as accurate images of their 'real' selves, especially when the photographs were taken several years ago.

The second meaning of the word image, therefore, refers to the original definition of photography as painting with light. It suggests that an image is essentially produced through an interpretative act whereby the subject's body is clothed and adorned in particular ways and framed in a setting of material objects, all of these carrying a specific symbolic value, emotional tone, and resonance. The image is, then, a social construction that frames a world in order to make sense of a vast array of sensory stimuli. As a photograph relates to a specific point in the lifetime of a person and his or her relations to other persons at that time, it carries hidden significances and emotional charges that are themselves unstable, altering with the changing vicissitudes of the person's subsequent experience. It is also open to changing interpretations of history, as in the case of recent analyses of Victorian photography and, in particular, sociological analyses of photographs of older people taken during the closing decades of the nineteenth century. This research shows, for example, how photographs of old people living and working in rural areas of Scotland are not 'natural' images but socially constructed compositions deliberately framed to reflect current social beliefs about the simplicity and integrity of country life.

Images and Stereotypes

An appreciation of the complexities of images and the theorization of their role in the social construction of reality is now influencing research into the social stereotypes of aging and old age. The word stereotype is derived from the Greek *stereos*, meaning form or solid, and *typos*, meaning an impression or model. The process of stereotyping is one in which the subtle differences and nuances that distinguish one individual older person from another are dissolved in order to transform aging into one uniform process. Stereotypes of old men and old women are often regarded as displeasing and offensive by older people because they convey the impression that individual differences and distinctions are somehow dissolved or destroyed by biological age. Moreover the stereotyping of old age as a single uniform process with similar effects on all older people regardless of culture, gender, time, and place, is seen as having a negative effect on the quality of later life precisely because public images of old age in Western culture have tended to focus on its negative aspects. In general, the stereotype old is a social category that implies that every old person is not eligible for full acceptance in social life. One of the clearest examples of the stigma of aging is age discrimination in employment in which people over a certain age are barred from applying or are dismissed. Such barriers may, of course, exist only in the form of unwritten rules or understandings that are never explicitly advertised but their ultimate reference point is an image of older age as a social stigma (*see* Ageism and Discrimination).

At the same time it must be remembered that the effects of stereotypes of aging are not always as clear cut as is sometimes imagined. Not all stereotypes of old age are negative, and stereotypes of aging are often highly ambiguous precisely because old age is not experienced as a single uniform condition. Yet, because the basic social function of stereotypes is to make sense of complex experiences and to reduce tangled patterns of information into an easily communicable set of images, there is a strong possibility that stereotypes may give highly misleading messages to the wider public. A good example is that of the grandfather and grandmother whose popular image is that of gentle, socially disengaged, and desexualized men and women with white hair and ready smiles who dote continuously upon their grandchildren – figures, moreover, who are often White and middle class. The fact that large numbers of

grandparents in Western societies are in their 40s and 50s means that real-life grandparents have an image problem. In this context it is interesting to note that a number of popular magazines have come into existence to cater to a new generation of grandparents who do not identify with this stereotypical image.

Further evidence of the misleading stereotyping of the aging process involves the binary distinction between images of youth, usually represented in Western stereotypes as the most active and desirable phase of life, and images of old age as a period of decline and decay, one that is at best a preparatory stage for death and the afterlife. A typical historical example can be found in an engraving by Jorg Breu the Younger published in Augsburg in 1540. Entitled "The Ten Ages of Man," it displays life as a series of steps leading first of all progressively upward from birth through youth to the high point of middle age (what is often described as growing up) and then, in the second major phase, stepping inexorably downward through old age toward death and finally the afterlife (what is often described as growing old). In this compelling image, which has for centuries exercised a pervasive influence over the Western imagination, the life course of every individual is structured in terms of series of predetermined steps that he or she must follow. It is an inflexible image and it does not, therefore, allow any possibility of alternative interpretation.

As a characteristic example of the ages of man tradition that continued to stereotype the life cycle well into the nineteenth century, Breu's engraving confirms a clear relationship between old age and decrepitude. The final stage of life in the material world is represented in the image of a bowed and bearded old man, as one of fatigue, invalidity, and preparation for death.

Prior to the seventeenth century, Western images of life as a series of ages represented life in masculine terms. The images of the ages of life were images of men. But during the seventeenth century artists began to draw distinctions between the typical stages of the life of man and the stages of life of woman, the ages of woman being defined in terms of virtuous domesticity. Prescribed models of the ages of woman display the same upward progression to the peak of middle age, followed by a series of steps or stages downward to a bedridden old age, death and immortality. In all these images, the virtuous – whether male or female – are rewarded with a heavenly afterlife, and the vicious are punished in hell. Such images continue to influence stereotypes of the life course in present-day society, the only significant difference being the absence of an explicitly religious cosmology.

Breu's work is a typical example of the social construction of stereotypes of old age in order to prescribe moral distinctions between virtuous and vicious aging. The boundaries between the ages of life that constitute the life course and the boundaries between positive (moral) and negative (immoral) aging are rigidly defined. This practice has a long history in Western culture and can be traced as far back as classical antiquity with a line of continuity stretching up to the present day. Art historians have shown, for example, in seventeenth-century Holland, how stereotyped images of older men and women were used to depict the moral message of the rewards of the virtuous life for men and women alike. Paintings of avaricious and lewd old men and women stand in deliberate contrast to images of virtuous merchants, craftsmen, and housewives who diligently carry out their gendered duties in expectation of a reward in the next world. The division of labor between men and women is clear but the moral stereotyping of aging as a journey of life is the same for both.

Similarly, in nineteenth-century painting, there is a pronounced tendency to represent the idealized form of old age as a final stage of dedicated domestic seclusion, frequently against the backdrop of a rural environment. In addition to framing the potentially threatening physical decline of old age within a comforting domestic setting, such images also reflect nostalgia for a disappearing rural life in a society undergoing rapid modernization with its attendant urbanization and expanding consumer culture. Such nostalgia involves a dual repression of the complexities and often harsh nature of rural life and the realities of growing old in a world where competitive individualism was placing an even higher value on the active physical body. Increasingly in the nineteenth century, images of old age reflected a moral distinction between those who aged well, that is, preserved their independence to their last breath, and those who aged badly or gave in and became dependent on others.

The same process of binary stereotyping occurs in the case of portraiture, an art form whose ostensible purpose since the Renaissance has been the representation of the visible appearance of individual character as revealed in the face and bodily comportment. Yet even when artists set out to paint a portrait of an identifiable individual who has attained old age, their efforts often incorporate elements of stereotypical conventions concerning a 'good' (or morally worthy) and a 'bad' (or socially deviant) old age.

The more general point to be made, therefore, is that images of old age should often be viewed not so much as descriptions or documentary records of the

actual historical conditions of older people, but as prescriptive social texts. Art historians often emphasize the distance that can be assumed to exist between, for example, the prolific images of old age in paintings that were produced in The Netherlands during the Golden Age of the seventeenth century and the everyday lives of those relatively small numbers of men and women who actually lived long enough to experience old age. These images should be viewed as reflections of the beliefs and traditional conventions governing the pictorial representation of older people as social types. Good examples are the inappropriately amorous old woman in a brothel and the rich old man who foolishly married a young wife and who, for the amusement of the audience, is being conspicously cuckolded.

The imaging of old age as a symbol of social or political virtue can be traced back to the sculpted portrait busts of prominent figures in classical antiquity. At one period in the history of ancient Rome, from the second century BC to the sixth century AD, portrait busts of elder statesmen were sculpted to give explicit facial expression to idealized political virtues. The signs of aging were carved into these in order to give enduring form to the public virtues of long service and stability as perceived in the faces of their living models. As such, they were celebrations of an association between old age and social and political stability, of the perception of a close interrelationship between the virtuously aging individual face and a public life dedicated to duty and self-discipline. This close physiognomic relationship between the public and the private, the inner subjective self and the outer public social identity, was reflected several centuries later in portraits painted by the German artist Albrecht Dürer (1471–1528). The portraits he painted toward the end of his own life of a number of notable converts to the Lutheran religion in Germany have been described as a deliberate attempt to reveal the outward signs of the inner spiritual transformation of men who had been converted to the new religion. It has been argued that Dürer's portrait of Frederick the Wise (1524), who died within 2 months of its completion, was intended to represent the face of an older man who had been restored through religious conversion to a youthfulness of spirit. In both Roman antiquity and sixteenth-century Lutheran Germany such images of the visible appearance of aging were specifically created as icons of exemplary social qualities. As portraits of recognizable individual persons who were growing older, and therefore in this sense images of aging, they are also expressions of predominant social aspirations concerning forms of spiritual growth and development.

Images of old age continue up to the present day to be constructed as moral images or metaphors of social life, symbolizing the beliefs and value of the age. It is the very conventionality of the belief system underlying traditional images of old age – their stereotypical quality – that has ensured their continued influence up to the present day.

At the same time, there are significant signs that a major transformation in the imaging of aging has been slowly emerging since the mid-nineteenth century. One of the most obvious differences between traditional methods of image production (drawings, paintings, etchings, and so on) and those in use today is the emergence of new techniques of image production and reproduction associated with developments in consumer culture. Also radically different are the means of communicating images and distributing them to a mass audience. Since the nineteenth century, innovations in photography, film, television, and video have vastly increased the number of images in circulation. Moreover, the need to find outlets for mass-produced goods resulted in the proliferation of department stores, shopping malls, and arcades and in the development of visually sophisticated advertising techniques. These processes of mass marketing helped to produce the consumer culture 'dream worlds' in which it became possible to attach a whole range of romantic and exotic imagery to mundane goods. Since the mid-nineteenth century, therefore, goods have been increasingly advertised in terms of their value in enhancing the lifestyle of the purchaser. They are no longer bought simply because they satisfy basic human needs such as hunger, warmth, and shelter. Consumer goods should not be regarded as solely material things, but as containing a strong symbolic component. In effect they act as communicators that engage the admiration, approval, and envy of others. In this context it is the emphasis on the shift from the producing to the consuming body that has a crucial significance for images of aging.

In a world facing for the first time in human history the global prospect of an aging population, the image-saturated consumer culture constantly valorizes bodies that epitomize youthful energy, fitness, and activity. There is a tendency to present bodies, social relationships, and lifestyles as things that need working at, things which can be reshaped and renewed. Indeed the need to combat a fateful sense of bodily fixity and decline is often presented as a moral duty. The result is a foreground of age consciousness and an ageist rejection or denial of the biological decline of later life. Unlike the traditional images of the ages of man and of woman, contemporary images of the life course attempt to eliminate the

downhill stages to death and the after life and to replace them with an extended plateau of middle life. Ironically enough, the virtuous response to growing older, portrayed as an essentially spiritual acceptance of physical decline and the inevitability of death that we saw in the traditional iconography of aging, is now located in the celebration of resistance to aging and the rejection of old age. In contrast, to age negatively is to let oneself go – in effect, to abandon the struggle to maintain a youthful appearance and lifestyle.

This rejection of the physical realities of old age in favor of images of a perpetual state of middle age both reflects and gives expression to the ambiguities and uncertainties which increasingly surround old age in contemporary society. As the population of older people expands, particularly the proportion of people aged 70 and over, evidence from empirical research into the everyday lives of older people clearly suggests that the actual experiences of old age are much more varied and often much more positive than ageist stereotypes imply. Even when suffering from ill health or a serious physical disability, many older people continue to enjoy independent and fulfilling lives. These findings lend further support to the argument that many of the negative aspects of aging are not biologically or chronologically determined. Rather, they can be shown to be the result of the meaning that individuals give to the aging process in later life. The images they draw upon to construct these positive meanings are therefore of great significance.

It should also be emphasized that the largest proportion of people in the age category 75 plus are women. It is now important to construct images of aging that represent the predominance of women in this category and give much greater prominence to positive images of women in later life. This task is seen as particularly important because it is increasingly acknowledged that women suffer from the double jeopardy of ageism and sexism.

Interest in images of aging has gradually increased among gerontologists and professional groups working on behalf of older people throughout the Western world. In the United States, the Gray Panthers, the National Coalition on Aging, and the AARP battle to reverse ageist stereotypes of older people as socially dependent and disengaged members of the population. Increasing publicity has also been given in recent years to the positive contribution older people make to social life. The basic assumption here is social constructionist. Older people have unjustly been subjected to the harmful effects of negative stereotypes, and those concerned with promoting the interests of older people in the context of an aging world must learn to construct and deploy a new multicultural positive imagery of old age.

At the present time there is a strong tendency for the positive images of aging that have been constructed to counteract negative stereotypes to overemphasize the qualities of youthfulness and as a result to foster a sense of disjunction between the body and the self. Those old people whose bodily appearance does not conform to the youthful stereotype of aging (i.e., whose bodies visibly display the physical signs of aging – wrinkling, hair loss, graying of the hair, reduced flexibility and mobility, impairment of sight and hearing) often express the feeling of being trapped within an aging body. This sense of entrapment has been described as the mask of aging, a term that refers to the ways in which the aging body can no longer express the subjective experience of the inner self. The biological body grows older but the inner self appears to be ageless or fixed at some earlier point in the life course. In its most extreme manifestation, the case of Alzheimer's disease, one of the most distressing experiences of both caregivers and sufferers is that of an essentially youthful inner self relentlessly imprisoned within an old and decaying body. The predominant image here is that of a dualistic contest between two opposing forces: the biological body and the subjective self (*see* Dementia).

Images of Aging in a Multicultural World

There are two significant indications of the potential for expanding the range of positive images of aging that are of increasing interest to gerontologists. The first is the growing awareness of a multicultural world. The second is the realization that scientific discoveries and technical innovations have far-reaching consequences for the aging process.

Awareness that we live in a world characterized by multicultural variations is displacing the older sociological view of people bonded together through a common culture with its shared beliefs and values. It is becoming apparent that societies consist of a diversity of cultural groups often engaged in struggles for equality and respect. Among these are ethnic groups and groups of disabled people. Although it is now recognized that biological aging as such is not a unifying force as far as older people are concerned, it is also the case that potentially powerful groups of older people do exist and show signs of becoming increasingly conscious of their social position.

In the not-too-distant past when images of aging were collected for display at conferences and exhibitions or as illustrations in books and journals, there was often a tendency to present oversimplified and sometimes romantic images of old age. The

predominant image of aging was very often White and middle class, excluding a wide range of other social groups. References to variations in attitudes to aging according to socioeconomic status (SES), ethnic background, and gender tended to be glossed over. Since the late 1980s, however, gerontologists have paid much more attention to class, gender, regional, and ethnic differences.

A useful example is the image of old age as a time of infantilization, as a second childhood. Because Western culture places such a strong emphasis on mature adulthood, there has been an emphasis on the traditional model of the life course for both childhood and old age to be represented as protected and dependent stages of less than full adult status. This continues to be reflected today in the treatment of older people as if they are dependent children, especially by professional caregivers in institutions. Ageism can therefore operate through the dominance of images of dependency that take away the adult status and personhood of the elderly. For many gerontologists and members of interest groups concerned with the rights of older people, infantilizing images of older people must be contested and displaced.

Today, however, the negative image of old age as a second childhood is being reappraised. In Japan, for example, once an individual is past the age of 60, he or she is assumed to have completed the first cycle of life and to have entered another cycle in which childish and mischievous behavior is not only expected but looked upon with affection. In Japan older people may be perceived as 'cute,' and as such the recipients of affection from young people, an example being the centenarian twins Kin and Gin, who became media celebrities. In such a cultural context the wrinkles, graying hair, and slurring speech may be ignored, and even perceived positively as signs that older people have attained a state of grace and are nearer to God and the next world. Respect for the outward physical signs of biological aging, expressed in the form of positive images of the second childhood, is an indication of the filial pietism and paternalism that conditions the treatment of older people in Japan.

Any consideration of multiculturalism and therefore diverse and sometimes competing images of aging alerts us to the danger of pushing the parallel between ageism, racism, and sexism too far. Although race and gender continue to be constituted as master categories (relatively unambiguous social categories that entail discrimination and power deficits for the outsider group), such a division is by no means so clear-cut with reference to images of older people and their relationships with the young and middle aged. Unlike the social oppositions of race and gender, youth, middle, and old age are essentially transitional statuses within a universal process of biological aging. As transitional statuses they are reshaped by cultural change. The move toward cultural diversity indicates a richer repertoire of images of aging in the forseeable future. There are signs of this already: traditional groups of elders whose lives and attitudes toward aging reflect earlier twentieth-century expectations are being displaced by new generations of the young old, third agers, aging gays, and many others. A stage in social life has been reached where traditional images, although most certainly of historical and sociological interest, no longer seem relevant.

This view of a rapidly emerging cultural disjunction between even the immediate past, the present, and the future is reinforced by the second significant social transformation. This is the effect of scientific research into the aging process and technological innovations.

The interaction between biology and culture, reflected in studies of the social effects of images of aging, means that human beings are essentially unfinished creatures. Human bodies and experiences of human bodies change with innovations in organ replacement surgery, plastic surgery, and genetic engineering. Such developments are inevitably reflexive: they feed back into the actual experiences of being human. It is now accepted that it is possible to intervene in several of the life processes, including some associated with aging, and to create, so to speak, new human bodies from old. It is therefore possible to identify three developments that will influence images of aging in the future. The first is the capacity to change and modify the external appearance and thus control the image of the aging body. Significantly, plastic surgery now penetrates deeper and deeper below the surface of the skin to sculpt the very structural framework of the body. The second is the ability to reconstruct the inner body by repairing or replacing damaged or decayed body parts. Scientific research is currently on the point of understanding the process of cellular aging so that the 'natural' process of decline can be halted or even reversed. This third development entails not so much the repair of the body, but a mode of escape from its confines. Developments in information technology offer the prospect of the construction of cyberspace and virtual reality. This will allow people with sensory impairment and limited mobility the capacity to move freely in highly realistic simulated environments that engage the full range of human senses and offer an enhanced capacity for interaction with others on a more equal basis. A human body

damaged or reduced by the aging process may no longer need to represent a prison to the inner self.

The potential of these technological developments coupled with our increasing sensitivity to multiculturalism and global diversity holds out the prospect of a more complex and differentiated set of images of aging in the future. It is clear that there is not one essential process of aging but many. It is also clear that to make sense of these social transformations in the future, we will need not one gerontology, since the subject of gerontology is becoming so diverse, but many.

Immune System

N S Shah and W B Ershler, Institute for Advanced Studies in Aging and Geriatric Medicine, Washington, DC, and National Institute on Aging, Baltimore, MD, USA

Published 2007 by Elsevier Inc.

Glossary

Dysfunctional T Cells – Memory cells with a diminished ability to secrete interferon-y after specific antigen stimulation.

Immunosenescence – Progressive decline in immune function that develops with age.

Innate Immunity (also called natural immunity) – Immunity that does not require prior antigenic sensitization.

T cells (also called memory cells) – Cells that have previously been exposed to an antigen and then play a role in long term immunity to that substance.

Introduction

There is a decline in immunity with age. Of all the cellular elements that comprise the immune system, T cells are most affected by age. This may be linked to a relentless and universally occurring age-associated atrophy of the thymus gland and resultant shrinkage of the naive T cell compartment. As T cells are both effectors and regulators of the composite immune response, the age effects can be observed with both antibody-mediated and cellular immune

responses. However, the decline in immune function due to aging (immune senescence) is insufficient to explain the extent of immune deficiency seen in most elderly. Various secondary causes, including poor nutrition, comorbid diseases, diminished integrity of organ systems, medications, social isolation, and physical inactivity, contribute to the commonly observed immune dysfunction. Nutritional supplementation and vaccination are the cornerstones of immune reconstitution, and there may be benefit from exercise, but this remains controversial.

Immune function is essential for the life of all mammals. Abnormalities in immune function are related to increased incidence of infections and worsened outcomes from seemingly unrelated diseases, such as diabetes, Alzheimer's disease, and atherosclerosis. Also, deficiencies in immune regulation can lead to autoimmune diseases and malignancies.

The immune system undergoes various insults throughout life, and as a result there are adaptive and maladaptive changes, ranging from involution of the thymus gland to alteration in functions of T and B lymphocytes. Some aspects of the immune system, such as adaptive immunity, are affected more than others.

These changes, termed immunosenescence, are seen in all elderly, including the healthiest aging population. Immunosenescence has been causally linked to three major health consequences: increased infections, autoimmunity, and failing immune surveillance, which may lead to cancer. Current evidence suggests that such decline in immune function is generally mild in nature. However, there are several secondary causes that weaken the immune system further, such as poor nutrition, comorbid disease, and medications, as well as changes in structure and function of various organ systems.

Immunosenescence

Immunosenescence is a term applied to the progressive decline in immune function that develops with age. The immune system can be divided into two major compartments: innate and adaptive. Innate immunity is conferred by neutrophils, monocyte-macrophage, and NK (natural killer) cells and does not require prior exposure to effect function. Adaptive immunity confers protection against specific antigens. T cells and B cells are essential components of the adaptive immune response. Much research has focused on adaptive immunity and T cell function in the context of aging.

Adaptive Immunity

It has been demonstrated that even at the most advanced ages, total lymphocyte count and the percentage of T and B cells remain relatively unchanged. Though a decrease in lymphocyte count is associated with increased mortality, it is not an age-related change.

Cellular Immunity

Major change occurs in the thymus gland with age. The gland itself undergoes a well-defined involution, with almost complete replacement by fibrous tissue by 60 years of age, with a corresponding decline in the appearance of detectable thymic peptides in the peripheral blood. The thymus gland provides the microenvironment for maturation of naive T cells, and with a reduction of these there is a relative expansion of committed (memory) T cells. Memory cells are those that have been previously exposed to antigen (a foreign substance, usually protein), and they play a role in long-term immunity to that substance. These memory cells cannot act against any other antigen(s). The memory T cells seen in the elderly may be of less proliferative capacity and directed at only the most specific of antigens (oligoclonal), and thus aged T cells, although quantitatively normal, are said to have less antigenic variability. Output of naive T cells is important to keep the antigenic repertoire broad. A large repertoire means a greater variety of T cell receptors (TCRs) that can specifically bind to a wide variety of antigens. With a limited supply of naive T cells in older adults, this repertoire shrinks and susceptibility to novel antigens increases.

Proliferation of T lymphocytes in response to nonspecific mitogens and specific antigens is decreased in the elderly. Interleukin-2 (IL-2) is an important cytokine that promotes T cell proliferation. Decreased numbers of IL-2-secreting cells, decreased blood levels of IL-2, as well as decreased IL-2 receptors and IL-2 receptor-specific mRNA have been demonstrated in cells from old donors.

T lymphocytes can be divided into two broad categories based on the appearance of characteristic proteins on their surface: CD4+ (T helper [Th]) and CD8+ (cytotoxic) cells. Both CD4+ and CD8+ cell populations demonstrate expansion by memory cells with advancing age and a relative reciprocal decline in naive cells. It is known that naive cells are more potent producers of IL-2 and so the diminished IL-2 levels, and, thus, the diminished IL-2 response described with aging may be thereby explained. The Th cells are further classified as Th_1 and Th_2 based on the cytokines produced. Th_1 cells produce IL-2, IL-12, and interferon-γ, and they promote cellular immunity. On the other hand, Th_2 cells produce IL-4, IL-5, IL-6, and IL-10 and promote humoral

(antibody) immunity. There is a shift in helper T cells from Th_1 to Th_2 with advancing age. This may underlie decreased cellular immunity seen with age. Delayed type hypersensitivity (DTH), a function of cellular immunity, is also decreased with age, and this is witnessed by reduced skin test reactivity. As DTH is responsible for controlling and eradicating intracellular pathogens, increased reactivation tuberculosis and herpes zoster, which are caused by intracellular pathogens, are seen with age.

Another striking feature of the aging immune system is an accumulation of dysfunctional T cells. A greater proportion of cytomegalovirus (CMV)-specific clonal expansion of CD8 cells is seen in the elderly. These cells are memory cells, and they are dysfunctional because of diminished ability to secrete interferon-γ after specific antigen stimulation.

Aging is also associated with accumulation of cellular damage caused by oxidative stress produced by aerobic metabolism within cells. Such oxidative stress leads to peroxidation and altered fluidity of the cellular membranes. Because the cell membranes are important components in signal transduction, a decline is observed in cell activation. For example, lymphocytes from older donors have measurable defects in the calcium signaling cascade. Such defects combined with lower synthesis of, and response to, interleukin-2 lead to poor proliferation of T cells. Fewer T cells from older humans progress through the cell cycle after activation, and even fewer cells then re-enter the cell cycle to continue proliferation.

Humoral Immunity

Humoral immunity is a function of B cells. Circulating B cell numbers remain constant throughout the life span. However, there are subtle changes in the site of production. New B cells are generated in bone marrow. However, in aged animals an increased proportion of peripheral B cells is generated from self-renewing clones of CD5+ marginal zone cells. In fact, the proportion of marginal zone B cells increases from 5% in young mice to 30% in older mice. As antibody repertoire depends on somatic hypermutation in new B cells generated in bone marrow and not on clonal expansion of marginal zone type cells, there is a shrinkage in antibody repertoire.

The levels of IgG and IgA may be elevated, while the levels of IgM typically are constant with age. Although the total amount of immunoglobulins are thus normal or slightly elevated, declines in specific antibody titers are noted. Also, in old animals, antibody production with low affinity for antigens is observed, which would further undermine the immune response. General characteristics of humoral immunity in the elderly include a longer time to development of peak antibody titers, a lower level of the peak titer, and a more rapid decline after immunization. Clinically, these changes in humoral immunity are evident by poor responses to vaccines as well as increased infections by infectious agents.

The dysregulation of immune responses, discussed previously, also accounts for the inappropriate appearance of antibodies to self-antigens (autoantibodies). Organ-specific antibodies, such as antithyroglobulin and antiparietal cell antibodies as well as non-organ-specific autoantibodies (e.g., antinuclear antibody [ANA] and rheumatoid factor [RF]), appear more commonly with advanced age. Circulating immune complexes may also increase with age. Curiously, the presence of these markers of dysregulated humoral immunity has less clinical significance in older patients. For example, young individuals found to have ANA are more likely to have associated illnesses, such as systemic lupus erythematosus, compared with older individuals with the same level of ANA.

Innate Immunity

Innate immunity, also termed natural immunity, does not require prior antigenic sensitization. Neutrophils, macrophages, and natural killer (NK) cells form the cellular component of innate immunity. The protective efficacy of these cells depends on their numbers, endothelial adherence, chemotaxis, and phagocytosis.

The number of neutrophils remains constant with increasing age, and so does the proliferative capacity of neutrophils in response to growth factors (e.g., CSF-GM and IL-3). However, neutrophil proliferation can be challenged under severe and persistent infection, which may overwhelm the proliferative capacity and result in neutropenia. Although *in vitro* immune function is relatively unaffected by age, fewer neutrophils arrive at the site of skin wounds in older people. Also, an age-related reduction in phagocytic capacity is observed. This reduction in phagocytic activity is thought to be due to decreased number of microbes ingested rather than a reduction in number of phagocytosing neutrophils.

Absolute numbers of macrophages remains unaffected by age. However, more macrophages are required to elicit optimal T cell response to a mitogen. Upon stimulation by interferon-γ, aged macrophages have reduced capacity to upregulate MHC class II molecules. Such decreased expression of MHC II molecules coupled with reduced interferon-γ signals

from T lymphocytes can undermine antigen presenter function of macrophages.

It is generally agreed that NK (natural killer or large granular lymphocytes) cell function remains unchanged with age, but NK cells increase in number, and so their activity on a per cell basis is though to be reduced with advancing age. In general it is believed that NK cells from elderly donors have defective response to cytokines with a limited subsequent capacity to develop lymphokine activated killer cells. Several experiments have shown that dietary supplementation of elemental zinc can significantly reduce age-associated decline in NK cell function, and this may translate to a reduction in infection relapse, highlighting the importance of nutrition for optimal immune function.

Secondary Causes of Immune Dysfunction

Changes seen in the immune system of healthy older people are relatively small. These changes confer a modest increase in the risk of developing infections. However, the observed impact of age on various infections is out of proportion to what might be expected from immunosenescence alone. Various secondary causes are responsible for this.

It is felt that the age-associated wear and tear of various organ systems predisposes the elderly to infections. Prolonged recumbence, along with a poor cough reflex, impaired ciliary function in respiratory epithelium, and impaired swallowing may predispose a frail older individual to pneumonia. A decreased function of alveolar macrophage may further aggravate the condition. Similarly, benign prostatic hypertrophy (BPH), which leads to stasis of urine in males, and the postmenopausal state in females contribute to urinary infections. These changes in addition to indwelling catheters or urinary and/or fecal incontinence may lead to urinary tract infections. Incontinence, poor integrity of skin, and delayed wound healing predispose to skin infections that are harder to treat.

Institutionalized elderly, who are exposed to many antimicrobial agents, develop infections with unusual and resistant organisms such as methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant *Enterococcus* spp. (VRE), and multiresistant Gram-negative rods that produce extended spectrum beta-lactamase (ESBL). Such infections are much more difficult to treat. It is important to remember that classic signs of infections may be absent in older people. Subtle changes, including minor changes in mental status or decreased activity, may be the only clinical indicator of underlying infection; more typical signs, such as fever, cough, or painful urination, might very well be absent. Due to slower rates of metabolism, older people may have a lower average body temperature, and fever may not be observed even with serious systemic sepsis. Instead, a change in body temperature is a more reliable indicator for development of pyrexia. It should also be remembered that hypothermia is an ominous sign in this age group. Thus, aggressive management of elderly with early use of potent antimicrobials is advocated by many, but this practice may increase the prevalence of infections with resistant organisms.

Most elderly have two or more coexisting chronic medical conditions and are likely to be receiving prescription medications for them. High blood pressure, diabetes, chronic lung diseases, cardiovascular diseases, cerebrovascular pathology, and various malignancies are commonly observed in the elderly. Analgesics, non-steroidal anti-inflammatory agents, corticosteroids, antithyroid medications, antibiotics, antipsychotics, antidepressants, hypnotics/sedatives, anticonvulsants, antihypertensives, diuretics, histamine blockers, hypoglycemics, and other medications (such as allopurinol) commonly prescribed in old age may suppress the inflammatory immune responses. Thus, both the comorbid illness and its treatment may play a role in diminishing immune function in older people.

Adequate nutrition is needed to maintain immune function. Both macronutrients and micronutrients, including vitamins and essential minerals, especially zinc and selenium, are important in this regard. Poor nutrition is correlated with lower lymphocyte counts. Absolute lymphocyte counts less than 1500 cells/mm^3 correlate with some degree of malnutrition, while a count less than 900 cells/mm^3 is associated with severe malnutrition and immunodeficiency. Malnutrition affects up to half of all patients with dementia, making it a widely prevalent problem. Furthermore, these patients have a fourfold increase in rates of infection. It has also been shown that nutritional intervention in malnourished ambulatory elderly leads to reversal of changes seen in immune function.

Stress and other psychological factors including depression may impair immunity. Social isolation and marital discord impair immune function. Also, it has been shown that chronic stress can impair immunity conferred by the influenza vaccine. Furthermore, improving social contact has been shown to favorably affect immune function by laboratory parameters.

Infections Commonly Seen in Elderly

Influenza

Influenza epidemics are a significant cause of morbidity and mortality in the elderly. Declining immune

function plays an important role in worsened outcomes. It is generally held that humoral immunity is responsible for prevention of influenza, while cell-mediated immunity is responsible for recovery from influenza by clearing the virus. Peak antibody titers, whether due to natural infection or vaccination, decrease with advancing age. Rates of development of protective antibody titers in response to vaccine decrease from over 60% in the young to 30% or less in the elderly. However, immunized elderly, although not absolutely protected, have less severe infections, and thus widespread vaccination programs are enthusiastically endorsed. The vaccine is cost effective, as it decreases the mortality and morbidity burden by two-thirds.

Pneumonia

Infections of the lower respiratory tract are one of the leading causes of morbidity and mortality in the elderly. Pneumonia, commonly observed in the elderly, is responsible for over half a million hospitalizations every year. The mean age of patients requiring hospitalization is over 70 years, and age alone is a risk factor for developing pneumonia. Prolonged recumbence, diminished swallow, and poor ciliary function are important risk factors of pneumonia. Many microorganisms are implicated in the pathogenesis of the diseases, but *Streptococcus pneumoniae* is by far the leading pathogen, with more than half of all cases attributed to it. The 23-valent pneumococcal vaccine is an attempt to contain the infection, especially in the era of multidrug-resistant organisms. The currently available vaccine is relatively weak, particularly in the elderly, and the absolute effectiveness has been questioned. However, it has been shown that there is a significant reduction in pneumococcal bacteremia in recipients of the vaccine, though it may not decrease the rate of infection. The vaccine should be administered to those over 65 years of age, and if they had any dose of vaccine before 65 years of age, a repeat dose should be administered 5 years after the initial dose.

Herpes Zoster

Herpes zoster is caused by varicella zoster virus. The virus resides within the nervous system (in dorsal root ganglia) and is held in check by competent immune function. However, with immune deficiency, such as in patients with cancer, transplant recipients, or those of advanced age, the virus is reactivated and cutaneous infection (shingles) is the result. Complications of zoster infection are more frequently observed in patients who are over 60 years of age, with postherpetic neuralgia being the most common and most disabling of these. A vaccine for zoster has recently been developed, and a recently published, randomized trial of this vaccine decreased the incidence of the disease by half and the incidence of postherpetic neuralgia by two-thirds.

Urinary Tract Infection

Urinary tract infection (UTI) is the most common infection observed in the elderly. Although usually mild and treated on an outpatient basis, UTI may also be responsible for sepsis and hospitalization in many, and even death in some cases. The prevalence of UTI increases from 2% in young women to 10% in women over the age of 65. Also, in males bacteriuria, which is almost non-existent at younger ages, increases to 5% in those over the age of 70 years, with the onset of benign prostatic hypertrophy (BPH). Including asymptomatic bacteriuria, UTI occurs in 25–40% of women and 15–40% of men in long-term care. Many elderly, especially institutionalized individuals, may have colonization of the urinary tract without any symptoms. Asymptomatic bacteriuria has not been shown to deteriorate health status, increase morbidity in terms of quality of life, or lead to renal dysfunction, nor has it been associated with an increase in mortality.

One-third of transfers from nursing homes to acute-care facilities are the result of UTIs. The predominant organism for urinary infection in elderly females in *Escherichia coli,* whether institutionalized or not, while *Proteus mirabilis* is the most common organism in institutionalized males. *Providentia stuartii* is an organism that is virtually found only in institutionalized individuals. Infection with this organism is more likely to be seen in several residents of a facility.

As mentioned previously, typical signs of UTI observed in younger patients (pain upon urination, symptoms of retention or incontinence, and fever) are frequently absent in elderly patients. Usual presentation of urinary infection is seen as classic dysuria, pyelonephritis, urinary retention, or new incontinence and fever with indwelling catheter. Complicating the clinical picture further, when fever occurs in a patient without urinary symptoms but with a positive urine culture, the positive predictive value of such a culture is only 12%, and thus caution should be exercised before attributing fever in these patients to a UTI. Similarly, non-specific functional decline in an older person could possibly reflect a new UTI, but the presence of a positive culture does not make this a certainty.

HIV

The mean age at the diagnosis of infection with the human immune deficiency virus (HIV) has increased

in last decade. Currently, 10–15% of all newly diagnosed cases of HIV occur in patients over 50 years of age, and 2% of all new cases are 65 years or older. Whereas earlier cases in older patients were associated more closely with transfusion risk, now the predominant form of HIV spread is sexual transmission.

Diagnosis and management of HIV infection in older individuals pose a substantial challenge. The diagnosis is less commonly considered and thus is often made later, and prognosis is thereby worsened. Presentation of HIV infection as AIDS-related dementia and neuropathy may be hard to distinguish from other cases of such syndromes based solely on symptoms, and HIV testing is often not employed with older adults. HAART (highly active antiretroviral therapy) has significantly improved outcomes in all age groups, although immunological recovery is less complete in older patients. Another challenge in the treatment of older adults with HIV is increased drug interactions and end organ damage.

Tuberculosis

More than 20% of the cases of tuberculosis occur in adults over the age of 65 years. However, in the cohort of elderly White males, the incidence of tuberculosis is now primarily in this age group (over 65 years), having doubled in 10 years from 29% of cases to 58%. Elderly individuals are four times as likely to develop tuberculosis as their younger counterparts. However, if they are nursing home residents, this risk is increased by an additional threefold.

Finally, with regard to diagnosis, it should be remembered that older people have less adequate delayed type hypersensitivity (defiant cell-mediated immunity), and thus skin tuberculin testing is a less reliable marker of infection, but should still be employed.

Cancer and Immunity

Cancer is a disease of older people; 60% of all cancer occurs after the age of 65 years, and this age group sustains 70% of all cancer mortality. Some have speculated that a decline in immunity is one of the many reasons, if not the most important reason, why cancer incidence increases with age. However, others have pointed to the types of tumors that occur most frequently in the elderly (prostate, colon, lung, breast carcinomas), which are quite distinct from the tumors seen in profoundly immune-deficient states (lymphoma, leukemia, and Kaposi's sarcoma). It is likely that the most important explanation for the increased incidence of cancer in old people has little to do with immunity and more to do with the prolonged time it takes to develop an invasive cancer (e.g., decades for most epithelial tumors). The role of immunosenescence in cancer development is at best questionable.

Immune Reconstitution

Efforts to improve age-reduced immune function have met with only moderate success. However, it should be recalled that the composite immune capacity of an older person is only altered in part because of advanced age. Greater negative impacts are more likely to be effected by the presence of comorbid illness, malnutrition, medications, or physical deconditioning. Nonetheless, the beneficial effects of certain efforts have been clearly demonstrated, whereas others have marginal effects or remain controversial. A brief summary of efforts at immune reconstitution follows below.

Nutritional Supplementation

Importance of adequate nutrition cannot be overemphasized. Assuring overall nutritional adequacy, including the supplementation of micronutrients, is the cornerstone of this approach. Various trials using laboratory indicators of immune function and infection rates have shown benefits of nutritional supplementation. It should, however, be noted that overzealous replacement of any one nutrient can lead to adverse consequences and may create problems with absorption of other nutrients. For example, very large doses of vitamin A can lead to toxicity, but its precursor beta carotene is considerably safer. Excessive zinc supplementation can interfere with iron absorption and lead to iron deficiency and anemia. What is an optimal supplementation? Iron deficiency is common in the elderly. Many studies have shown that zinc is essential to maintain function of the immune system. The daily need for zinc is about 25 mg, of which 11 mg is provided by diet, and so 14–15 mg/day of zinc may be an optimal dose. Many trials have studied vitamin E, a potent antioxidant. The optimal dose for vitamin E seems to be in the range of 200 IU. Also, 100 μg selenium, when given with zinc, reduces infections independent of vitamin supplementation. As pointed out earlier, large doses of any one nutrient may be harmful, and singling out any one nutrient may not be physiological, as with time, deficiency of the other nutrients may develop. Thus, an adequate approach would be a multivitamin and trace mineral supplement containing zinc (14–20 mg), selenium (100 μg), and vitamin E (200 mg). That stated, it should be further emphasized that optimal nutrition

remains incompletely understood, and contradictory studies for each of the mentioned nutritional supplements have been reported.

Vaccines

Various vaccines have well-established roles in prevention of infectious diseases at all ages. Pneumococcal, influenza, and tetanus vaccines are effective in preventing disease and decreasing mortality in the elderly. With age, the time to development of protective antibody titers after vaccination is delayed, peak antibody titers are lower, and there is a faster decline of the protective titers. Yet healthy elderly (without extensive comorbidity) may reach titers, although lower than observed in younger recipients, that are protective. Furthermore, even without reaching protective titers, when the target infection occurs, the clinical severity is likely to be less.

Exercise

The capacity for exercise to reconstitute age-reduced immunity remains controversial. Acute bouts of strenuous exercise are deleterious to immune function, but moderate aerobic activity has been correlated with better functioning, at least as measured by *in vitro* assays. Elderly who regularly exercise and are overall well conditioned have demonstrably better immune function. On the other hand, exercise programs undertaken after the onset of immune dysfunction do little to enhance immunity. Because many of the studies evaluating effects of exercise were cross-sectional, it remains to be determined if the better immune function observed in well-conditioned elderly is due to the effects of exercise or is a result of overall healthy lifestyle choices.

Novel Approaches

Various novel approaches to enhance immunity have also been tried, including hormonal replacement including thymic hormones, intravenous immunoglobulin, and caloric restriction. At present the data do not support the non-investigational use of any of these approaches.

Caloric restriction without malnutrition has produced promising results in murine models, showing prolonged survival and immune competence into late life. Similar studies in non-human primates are also ongoing and have shown encouraging results. The National Institute on Aging has recently initiated similar nutritional intervention studies in humans.

Summary

Diminished immunity in the elderly is complex and multifactorial. There is no question that aging itself diminishes endogenous immune function, but the clinical consequence of this degree of impairment is likely to be slight. Reactivation of latent infections, such as herpes zoster or tuberculosis, may be caused by this impairment, and certainly a diminished response to influenza and pneumococcal vaccines has been demonstrated in otherwise fit elderly. The typical geriatric patient, however, may have a more profound immune deficiency because of the coexistence of diseases, malnutrition, and the use of powerful medications. Such patients are clearly more susceptible to infection and possibly other diseases, including certain malignancies, on the basis of this composite immune deficiency. Efforts to reconstitute age-associated immune deficiency have had limited success; further research of the traditional approaches using rigorous clinical trial methodology as well as the development and investigation of novel approaches are warranted.

Information Processing/Cognition

B Bucur and D J Madden, Duke University Medical Center, Durham, NC, USA

Glossary

Attention – The limited resources or mental energy required for task performance, the selection of relevant information from the environment, the simultaneous division of focus between tasks or stimuli, or the monitoring of the environment for a particular event over an extended period of time.

Reaction Time (RT) – The minimum amount of time, measured from the onset of the stimulus to the execution of a response, needed to make a correct response.

Speed-Accuracy Operating Characteristic – Accuracy decreases as a function of increasing speed.

Introduction

Modern cognitive psychology and the information processing approach came into prominence during the 1960s due, in part, to the limitations imposed by behaviorism, the dominant paradigm in psychology at that time. By restricting explanatory constructs entirely to observable behavior, behaviorism led researchers to neglect mental processes used in memory, attention, and problem solving. At the same time that the information processing approach was flourishing, there was also a great deal of research being conducted examining the biological and cognitive changes in older adults. Thus, the information processing approach has long been used in the psychology of aging to investigate the cognitive abilities of older adults.

The first goal of this article is to provide a description of the information processing approach along with some of the methods used to investigate the various components of cognition. It then describes the use of these methods to investigate normal, age-related changes in a variety of cognitive domains along with a description of compensatory mechanisms used to offset some of these declines. The article concludes with a discussion of the cognitive neuroscience of aging, a relatively new field of science concerned with investigating age-related changes in the brain and how they relate to age deficits in cognitive performance.

Understanding Components of Complex Processes

In the information processing approach, reaction time (RT) is an important variable of interest. Reaction time is traditionally defined as the minimum amount of time, measured from the onset of the stimulus to the execution of a response, needed to make a correct response. Thus, we can observe variations in measurable aspects of behavior, especially RT, and from these variations make some inferences regarding the nature of the underlying mental events – the information processing architecture – leading to responses in perceptual and cognitive tasks.

Subtraction Method

In 1868, the Dutch psychologist Donders proposed the subtraction method as a procedure for estimating the amount of time occurring during mental events. The method involves subtracting the RTs between tasks structured to differ in specific ways. For example, consider three different RT tasks, Task 1, Task 2, and Task 3, illustrated in **Figure 1**. Task 1, a simple RT task, involves the presentation of a single stimulus and a single response, for instance, pressing a key whenever a light is presented. Task 2, go/no-go, involves presenting two stimuli along with a single response. In this task, a light could occur in either the left or the right position; however, a response would be made only if the light appeared in the right position. Participants would refrain from making a

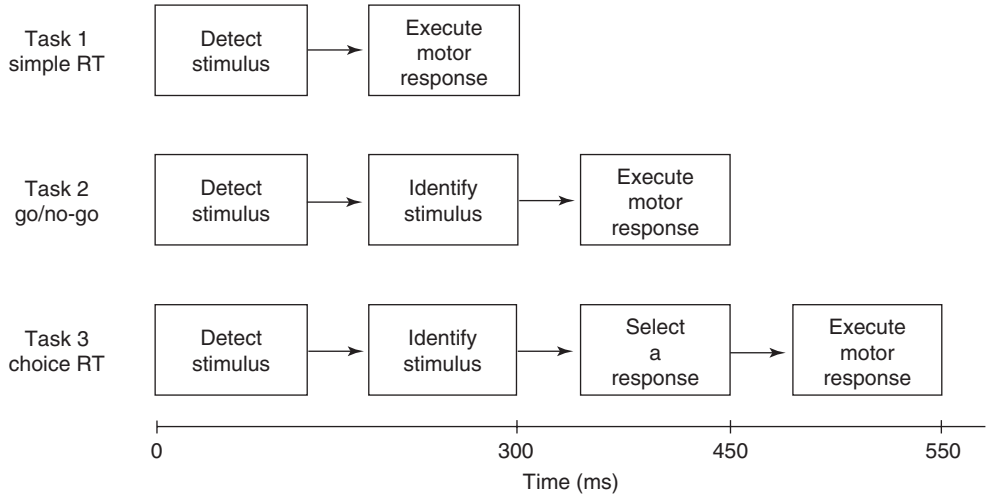

Figure 1 Donder's subtraction method. Tasks are constructed to isolate various processing stages. Task 2, for instance, takes longer than Task 1 due to the insertion of an additional processing stage representing the identification of the stimulus. To obtain the time required to identify the stimulus, the mean RT for Task 1 is subtracted from the mean RT for Task 2.

response when the light appeared in the left position. Finally, Task 3, choice RT, involves the presentation of two stimuli along with two responses, for instance, pressing one key when a light is presented on the right side of the computer screen and another key when the light is presented on the left side. This method is based on the assumption that Task 2 contains all the stages of Task 1 with an additional inserted stage representing the time required for stimulus identification. Further, this method assumes that Task 3 has all the same stages as Task 2, with an inserted stage representing the time needed to select a response. As shown in **Figure 1**, to estimate the amount of time needed to identify a stimulus, the mean RT from Task 1 is subtracted from Task 2. Similarly, subtracting Task 2 from Task 3 provides an estimate of the amount of time needed to select a response.

Note, however, that this method assumes that the only difference between each of these tasks is the addition of a single processing stage, either stimulus discrimination or response selection. A complication is that the insertion of an additional stage may in some instances also influence other stages of processing. Further, this method requires an *a priori* theory regarding the information processing stages required by a particular task.

Additive Factor Method

In contrast to the subtraction method, the goal of the additive factor method is to provide evidence for the existence of discrete processing stages rather than simply determining the amount of time required for processing at a particular stage. The additive factor method relies on the interpretation of the results in performance associated with particular variables (or factors) that can be varied systematically. These factors are features of the task, such as the degree of noise in the stimulus or number of responses, which can take on a number of empirical values. If factors have only additive effects on RT (i.e., statistical main effects), it is concluded that each of these factors is independent and affects separate processing stages. For example, if the increase in RT associated with increasing noise in the display, relative to a clear display, was the same regardless of the number of responses that were required, then it would be concluded that in this task the perceptual noise and response selection factors are additive and that the encoding and response stages are separate. In contrast, the finding of significant statistical interactions between pairs of factors (e.g., a greater effect of noise on RT when the number of required responses increased) represents a situation where the two factors are not separate and additive but instead interact, having some influence in a common processing stage.

This method was first used by Sternberg to investigate processes involved in short-term memory. In this experiment, participants viewed a memory set of sequentially presented digits and then after a brief delay saw a probe letter. Participants made a positive response if the probe was part of the previously presented memory set, otherwise they made a negative response. Sternberg studied the effects of several factors, including the visual quality of the digits (clear or degraded), memory set size (1–6 digits), response type (positive or negative), and response type frequency (e.g., percentage of trials in which a positive response was required). These various manipulations

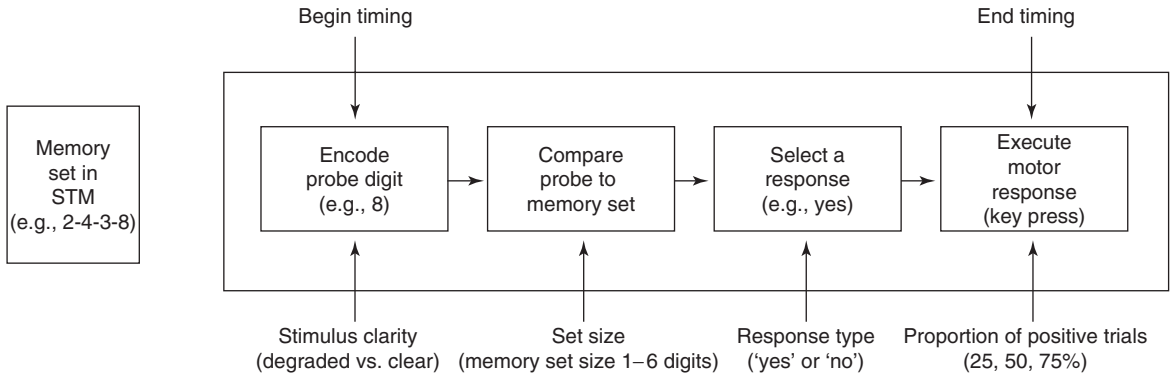

Figure 2 Additive factors methodology showing the factors proposed to affect various processing stages. Timing begins at the onset of the probe digit, after the memory set has been encoded, and ends when the appropriate key is pressed to indicate a response.

had additive effects on RT, suggesting that this task involved four processing stages, illustrated in **Figure 2**: an encoding stage; a comparison stage, in which the internal representation of the memory set is compared to the probe digit; a response selection stage; and a response execution stage, in which the observer executes a motor response by pressing the appropriate key.

From an information processing perspective, chronological age can be considered another factor, and the pattern of additivity and interaction, among age and other experimental variables, can be used to identify the locus of age-related change within a particular task. In the case of short-term memory, for example, interactions with age have been observed with virtually all of the stages. Age-related slowing is thus not restricted to peripheral processes of encoding and responding but is also associated specifically with the search through the items in short-term memory.

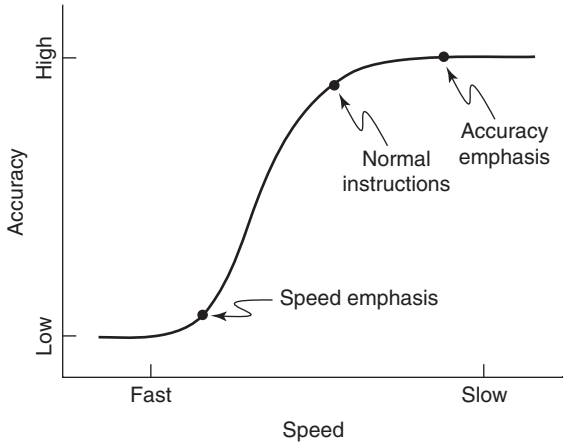

Figure 3 A speed–accuracy operating characteristic. Points on the curve represent the hypothetical results that would be achieved in an experiment placing varying degrees of emphasis on speed versus accuracy.

Speed–Accuracy Tradeoffs

As mentioned previously, RT is defined as the minimum amount of time that participants need to make a correct response. In practice, however, that minimum point is difficult to define. For any particular response, how can we be sure that the participant could not have responded more quickly and still have been correct? Thus, it is usually necessary to elicit a small proportion of incorrect responses, to provide some indication that participants are attempting to respond quickly. On the other hand, the majority of responses must be correct, to ensure that there is reliability in the RT data and that the participant is not simply guessing. Information processing tasks thus usually assume a particular relation between speed and accuracy. A typical pattern of results is that accuracy decreases as a function of increasing speed. This pattern can be observed empirically by requiring participants to place a varying degree of emphasis on speed versus accuracy. The speed–accuracy operating characteristic in **Figure 3** represents these results, with fast, inaccurate responses represented to the left and slow, accurate responses represented at the right.

One difficulty in interpreting age-related changes in RT is that different groups of participants may vary in their emphasis on speed versus accuracy, that is, in the relative proportion of errors they will accept in attempting to respond as quickly as possible. Thus, differences in RT between younger and older adults may not be due entirely to differences in processing speed but also to differences in setting a response criterion on the speed–accuracy function.

Distributional Analyses

The approaches just described typically use some index of central tendency (e.g., mean or median) to

summarize performance across many trials in each task condition. Typically, however, the RT data are not distributed normally but rather are skewed positively (i.e., extreme responses are more likely to be slow than fast). Thus, using a summary index ignores potentially important information in the data. By using the entire distribution of RTs, researchers found that age differences increased in magnitude for the slower responses in the distribution, a pattern thought to reflect age-related difficulties in concentrating or ignoring task-irrelevant information.

These types of distributional analyses are related to a more general emphasis on developing a formal model of the information processing components required by a particular task. Rather than focusing on the effects of individual variables, as in the subtraction and additive factor methods, formal modeling approaches emphasize the estimation of model-based parameters representing specific information processing components. Researchers can then test whether there is an adequate fit between the observed data (both RT and accuracy) and the values predicted from the model. If this fit is adequate, then the specific parameters are interpretable. For instance, a model may include different parameters for decisional processes, non-decisional processes (e.g., perceptual motor processes), and the amount of information and time required to reach a decision. Using this approach, several researchers have found that, compared to younger adults, older adults exhibit larger non-decisional components and require the accumulation of more stimulus information before initiating a response.

Generalized Slowing Explanations of Age-Related Decline

As noted previously, age-related slowing occurs in many aspects of information processing. An early study by Brinley raised an enduring question, regarding the degree to which age-related slowing is general or task-specific. It slowing is a general property of the aging central nervous system, then the types of task-specific analyses provided by information processing techniques may not be necessary. To investigate this issue, Brinley tested younger and older adults on a variety of tasks tapping verbal ability, arithmetic skills, and perceptual processing. In each if these categories, some tasks required shifting attention across trials while other tasks did not. When the mean RTs of the older adults, in each of the task conditions, were plotted as a function of the corresponding mean RTs of younger adults, Brinley found that the performance of older adults could be expressed as a highly linear function of the younger adults' RT ($r = 0.99$). In this type of analysis, currently known as a Brinley plot, slopes greater than 1.0 provide evidence that age-related decrements reflect declines in speed of processing, relative to younger adults. In other words, due to the aging process, older adults may exhibit a generalized decrement in speed of processing, rather than one associated specifically with certain information processing stages. Numerous studies using Brinley's technique provide support for these types of generalized slowing models. It should, however, be noted that not all researchers agree with the generalized slowing interpretation of the Brinley plot analysis and instead argue that the obtained slowing function represents the relative standard deviations in RT for older versus younger adults (**Figure 4**).

Building on this earlier work investigating slowing in older adults, Salthouse presented his processing speed theory, which proposed two mechanisms to explain the relationship between age-related changes in speed and age-related changes in cognition, a limited time mechanism and a simultaneity mechanism. The limited time mechanism represents the fact that older adults are not able to complete the processing of earlier operations in the available time, whereas the simultaneity mechanism represents the fact that due to slowing, the products of earlier operations are lost and become unavailable for use during later processing stages. An approach used by Salthouse and others is to assess the speed of processing independently, by having participants complete elementary perceptual-motor tasks such as simple RT, choice RT, or digit-copying tasks. Then, when assessing age

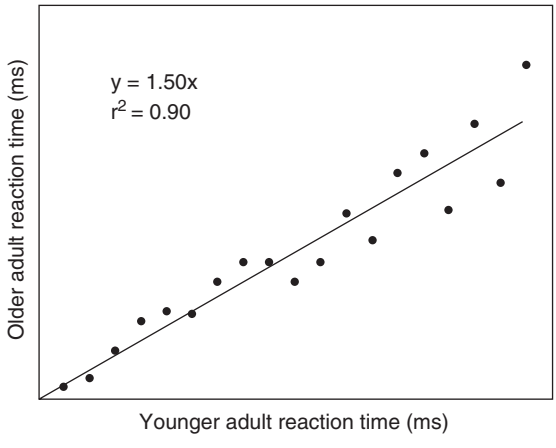

Figure 4 A Brinley plot showing the mean RTs for older adults plotted as a function of the mean RTs for younger adults. Reprinted from Madden DJ and Whiting WL (2004) Age-related changes in visual attention. In: Costa PT and Siegler IC (eds.) *Advances in Cell Aging and Gerontology,* p. 48, Copyright (2004) with permission from Elsevier.

differences in some outcome measure of cognitive performance, the mediating influence of elementary processing speed can be determined from hierarchical regression procedures. Using this approach with a variety of cognitive tasks as outcome measures, researches have found that the age-related variance in task performance was substantially reduced, or eliminated entirely, after controlling for processing speed, thus providing further support for generalized slowing.

Generalized slowing explanations are appealing because they provide a parsimonious explanation for the differences between younger and older adults. However, other explanations may account for these cognitive declines including reduced processing resources, inhibitory deficits, attentional control deficits, and reduced working memory capacity. Thus process-specific influences, as well as generalized slowing, are needed to explain age-related deficits in cognitive performance. The following sections on memory, attention, and problem solving will highlight several areas of cognition including task-specific versus generalized slowing explanations for age-related declines.

Memory

Difficulty remembering information is usually one of the first cognitive changes that people notice as they grow older. For instance, older adults may notice that they are misplacing their keys more frequently or are relying more often on calendars to remember appointments. Indeed, as noted previously, laboratory investigations of memory have found age-related declines on several processing stages within memory tasks. Not all aspects of memory, however, are affected equally by the aging process. To make sense of this diverging pattern of results, it is useful to understand some of the various structures that comprise the memory system.

Typically, long-term memory is subdivided into declarative or explicit memory and procedural or implicit memory. This distinction is based on whether information is intentionally retrieved (explicit) or whether information indirectly influences some other behavior, without the conscious retrieval of that information (implicit). Declarative memory is further subdivided into episodic memory (memory for specific episodes or contexts) and semantic memory (memory for general, context-independent knowledge). A typical finding is that smaller or non-existent age differences occur in tasks thought to measure implicit compared to explicit memory. However, within the explicit component of memory, dissociations are also found between semantic and episodic memory.

Explicit versus Implicit Memory

Explicit memory is traditionally measured using tests of recall and recognition, in which participants consciously refer back to the original learning or encoding of the material to complete the test. In contrast, implicit memory tests indirectly assess memory by having participants complete tests that are supposedly unrelated to the encoding condition. For example, in word stem completion, a commonly used implicit memory test, participants are provided with the first few letters of a word followed by a blank space (e.g., m a i). Participants are more likely to use the word 'maiden' to complete the stem if they had previously encoded that word rather than the more commonly occurring word 'mail.' Implicit tests such as word stem completion are useful in investigating learning that occurs indirectly, without conscious awareness. Researchers have often found that age-related decline is minimal for these types of implicit memory tests. Although under some conditions age-related decline for implicit memory does occur, it is generally the case that implicit memory is relatively spared in older adults.

Episodic Memory

Most research provides evidence that pronounced age deficits are observed for episodic memory – memory for specific, context-dependent information. An everyday example is remembering whether or not one has taken their medication that morning. In the laboratory, episodic memory is tested using recall and recognition tests. In these tests, which typically use accuracy as the variable of interest, participants are presented with lists of stimuli (e.g., pictures, words) and are instructed to try to remember the information over a period of time. In tests of recall, participants are then required to reproduce or recall the information, whereas on tests of recognition, participants are presented with stimuli, some of which were presented during the original encoding, and are then asked to determine whether the material was presented previously. A typical finding is that for tests of recall accuracy, large age deficits are found, whereas for tests of recognition accuracy, the age deficits are usually smaller or non-existent.

This pattern is believed to reflect the differential reliance by older adults on environmental support. Converging evidence for this idea has been obtained using the RT distribution approach described earlier. The effects of age in RT on a recognition memory test were completely eliminated after controlling for the fastest responses of the distribution, a finding consistent with a generalized slowing account of aging. For recall RT, however, age continued to be a

significant predictor of performance, a finding that supports the environmental support theory. Further, age differences are even more pronounced when older adults have to remember the specific source or context of the information, for instance, whether a news story was read in the newspaper or heard on the radio. Thus, an increased reliance on environmental support would be useful in offsetting a deficit in identifying the original context of memory information. As mentioned earlier, older adults also tend to be more distracted by irrelevant information, and environmental support would aid the ability to focus on task-relevant information.

Semantic Memory

Researchers have conceptualized semantic memory as being organized as a linguistic or conceptual map, consisting of a network of nodes or concepts linked together by a series of pathways. The degree of relatedness among concepts is expressed in terms of the length of the pathways. Thus, related concepts such as robin, bird, and fly would have relatively short pathways between them, whereas the pathway from robin to bulldozer would be relatively longer. Once a concept is activated (e.g., bird), activation tends to spread to other nearby nodes (e.g., wing, feather), thus activating them in the process. Further, it has been proposed that concepts that are activated frequently become strengthened and become easier to retrieve compared to concepts that are activated less frequently.

Age differences in semantic memory tasks such as vocabulary, general knowledge, and word identification tend to be small in magnitude, after controlling for slowing at the perceptual motor level. Researchers also use lexical decision tasks to investigate how information is stored and activated in semantic memory. In these tasks, participants are presented with a string of letters and are required to make a decision as to whether the letter string forms a word (e.g., bank) or a pronounceable non-word (e.g., tolph). A typical finding is that people are faster to respond to higher-frequency compared to lower-frequency words (i.e., the word frequency effect). Similarly, when memory information related to the target word is activated in advance (i.e., primed) by the presentation of a semantically related word, responses are faster than when the target word is not primed. These effects of word frequency and priming tend to be at least as great for older adults as for younger adults, implying a preservation of semantic memory functioning.

Although many components of semantic memory are relatively preserved with increased age, one common memory problem for older adults involves the retrieval of familiar information from semantic memory, for instance, the names of objects and individuals. One example of this is the tip-of-the-tongue (TOT) state, in which the individual is unable to retrieve familiar information but has the feeling that the information is available (i.e., is still located in semantic memory). Although both older and younger adults experience TOT states, laboratory investigations have found that older adults experience significantly more TOT states than younger adults. One explanation for increases in TOT states in older adults is the transmission deficit hypothesis. According to this hypothesis, connections between nodes become weak with increased age, resulting in impaired transmissions between nodes. The reason for age-related increase in TOT states is not entirely clear, but it may be related to the additional redundancy among pathways available for semantic information, relative to the pathways for linguistic sounds (i.e., phonology) that are needed to retrieve specific words.

Attention

Attention can be viewed in several ways: as the limited resources or mental energy required for task performance, the selection of relevant information from the environment (selective attention), the simultaneous division of attention between tasks or stimuli (divided attention), or the monitoring of the environment for a particular event over an extended period of time (vigilance). Many laboratory tasks as well as everyday tasks (e.g., driving) may comprise a combination of various forms of attention. Although older adults experience deficits in many attentional components, there is some preservation of attentional functioning with age as well. This discussion is restricted to the visual modality, which has comprised the majority of the published research reports, but related findings have also been observed in the auditory modality.

Processing Resources

One conceptualization of attention is that it is a limited supply of processing resources required for the performance of other cognitive tasks. In dual-task situations, for example, as the primary task becomes more demanding (e.g., driving under adverse conditions), additional attentional resources can be allocated to the primary task by reducing those being used by a secondary task (e.g., lowering the volume on the radio). Based on the results of laboratory dual-task experiments, researchers have proposed that age-related deficits on cognitive tasks are due to

reductions in processing resources (i.e., the resource deficit hypothesis). Performance in the dual-task condition is usually worse than when either task is performed separately, with greater decrements exhibited by older adults. To assess the cost of performing the two tasks separately, an attention operating characteristic (AOC) is constructed, with data from Task 1 plotted along the *x*-axis and data from Task 2 plotted along the *y*-axis. Task priority can be manipulated by including conditions in which participants prioritize Task 1, Task 2, or both tasks. The area above the AOC represents the cost of performing the two tasks simultaneously. A typical finding using the dual-task procedure is that older adults show a greater divided attention cost than younger adults.

The resource deficit approach has often been criticized due to the lack of an explicit definition of resources and how they are to be measured. Thus, researchers have specified particular components that could be considered resources, including speed of processing, working memory capacity, and inhibition. One of these proposed processing resources, working memory, has been conceptualized as the component of memory responsible for the simultaneous storage and processing of information. Researchers have proposed a model of working memory consisting of two components that maintain verbal/phonological and visual information in memory over time. This model of working memory also proposes an executive control system that coordinates and controls the flow of incoming information to these two systems. This proposal has been tested with tasks measuring verbal reasoning and spatial abilities using the hierarchical regression technique described previously. As predicted, the statistical control of working memory resources (as assessed by an arithmetic span task) attenuated the effects of age on both of the cognitive tasks.

Selective Attention

In visual search tasks, participants are required to identify a target item from among one or more distractor (i.e., irrelevant) items, with the total number of items in the display (i.e., display size) varying across trials. As display size increases, search becomes more difficult or less efficient. By varying display size it is possible to determine the relative efficiency of the search and whether specific types of attentional manipulations (e.g., providing a spatial cue) facilitate search. To illustrate, searching for a specific book among six books is much easier than searching for the same book among an entire shelf of books. The less efficient search among an entire shelf of books can be made more efficient by top-down (i.e., goal-directed) knowledge that the target book is located on the right side of the shelf. Further, a red book among a shelf of tan books will capture attention in a bottom-up or stimulus-driven fashion and will facilitate search if the red book also happens to be the book that one is looking for. Reaction time is analyzed as a function of display size. Efficient searches tends to have linear RT $\times$ display size slopes that are less than 10 ms per item; search slopes of 20–30 ms per item or greater indicate less efficient search.

Researchers interested in possible age differences in visual search performance have compared performance in feature search tasks, in which a target item is defined by a single feature (e.g., searching for a T among Os), to performance in tasks in which the target is defined by a conjunction of two features, for instance, searching for a T from among Ls and Fs. The general finding from this research is that larger age differences are found in conjunction tasks compared to feature search tasks in which target items tend to pop out from among the distractors in the display. Different forms of improving search efficiency, however, such as using consistent target and distractor colors within a block of trials, or cuing the spatial location of the target, tend to be at least as effective for older adults as for younger adults.

In addition to selecting relevant information, selective attention also involves the ability to inhibit irrelevant or distracting information. The Stroop task is often used to measure the degree of interference produced when participants are presented with irrelevant information. In a typical computerized version of this task, participants are presented with words printed in colored ink and are simply instructed to name the color of the ink in which the word is printed. Sometimes the identity of the word is congruent with the ink color (the word 'red' printed in red ink) and sometimes it is incongruent (the word 'red' printed in green ink). Thus, on incongruent trials, the relatively automatic process of reading must be inhibited in order to comply with the instructions of the task. For both older and younger adults, RT tends to be higher in the incongruent condition, with older adults showing greater susceptibility to Stroop interference than younger adults. This age difference remained even after using procedures to control for generalized slowing. In a variant of this task, researchers presented the color name in a neutral color that was spatially separated from a block of color (congruent or incongruent with the word). In this situation, older adults are similar to younger adults in being able to use the spatial information to successfully inhibit the irrelevant information, thus reducing Stroop interference.

Divided Attention

Age-related decline in cognitive tasks tends to be most pronounced when some division of attention is required. Attention can be assessed by having participants perform two tasks concurrently (the dual-task procedure), as mentioned previously, or by having them switch unpredictably between two different types of tasks (i.e., task switching). In a task-switching procedure, participants perform two different choice RT tasks in separate blocks containing only a single type of task and in blocks in which both tasks are randomly intermixed. For instance, one task may require participants to decide whether a digit is odd or even, while the other task may require participants to judge whether stimuli are smaller or larger than a computer monitor. Successful performance of this task requires various attentional control processes such as inhibiting the previously relevant task along with the activation of the current task. The results from this research show that older adults exhibit greater task-switching costs when switching between different single-task blocks (global task switching) compared to switching between tasks within a mixed block of trials (local task switching). Further, the costs associated with global task switching appear to be greater than those predicted by a model of generalized slowing, whereas the costs associated with local task switching are more consistent with a model of generalized slowing. Thus, consistent with some of the research investigating working memory performance, this research shows that older adults tend to show the most pronounced age-related decline on tasks that require a great deal of attentional control.

Sustained Attention

In sustained attention or vigilance tasks, participants are required to monitor the environment over an extended period of time while searching for a predefined target. One commonly used vigilance task is the Mackworth clock test. In this task, participants are required to monitor the movements of a pointer on a clocklike device over the course of an hour. The pointer typically moves one step at a time with relatively infrequently occurrences when the pointer moves two steps. The goal of the task is to detect all the two-step movements of the pointer. On tests of simple vigilance older adults typically do not show decrements in performance compared with younger adults. However, when complex vigilance tasks are used, for instance, detecting a small red square among larger red squares, age-related declines are observed, especially if the stimuli are visually degraded or presented at a rapid rate. Further, these age differences remain even with extensive practice on the task.

Problem Solving

Researchers interested in problem solving have been especially interested in how problem-solving abilities change as people age, because these abilities have typically been defined as fluid abilities and thus tend to show sharp declines with age. The processes required for the solution of any problem consist of three sequential stages: preparation, production, and judgment. During preparation, the initial state of the problem is identified and an internal representation of the problem is formed. Next, during the production stage, relevant information is retrieved from long-term memory to assist in the generation of an appropriate problem-solving strategy. Finally, during the judgment stage, the proposed solution is evaluated to determine whether the problem has been correctly solved. Age differences are typically observed in the first two sequences of problem solving because of age-related declines in working memory capacity and greater difficulty inhibiting irrelevant information. However, some research suggests that older adults tend to be more cautious, which would affect the judgment stage. Many investigations of problem solving rely on accuracy rather than RT measures and use the verbal reports of participants to reveal their problem-solving strategies.

The Tower of Hanoi task is one example of an information-processing task that measures how people solve problems. In this task, participants are presented with three pegs. The first peg contains three different-sized disks, A, B, and C. The largest disk (C) is on the bottom, the next largest disk (B) is in the middle, and the smallest disk (A) is on top. The other two pegs are empty. The goal is to move the three disks from the first peg to the third peg so that C is on the bottom, B is in the middle and A is on top, with the constraint that only one disk can be moved at a time and that a larger disk can never be placed on a smaller disk. Research comparing the performance of younger and older adults has found that initially older adults use more moves to obtain the correct solution and take longer to perform each move compared to younger adults. Both age groups, however, are able to improve their performance over several blocks of trials, indicating that this type of fluid ability can be improved through practice.

A current trend in cognitive psychology involves the investigation of everyday problem-solving abilities and how they may change as a function of increased age. Because everyday problems may be less abstract and more relevant to older adults,

researchers speculated that this type of problem solving would not show pronounced declines with age. In these tasks, participants are asked to solve a series of everyday problems (e.g., what would you do if you turned on your oven and after 10 minutes noticed that it was not getting warm?). Raters then judged the responses according to the overall quality of the response as well as the likelihood that the response would solve the problem. Even when the scenario involved realistic events, older adults still performed more poorly than either younger or middle-aged adults. Although older adults tend to perform more poorly than younger or middle-aged adults on a variety of problem-solving tasks, there is evidence that older adults can improve their problem-solving capabilities through the use of specific skill training and interventions.

Compensatory Mechanisms

It is possible for older adults to compensate for some age-related cognitive declines through practice and experience. In other words, the development of crystallized abilities through experience can offset some of the biologically based declines that are normally experienced on tests requiring fluid abilities. To investigate how older adults use compensation and expertise to offset losses, one researcher investigated how skilled older adult typists are able to maintain high levels of performance on the task of typing. In this sample of older and younger adults there was no correlation overall between age and typing performance. Participants completed a variety of tasks, including simple RT tasks and typing tasks, which varied the amount of text available to view while typing. The compensatory mechanism revealed in this study was that older adults had a larger eye–hand span, the minimum amount of preview needed to approximate normal typing speeds, than the younger adults. In other words, to compensate for declines in speed of processing, older adults were able to look ahead a few more extra text characters than the younger adults.

Cognitive Neuroscience of Aging

Cognitive neuropsychology involves investigating how various cognitive processes are linked to various structures in the brain. Although researchers have long been interested in these issues, the development of structural and functional neuroimaging techniques within the last 20 years has led to a rapid increase in our understanding of the brain–cognition relationship and how this changes as a function of increased age. Two widely used methods are positron emission tomography (PET) and functional magnetic resonance imaging (fMRI). In PET, changes in regional cerebral blood flow (rCBF) are measured from the tissue clearance of a radionuclide tracer, either at rest or during the performance of a cognitive task. The more recently developed technique, fMRI, measures changes in the blood oxygen level dependent (BOLD) signal. The BOLD signal (which is correlated with cerebral blood flow), is obtained from an MRI scan, using magnetic field and radio frequency pulses, and thus avoids the administration of a radionuclide tracer. Both PET and fMRI measure the changes occurring in gray matter (i.e., cortical regions) during task performance. These cortical regions, however, are interconnected by white matter tracts that may also undergo changes as a function of age, thus impairing the transmission of information between brain regions. Researchers interested in changes in white matter integrity use a recently developed technique called diffusion tensor imaging (DTI). This method measures the displacement of water molecules across tissue and thus allows researchers to investigate changes in white matter integrity as a function of age.

Using fMRI, researchers have proposed that a frontoparietal brain network is involved in the performance of attentional tasks that require the use of top-down attentional control processes. Deep gray matter structures such as the thalamus and basal ganglia are also thought to play a role in attentional processing through connections with the frontoparietal network. These investigations suggest that age-related decline occurs in the activation of the occipital cortex. In addition to decreased activation in visual areas, increased activation is often observed in the frontoparietal attentional network, especially the dorsolateral prefrontal cortex. Further, increased activation of deep gray matter along with parietal cortex have also been observed for older adults. A similar pattern of results has also been found using PET in a comparison between selective and divided attention performance in younger and older adults. Larger age differences were found in RT and accuracy on the divided attention task, compared to the selective attention task, as well as in rCBF. For younger adults in the divided attention task, greater activation was obtained in the occipital cortex, whereas for older adults, greater activation was obtained in the prefrontal cortex (PFC). Based on these results, researchers have proposed that older adults compensate for declines in areas of basic visual processing (occipital cortex) by recruiting additional areas in the frontoparietal network.

Imaging procedures are also used to investigate the brain regions activated during memory tasks. For

instance, researchers interested in brain regions involved during episodic memory have found that for younger adults, brain activity tends to be greater in the left PFC during encoding, whereas during retrieval, the right PFC shows greater activation. For older adults, however, bilateral activation has been observed during both encoding and retrieval. This reduction in asymmetry may be another form of compensatory mechanism. Studies have supported this hypothesis by demonstrating that increased bilateral activation is associated with better performance on the cognitive task.

Investigations of white matter tracts have also yielded important information regarding the relationship between declines in cognitive tasks and deterioration in white matter tracts that impair the transmission of neural information between cortical regions. Using DTI, researchers have found greater declines in the integrity of the white matter in anterior regions compared to more posterior regions. Interestingly, these declines in white matter integrity were associated with decreased performance on cognitive tests requiring a high level of attentional control.

Conclusions

Older adults experience age-related declines in many areas of cognition, but these declines are not universal; they instead represent a complex pattern of stability and loss. Although losses have often been explained in terms of a generalized slowing account, it is clear from the research that process-specific as well as generalized slowing models are needed to account for these age differences. Recent advances in neuroscience will allow researchers to combine the information-processing approach with imaging techniques such as fMRI and DTI, leading to a better understanding of the brain–cognition relationship and how this changes as people grow older.

Inhibition

J M McDowd, University of Kansas Medical Center, Kansas City, KS, USA

Glossary

Distraction – The state of having been diverted from a previous focus of attention, usually by some other, irrelevant stimuli.

Facilitation – The cognitive process by which relevant information is given priority in the limited-capacity information-processing system.

Inhibition – The cognitive process by which irrelevant information is prevented from gaining access to the limited capacity information-processing system.

Selective Attention – The interaction of facilitative and inhibitory processes that control the focus of information processing, allowing the individual to concentrate on relevant information and ignore irrelevant information.

Visual Search Paradigms – Any of a variety of tasks that require the individual to locate a target item in a display containing both relevant and irrelevant items.

Introduction

Because the momentary capacity of the human information-processing system is limited, access to the system must be controlled so that relevant information is processed and irrelevant information is not. Selective attention is typically the mechanism that controls access to the processing system. This mechanism is hypothesized to involve both the facilitation of relevant information and the inhibition or suppression of irrelevant information (e.g., irrelevant sensory stimuli). Breakdowns in inhibitory function result in distraction and an associated decline in information-processing efficiency. Thus, in the domain of cognitive function, inhibitory processes are thought to facilitate the selective processing of information to maximize the behavioral efficiency of the individual.

Inhibition in Information Processing

In the context of adult development and aging, the notion that altered inhibitory function might underlie many age-related cognitive changes has been considered since the 1950s. Birren (1959: 37) stated the notion of inhibitory decline "has heuristic value for many reported age differences." Pavlov hypothesized that age-related declines in inhibitory function produced the difficulties he observed on the part of older adults in discrimination learning tasks, in extinguishing previously learned responses, and in the control of language functions. In the intervening decades, a number of lines of work have been initiated to further examine the role of inhibitory function in age differences in cognitive abilities. Although initially postulated as a general age-related deficit potentially underlying many of the cognitive changes associated with age, the conclusion from a considerable body of work is that age-related inhibitory deficits are observed in some tasks but not in others, thus circumscribing its explanatory utility.

Physiological Indices of Inhibition

The Orienting Response

Studies of the autonomic orienting response (OR), a complex pattern of physiological changes elicited by novel and/or significant stimuli, provide one approach to understanding the role of inhibition in information processing. These studies assume that the OR indexes the engagement of attention and that the magnitude of the OR indexes the extent to which attention is engaged. A further assumption is that inhibitory processing modulates the OR in line with current task demands and behavioral goals. That is, when information is no longer significant or novel, the OR is suppressed. An age-related inhibitory deficit would thus manifest itself as a pattern of ORs that continue to be elicited even after novelty or significance has worn off, or that are elicited in response to stimuli that are not relevant to the current circumstances.

Studies using the OR to index attention and the suppression of attention in young and old adults have provided some evidence for an age-related decline in the efficiency inhibitory function. For example, in a task requiring individuals to attend to some stimuli and ignore others, young adults showed evidence of differential orienting, but older adults did not. That is, to-be-ignored stimuli elicited the same physiological response in older adults as the task-relevant information, indicating a failure of inhibitory processes to modulate and suppress a response to the irrelevant information. This pattern of results suggests that older adults are less efficient in the

control of attention and so may be less efficient information processors (*see* Attention).

Brain Activity and Functional Imaging

Inhibitory processes in cognition are typically associated with the frontal lobes of the brain, more specifically, the dorsolateral prefrontal cortex (DLPFC). Two types of approaches have been applied to understanding the brain activity associated with inhibitory processes in aging. In the first approach, inhibitory task performance of older adults is compared to that observed in people with DLPFC damage. Findings from this approach indicate significant similarity between the two groups, suggesting that the function of the DLPFC is impaired even in normal aging and that it may be responsible for age-related inhibitory deficits.

The second approach involves functional imaging of brain activity during inhibitory task performance. Using fMRI technology, the brain areas active during inhibitory tasks can be identified, and age groups can be compared in terms of this activation. Although few studies have been published in this area, there is evidence indicating that both young and older adults show activation of the prefrontal cortex when engaged in a go/no-go task requiring inhibition of responses. However, older adults appear to show more extensive activation, in areas not activated by young adults. This pattern of findings may reflect compensation for altered inhibitory function among older adults, and appears to be a promising area for future research.

Behavioral Indices of Inhibition

Visual Search

Selective attention is the mechanism that facilitates the processing of relevant information and suppresses irrelevant information. Failures of selection result in the capture of attention by irrelevant information, commonly called distraction. Many studies in the literature have indicated that older adults are more susceptible to distraction than young adults, and these studies have been used as evidence to bolster the hypothesis that older adults are less able to inhibit irrelevant information than young adults.

In Patrick Rabbitt's classic work on age and distraction, young and older adults sorted cards on the basis of prespecified letters printed on the card. Rabbitt observed that the presence of irrelevant letters arranged randomly around the card slowed the sorting times of older adults more than it did for young adults. He concluded that the older adults were less able to avoid distraction than young adults. By implication, therefore, altered inhibitory processes have been deemed responsible for producing this pattern of results.

Rabbitt's work was followed by other studies designed to explore the parameters that determined the presence and extent of any age-related increase in distractibility. Visual search tasks have frequently been used to assess the efficiency with which individuals can locate and/or identify a target in the presence of distracting, non-target information. One of the generalizations that has emerged from this work is that when selection and suppression can be guided by physical cues such as color, shape, or location, older adults perform comparably to young adults. However, when there is uncertainty about what or where to attend to, older adults are typically at a significant disadvantage relative to young adults.

A similar pattern of results has been observed with the Stroop task. This task requires individuals to name the color in which a color word is printed. For example, if the word 'red' printed in green ink is presented, the task is to name the color 'green' and inhibit responding to the word 'red.' Older adults typically have more difficulty with this task than young adults, suggesting less efficient inhibitory processes. However, when the to-be-named color and color word are separated in space, inhibition of the color word appears to operate comparably in young and older adults. Together, these results suggest that age-related declines in the efficiency of inhibitory function seem to be modulated by task parameters that affect the ease of discriminating between relevant and irrelevant information.

Negative priming is another procedure that was thought to offer an index of efficiency of inhibitory function. Indeed, negative priming was one of the most common tests of age-related inhibitory decline in the 1990s. In this procedure, which involves targets and distractors, a distractor stimulus that is to be ignored on one trial becomes the to-be-attended stimulus on the subsequent trial. Empirically, it has been observed that responding is slowed in the trial sequence just described relative to a sequence in which there is no relationship between targets and distractors on subsequent trials. This lengthening or reaction time is termed negative priming. The initial theoretical interpretation of this phenomenon is that because the distractor stimulus is inhibited on the initial trial, processing that same stimulus on the subsequent trial will take longer because the effects of the previous inhibition will have to be overcome. Within this interpretation, the magnitude of the slowing, or negative priming, is then used to index the strength of inhibitory function. Subsequent work, however, has shown that the negative priming effect

can also be interpreted in terms of episodic retrieval processes, or in terms of a mismatch in a target/distractor tagging process. Because it is very difficult to disentangle these potential interpretations of age differences, negative priming has been virtually abandoned in the cognitive aging literature as a measure of inhibitory function.

Eye Movements

Although it still has a relatively small literature, eye movement technology has also been used to examine inhibitory function in young and old adults. For example, in the antisaccade task, participants are instructed to suppress the prepotent tendency to look toward a sudden-onset visual stimulus but to look in the opposite direction instead. The timing, extent, and direction of eye movements are measured using technology designed to reveal direction of gaze on a moment-by-moment basis. Because voluntary eye movements have been shown to be under the control of brain areas including the dorsolateral prefrontal cortex, the antisaccade task has been viewed as an index of both behavioral inhibition abilities and the integrity of the brain structures that underlie those abilities. Findings indicate that older adults are less successful at the antisaccade task than young adults because they have difficulty suppressing the strong tendency to first look toward the stimulus before they move their eyes in the opposite direction. These findings reveal an age-related inhibitory deficit that is mediated by the DLPFC. Eye movement technology is a powerful tool for evaluating hypotheses related to attention and aging; assuming the direction of gaze reflects the focus of attention, such technology can provide more direct measures of attention and distraction than are possible, for example, using only reaction time measures.

Working Memory

Inhibitory processes have also been hypothesized to play an important role in working memory and related language functions as they change with age. Inhibitory processes are assumed to limit the activation of semantic information for the task at hand. If inhibitory processes are operating at suboptimal efficiency in older adults, then irrelevant information may be activated and may serve to functionally reduce the capacity of working memory by unnecessarily taking up space there.

Studies using language materials with ambiguous interpretation have been used to test these ideas about inhibition, working memory, and language function. For example, ambiguous prose that might be interpreted in two or more ways is presented, followed by disambiguating information. Inhibitory efficiency is indexed by measures of the availability of the incorrect interpretation in working memory. This availability may be measured in priming tasks or implicit memory tasks. Several studies have shown that irrelevant information remains active longer in older adults than in young adults, reducing working memory capacity and decreasing the efficiency with which language information can be processed. It has been proposed that declining inhibitory function is responsible for these age-related changes. However, this conclusion remains controversial; on the basis of reinterpretation of these findings along with new findings, other reviewers have concluded that there is relatively little evidence for an age-related inhibitory deficit in language processing (*see* Memory).

Inhibition in the Social Arena: Verbal Communication

Inhibition not only suppresses selected inputs but also acts to control such outputs as inappropriate behaviors, which might otherwise interfere with normal social interactions. One area in which altered inhibitory function might affect social interactions is verbal communication. There is some evidence suggesting that older adults are more likely than young adults to exhibit off-target verbosity in conversation or related forms of communication. Older adults appear to be more vulnerable to the intrusion of personal experiences and memories into consciousness. Instead of gating out this information, they may include it in social exchanges regardless of its relevance to the topic at hand. One outcome of this verbosity might be reticence on the part of others to engage a verbose individual in conversation, which contributes to some level of social isolation of the verbose person. Thus, inhibitory deficits, if truly contributory to this pattern of interactions, can have negative consequences for the social well-being of older individuals.

Studies including measures of both off-target verbosity and psychometric measures of inhibitory processes have indicated a relationship between the two. That is, those individuals who score higher on verbosity measures do less well on the measures of inhibitory function. Although this relationship suggests a causal role for altered inhibitory efficiency in communication verbosity, other factors may also play a role. An individual's expectations about the constraints on the conversation, the relationship between conversation participants, and lifelong conversation patterns may all influence the direction a conversation may take. Specifying the precise role of

inhibitory processes remains for further study (*see* Language and Communication in Aging).

Inhibition in Mental Health: Selective Processing of Information

A number of mental health problems have been associated with reduced attention control. For example, in obsessive-compulsive disorder, depression, and schizophrenia it has been suggested that the intrusion of irrelevant or unwanted material into consciousness may contribute to cognitive inefficiency and/or psychological distress. Cognitive theories of depression hold that depressed individuals may be besieged by negative thoughts that overpower normal inhibitory processes. The depressed individual thus perceives or recalls primarily negative information, which in turn perpetuates the depressive episode. Although this view of depression is still controversial, a variety of studies using tasks such as the Stroop task are consistent with the hypothesis that depressed individuals have less efficient inhibitory control. The data on whether this deficit is exacerbated by age-related declines in inhibitory control are also a matter of some controversy. Among the few studies that have addressed this question, some report no greater deficits in older depressed individuals, whereas others have suggested that aging and depression have interactive effects to produce the greatest negative impact on behavior. Clearly, more work needs to be done to answer this important question regarding the combined effects of aging and depression on inhibitory function (*see* Depression).

Inhibitory dysfunction has also been identified as a fundamental component of the cognitive deficits associated with schizophrenia. Inhibition has been studied in individuals with schizophrenia using procedures similar or identical to those used to assess age effects: physiological orienting and habituation, negative priming, sensory gating, the Stroop task, and continuous performance tasks. The pattern of results indicates that inhibitory deficits in older adults and in individuals with schizophrenia are very similar. Unfortunately, very few studies have explicitly examined the combined effects of aging and schizophrenia on inhibitory function. Data from the few studies that have been conducted suggest that the deficits seen in older schizophrenics are greater than those seen in either normal aging or schizophrenia alone. Again, however, more work needs to be done before any strong conclusions can be drawn about the combined effects of aging and schizophrenia on inhibition in cognitive function (*see* Mental Health).

Summary and Conclusions

A variety of studies have provided evidence suggesting that inhibitory function declines with advancing age. However, a number of issues must be considered before any global statement can be made about aging and inhibitory function. For example, inhibitory processes can be observed at many levels of nervous system function, from synaptic connections to overt behavior. Evidence indicates that there are multiple types of inhibition and/or multiple inhibitory mechanisms that may play a role in age differences in inhibitory function. Age differences are observed on some tasks but not others. A fuller understanding of inhibitory function in aging requires the development of specific models that can integrate these various findings and that can be put to empirical test.

A second issue concerns the validity of measures of inhibitory function. In many cases, tasks that are assumed to measure inhibition need to have that assumption tested. The case of negative priming is a good illustration of tasks whose outcome is open to multiple interpretations. Most data collected with such tasks are not useful for evaluating inhibitory function, and much care is needed in order to assure the validity of assessments of inhibitory function.

And finally, individual differences in inhibitory function across age groups need to be understood and explained. Age does not perfectly predict inhibitory efficiency, and the other relevant factors must be identified in order to better understand the contribution of inhibitory function to cognitive aging.

Intelligence

M Lövdén and U Lindenberger, Max Planck Institute for Human Development, Berlin, Germany

that development of intellectual abilities can be mapped onto biological versus cultural ensembles of influence.

Glossary

Covariance Dedifferentiation – Stronger associations between the fluid mechanics and the crystallized pragmatics in old age as compared to young adulthood.

Crystallized Pragmatics – Content-rich abilities strongly driven by cultural systems of influence; typical examples are verbal knowledge and professional expertise.

Directionality Dedifferentiation – Decline in both the fluid mechanics and the crystallized pragmatics seen in very old age.

Fluid Mechanics – Abilities representing measurable outcomes of biological influences on intellectual development; basic information processes that are content poor and universal, such as processing speed and working memory.

Terminal Decline – Changes in intelligence associated with impending death. These changes may reflect causal structures other than those underlying normative age-graded changes, including cognition-influencing diseases.

Two-Component Models of Life Span Cognition – Models of intelligence disputing the existence of a unitary general intelligence construct and positing

Introduction

This article summarizes psychometric theorizing and evidence about intelligence in old age, with a focus on normal aging. First, two-component theories of life span changes in intelligence are introduced, and evidence regarding average population age gradients in intellectual abilities is summarized. Then, hypothesized normative and basic determinants of decrements in intellectual performance in old age as well as the extent and possible causes of individual differences in such decrements are reviewed. Finally, evidence is highlighted suggesting that many aging individuals possess sizable capacity for learning and plasticity, despite aging-related losses in average intellectual performance.

Two-Component Models of Life Span Changes in Intelligence

Two-component models of life span changes in intelligence posit that development of intellectual abilities can be mapped onto biological versus cultural ensembles of influences (see **Figure 1**). Typical contemporary examples for two-component models are the distinction between fluid and crystallized intelligence advanced by Raymond B. Cattell and John

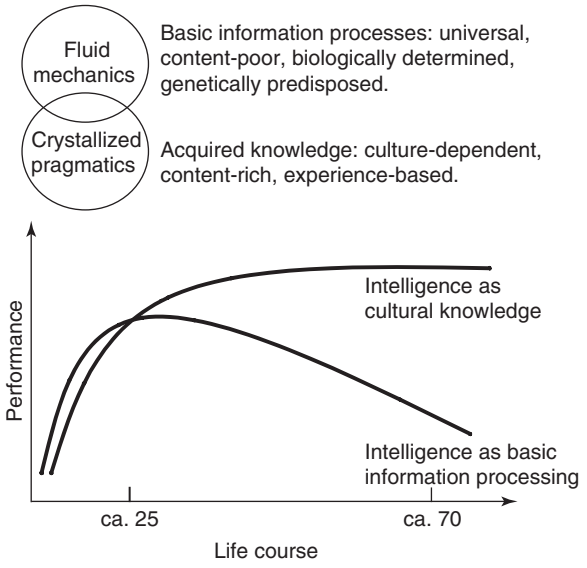

Figure 1 Two-component models of cognition. The top section defines the two categories of intellectual abilities and the bottom section illustrates postulated life span trajectories. In very old age, the trajectories become less differentiated because the fluid mechanics increasingly constrain the acquisition, expression, and representation of pragmatic knowledge.

Horn and the decomposition of cognition into mechanics and pragmatics proposed by Paul Baltes. Two-component models of life span changes in intelligence have a long history dating back to Johann Nicolaus Tetens (1736–1807), a philosopher and psychologist of the enlightenment era who noted that well-trained skills are less likely to decline with advancing age than the basic abilities underlying their acquisition. Thus, and most importantly, two-component theories dispute the validity of a unitary general intelligence construct in understanding intellectual development across the life span. Instead, at least two broad, ontogenetically intertwined but separable categories of abilities are needed to describe the basic properties of intellectual development.

The first collection of intellectual abilities represents measurable outcomes of the influence of the biological component on development. It manifests itself in cognitive processes involving extrapolation, reorganization, and transformation of novel information (i.e., reasoning) and in basic information processes such as working memory (i.e., the ability to maintain information online while manipulating it), processing speed (i.e., the speed with which elementary processing operations can be performed), and cognitive control (i.e., the top-down coordination and control of lower-level processing). Henceforth, these processes are referred to as the fluid mechanics of intelligence.

The second, more disparate category of intellectual abilities refers to procedural and declarative knowledge common to a given culture (e.g., verbal knowledge), but also to specialized and sometimes highly idiosyncratic (person-specific) knowledge such as occupational expertise, as well as to knowledge about the meaning and conduct of life. Henceforth, these processes are referred to as the crystallized pragmatics of intelligence. For examples of specific abilities and functions related to each of the two components, see **Figure 2**.

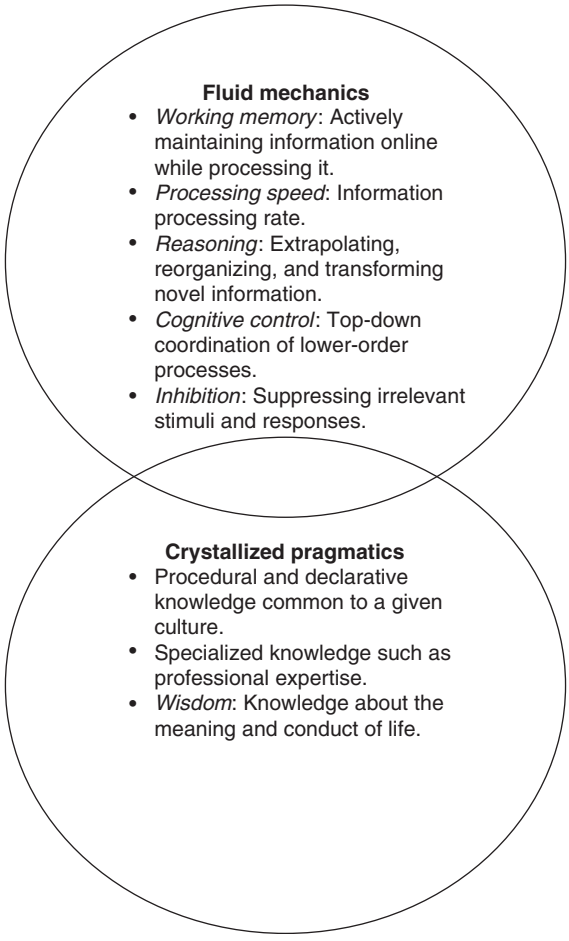

Figure 2 Exemplary functions and abilities in the broad domains of the fluid mechanics and the crystallized pragmatics.

Average Aging Patterns of Fluid Mechanics and Crystallized Pragmatics

The fluid mechanics are expected to decline after maturity. In contrast, the crystallized pragmatics are proposed to increase over the life span as long as knowledge maintenance and knowledge acquisition outweigh the adverse consequences of losses in the mechanics (see **Figure 1**). Empirical evidence is largely consistent with these propositions. Starting in young or middle adulthood, cross-sectional evidence

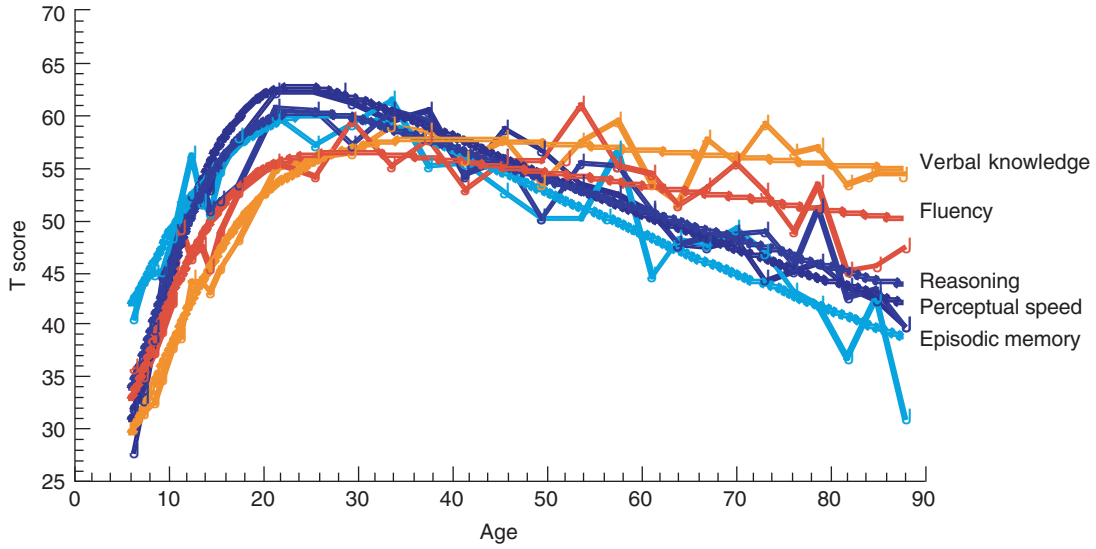

Figure 3 Cross-sectional life span age gradients for five different intellectual abilities. Verbal knowledge is a marker of intellectual ability from the domain of the crystallized pragmatics, whereas reasoning, perceptual speed, and episodic memory are intellectual abilities from the domain of the fluid mechanics. Fluency is generally regarded as a hybrid intellectual ability because it requires fast access to stored knowledge. The empirically observed age gradients are consistent with two-component theories of life span cognition. Adapted from Li S-C, Lindenberger U, Hommel B, Aschersleben G, Prinz W, and Baltes PB (2004) Transformations in the couplings among intellectual abilities and constituent cognitive processes across the life span. *Psychological Science* 15: 158.

reveals continuous decrements for abilities in the broad fluid domain. Age gradients in the domain of the crystallized pragmatics show greater variation within and between individuals in the transition from early to late adulthood, with the modal patterns of increments in young adulthood typically followed by asymptotic plateaus in middle and late adulthood, until modest decrements are discernible in old age (e.g., around 60–80 years of age) or very old age (e.g., over 80 years of age). For illustration, see **Figure 3**.

The maintenance of levels of intellectual performance in abilities belonging to the crystallized pragmatics well into old age is not confined to psychometrically assessed intellectual abilities from this domain such as verbal knowledge. Rather, maintenance is also observed for specialized and person-specific bodies of knowledge and for knowledge about the meaning and conduct of life. For example, reasoning about difficult life problems (e.g., a 14-year-old pregnant girl seeking advice) is unrelated to chronological age from early adulthood up to old age, and older individuals with an idoneous constellation of enabling personality dispositions, life experiences, and cognitive styles are among the top performers.

Longitudinal findings suggest a greater degree of similarity between the age gradients of the fluid mechanics and the crystallized pragmatics than cross-sectional evidence. Here, the fluid mechanics show decelerating increases across young adulthood, peaks in middle age, and accelerating declines thereafter. The dominant pattern of the pragmatics is one of stable, or even increasing, performance until old or very old age. Note, however, that longitudinal findings are often obtained from individuals who show more positive changes than the population from which they originate, and that retest effects may further bias age gradients in the positive direction.

In summary, and as predicted by two-component theories of life span cognition, available evidence underscores the multidirectionality of adult intellectual development. Considerable decline in the fluid mechanics and stability followed by late-life decline in the crystallized pragmatics constitute the classical pattern of the aging of adult intelligence.

The Dedifferentiation Hypothesis

The onset and amount of decline in the crystallized pragmatics during the transition from old to very old age is more variable than the divergence in age gradients between the fluid mechanics and the crystallized pragmatics observed during earlier periods of the life span. Whereas some studies report small negative age trends in crystallized pragmatics during early old age, with noticeable decrements appearing only at later ages, others report age-related decrements starting at about age 50. There is general agreement, however, that the preservation of crystallized pragmatics often observed for groups of older adults does not generalize to groups of very old

individuals. That is, for the period from early to late adulthood, cross-sectional evidence reveals monotonic decline in the fluid mechanics but stable or increasing performance levels for the crystallized pragmatics. However, in very old age, negative age gradients generally prevail for both the fluid mechanics and the crystallized pragmatics. Hence, in very old age, the difference in the directionality of the age gradients diminishes and eventually ceases to exist. In relation to the life span development of the fluid mechanics and the crystallized pragmatics, this pattern has been termed directionality dedifferentiation. Importantly, this pattern of directionality dedifferentiation also holds for longitudinal data. Furthermore, age-associated changes in the structure of intelligence are consistent with the notion of stronger relations among different intellectual abilities in old age relative to early adulthood. This finding has been referred to as covariance dedifferentiation.

A long-standing hypothesis in life span developmental research asserts that the functional organization of intellectual abilities undergoes decompression (differentiation) during maturation and again becomes more compressed (dedifferentiated) in old age. The differentiation-dedifferentiation hypothesis promotes a dynamic and process-oriented view of the structure of intellectual abilities. During childhood and old age, the operations and expressions of the diversity of cognitive abilities are posited as being constrained by the developmental status of the biological substrates of intelligence. In contrast, during maturation and in adulthood, biological-developmental constraints are relaxed, and other factors, such as interest and educational opportunities, occupy more prominent roles as determinants of individual differences in intellectual performance and development, leading to greater diversity in levels of functioning in different abilities. In old and very old age, the space of intellectual abilities becomes again increasingly dominated by an ensemble of common biological constraints on intellectual development. In terms of the two-component view of life span intelligence, old age decrements in abilities belonging to the domain of the crystallized pragmatics are induced by decline in the fluid mechanics. Put differently, the biological changes indicated by declines in the fluid mechanics hinder the acquisition, expression, and representation of pragmatic knowledge in old age when falling below thresholds that may vary from skill to skill. Conversely, at higher levels of functioning, development of the crystallized pragmatics is more dependent upon cultural-experiential factors, though biological factors continue to play a role.

The dedifferentiation hypothesis was sparked by early findings of increasing associations among different intellectual abilities from early adulthood to old age. More recent empirical evidence has generally bolstered the early findings, but some prominent exceptions are also available. Importantly, recent findings by Paolo Ghisletta and Ulman Lindenberger support the specific account of the dedifferentiation hypothesis, suggesting that decline in the fluid mechanics ultimately limits the acquisition, expression, or maintenance of the pragmatics in old age and thus drives late-life decline in the crystallized pragmatics. It follows that, with advancing adult age, between-person differences in levels of crystallized pragmatics, such as verbal knowledge, are increasingly determined by the functioning of the fluid mechanics, such as processing speed. Thus, in old age, expressing, maintaining, and acquiring knowledge are more and more dependent on biological vitality.

Basic Determinants of Decline in Fluid Mechanics

If decline in the fluid mechanics drives late-life decline in the crystallized pragmatics, then what drives decline in the fluid mechanics? Recent decades have witnessed a great number of predominantly cross-sectional studies attempting to identify information-processing mechanisms that act as domain-general pacemakers of decline in the fluid mechanics in old age. Among the most prominent constructs are processing speed, working memory capacity, and the ability to suppress irrelevant information (inhibition). Evidence supporting each of these three constructs as primary determinants of decline in a wide variety of fluid mechanics is available. However, all three constructs are relatively weakly grounded at the neurophysiological level, suffer from difficulties in making differential predictions, and often have been investigated in age-heterogeneous cross-sectional data sets, which are severely limited in inferential conclusiveness. Strengthening the link between aging changes at behavioral and neuronal levels of analysis probably offers a more viable route toward the identification of domain-general mechanisms of decline in the fluid mechanics.

In this vein, the emerging field of the cognitive neuroscience of aging has highlighted the central role of adult age changes in neuromodulation for intellectual aging. In particular, theoretical work by Shu-Chen Li and colleagues using neurocomputational modeling has suggested that age-based reductions in levels of the neurotransmitter dopamine is

apt to explain key phenomena of intellectual aging such as decrements in mean levels of performance, greater age deficits with more difficult tasks, lower maximum levels of performance, as well as increments in covariation between tasks across individuals, performance fluctuation, and interindividual differences. In addition, there are strong empirical relations among dopamine markers, adult age, and intellectual performance.

Morphological alterations and decreases in brain volume of the prefrontal cortex also have been associated with normal aging. Given that brain activity in the prefrontal cortex is functionally related to performance in central abilities of the fluid mechanics, such as reasoning and working memory, these findings suggest that anatomical, chemical, and functional changes in the prefrontal cortex and associated neuronal circuitries play a central role in late-life intellectual decline. Brain alterations in the medial temporal lobe and diencephalic systems are observed to a lesser extent with normal aging and appear to be more specifically linked to the onset and progression of age-associated dementing illnesses.

Normative and Non-normative Influences on Intellectual Development in Old Age

Average age gradients and the search for basic determinants of cognitive decline in old age serve important purposes. However, to understand the development of intelligence in old age, it is necessary to unpack the ingredients contributing to a particular score, for a particular individual, at a particular point in time. Intellectual development in old age is shaped by a wealth of additional developmental sources such as learning history, health status, distance from death, onset of pathology, and non-normative events, all of which are only loosely linked to chronological age. Thus, as suggested by Paul Baltes and others, three distinct but overlapping influences on intellectual changes in old age need to be set apart: normative age-graded influences, normative history-graded influences, and non-normative (idiosyncratic) influences. Normative in this context refers to influences that are relatively general to the population of aging individuals, such as declines in basic determinants of the fluid mechanics. Age-graded influences refer to those biological and environmental factors that are highly related to age and therefore shape the intellectual aging processes of most individuals. History-graded influences differ across birth cohorts, historical periods, or both. For example, substantial associations between birth cohorts and intelligence scores have been observed during the past century at the age of enrollment into military services. Finally, non-normative influences are more or less individualized conditions and events (e.g., rare illnesses, winning a lottery).

Between-Person Differences in Old-Age Intellectual Change: Risk and Protective Factors

Differences in intellectual performance between individuals are pronounced in groups of older individuals. In addition to stable differences in levels of intellectual performance, which are large throughout life, between-person differences in intellectual changes are also substantial within old age and are actually more pronounced in old age than during earlier periods of the adult life span. Furthermore, for the periods of old and very old age, between-person differences in change tend to be greater for the fluid mechanics than for the crystallized pragmatics, suggesting a predominantly biological origin. The following sections list some of the causal factors that contribute to the diversity of developmental patterns in intellectual functioning observed in old and very old age.

Terminal Decline

One important source of between-person differences in intellectual development in old age is terminal decline, denoting changes associated with impending death. These changes may reflect causal structures other than those underlying normative age-graded changes, for example, specific cognition-influencing diseases or global breakdowns of the biological system. Mounting evidence points to an association between performance on intelligence tests and longevity as well as between changes in intelligence and mortality. Importantly, directionality dedifferentiation might be driven by a subset of individuals in close proximity to death. Put differently, in a person entering the terminal decline phase, the crystallized pragmatics may grow increasingly dependent on the fluid mechanics, whereas the intellectual ability structure of a person of the same age who is more distant from death may remain more differentiated.

The existence of mortality-related changes in intelligence is suggestive of profound heterogeneity in development and warns against the uncritical practice of averaging individual differences in intelligence over a particular age. Average trends based on groups that are made up of mixtures of different types of individuals may yield a picture of intellectual development in old age that approximates, at best, an unknown proportion of the individuals constituting

this mixture. Thus, a focus on the individual, or at least on subgroups of individuals, is needed to understand intellectual development in late adulthood and old age. In the case of distance to death, aging-related changes and dying-related changes are confounded when performances of relatively healthy individuals and individuals experiencing terminal decline are averaged. Of course, if some of the causal structures promoting intellectual decline in old age are indeed mortality related, one would expect most individuals to sooner or later evince a pattern of dedifferentiation; that is, from a life span perspective, normally aging and terminally declining individuals do not denote mutually exclusive groups, but different sections of a developmental pathway.

Preclinical Dementia

Dementing illnesses, such as dementia of the Alzheimer type, are often preceded by a prolonged preclinical phase. During this period of time, dementia-related cognitive deficits are present but have not yet reached a diagnostic threshold. For instance, cognitive impairments several years prior to diagnosis have been shown to be sensitive markers of later dementia diagnosis. Preclinical cognitive deficits tend to be global, with impairments in episodic memory apparently being most prominent. Furthermore, impairments in functions that are normally relatively well preserved in old age, such as the crystallized pragmatics, may distinguish early dementia from aging. Given the accelerating increase of dementia incidence in old age, the proportion of individuals with preclinical dementia in the population is also bound to increase. This age-associated increase in the proportion of individuals suffering from preclinical dementia has led researchers to reconsider conclusions about normative age-related changes in intelligence. In analogy to removing individuals with terminal decline, removing individuals who later will develop dementia reduces the estimated size of the negative relation between intellectual performance and age.

Other Diseases

Many specific health-related conditions that affect intellectual performance increase in old age. Much research has addressed the effects of disorders to the circulatory system on intellectual performance. In general, this research has shown that circulatory disturbances, ranging from hypertension and cardiovascular conditions to stroke and vascular dementia, have profound effects on the brain and intellectual performance, especially in the fluid mechanics. Medial-temporal structures such as the hippocampus and related intellectual functions such as episodic memory appear to be especially sensitive to cardiovascular conditions including hypertension.

Elderly adults with diabetes tend to evince impaired intellectual performance. Furthermore, non-diabetic older individuals who have impaired glucose tolerance tend to show similar but less pronounced impairments in performance. Thus, there might be a continuum of intellectual performance deficits in diabetes that progresses from subclinical to the clinical phase.

As in earlier age periods, depression is related to lower performance on intelligence tests in old age. Again, the severity of depressive symptoms is related to intellectual performance, with individuals suffering from depressive symptoms performing at higher levels than clinically depressed individuals but at lower levels than non-symptomatic individuals.

Finally, various markers related to nutrition show an association with intellectual performance in old age. For example, relatively small (e.g., subclinical) deficiencies in vitamin B_{12} and folic acid appear to negatively affect intellectual performance.

Engaged Lifestyle

On the positive side, older individuals living an engaged and active life on average perform better on tests of intelligence than less active individuals. In addition, changes in intellectual performance in old age are associated with changes in lifestyle factors, such as engagement in leisure activities, activities in a social context, and intellectually stimulating activities. When analyzing longitudinal data from the Berlin Aging Study with dynamic modeling techniques, Martin Lövdén, Paolo Ghisletta, and Ulman Lindenberger recently provided direct evidence for the widely held but untested assumption that staying mentally and socially active attenuates intellectual decline in old and very old age.

The mechanisms through which engaged lifestyles influence intellectual development in old age are not yet well understood. The disuse hypothesis proposes that changes in lifestyle during old age (e.g., retirement, loss of spouse, and subsequent social isolation) may result in reduced levels of mental stimulation and subsequent magnification of cognitive decline. The cognitive reserve hypothesis asserts that life experiences during earlier periods of the life span, such as educational attainment, provide greater readiness for compensatory changes in response to age-related and disease-related neurophysiological decline and thus contribute to the resilience of late-life intelligence. Finally, lifestyle factors may also modify the course of neurophysiological changes underlying intellectual aging in more direct ways. For instance,

mechanisms of neuronal plasticity (see below) may function more efficiently in individuals with engaged lifestyles.

Most likely, several of these causal paths are operating in concert. Some of the behaviors associated with engaged lifestyle, such as physical activity and healthy nutrition, may reduce age-related negative influences on non-neural components of the brain, such as vascular changes including decreased blood flow, oxygen extraction, and glucose transport. For instance, mental stimulation may directly influence neurophysiological processes, whereas physical exercise may improve brain functioning indirectly but effectively through the cardiovascular route. Recent evidence based on animal models suggests that the two forms of stimulation may interact and reinforce each other.

Genetic Influences

Examination of associations between genetics and intellectual functioning in late life has been divided into two types. One class of studies has examined the overall influence of genetic variation by comparing dizygotic and monozygotic twins. In general, heritability in intellectual functioning (i.e., between-person differences accounted for by genetic differences) increases from about 35% during childhood to about 80% in middle adulthood. In old age, heritability tends to decrease to about 60%, perhaps pointing to a gradual breakdown of genome expression during the postreproductive period of the human life span. The other class of studies has focused on the role of specific genetic polymorphisms on intellectual functioning in old age. Here, the gene coding for the apolipoprotein E (APOE) has received most attention because carriers of a variant of this gene are considerably more likely to develop dementia. Even in samples of older adults screened for dementia, genetic variations in the APOE polymorphism are related to intellectual functioning. It remains to be seen whether this association reflects the presence of preclinically demented individuals. The influence of genetic variations on individual differences in neuronal organization and intellectual functioning is likely to become an active area of research in coming years.

Intellectual Plasticity in Old Age

Intellectual plasticity, or the ability to improve one's intellectual performance through experience (e.g., learning), continues to be present in healthy old age. For instance, training programs targeted at intellectual performance in the domain of the fluid mechanics do indeed lead to performance improvements. However, training gains are considerably smaller in older adults than in young adults. For instance, after instruction and training in a mnemonic technique for the recall of word lists, the distributions of young and older adults' memory performances become close to non-overlapping. In very old age, training gains are further restricted in size and compromised in quality.

Intellectual plasticity in old age probably reflects, for the most part, reactivation of existing and, to some extent, acquisition of novel intellectual strategies, rather than modification of fluid mechanic efficiency per se. As a consequence, positive transfer of training gains in a specific intellectual task to other tasks from the same or related intellectual abilities is generally small or absent. On a more promising note, recent aerobic fitness interventions with healthy older adults have been found to positively affect performance on a range of cognitive tasks that impose high demands on executive functions or cognitive control, that is, on mechanisms that are at the heart of the fluid mechanics. These positive changes appear to be accompanied by structural and functional alterations in relevant parts of the brain such as areas in the prefrontal cortex. Future research needs to further examine the amount, mechanisms, and moderators of neuronal and behavioral plasticity in late adulthood and old age.

Conclusion

Intelligence is a multidimensional construct that undergoes structural transformation from early to late adulthood and advanced old age. Two-component theories of life span intelligence posit two broad systems of influence, one biological and the other cultural. In early adulthood, the biology-based fluid mechanics and the culture-based crystallized pragmatics of intelligence are loosely coupled and display different age gradients, with decline for the fluid mechanics and stability or increase for the crystallized pragmatics. In old and very old age, declines in the fluid mechanics compromise the acquisition, expression, and representation of the pragmatic knowledge. The onset and nature of this transition differ from person to person and may be more dependent upon distance from death or cognition-related pathology than upon distance from birth. In the course of their lives, individuals experience unique constellations of normative, age-graded, and nonnormative influences. Intelligence is not necessarily structured similarly in different individuals just because they happen to be born at similar points in time. General regularities across groups of aging individuals in patterns of intellectual change in old and very old age can be discerned after sources of individual differences, such as

age-related pathology and terminal decline, have been identified and taken into account. Thus, understanding intellectual development in old age requires a multivariate, dynamic, and person-centered perspective.

International Perspective on Gerontology

G M Gutman, Simon Fraser University, Vancouver, Canada

Glossary

HelpAge International (HAI) – A global network of not-for-profit organizations whose mission is to work with and for disadvantaged older persons.

International Association of Gerontology and Geriatrics (IAGG) – National multidisciplinary societies concerned with research and training in gerontology and geriatrics.

International Association of Homes and Services for the Ageing (IAHSA) – Links organizations and individuals providing services for older persons, including shelter care as well as services designed to enable seniors to remain in the community.

International Federation on Ageing (IFA) – More than 100 organizations representing or serving older persons at the grassroots level including government agencies, for-profit groups, and individual members.

International Longevity Centers (ILCs) – A Network of independent, not-for-profit think tanks established to assist individuals and societies to address increased longevity and population aging in positive and productive ways and to highlight the contributions of older persons to their family and nation.

International Network for Prevention of Elder Abuse (INPEA) – Includes representatives from 12 countries with a commitment to worldwide prevention of elder abuse.

International Psychogeriatric Association (IPA) – Individuals and organizations whose direct concern is the mental health of the elderly, including representation from 67 countries.

Introduction

For the last several decades, international gerontology has largely centered on the activities of a relatively small number of non-governmental organizations (NGOs) that link organizations and individuals across the world that have aging and the aged as their primary focus. These NGOs include multidisciplinary professional associations such as the International Association of Gerontology and Geriatrics; specialized professional associations and networks such as the International Psychogeriatric Association and the International Network for Prevention of Elder Abuse; and advocacy/relief organizations such as the International Federation on Ageing, HelpAge International, and Help the Aged. More recently, the International Longevity Centers, a network of independent think tanks, has emerged. Paralleling these, disease-specific advocacy/support organizations such as Alzheimer's Disease International and the International Osteoporosis Foundation have been established, as well as federations of senior citizens' organizations such as the International Federation of Senior Citizens Organizations, the European Federation of Older Persons, and AGE, The European Older People's Platform.

This article begins with a description of selected international NGOs focused on aging, arranged chronologically in order of their establishment. This is followed by a description of key United Nations (UN) activities and agencies concerned with aging issues, which comprise the second major component of international gerontology. These include the 1st and 2nd World Assemblies on Ageing, the 1st NGO World Forum on Ageing, the UN Programme on Ageing, the World Health Organization's Ageing and Life Course Programme, and the International Institute on Ageing, UN–Malta. The article ends with a brief description of some international educational initiatives in gerontology/geriatrics and speculation on future developments of the field at the international level.

International NGOs Focused on Aging

International Association of Gerontology and Geriatrics (IAGG)

The IAGG, the primary international multidisciplinary professional association in the field, was formed and registered in Liege, Belgium in 1950 as the International Association of Gerontological Societies. Several years later it became known as the International Association of Gerontology (IAG), a name it held until 2005, when, reflecting changes in its composition over the years, its name was changed to the International Association of Gerontology and Geriatrics (IAGG). Members of the IAGG are national multidisciplinary societies concerned with research and training in gerontology or geriatrics. Until 2005, with the exception of the United States and United Kingdom, only one society per country was admitted to membership. Currently, the IAGG has 71 member organizations, in five regions and 64 countries, with a combined membership of over 46 000.

The objectives of the IAGG are the promotion of gerontological and geriatric research, training in the field of aging, and interests of member organizations in international affairs. These objectives are accomplished through special projects, a newsletter, a World Congress held every 4 years, as well as regional congresses that take place midway between World Congresses. The first World Congress of IAGG was held in Liege, Belgium in 1950. The next two, which will be the 19th and 20th, will take place in Paris, France in 2009 and in Seoul, Korea in 2013.

The IAGG is governed by a council consisting of representatives from each member society, their number determined by a formula based on the number of members enrolled in the society. The Executive Committee, consisting of the President, Secretary-General, Treasurer, Past-President, President-Elect, as well as regional chairpersons for Asia-Oceania, Europe, North America, and Latin America and the Caribbean, hold office for the period starting with the end of each World Congress and extending to the beginning of the next. The secretariat also

changes location every 4 years, moving to the country of the president.

The IAGG is a category III NGO with respect to the UN. At this level, the organization is recognized as a consultative source that can influence policy decisions. The IAGG is regularly consulted by both the UN Programme on Ageing and the World Health Organization's Ageing and Life Course Programme as well as other UN agencies such as the International Labor Organization, Pan American Health Organization, United Nations Development Program, and United Nations Population Fund. It has partnered with these organizations in the development of key programs, publications, and conferences. Recent examples include the *Research Agenda on Ageing for the 21st Century* and the Valencia Forum, an international scientific conference held immediately before the 2nd World Assembly on Ageing.

International Federation on Ageing (IFA)

The IFA was established in 1973. Its current membership includes more than 100 NGOs representing or serving older persons at the grassroots level, government agencies, for-profit groups, as well as individual members. Sixty-two countries are represented in its membership. Through its project and advocacy work, it seeks to influence and promote positive change for older people globally.

There are two categories of membership: full members and associate members. Full members comprise local, regional, provincial/territorial, or national non-governmental associations, including for-profit organizations, working with or representing the interests of older people. Fees vary according to the annual operating budget of the organization. Associate members may be individuals or groups but do not have voting privileges.

Since 1993, the IFA has held biennial global conferences. Its information dissemination activities also include two regular publications: *Intercom*, a newsletter that focuses generally on policy and practice and their impact on older persons and describes ongoing activities of the IFA and its affiliates, and *Global Ageing: Issues and Actions,* which devotes its two issues per year to special topics (e.g., in 2005 issue 1 was focused on elder abuse and neglect and issue 2 on Latin America's place in global aging).

The governing structure includes three elected officers (President, Vice-President, and Past-President) and a 16-person board of directors. Paid staff of the permanent secretariat, located in Montreal, Canada include a Secretary General, a Director of International and Corporate Relations, and two project officers.

International Psychogeriatric Association (IPA)

Founded in 1982, the IPA is composed of individuals and organizations whose direct concern is the mental health of the elderly. Membership was approximately 1200 in 2006, with representation from 67 countries. Individual members include psychiatrists, psychologists, nurses, primary care physicians, occupational therapists, social workers, and other health-care professionals. The IPA's objectives are to promote research and education, facilitate an international exchange of ideas on psychogeriatric issues, and foster cross-cultural understanding of the latest developments in the field. These objectives are achieved through publication of the *IPA Bulletin* and the journal *International Psychogeriatrics* as well as by hosting an International Congress every 2 years. Additionally, regional meetings are convened annually or biennially.

The IPA is governed by a 20- to 25-member Board of Directors, no more than two of whom reside in the same country. Individual members, like full members, pay dues, may hold office, and have full voting rights. Organizations or institutions wishing to exercise voting rights must designate an individual as its representative. The IPA's registered office is in Illinois.

It maintains relationships with many regional, national, and international organizations, including the World Health Organization, the World Psychiatric Association, Alzheimer's Disease International, the European Association of Geriatric Psychiatry, IAGG, and the World Federation of Neurology.

HelpAge International (HAI)

Established in 1983, HAI is a global network of not-for-profit organizations whose mission is to work with and for disadvantaged older persons. This is accomplished by supporting programs, giving a voice to older persons, and influencing policy at local, national, and international levels. Originally formed by agencies in five countries (Canada, Colombia, India, Kenya, and the UK), the HelpAge network now consists of more than 70 affiliated organizations in 50 countries.

HAI has two regular publications, both published twice a year: *Ageways*, which features practical information on aging and development, particularly good practices developed by affiliated organizations, and *Ageing and Development,* which is targeted to policy makers, program planners, and researchers concerned with development and poverty reduction. Additionally, regional newsletters are published three or four times a year. These include *Aging in Africa*, *AgeNews Asia/Pacific*, *Kyrgyzsian Newsletter,* and *Moldova Newsletter.*

HAI is governed by a Board of Trustees, which includes representatives of affiliated organizations. It has a secretariat with offices in London, Brussels, and the United States, maintains five regional centers (in Africa, Asia/Pacific, Latin America, the Caribbean, and Eastern Europe/Central Asia), and supports seven national programs and a number of emergency programs.

International Association of Homes and Services for the Ageing (IAHSA)

IAHSA, founded in 1994, links organizations and individuals providing services for older persons. These include shelter care options (e.g., independent living, assisted living, hostels, group homes, nursing homes, retirement villages) as well as services designed to enable seniors to remain in the community (e.g., adult day care, home care, home nursing). While IAHSA is a non-profit organization, its membership includes all ownership types, including profit, not-for-profit, and governmental, ranging from single-site facilities to associations representing large numbers of service providers. The IAHSA network extends to over 12 000 service providers in approximately 30 countries.

Three major foci for IHASA are the workforce, technology, and new care models. Activities include organizing an international conference every 2 years and partnering with other organizations on special projects. IHASA has an ongoing relationship with the Center for Aging Services Technologies (CAST) with respect to research and development of assistive technology and with the Institute for Future of Aging Service, an applied research unit of the American Association of Homes and Services for the Aging (AAHSA), concerning the long-term care workforce.

IAHSA is governed by a 15-member Board of Directors. Its staff consists of an Executive Director, Director of Professional Development, Program Administrator, as well as the President and CEO of AAHSA, in whose Washington, DC offices IAHSA's secretariat is located.

International Network for Prevention of Elder Abuse (INPEA)

INPEA, founded in 1997, in Adelaide, Australia at the 16th World Congress of the IAGG, has four main objectives:

1. to promote public awareness of abuse and neglect of older persons
2. to promote education and training of professionals and paraprofessionals in identification, treatment, and prevention
3. to engage in advocacy on behalf of abused and neglected elders
4. to stimulate research into the causes, consequences, prevalence, treatment, and prevention of elder abuse and neglect.

At the time it was established, representatives from 12 countries were recruited. Currently, INPEA has an organizational structure that includes an international slate of officers, six regional representatives (for Africa, Asia, Europe, Latin America, North America, and Oceania), 32 national representatives, four special advisors and, as is the case with most of the other international gerontology organizations listed here, a representative to the UN and to the Committee on Aging in New York. (The Committee on Ageing is a subcommittee of CONGO, the Committee of Nongovernmental Organizations in Consultative Status with the UN. Like the UN, it has branches in New York, Geneva, and Vienna.) In 2002, INPEA became a Standing Committee of the International Association of Gerontology and Geriatrics.

As part of its commitment to worldwide prevention of elder abuse, INPEA is dedicated to global information dissemination. Toward this end, INPEA produces a quarterly newsletter, available in both print and electronic formats. Research activities include a study, undertaken in partnership with the WHO Ageing and Life Course Programme, of older persons in community and primary health-care settings in eight countries (Argentina, Austria, Brazil, Canada, India, Kenya, Lebanon, and Sweden). The report, entitled *Missing Voices: Views of Older Persons on Elder Abuse*, was launched at the 2002 2nd World Assembly on Ageing in Madrid. Projects in progress include an environmental scan of information, resources, and services worldwide on issues of abuse of older adults. Called *World View on Elder Abuse and Neglect*, the goal of the project is to identify gaps and develop interventions and strategies to fill them. World Elder Abuse Awareness Day, which takes place on June 15, was initiated by INPEA in 2006.

International Longevity Centers (ILCs)

The ILCs are a network of independent, not-for-profit think tanks established to assist individuals and societies to address increased longevity and population aging in positive and productive ways and to highlight the contributions of older persons to their family and nation. The first two were established in 1990, in the United States and Japan. These were followed in chronological order of establishment by ILCs in the UK, France, the Dominican Republic,

India, and most recently (2005) Argentina. The centers work collaboratively and independently and each has a separate website describing its activities.

International Networks of Seniors Organizations

In addition to the organizations described previously, which are comprised of groups and individuals who work for seniors, there are a number of international networks of senior citizens organizations. These include the European Federation of Older Persons (EURAG), which was founded in 1962 and which has members in 32 European countries, and the International Federation of Senior Citizens Associations (FIAPA), which was established in 1971 as an international NGO linking seniors organizations in French-speaking countries in Africa, Asia, Europe, and the Indian Ocean. Additionally, there are organizations that serve as umbrella groups both for national and regional organizations of older persons and for organizations promoting the rights of older people. Examples include AGE, the European Older People's Platform. Established in 2001 to promote the interests of older people in the European Union, AGE is open both to EU national and regional organizations of older persons and organizations working for older persons. Readers should also see the website of the AARP for information on its Global Aging Program. While technically a national organization, AARP has had longstanding involvement in international gerontology. The same is true of Help the Aged, a UK charity that designates approximately 25% of its expenditures to overseas work, much of it in partnership with the HelpAge International network.

UN Aging-Related Activities and Agencies

1982 and 2002 World Assemblies on Ageing

The UN has convened two watershed gatherings concerned with aging and the aged. The first was a World Assembly that took place in 1982 in Vienna. The resulting *Vienna International Plan of Action on Ageing* (*Vienna Plan*) drew attention to the demographic changes that were occurring, at that time mainly in the developed world, and the need to recognize the elderly as a vulnerable population. The 2nd World Assembly on Ageing took place April 8–12, 2002 in Madrid, Spain. This assembly brought together delegations from the 192 member states of the UN to discuss and finalize an international strategic plan of action on aging for subsequent endorsement by the UN General Assembly and implementation by the UN member states. *The Madrid Political Declaration and International Plan of Action on Ageing* (*Madrid Plan*), like the *Vienna Plan*, is intended to provide a blueprint for governments in addressing the challenges of population aging. The document is comprehensive, containing 35 objectives and 239 recommendations for action, organized around three themes or priority directions:

1. Older persons and development
2. Advancing health and well-being into old age
3. Ensuring and enabling supportive environments.

The first priority direction draws attention to the fact that currently about two-thirds of all persons aged 60 and over live in developing countries and that by 2025 the proportion will increase to 75%. In doing so, it underscores the fact that while some are vulnerable, many are resources for development within the context of their family, community, and country. The second priority direction underscores the need for policies that promote good health in childhood and throughout the life course as a means of attaining a healthy old age. The third promotes policies and programs that will provide the basis for secure aging.

NGO World Forum on Ageing

Most of the delegates to the 2nd World Assembly on Ageing were elected and appointed government officials. Civil society was represented in a parallel event, held in Madrid on April 5–9, 2002. Nearly 1000 NGOs from five continents participated in the first NGO World Forum on Ageing. The main topics of discussion, summarized in the *Final Declaration and Recommendations of the World NGO Forum on Ageing*, centered on economic development and humanitarian aid rights of older persons, health care, housing, and consumption.

Valencia Forum

In the week prior to the 2nd World Assembly on Ageing (April 5–9, 2002), the IAGG brought together researchers, educators, and practitioners with expertise in gerontology and geriatrics in Valencia, Spain. The objective of the gathering, called the Valencia Forum, was to distill their knowledge and experience on how best to address issues associated with global aging, with particular emphasis on identifying information gaps and research priorities. These were articulated in the *Research Agenda on Ageing for the Twenty-First Century* (RAA-21), the product of a multiyear collaboration between the IAGG and the UN Programme on Ageing, which was endorsed by the Valencia Forum's participants. The research agenda was subsequently presented, together with a

report of the Valencia Forum, at an official roundtable at the World Assembly on Ageing held on April 9, 2002. The UN General Assembly in its 2002 resolution "Situation of Older Women in Society" welcomed the adoption of RAA-21 by the Valencia Forum. It was presented at the UN Economic Commission for Europe Ministerial Conference on Ageing, held September 11–13, 2002 in Berlin, Germany. Also, specific reference to RAA-21 was made at the UN Economic and Social Commission for Asia and the Pacific (ESCAP) Asia Pacific Follow-up to the 2nd World Assembly on Ageing held in Shanghai, China on September 23–26, 2002.

UN Programme on Ageing

The UN Programme on Ageing is located administratively within the Division of Social Policy and Development, Department of Economic and Social Affairs. Major responsibilities of the unit include ongoing coordination of UN activities in the area of aging, including promotion and monitoring of international policy and programs on aging; coordination of the International Year of Older Persons (1999), coordination of substantive preparations for the 2nd World Assembly on Ageing in Madrid (2000–2002), and post-Madrid, monitoring of implementation of the *Madrid International Plan of Action on Ageing*. The Programme on Ageing is also continuing its collaboration with the IAGG with respect to further development of the RAA-21 to reflect regional research priorities.

During 2003–2005, a series of workshops were held that focused on formulating regional research priorities, where possible in connection with the elaboration and adoption of regional strategies for the implementation of the *Madrid Plan*. The first of these was held in Cape Town, South Africa in association with the African regional conference GeriatrixAfrica '03 in March 2003. A report of this consultation was published in the July 2003 *IAG Newsletter*. Three subsequent regional consultations were convened, in the European, Latin American and the Caribbean, and Asia Pacific regions. The ESCAP and Economic Commission for Latin America and the Caribbean (ECLAC) regional implementation strategies for the *Madrid Plan* include specific recommendations for developing research agendas on aging at regional and country levels.

The programme's website contains all of the major documents from the two World Assemblies held to date, the NGO World Forum on Ageing, Valencia Forum, etc. An informal e-mail newsletter published by the unit, called the *UN Network on Ageing*, may also be found on the programme's website. The programme also maintains a very helpful searchable database on policies and programs on aging of UN member states.

WHO Life Course and Ageing Programme

The WHO Life Course and Ageing Programme is headquartered in Geneva within the Division of Non-communicable Diseases and Mental Health. Its mandate is to undertake projects and programs and develop publications aimed at improving the health and well-being of older persons. Recent examples include *Active Ageing: A Policy Framework,* developed as WHO's contribution to the 2nd World Assembly on Ageing, and *Towards Age-Friendly Primary Health Care*, a project developed in response to attention drawn in the *Madrid Plan* to the multiple barriers (physical, psychological, attitudinal, and financial) that older persons often encounter when attempting to access health services.

Recognizing that such barriers can have a large impact on older people's health, the latter project was aimed at determining what makes primary health-care services age friendly. Via focus groups conducted in five countries, the project documented the views of older people as well as those of health-care providers on whether primary health-care services are accessible, appropriate, and affordable for older persons; identified some of the most common barriers to primary health care for older adults in the areas of information, education, training, management, and the physical environment; and established a set of general principles for making primary health care more age friendly. Advocacy materials and a 'tool box' of materials on how to make primary health-care centers more age friendly are currently being compiled. A similar model is being followed in an international project concerned with making large and small cities more age friendly. This project, one of three major projects undertaken in partnership with the Public Health Agency of Canada, brings together researchers, community development experts, and seniors advocates from approximately 20 countries to address barriers to the full participation of older persons living in urban environments and ways these barriers may be overcome. Like the *Age-Friendly Primary Health Care* project, the goal is to develop a template or index and a tool kit that cities around the world can use to improve the quality of life of their older citizens. The other two projects sponsored by the Public Health Agency of Canada also merit special mention. One consists of an international falls prevention initiative, while the other focuses on disaster and emergency preparedness and planning. The costs in human suffering and

to health-care systems attributable to falls among seniors has been known for some time. Mortality data from Hurricane Katrina document another area in which the elderly are very much a vulnerable population.

Further examples that demonstrate the breadth of work undertaken by the WHO Life Course and Ageing Programme include a global survey on geriatrics in medical school curricula; a partnership with Health Canada and INPEA with respect to raising awareness of and prevention of elder abuse; the development of a global strategy on diet, physical activity, and health presented at the World Health Assembly in 2004; and the organization of a series of activities promoting physical activity in older age. The latter include the Global Movement for Active Ageing (a network of organizations and individuals from different disciplines that aims to influence policies and practices toward active aging); the Global Embrace (worldwide intergenerational walk events that take place annually around the UN International Day of Older People in October); and the Move for Health initiative (targeting all age groups and anchored on national models such as the Agita Brazil program).

International Institute on Ageing, UN–Malta (INIA)

Malta (in 1968) was the first country to draw the attention of the UN to aging as a matter of international concern. In 1979, the 35th General Assembly called on the Secretary-General to convene what was to become known as the 1st World Assembly on Ageing. In its resolution it recommended the promotion of training and research, as well as the exchange of information and knowledge, in order to provide an international basis for social policies and action. The *Vienna Plan* recommended the establishment of practical training institutes that would act as bridges between developed and developing countries. In 1987, the UN signed an agreement with the government of Malta to establish the International Institute on Ageing (INIA) as an autonomous body under the auspices of the UN and the host government. INIA is unique among the many gerontology centers that now exist around the world in having such an affiliation with the UN.

In accordance with its mandate, the institute's main objectives are to fulfill the training needs of developing countries. Since its establishment, INIA has trained approximately 2000 candidates from 133 countries in its programs held in Malta. Since 1995, it has hosted *in situ* training programs in 17 countries. The training programs are targeted for persons holding positions as policy makers, planners, program executives, educators, professionals, and paraprofessionals who work, or intend to work, in the field of aging or with older persons. The training programs are reinforced by INIA's other activities, which include data collection, documentation, information exchange, and technical cooperation, as well as research and publications.

INIA operates under the guidance of an International Board consisting of nine members. The Chair and six members are appointed by the Secretary-General of the UN, and two members are appointed by the government of Malta.

International Education Initiatives

In recent years, international training initiatives have expanded from short-term courses such as those offered by INIA to include cross-national postgraduate programs. These include the European Masters Programme in Gerontology, which is an interdisciplinary joint program, supported and delivered by 22 European universities, and the international continuing medical education certificate program offered by the European Academy for Medicine of Ageing. The latter, a 2-year modular training program, is designed to update knowledge, train teaching skills, and foster research in geriatric medicine as well as serve as a network for practicing geriatricians in Europe. New initiatives include a proposed Asia Pacific Academy for Health, Medicine and Ageing. The mission of the academy is to enhance the quality of professional education of its members and associate institutions in gerontology and geriatric medicine. Plans include fostering joint education, training, research, and service projects, disseminating scientific and health-care information, and stimulating intersectoral collaboration among governmental, non-governmental, and academic institutions. Inaugural members of the academy are the Novartis Foundation for Gerontology, the Centre for Ageing Studies (Adelaide, Australia), the Tsao Foundation (Singapore), the Hong Kong Institute of Gerontology, the Beijing Institute of Gerontology and Geriatrics, Population and Development Studies Center, and the Center on Ageing Studies (Renmin University of China, Asia Training Center on Ageing), and the International Association of Gerontology and Geriatrics, Asia/Oceania Region.

In addition, individual universities around the world are reaching out to international students, offering graduate education in gerontology and geriatrics online or in partnership arrangements, such as those of the University of New England, Australia and the Chinese University of Hong Kong, that combine online learning with *in situ* workshops, thereby

increasing accessibility for practicing professionals. Since 2001, the International Association of Gerontology and Geriatrics has maintained a worldwide listing of universities offering masters and doctoral degrees in gerontology on its website. Each succeeding year, the list has expanded.

Future Developments

The list of national gerontology and geriatrics societies has also expanded. With global aging, this trend is expected to continue. It reflects the development within countries of cadres of researchers, educators, and service providers specializing in gerontology and/or geriatrics who seek the company of others in the field to advance their personal knowledge, collectively impact local, regional, and national policies and programs, and to advocate on behalf of seniors. International gerontology offers opportunities to further expand their horizons and for cross-fertilization and collaboration across national borders and boundaries. Increasing numbers of individuals are taking advantage of these opportunities as evidenced both by the proliferation of international conferences, workshops, and symposia that have been organized over the past decade and by the increasingly large and geographically diverse attendance patterns they are showing. Around the world, individuals and governments are recognizing the value of international cooperation and collaboration with respect to research and education in gerontology and geriatrics as well as global sharing of best practices in services for seniors and their care providers, service delivery systems, and public policy.

Language and Communication in Aging

M R Clark-Cotton and R K Williams, Boston University School of Medicine, Boston, MA, USA
M Goral, Boston University School of Medicine, Boston, MA, USA, and City University of New York Graduate Center, New York, NY, USA
L K Obler, City University of New York Graduate Center, New York, NY, USA, and Boston University School of Medicine, Boston, MA, USA

Glossary

Aphasia – Loss of or impaired ability to speak, write, or understand language due to brain damage.

Dementia – Lasting deterioration of cognitive abilities resulting from any of a number of diseases affecting the brain.

Lexicon – Words or the vocabulary of a language as distinguished from its grammar and construction.

Syntax – The way in which linguistic elements (as words) are put together to form constituents (as phrases or clauses).

Introduction

It is commonly known that the loss of auditory and visual acuity leads to communication problems in many older adults. Some of these difficulties, such as problems reading small print or trouble hearing in noisy settings, can often be improved with corrective tools such as eyeglasses and hearing aids, or by environmental changes. Reports from older adults that common language tasks such as naming a particular object during conversation become more difficult in their 60s and 70s have been confirmed experimentally. In many cases, these difficulties cannot be fully explained by sensory deficits. This article reviews age-related changes in language as well as sensory, cognitive, and neurobiological factors that might underlie them. It also briefly considers the effects of interacting social factors, such as economic status, level of education, and gender, on language performance. The article concludes with a brief discussion of some pathological changes in language associated with neurological disorders.

Everyday Experiences of Older Adults

Whereas many language skills remain well-preserved in old age, older adults often perceive a decline in their communicative abilities. The most common language-related complaints include problems finding words in conversation, difficulty understanding spoken language under certain circumstances, and confronting ageism.

Finding Words

Diary studies, questionnaires, and anecdotal reports have demonstrated that older adults often experience difficulty finding the names of people, places, and objects. All speakers are familiar with the feeling that the word they want to use is 'on the tip of their tongue,' a phenomenon known as a tip-of-the-tongue (TOT) state. When older and younger adults are asked to keep a diary of their TOTs, older adults report significantly more TOTs than younger adults. Problematic words may include both low-frequency items and names of common objects. The words can often be successfully retrieved later.

Understanding Speech

Older adults often report difficulties understanding speech in less than ideal listening conditions: when the speech rate is fast, when there are competing stimuli (e.g., in a noisy room), or when they cannot see their conversation partner (e.g., on the phone). Whether this difficulty results from loss of hearing sensitivity, reduced central auditory processing ability, and/or cognitive decline is not well understood.

Ageism, Stereotypes, and 'Elderspeak'

Although some older adults (particularly those with neurological disorders) do have debilitating communication disorders, most healthy adults can

communicate effectively throughout their lives. However, in most industrial societies and Western cultures, older age is associated with some stereotypes and negative expectations, including false assumptions about communicative ability. For example, many people believe that, as a group, older adults are excessively talkative or poor at keeping a conversation on-target, a generalization that is not true for all older adults. It has also been shown that speakers often modulate their language, or use 'elderspeak' when addressing older adults, perhaps in an unconscious effort to compensate for a perceived hearing or comprehension deficit. This accommodation, which often comprises simplified structures, shorter utterances, a slower speech rate, and exaggerated intonation, may be useful to facilitate comprehension, but could also be perceived as patronizing, denoting a negative attitude and disrespect. Such ageist stereotypes have been reported in intergenerational communications, with both the younger interlocutors and the older adults themselves expecting the older speakers to have more communication difficulties.

Experimental Studies

Experimental studies suggest that some language abilities change with increasing age, while others vary little throughout the life span. In studies of language use, the following domains are often defined: phonological (relating to language sounds), lexical (word-level), semantic (relating to meaning), syntactic (phrase- or sentence-level), discourse (relating to groups of phrases or sentences), and pragmatic (relating to real-world or contextual knowledge). In reality, these domains are not easily separable. For example, the lexical skill of retrieving words requires the semantic knowledge of their meaning, and groups of sentences cannot be organized into meaningful discourse without an understanding of the listener's real-world expectations. Nevertheless, it is useful to discuss changes in adult language skills (in both production and comprehension) in the context of these domains. The findings reviewed in this section refer specifically to language abilities in healthy older adults, rather than in those impaired by brain injury or a neurological disorder. It is important to note that these changes are quite subtle. They become noticeable only in experimental settings and do not usually, create a daily communicative burden in older adults' lives.

Phonological Skills

It is commonly recognized that older adults' speech is qualitatively different from that of younger adults. It has been shown that listeners can reliably distinguish between older and younger adults, although they might not be able to describe the differences. Older adults' speech is usually lower in volume, slower, and somewhat less precise in articulation (the movements of the mouth and tongue that produce speech) than that of younger adults. Older adults' speech can also be less fluent, including more pauses, fillers, repetitions, and corrections. However, in the absence of overt damage or disease processes, speech skills in older adults remain sufficiently high for everyday communication.

Research studies have suggested that older adults have more difficulty in processing speech input than younger adults. Although hearing loss has been highly correlated with speech-processing difficulty, it has been documented that older listeners have particular difficulty with several forms of distorted speech, including noisy, reverberant, and time-compressed speech, beyond what the loss of hearing sensitivity might predict.

Lexical Skills

Word-level production in older adults has been particularly well studied, in part because lexical retrieval, the spontaneous production of a specific word, is anecdotally reported to decline with increasing age. In list generation tasks, in which participants are asked to name as many items as possible from a single category (e.g., animals) in a fixed amount of time (usually 1 min), older adults produce fewer words than younger adults. Studies have also confirmed that older adults are slower and make more errors than younger adults in naming objects depicted in pictures. Difficulty has been documented for adults as young as in their 50s, but significant age differences are usually found only for individuals who are 70 years and older, as seen in **Figure 1**.

Because the retrieval difficulty is often overcome with the assistance of semantic or phonemic cues, it seems clear that knowledge of the words is intact, even when their phonological form is inaccessible. Indeed, vocabulary knowledge shows little evidence of decline with increasing age. Although some studies have suggested that the quality of definitions given by older adults is poorer than that of younger ones, the preponderance of the evidence suggests that adults maintain their knowledge of word meanings and can continue to build their vocabularies well into their later years.

Semantic Skills

There is good reason to believe that semantic abilities remain largely intact throughout adulthood. As noted previously, word retrieval studies show that,

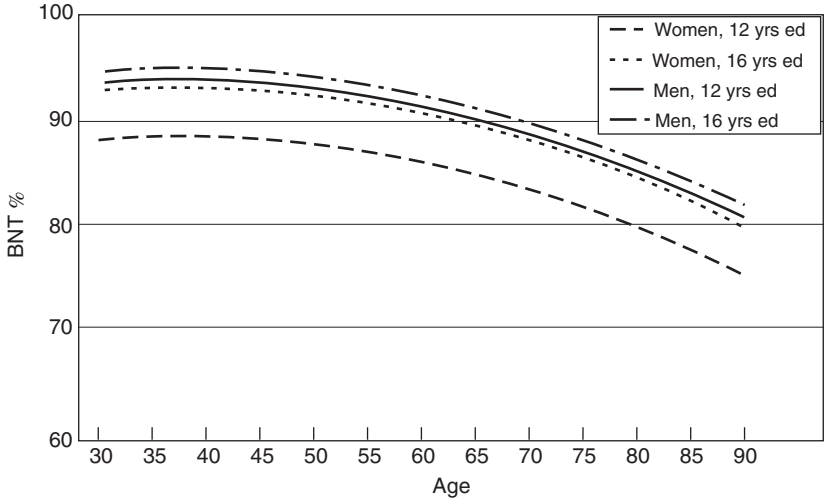

Figure 1 Predicted performance (% correct) on the Boston Naming Test by age, gender, and education. Reprinted from Connor LT, Spiro A, Obler LK, and Albert ML. *Journal of Gerontology: Psychological Sciences* 59B(5): P203–P209 (2004). Copyright © The Gerontological Society of America. Reproduced by permission of the publisher.

even when older adults report difficulties in finding a word, they are still able to produce the word when cued, suggesting that they retain their underlying knowledge of its meaning. Older adults' generally good performance on vocabulary tests also indicates intact semantic knowledge. Furthermore, in lexical decision tasks, semantic priming (the phenomenon of recognizing a word more quickly when it is preceded by a semantically related word) appears to be equally robust in older and younger adults. Likewise, studies of sentence comprehension have confirmed that older adults' capacity to comprehend words in sentences appears intact, unless the sentences are complex or posit counterintuitive statements.

Syntactic Skills

Syntactic production skills are those with which a speaker or writer organizes words into grammatically acceptable phrases and sentences. Sentences may be syntactically simple (containing only one clause) or more complex (with one or more dependent clauses). In spontaneous speech and in diaries, older adults show evidence of declining syntactic abilities, as they tend to use simpler syntactic structures and make more errors than younger adults.

Moreover, there is evidence that the comprehension of sentences becomes more difficult with increasing age. Older adults are slower and less accurate than younger adults in paraphrasing, answering questions about, and making judgments about syntactically complex sentences. These changes have been reported in both reading and listening skills. The sentences that cause older adults difficulty are typically unusually long, somewhat counterintuitive, syntactically complex, or not fully comprehensible by context alone. For example, the sentence 'The patient who examined the physician completed the forms' is difficult syntactically and pragmatically – syntactically because a dependent clause, 'who examined the physician,' is embedded in the main clause 'the patient completed the forms,' and pragmatically because patients do not usually examine physicians. These types of complexities often force listeners to use their working memory to repeat sentences to themselves as they listen. It is not yet clear whether syntactic knowledge itself or the ability to use that knowledge efficiently is impaired in older adults who find these sentences difficult to process.

Studies of resource allocation during language processing also suggest that older and younger adults show differences in processing complex sentences. Younger, but not older, adults have been shown to allocate longer reading times to more complex syntactic structures (e.g., object-relative sentences) than to less complex ones (e.g., subject-relative sentences), as seen in **Figure 2**.

Discourse Skills

Studies of discourse in older adults have examined naturalistic (e.g., spontaneous conversations, letters) and elicited production (storytelling, picture descriptions) and found some evidence of differences between the discourse of older and younger adults. However, individual differences in discourse performance are great among adults of all ages, making it difficult to generalize across age groups. More than in other language domains, personal style contributes to

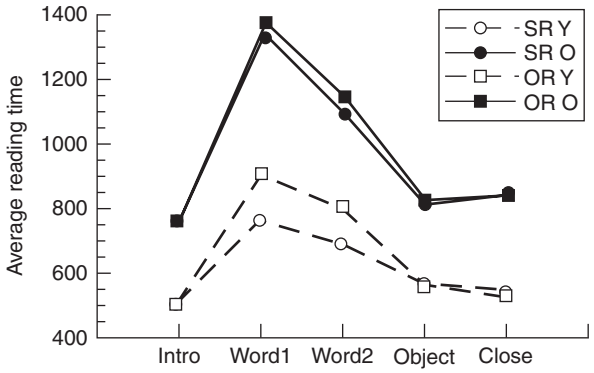

Figure 2 Average reading times (milliseconds) for complex sentences by age and syntactic structure (Y, younger adults, ages 19–27; O, older adults, ages 59–80; SR, subject-relative sentences; OR, object-relative sentences). discourse performance. (Quite simply, some people love to talk, while others are more reserved; whereas some elaborate, others speak tersely.)

The belief that older adults tend toward greater verbosity has been verified in some studies. In these cases, the talkativeness seems to have been partly motivated by social needs unrelated to age; the more talkative older adults tended to be more outgoing and less concerned with others' opinions of them. This loquacity might also be prompted by lexical retrieval or memory problems, as people circumlocute (describe a word or its characteristics instead of speaking the word itself) around their targets. The additional possibility that some of these verbose adults are in the early stages of dementing disorders cannot be excluded.

The use of referring expressions (e.g., pronouns) has also been reported to differ in older and younger populations. To use these expressions clearly, speakers must mark the antecedent (the word for which the pronoun stands) unambiguously. Older adults tend to be less specific in their use of referring expressions. As with other differences, it is not clear whether these ambiguities are related to cognitive deficits such as memory and attention, problems comprehending the topic, or pragmatic difficulties in recognizing the listener's perspective.

Older adults are often less skilled in retelling stories or giving instructions for completing a task, as they omit more essential elements than younger adults, creating discourse that is less fluent and harder to follow. However, the quality of discourse is not easily quantified. Some evidence suggests that, using more subjective measures of discourse ability (e.g., clarity, interest to the listener), older adult discourse appears superior. Older adults have shown some evidence of poorer comprehension and organization of discourse in story recognition or recall tasks, with more difficulties drawing inferences and logical conclusions, organizing the story elements, and remembering the stories after a delay.

Pragmatic and Non-verbal Skills

Few systematic examinations of older adults' abilities to use pragmatic skills have been undertaken. However, in examinations of other linguistic abilities, real-world expectations are often manipulated. As noted in the discussion of syntactic skills, older adults tend to have an especially difficult time processing complex sentences when they are counter to real-world expectations. For older adults with impaired hearing, access to non-verbal cues is especially important. Some researchers have reported that older adults are poorer than younger adults at identifying an emotion encoded in a facial expression without the aid of auditory cues.

Factors Contributing to Language Change

Sensory, cognitive, and neurobiological changes have all been shown to explain some of the language differences between older and younger adults. Sensory deficits that clearly contribute to language deficits include loss of visual and aural acuity. Non-linguistic cognitive abilities such as cognitive speed, working memory, executive function, and possibly attentional inhibition have been shown to decline with increasing age and have been hypothesized to mediate some age-related language changes. This section gives an overview of the sensory, cognitive, and neurobiological changes that have been implicated in language performance. Changes in the brain and sensory organs are often thought to cause cognitive changes that, in turn, result in changes in language performance. However, it has also been hypothesized that a common factor leads to sensory, cognitive, and language deficits. This view, termed 'the common cause hypothesis,' posits that decline in sensory abilities is not the cause of cognitive decline, but rather a marker of the same physiological changes that lead to cognitive deficits.

Sensory Changes

Sensory changes in the visual and auditory modalities accompany the process of healthy aging. These changes have implications for successful communication in older age.

Vision changes associated with aging may include peripheral problems such as presbyopia, miosis,

cataract, and posterior vitreous detachment, as well as disorders like glaucoma, macular degeneration, and diabetic retinopathy (*see* Vision). These disorders may cause a range of symptoms, from difficulty focusing on nearby objects and diminished night vision to blindness. Decreased visual acuity has both direct and indirect effects on communication. Visual input is integral to typical conversation. Nonverbal cues supplement verbal communication, and their absence or lessening makes conversation more difficult. Furthermore, reading and writing skills may be compromised. Indirectly, loss of vision affects social interaction in older age. The ability to view movies and television is reduced, and driving skills may be compromised, which may lead to reduced social activity and increased isolation. Decreased ability to read instructions on medication packages or any number of forms may be harmful as well.

Hearing impairment associated with older age (presbycusis) includes changes in the ear, the auditory nerve, and the auditory pathways (*see* Hearing). These changes are associated with loss of sensitivity, especially for high-frequency sounds, and often with poor sound discrimination and impaired speech recognition.

On pure tone testing, age-related changes are typically characterized by a high-frequency loss that becomes progressively more severe with advancing age. Whereas not all age-related hearing changes directly affect speech recognition skills, a decline in speech recognition often corresponds to pure tone loss. However, the relation between older adults' ability to understand speech, particularly in noisy conditions, and their peripheral hearing loss has been a matter of debate.

One approach, the peripheral hypothesis, maintains that difficulty understanding speech can be accounted for by hearing loss as measured by pure tone. Several studies have demonstrated that older adults with unimpaired hearing perform as well as younger adults, whereas younger adults with hearing impairment perform similarly to older adults with hearing impairment. In contrast, other studies demonstrated that older adults with normal hearing performed less well than younger adults on measures of speech recognition in noise, which suggests that older adults may experience difficulty with speech perception (at least in noisy conditions) beyond their threshold sensitivity. These latter findings lead to the hypothesis of a central auditory processing deficit.

Whether the deficit is predominantly peripheral or central, hearing changes are very common in individuals 65 and over, and their impact is often underestimated. Older adults who suffer uncorrected hearing impairment tend to minimize their social interaction and self-rate their psychosocial, emotional, and recreational impairment as greater than older adults with no hearing loss.

Despite the wide availability of hearing aids, including some very sensitive and advanced instruments, the majority of older adults with hearing loss do not use hearing aids. According to surveys, perhaps 20% of the hearing-impaired older population use hearing aids. Reasons for this low proportion of users may include reluctance to admit to hearing loss, which is associated with being old and/or disabled, low tolerance for a noisy environment often exaggerated by the hearing aids, difficulty handling the small devices, and affordability. Appropriate fitting is crucial, and should be made on the basis of physical (e.g., type of hearing loss, structure of the ear), psychosocial (e.g., motivation, lifestyle), and financial criteria. Also important is the postfitting process, during which the aids are evaluated and adjusted. Studies of self-report on use and satisfaction (most commonly used is the 25-item Hearing Handicap Inventory for the Elderly [HHIE]) demonstrate that those who are fitted properly can derive dramatic benefit from hearing aids.

Non-linguistic Cognitive Changes

Leading theories of language performance in aging propose that an age-related decline in language is mediated by changes in cognitive skills, such as processing speed, working memory, executive function, and attention. Such skills are relevant to performance on language tasks that are harder for older adults, and there is evidence that all of them decline with increasing age.

Slower cognitive processing has been theorized to mediate age-related cognitive decline. Older adults usually take longer than younger adults to complete most cognitive tasks. Slower performance has been demonstrated even when the speed it takes to perform the motor aspects of the tests has been accounted for. Slowed processing could affect a number of the language tasks in which speed is measured or time is restricted, including list generation, picture naming, and auditory comprehension. Although cognitive speed has been related to performance on these tests, it is not sufficient to explain older adults' difficulties with such tasks.

Working memory skills, the ability to simultaneously remember and manipulate information, are also known to decline with increasing age. Older adults experience difficulty on tasks that require them to remember numbers, words, or shapes while performing a second task such as reading sentences

or computing numbers. In the verbal domain, good working memory skills are useful in auditory sentence comprehension, as the listener determines who is doing what to whom, especially when sentences are long and complex. Indeed, compromised working memory skills have been proposed to underlie older adults' difficulty in processing syntactically complex sentences and recalling information from written or auditory discourse, as mentioned above.

Executive function refers to the set of cognitive skills, such as identifying options, setting goals, initiating behavior, and tracking performance, that allow a person to successfully plan and execute a task. Older adults often demonstrate impaired performance on tasks that measure these abilities. It has been proposed that executive dysfunction accounts for certain impairments in language skills. For example, list generation tasks utilize executive function skills such as switching between semantic subcategories (e.g., farm animals and house pets).

Attentional inhibition refers to the ability to attend to relevant stimuli while ignoring irrelevant information. Although no consensus exists as to whether older adults do in fact exhibit deficits in attentional inhibition, difficulty inhibiting non-target words could contribute to lexical retrieval errors, resulting in the generation of a related but incorrect word (e.g., 'chair' instead of 'stool'). Moreover, in comprehension tests, an inability to ignore noise or irrelevant information may hinder understanding of the target material. For listeners presented with long auditory or written passages, difficulty attending to the relevant information while ignoring extraneous details could impair the ability to report the gist of the discourse or answer questions about it.

Neurobiological Changes: Anatomical, Chemical, and Physiological

The adult brain may exhibit many changes as it ages, including a reduction in volume, alterations in activation patterns, and differences in neurotransmitter circuits. Shrinkage of the brain may be related to changes in the white matter, the myelinated axons that carry neuronal signals. Structural imaging studies have shown that white matter volume decreases and that white matter hyperintensities increase; both these phenomena have been associated with worse performance on tests of executive function, processing speed, and explicit memory. Functional imaging studies reveal that some older adults show bilateral activation of the dorsolateral prefrontal cortex (rather than the typical left hemisphere activation seen in younger adults) when performing verbal working memory tasks. This bilateral activation could be either a compensatory mechanism or the result of an inability to suppress activation. Changes in the neurotransmitter dopamine also occur in the older adult brain, as dopamine concentration and receptor density decline with increasing age. Dopamine has been associated with psychomotor speed tests and cognitive functions.

Explaining Individual Differences

While older adults as a group show the patterns of language change discussed above, the performance of individual adults varies considerably, with some people showing a measurable decline in their 70s and 80s and others performing quite well throughout their lives. What accounts for this within-group variability is an important question for both experimental studies and clinical assessments.

A number of social variables, including the education, socioeconomic status, and gender of the participant, have been reported to contribute to individual performance differences on language tests. For example, a person with an advanced degree is likely to have more experience in defining the obscure words found on a vocabulary test than a high school graduate. Indeed, research studies on the relation between language and cognition have reported that on such measures, individuals with higher education outperform individuals with lower education.

Other aspects of performance variation are more personal, such as motivation, interest, cognitive style, and depression status. Understandably, individuals do better on tasks that tap their own interests and strengths and those that they find relevant to their own lives. With respect to motivation, low expectations by either the participant or the examiner have been related to poorer performance. Lack of motivation may be a manifestation of fatigue or illness, which also may contribute to poor performance.

Certain aspects of the assessment setting have also been shown to influence individuals' performance differently. Adequate lighting, readable print, and minimal noise are essential for maximizing the performance of hearing- or vision-impaired participants. For tasks that are unfamiliar, adequate practice opportunities before assessment begins have been shown to help older adults more than younger adults. An institutional effect has also been observed, as community-dwelling individuals tend to perform better than those who reside in nursing homes.

In most language and cognitive domains, there are little data on the performance of older individuals who are bilingual and bicultural. Indeed, since the 1990s, clinicians and researchers have begun to

emphasize the need to establish norms for bilingual participants on commonly used neuropsychological and language tests. Testing bilinguals in both their languages demonstrates that proficiency in each language affects levels of performance. In addition, the mean scores obtained for bilingual participants differ from those of monolingual individuals. For example, bilingual speakers may name fewer pictures correctly and generate fewer words on list generation tasks in each of their languages than expected on the basis of monolingual norms. Lower scores of bilinguals on normative tests developed in English, as well as tests translated into other languages, may be due in part to language-specific differences. Variations in word length, semantic relations, and level of proficiency may interact with test materials as they are translated or adapted from one language to another. Not only language considerations but also cultural differences should be addressed when bilingual individuals are concerned. Cultural differences can account for different approaches to problem solving and dealing with task demands, as well as for varying strategic flexibility. Furthermore, attitudes toward older individuals vary across different cultures, affecting communication between younger and older adults.

Language and Communication Disorders

Brain injury or neurodegenerative disease often produces serious language disorders in adults. This section gives an overview of the language problems that result from two types of neurological disorders to which older adults are disproportionately subject: cerebrovascular accident (commonly called stroke), which may lead to aphasia, and dementia of the Alzheimer type. It also briefly considers the implications of aging for adults with childhood language disorders.

Aphasia

Aphasia (*see* Language Disorders: Aphasia) is an acquired language disorder resulting from injury to the brain, usually a stroke in the left hemisphere. The spontaneous speech of a person with aphasia is almost always somewhat impaired, and other language abilities such as reading, writing, repetition, and comprehension may also show deficits. Aphasic disorders may be broadly categorized as fluent or non-fluent. The non-fluent aphasias include global aphasia, Broca's aphasia, and transcortical motor aphasia. Among the fluent aphasias are Wernicke's aphasia, transcortical sensory aphasia, conduction aphasia, and anomic aphasia. Patients with fluent aphasias tend, on average, to be about a decade older than patients with non-fluent aphasias.

Language in Dementia of the Alzheimer Type

The language changes that accompany dementing disorders are most pervasive in dementia of the Alzheimer type (DAT) (*see* Dementia; Dementia: Alzheimer's). Although language skills, like other cognitive abilities in people with DAT, follow a progressively declining course, a number of linguistic domains remain relatively intact in both the early and middle stages of the disease. Because the motor speech skills (such as articulation, resonance, and phonation) that produce language sounds are largely intact, words are generally intelligible, even when their meaning becomes distorted. Output follows the phonological rules of the language. For example, speakers do not substitute sounds characteristic of their language for those found in another language, or produce sound combinations not found in their language. People with DAT also tend to follow the syntactic conventions of their language. For example, they do not usually violate the morphosyntactic rules by which affixes are added to words to mark their use in a sentence. Prosody (the distinctive rhythm of speech, which rises and falls in predictable ways) is also normal in speakers with DAT.

Despite these preserved skills, the language of people with early-stage DAT is characterized by impairments in lexical retrieval and discourse competence. Speakers with DAT often show great difficulty in retrieving words, substituting either a semantic or phonemic paraphasia (word production error) for the target word, or using a vague filler such as 'thing' in place of a more meaningful word. The coherence of the speech is further hampered by tendencies to wander from the conversation topic and to repeat words or phrases. Since the speaker's prosody and grammar are normal, the word-finding difficulties may complicate, but do not preclude, conversation in the early stages of the disease. As to comprehension, complex discourse will present a challenge.

In the middle stages of DAT, language difficulties substantially impair communication. Lexical retrieval problems become more severe, giving way to large gaps in conversation and circumlocutions, descriptions of a target word or its functions that are spoken in place of the word itself. Speakers also begin to show a variety of difficulties with discourse-level language. The early-stage tendency to lose the topic of the conversation becomes more pronounced, such that the discourse becomes virtually incoherent. The speaker often appears unaware of the listener's knowledge of or interest in the topic. Bilinguals with

DAT may use a language with a conversation partner who does not know the language; before their dementia they would have avoided doing this.

By the late stages of DAT, speech is virtually incomprehensible, and in the most severe cases, speech ceases completely. Comprehension is also severely impaired, such that patients are unable to engage in meaningful communication.

Developmental Language Disorders

An area that has not been well studied is the language performance in adulthood of people with developmental language disorders (e.g., stuttering, dyslexia). Diagnosis and treatment of childhood language problems were much less available when contemporary older adults were children, and many people who would now be recognized as having disordered language were not identified as such in childhood. This makes a systematic study of age-related changes in individuals with developmental language disorders difficult, but a consideration of this subgroup of older adults is important to developing a fuller understanding of language changes in aging.

Summary

Most healthy adults communicate successfully throughout their lives, but experimental studies have illuminated subtle differences in performance on language tasks after middle age. Some of these changes, such as poorer speech processing and less accurate are undoubtedly related to the loss of auditory acuity. Studies have also shown that older adults have more difficulty finding specific words, and making inferences from complicated discourse. On the other hand, the semantic knowledge of words and the understanding of real-world expectations, as well as certain storytelling skills, appear to remain unimpaired.

Diminishing cognitive skills such as cognitive speed, working memory, executive function, and attention have been suggested as mediators of declining language skills. Overall health and its related factors of fatigue and motor speed also contribute to performance, especially in time-limited assessments. Individual performance is further influenced by social variables such as level of education, gender, culture, and socioeconomic status, and by behavioral factors such as motivation, interest, and the comfort of the assessment environment.

Language Disorders: Aphasia

H A Whitaker, Northern Michigan University, Marquette, WI, USA

This article is a revision of 'Aphasia Syndromes' in *Encyclopedia of Language and Linguistics,* 2nd edition, volume 1, pp 321–327, Copyright 2006, Elsevier Ltd.

Glossary

Agrammatism – Characterized by articles, auxiliary verbs and some prepositions omitted or unrecognized in speech and writing.

Agraphia – Characterized by an inability to produce written language.

Alexia – Characterized by an impaired ability to recognize words and/or letters, thus affecting the ability to extract meaning from written text.

Anomia – Characterized by a struggle to find appropriate words in naming items and conversational speech.

Anomic Aphasia (also known as amnestic aphasia, nominal aphasia, and semantic aphasia) – Characterized by a failure to name or to retrieve names, and common and proper nouns in speech.

Apraxia (also called aphemia) – Characterized by errors in the selection or ordering of sounds such that resulting erroneous words sound like the target word but have the wrong meaning or are so distorted as to be non-words.

Broca's Aphasia (also known as verbal aphasia, expressive aphasia, and motor aphasia) – Characterized by speech output exhibiting poorly articulated words with missing, added, or transposed sounds, difficulty initiating speech, and reduced vocabulary.

Conduction Aphasia (also called central aphasia, repetition aphasia, and afferent motor aphasia) – Characterized by the repetition of individual sounds or words in speech.

Global Aphasia (also called total aphasia) – Characterized by equal impairment of all language modalities.

Wernicke's Aphasia (also called syntactic aphasia, sensory aphasia, and receptive aphasia) – Characterized by impairment in the understanding of spoken language.

Introduction

Kertesz (1979: p. 2) defined aphasia as "a neurologically central disturbance of language characterized by paraphasias, word finding difficulty, and variably impaired comprehension, associated with disturbance of reading and writing, at times with dysarthria, non-verbal constructional, and problem-solving difficulty and impairment of gesture." Goodglass and Kaplan (1983: p. 5) defined aphasia as "the disturbance of any or all of the skills, associations and habits of spoken or written language produced by injury to certain brain areas that are specialized for these functions." Basso and Cubelli (1999: p. 181) defined aphasia as "a disorder of verbal communication due to an acquired lesion of the central nervous system, involving one or more aspects of the processes of comprehending and producing verbal messages." Implicit in these definitions, of course, is a definition of language, itself a relatively complex concept.

The clinical syndromes of aphasia have been associated with particular anatomical loci in the central nervous system in the literature since the nineteenth century. Contemporary research, particularly aided with the used of modern brain-imaging techniques, suggests that in addition to the so-called classical language areas of the dominant (usually, left) hemisphere's cortex (Broca's area, Wernicke's area, etc.), many other areas of the central nervous system participate in language processing, including subcortical structures (including the basal ganglia, cerebellum and thalamus), other cortical areas of the dominant hemisphere (including inferior and mesial temporal lobe and insula) as well as various regions of the non-dominant hemisphere. This article focuses on aphasia as a behavior and not its anatomical substrate.

Approaches

In broad outline, there are two approaches to understanding the nature of aphasia. The first is concerned with functional components, what people do when engaged in language behaviors; the four modalities of language – speaking, listening, reading, and writing – are examples of functional components. Other functional components of language include being able to repeat what is said, initiating speech, speaking fluently, being able to name things and people, and being able to clearly articulate words. This approach to aphasia has typically been clinical; identifying impaired functional components of language in conjunction with impairments in one or more of the four modalities has led to a clinical classification of the aphasias that is used in assessment, rehabilitation, and research. An active area of

research in this approach has been correlating the loci of brain lesions with functionally identified syndromes of aphasia.

The second approach might be termed neurolinguistic; it is concerned with the structure of language and which linguistic structures are impaired in aphasia. This approach begins with analyses of aphasic language in terms of linguistic levels – phonological, morphological, syntactic, semantic, and discourse – and then may take either an experimental or applied tack, correlating linguistic deficits, brain lesions, and clinical syndromes. The neurolinguistic approach typically furnishes linguistic details to the functional-clinical approach, particularly in research applications.

Studying the localization of lesions that cause aphasia was at one time of major clinical importance; modern imaging techniques, applied to both brain-damaged aphasic patients and non-brain-damaged experimental subjects, have shifted emphasis to questions of which parts of the brain subserve which language functions and/or which language structures. A reasonable goal would be to identify a unique brain structure and its connections, damage to which caused a well-defined clinical aphasia syndrome and a well-defined linguistic impairment.

Functional-Clinical Aphasia Syndromes

Broca's Aphasia

Broca's aphasia has also been called verbal aphasia, expressive aphasia, efferent motor aphasia, and motor aphasia. The primary modality of language that is affected is speech production, but writing is often affected, too. Comprehension of spoken language and reading are usually much better preserved. According to the older scheme of dividing the aphasias into fluent and non-fluent, Broca's aphasia is the common variant of non-fluent aphasia. Speech output tends to exhibit poorly articulated words with missing, added, or transposed sounds, and there is usually difficulty in initiating speech. The range of vocabulary is often reduced from premorbid levels, and speech output tends to rely a great deal on basic, highly familiar, and thus overlearned speech patterns. Speech is likely to be in short phrases with fewer words than expected, punctuated with frequent pauses. Commonly seen in Broca's aphasia is agrammatism, speech and writing in which the small elements of grammatical structure, typically the so-called function words such as articles, auxiliary verbs, and some prepositions, are omitted or unrecognized. Anomia is also fairly common, causing patients to struggle with finding the appropriate word, both in conversational speech and in confrontational naming. Although comprehension is noticeably better than production, some patients with Broca's aphasia have difficulty comprehending less frequent syntactic structures, although most demonstrate the ability to comprehend single nouns, verbs, or adjectives. Errors may occur in word order, which is called paragrammatism, but this is more common to Wernicke's aphasia (discussed next). Nouns tend to be preserved better than verbs and adjectives in Broca's aphasia, but grammatical function words are the most impaired. A concomitant of the shorter phrases and frequent pauses seen in Broca's aphasia is an impairment in prosody, alterations such as impaired inflection, pitch, and rhythm; this is commonly referred to as dysprosody. Repetition often shows the same impairments as in conversational speech. Writing in Broca's aphasia tends to be impaired analogously to speech output, but reading ability may be only mildly impaired; writing will exhibit misspellings, letter omissions, poor formation of letters, and agrammatism. Patients with Broca's aphasia are generally more aware that their speech and language is impaired than those with Wernicke's aphasia and thus may struggle to produce more correct responses.

The lesions typically leading to Broca's aphasia most often affect both the inferior frontal lobe and the anterior inferior portion of the parietal lobe; this is generally more extensive than the part of the third (inferior) frontal gyrus and surrounds that have been identified as Broca's area.

Wernicke's Aphasia

Wernicke's aphasia has also been called syntactic aphasia, acoustic aphasia, sensory aphasia, and receptive aphasia. The primary modality of language that is affected is speech perception, and reading may be affected, too. The ability to produce speech and the ability to write are usually much better preserved, although the content of speech and writing will likely be impaired. According to the older scheme of dividing the aphasias into fluent and non-fluent, Wernicke's aphasia is the common variant of fluent aphasia. The salient feature of Wernicke's aphasia is an impairment in understanding spoken language, particularly when the content of the spoken language is not predictable from the context or not otherwise highly familiar. In milder forms, comprehension may be contextually appropriate, e.g., a discussion of the weather, but lacking in details, e.g., unable to distinguish partially cloudy from overcast. On the other hand, the speech of the Wernicke's aphasic patient may appear articulatorily fluent but paraphasic, that is, an intrusion of non-words, words out of order, and word choices that are marginally related or unrelated

to the topic of the conversation. Paraphasias may appear in any variety of aphasia, but they are typically more prevalent in Wernicke's aphasia. As in Broca's aphasia, grammar may be affected, rather than function words being omitted, they are more likely to be used improperly or added extraneously. Grammatical word order constraints may be violated, a syntactic impairment called paragrammatism. Wernicke's aphasic patients are not likely to use complex sentence structure but rather will resort to simple, common declarative word order. Occasionally, patients with Wernicke's aphasia may talk excessively, even to the point of adding unrecognizable syllables, words, or phrases to their speech, a phenomenon known as jargon aphasia. Most researchers consider jargon aphasia to be a subtype of Wernicke's aphasia. In jargon aphasia, the jargon aphasic errors may be literal (single sounds), verbal (added words that are recognizable), or neologistic (added words that are unrecognizable). The patient with Wernicke's aphasia may be able to write letters and words correctly as a motor action, but the output reflects the patient's fluent paraphasic speech, including a disorganized and rambling style, occasional to frequent repetitions of words or phrases, jargon aphasic errors, and a lack of recognizable content. Reading tends to follow auditory comprehension ability, typically impaired.

The lesions responsible for Wernicke's aphasia are typically in the middle to posterior temporal lobe, particularly the superior gyrus, but frequently the middle temporal gyrus as well. These lesions often continue back to the junctions of the temporal lobe with the occipital and inferior parietal lobes, in the areas named the supramarginal and angular gyri.

Conduction Aphasia

Conduction aphasia has also been called central aphasia, disorganized execution of the encoding program related to disturbed auditory feedback, repetition aphasia, and afferent motor aphasia. The primary function of language that is affected is the repetition of speech, whereas comprehension and production tend to be much less impaired. Conduction aphasic patients frequently attempt to correct their repetition errors, implying a better preserved comprehension. The repetition errors may be at the level of individual sounds or words; repetition may exhibit an agrammatic character. The speech of the patient with conduction aphasia is more often like that seen in Wernicke's aphasia but sometimes is like that seen in Broca's aphasia. In addition to the repetition deficit, patients with conduction aphasia are often afflicted with anomia; literal paraphasias (substitution of sounds) may intrude in both spontaneous speaking and in attempts to repeat what is heard. Within single words or very short phrases, articulatory fluency may be good, but patients with conduction aphasia typically display phonemic (or literal) paraphasias, a substitution of sounds. Although within-phrase syntactic patterns tend to be normal, many conduction aphasic patients have difficulty with sentences containing pronouns and grammatical function words, as well as polysyllabic words. Other characteristics that may be found include difficulties in writing, showing some forms of agraphia and ideomotor apraxia. Writing ability usually parallels speech output, showing deficits in spelling and letter omissions or substitutions. As is the case for Broca's aphasia, conduction aphasic patients are typically aware of their speech and language deficits.

The lesions leading to conduction aphasia tend to be located in and around the supramarginal gyrus and the arcuate fasciculus; the latter pathway connects the temporal lobe to the frontal lobe. Other lesions are along the border of the Sylvian fissure, extending to the subjacent white matter.

Anomic Aphasia

Anomic aphasia is also known as amnestic or amnesic aphasia, nominal aphasia, and semantic aphasia. The primary modality of language that is affected is speech production, restricted to the production of names, but it is most easily observed by asking an aphasic patient to name an object, so an input problem cannot be excluded. Anomia is described by the failure to name or to retrieve names, common and proper nouns; auditory comprehension is either unimpaired or only mildly impaired. One manifestation of anomic speech is a fluent output that lacks the nouns and verbs related to concepts. As a result, speech may be described as empty. Speech rate, articulation, and, surprisingly, grammar are typically normal, and the on-line deficits in word retrieval may be signaled by noticeable pauses. Accompanying impaired naming is the inability to comprehend nouns or verbs in isolation; however, object recognition is usually quite good. Although reading and writing are usually preserved, in severe cases of anomia there may be an anomic alexia or anomic agraphia. Some degree of anomia is found in virtually all varieties of aphasia; in part for that reason, no specific localization for the causative lesions has been or is likely to be documented.

Global Aphasia

Global aphasia has also been called total aphasia. All language modalities are affected in global aphasia to an equal degree, unlike the other aphasias, in which a

processing disparity among the modalities is evident. The causative lesions leading to global aphasia are typically very large, subtending all or most of language cortex.

Single-Modality Functional-Clinical Aphasia Syndromes

There are a number of aphasia syndromes that predominantly affect a single language modality.

Apraxia of Speech

Apraxia of speech has also been called aphemia, verbal apraxia, articulatory apraxia, and anarthria. Not all researchers agree that this is an aphasia syndrome; it is included here because, by definition, motor control of the speech musculature is not affected in apraxia of speech, in other words, it is independent of dysarthria. Apraxia of speech often accompanies Broca's aphasia but may be an independent, modality-specific impairment. The modality affected is speaking, and the problems are best described as errors in the selection or ordering of sounds such that the resultant erroneous words either sound something like the target word but have the wrong meaning or are so distorted that they are no longer words of the language.

Alexia with Agraphia

Alexia and agraphia are, respectively, input and output impairments of written language. Alexia and agraphia may occur independently or together; alexia with agraphia has also been called parietal-temporal alexia, central alexia, semantic alexia, angular alexia, and letter blindness. The primary modalities of language that are affected are reading and writing. Patients suffering from alexia with agraphia display impairments in both reading and writing skills. In general, their ability to copy words tends to be better preserved than their spontaneous writing ability. The inability to read and write extends into domains other than visual language: numbers, musical notation, and chemical formulas can also be impaired. Speech output and auditory comprehension may be somewhat impaired but typically only in a mild form of anomia. Both the location and the size of the lesion will strongly influence the manifestation of any aphasia, but these are particularly relevant in the impairment described as alexia with agraphia; the causative lesions are predominantly found in the region of the angular gyrus.

Pure Word Deafness

Pure word deafness has also been called auditory agnosia, isolated speech deafness, and subcortical sensory aphasia; the modality affected is hearing. It causes patients to be unable to recognize speech sounds, while being able to hear non-language environmental noises, animal sounds, and music. Other language modalities – speech production, reading, and writing – generally remain intact. Lesions typically leave Wernicke's area undamaged, but destroy both Heschl's gyrus (primary auditory cortex) in the language hemisphere and the afferent auditory pathways coming from the non-language hemisphere. The functional result is that Wernicke's area behaves as though it is isolated from auditory language input; the patient can hear but cannot understand or repeat speech sounds. Except for the severely impaired input processing of speech, the patient with pure word deafness does not otherwise function like someone with Wernicke's aphasia. Auditory agnosia, which also reflects impaired processing of speech sounds, additionally reflects an impairment in processing non-language environmental sounds.

Agraphia

Agraphia, an inability to produce written language, has several neurolinguistic variants, which are discussed later in the neurolinguistic structures section. Functionally, it may appear as a written form of Broca's aphasia and, since written language so often mirrors spoken language, is typically associated with an aphasia. But, because writing also includes visuospatial skills as well as motor skills that differ from speech, impairments in spatial orientation or visual discrimination can cause agraphia without aphasia. Cases of pure agraphia frequently report damage within the frontal lobe, but a few cases have also shown damage within the left superior parietal lobe.

Alexia

Alexia is an acquired reading problem exhibited as an impaired ability to recognize words and/or letters, thus affecting the ability to extract meaning from written text. There are several varieties of alexia, including literal alexia (also referred to as letter blindness because the problem is primarily with individual letters), verbal alexia (also referred to as word blindness because whole words are primarily affected), general alexia (which refers to reading impairments that affect grammatical and/or semantic processing more than letters or words), and hemialexia, more commonly called neglect alexia (which refers to the impairment of attending to only half of a word or a line of text). In so-called pure alexia, written language stimuli are seen but not recognized as letters, as words, or both. In these cases, lesions tend to compromise the visual association cortex in the

language hemisphere together with the callosal fibers projecting from the other hemisphere, effectively isolating central language brain areas from visual input. There is a variant of pure alexia called letter-by-letter reading; such patients seem to process words by reading one letter at a time aloud before the word is identified. In some cases of alexia patients may successfully comprehend words if they are spelled out loud or traced on the palm, thus bypassing visual input to access the language core brain regions.

Transcortical Aphasias

The transcortical aphasias are sometimes known as the echolalic aphasias; there are three types, transcortical sensory, transcortical motor, and mixed transcortical, the latter sometimes known as the isolation syndrome. The modalities of language that are affected are speech comprehension (transcortical sensory) and speech production (transcortical motor) in the context of a sometimes dramatic spared ability to repeat, thus contrasting with conduction aphasia. In discussing the transcortical aphasias, it is useful to consider the notion of the language core, the temporo-parieto-frontal cortex of the language-dominant hemisphere in which resides the ability to repeat what is heard as well as the ability to process the basic sounds and word and sentence structures of one's language. Originally, the term transcortical meant that an ability to reproduce the sound structure or representation of a word was preserved, in the context of being unable to construct its meaning; this could be considered analogous to an ability to repeat a word in a foreign language that one does not understand. The predominant anatomically distinguishing feature of these aphasias is that the causative lesions are largely extra-Sylvian in location, that is, outside the classic language core. The following provides a brief overview of the generally accepted classical forms of the transcortical aphasias.

Transcortical Sensory Aphasia Transcortical sensory aphasia is an uncommon form of aphasia that may occur when a lesion functionally isolates Wernicke's areas from the rest of the brain, leaving the reception-to-output sufficiently unimpaired that repetition is preserved; neither speech comprehension nor spontaneous speech remain intact. The simplest way to describe transcortical sensory aphasia is to think of it as a form of Wernicke's aphasia in which the patient exhibits a severe comprehension deficit, but in which repetition, and thus articulation, is well preserved. In spite of intact articulation, the repeated speech of the transcortical sensory aphasic patient may be paraphasic, neologistic, anomic, and even echolalic. Typical output may appear to be uninhibited. Patients with transcortical sensory aphasia typically tend to be unaware of their impairment; as might be expected, their speech is occasionally misinterpreted as a psychogenic problem, such as schizophrenia. Writing ability is usually disturbed in a manner similar to that of patients with Wernicke aphasia.

Transcortical Motor Aphasia Transcortical motor aphasia, another form of the transcortical aphasias, is sometimes known as dynamic aphasia or anterior isolation syndrome. Functionally, the causal lesion separates the processing of speech from the mechanisms for initiating the action to speak. Patients with transcortical motor aphasia tend to appear mute, or nearly so, and may even have an associated general akinesia, an inability to initiate action. Although transcortical motor aphasia impairs the ability to initiate speech, once such patients begin talking, speech output is typically relatively intact. Comprehension will be relatively normal, as will repetition. Prosody, articulation, and grammatical structure remain quite preserved even if verbal output is interrupted by incomplete sentences, verbal paraphasias, or false starts. When asked to say something, or otherwise initiate a response without cues, these patients have a great deal of difficulty responding; however, when asked to repeat words, phrases, or sentences, performance is characteristically flawless. There is a range in ability in word retrieval, with some patients being able to perform well on tasks such as object naming. Verbal output may improve if related to common, repetitious material. The lesions that lead to transcortical motor aphasia are typically found on the mesial surface of the anterior left frontal lobe, near supplementary motor cortex, or along the lateral aspect of the left frontal lobe; in either case these lesions fall outside of what is traditionally thought of as Broca's area. Presumably the lesions impinge on an anterior cortical or subcortical site that forms part of a circuit linking the motor speech area with the supplementary motor area and certain limbic structures considered essential for the initiation of speech and other actions.

Mixed Transcortical Aphasia Mixed transcortical aphasia, known also as the isolation syndrome, may be associated with Pick's disease or carbon monoxide poisoning affecting the so-called watershed region of the cerebral vasculature; the language core, the peri-Sylvan speech areas, are functionally isolated from other brain functions, particularly higher-order cognitive functions. The one remaining language

function is a striking ability to repeat words, phrases, and on occasion whole sentences. The isolation syndrome is most clearly the functional opposite of conduction aphasia; the former patient can only repeat speech, while the latter cannot repeat speech. Although articulatory fluency generally remains well preserved, the quasi-automatic repetition, often a frank echolalia, is prominent in a context of few if any other intact language functions. There is typically a complete alexia and agraphia, with an occasional ability to scribble meaninglessly. As pointed out by Benson and Ardila, other than the ability to repeat, patients with mixed transcortical aphasia exhibit the characteristics common to global aphasia.

Neurolinguistic Structures

The second approach, a neurolinguistic analysis of the aphasias, focuses on which linguistic components of language are affected by brain damage, within the framework of five, sometimes six, components of language: (1) phonology, or the sound system, (2) morphology, or the structure of words, (3) syntax, or the grammatical system, (4) semantics, or the system of meaning, (5) narrative or discourse, or the component that strings sentences together in coherent syntactic and semantic structure, and (6) the pragmatic or language use system. Linguistic-based descriptions of aphasic errors are neutral as to whether the errors are seen in speech production or comprehension or in written language. It is typical that the degree of impairment (percentage of errors seen on testing) of linguistic components is different in different language modalities; for example, a Broca's aphasic patient is likely to exhibit more severe agrammatism in speaking than in comprehending. It is occasionally documented that the linguistic impairments are overwhelmingly in one modality (e.g., being able to recognize grammatical errors but being unable to avoid producing them); this can lead to interesting theoretical issues regarding the nature of the language core brain areas, which are beyond the scope of this article.

Phonological Disorders

Phonological disorders are typically described in terms of phonemes, the minimal significant unit of sound in a language, or graphemes, the equivalent for the writing system. Errors may be described as substitutions (e.g., *bit* for *pit*), omissions (e.g., *cook* for *crook*), or sequencing errors (e.g., *cattle* for *tackle*, as sounds). Other phonological errors include problems with the control of prosody: syllables may be shortened or lengthened incorrectly, pitch contours may signal a question when a statement was intended, or speech may be louder or quieter at inappropriate times.

Morphological Disorders

Morphological disorders affect a word's affixes, either (a) the inflectional affixes such as mark plural vs. singular, third person singular vs. first person singular, or past vs. present tense (e.g., *three cat* for *three cats*, *he will jumped* for *he will jump*) or (b) the derivational affixes such as mark words as nouns, verbs, or adjectives (e.g., *nationalness* for *nationality*).

Syntactic Disorders

Syntactic disorders, agrammatism, affect the grammatical structure of phrases and sentences. Obviously, if disorders of derivational or inflectional affixes discussed previously were to impact the grammatical correctness of a phrase or sentence (e.g., *he's a regularity guy* for *he's a regular guy*) one would speak of a syntactic deficit that manifested as a morphological error. The more common form of agrammatism is seen as the omission of grammatical function words (e.g., *boy hit ball* for *the boy was hit by the ball*), which clearly impacts the meaning of the sentence as well as its grammaticality; thus, as was the case with morphological disorders, syntactic disorders can overlap semantic disorders, too. A rarer form of syntactic disorder known as paragrammatism results in the inappropriate use and ordering of grammatical function words, rather than their omission (e.g., *in on a the by a flower pot* for *in the flower pot*). Additional syntactic disorders involve the simplification, ordering, substitution, or omission of phrase- and sentence-level structures that may interact with impairments in meaning. For example, if *what the pot put on the table was the boy* were substituted for *it was the pot that the boy put on the table*, or, *what the boy put on the table was the pot*, one would note that the grammatical errors of substitution and ordering resulted in a change in meaning. As will be readily surmised, agrammatism is frequently, though not exclusively, seen in Broca's aphasia; paragrammatism is less frequently seen in Wernicke's aphasia because word order violations are infrequently observed syntactic disorders.

Semantic Disorders

Semantic disorders can take any number of forms, depending upon what aspect of the semantic system is impaired. Substitution of similar-meaning words is common (e.g., *concert* for *orchestra*) as is the interchange of superordinates and subordinates (e.g., *animal* for *dog*). A common strategy for anomic patients is to substitute an indefinite noun for an inaccessible

one (e.g., *something* or *stuff* in place of *shirt* or *clothes*). Semantic disorders may also impair knowledge of features of objects (e.g., being unable to indicate that a fire truck is red or that grass is green) or attribute incorrect features to objects (e.g., something inanimate is given attributes of being alive).

Narrative Disorders

Narrative or discourse disorders will affect the coherent stringing of sentences or phrases together in conversation, for example, changing a pronoun so that it no longer refers back to the person who is being discussed or inappropriately changing the time frame of a narrative. Pragmatic disorders refer to impairments in language use, for example, no longer understanding that the statement "I could use some salt on my roast beef" is an indirect request to another person to pass the salt shaker to the speaker. It will be immediately apparent that, just as with morphological and syntactic disorders, higher level problems with discourse and pragmatics may be described in terms of semantic or syntactic errors. The different linguistic components of language, levels, are simultaneously present when language is being used.

Alexias

The analysis of neurolinguistic structures has led to a syndrome classification of reading and writing disorders as follows. Three alexias have been defined in terms of the putative locus in a psycholinguistic model of reading: deep alexia, phonological alexia, and surface alexia.

Deep Alexia Patients with deep alexia usually have sustained a lesion sufficiently large to produce an aphasia, frequently a Broca's aphasia; their reading is characterized by semantic errors in reading aloud (the error is semantically related to the target word) and may also show visual errors (the error is visually similar but otherwise unrelated to the target word), morphological errors (the error is a morphological variant of the target word), a concreteness effect (concrete words are easier to read than abstract ones), and difficulty in reading grammatical function words. Word frequency and word length may also impact the prevalence of reading errors. Patients with deep alexia are impaired in grapheme-to-phoneme conversion; as a result, they have a pronounced inability to read non-word letter strings that could be possible words in the native language (e.g., for English, the string *vib* or *phite*).

Phonological Alexia Phonological alexic patients can read real words but because they also have a major problem with grapheme-to-phoneme conversion, they have difficulty reading pronounceable nonwords, as is the case with deep alexic patients. Patients with phonological alexia typically do not make the semantic errors seen in deep alexia; otherwise, the boundary between deep and phonological alexia is not always sharp and some patients seem to have many characteristics of both types. It has been reported that deep alexia may evolve to phonological alexia in the course of recovery.

Surface Alexia Patients with surface alexia have a reading impairment characterized by their ability to read orthographically regular words (note that about 75% of the English lexicon is orthographically regular, e.g., words such as *top, jelly, sing*) but a pronounced difficulty reading orthographically irregular words (in English, words such as *pint, come, bury* are orthographically irregular). Errors made by surface alexic patients on irregular words tend to be regularizing errors, that is, pronouncing them as though they were orthographically regular. Surface alexic patients are able to read pronounceable nonwords, e.g., *heaf* would be read to rhyme with the word *leaf,* which is regular, but not *deaf,* which is irregular.

Agraphic Disorders

As with reading impairments, there are three main linguistic forms of agraphic disorders. The first is phonological agraphia, which is an impairment in writing pronounceable pseudowords to dictation, with a much better preserved ability to write real words and occasional difficulties with grammatical function words and abstract words. A second form is semantic agraphia, which can occur with focal lesions but is more commonly found in the early stages of senile dementia of the Alzheimer type; such patients may write real words and pseudowords normally to dictation, but they make frequent semantic errors in written confrontation naming or written descriptions. A third form is lexical agraphia; these patients preserve the phonological form of the word when writing, but produce spelling errors that normalize spelling to approximate to how the word sounds.

Conclusion

In conclusion, the main recommendations today for continued use of the functional/clinical aphasia syndromes, the so-called classical syndromes, reviewed here are convenience and consistency. A great deal of modern research in neurolinguistics, clinical neuropsychology, and the cognitive neurosciences employs the classical aphasia syndromes for identifying patient groups, notwithstanding the research in the late twentieth century that casts doubt upon the

validity of the consistent location of causative lesions, other research that questions the logical coherence of the symptomatology of syndromes, and still other research that questions the possibility of studying groups of patients classified in terms of these syndromes. The most widely used test battery in the United States, the Boston Diagnostic Aphasia Examination (BDAE), from which the major aphasia syndrome typology originates, claims to be able to classify only about three-fourths of all patients with language impairments. One may still argue, and many contemporary publications will attest, that the patients who can be so classified into syndromes can, sensibly and statistically, be grouped under these headings for research purposes. In contrast, a linguistic typology of aphasia, a classification of neurolinguistic impairments, would only be challenged by a better linguistic theory. Such a classification does characterize aphasic impairments even if it does not neatly align with functional and clinical categories, nor does it neatly align with particular brain regions as revealed by lesion localization or imaging techniques. Caveat emptor.

Glossary

Aphasia – Acquired, usually abrupt-onset language impairment resulting from brain damage.

Dementia – Acquired disorder of cognitive and self-management abilities, that may be characterized by progressive decline of memory, judgment, and abstract thinking, as well as changes in personality.

Discourse Skills – Skills allowing the appropriate use of pronouns, intonation patterns, and meeting social expectations in conversation.

Lexical Skills – Skills that relate to the production and comprehension of individual words.

Syntactic Skills – Skills that enable a person to understand and use conventional rules of grammar.

Overview of Language Disorders in Older Adults

Language disorders in older adulthood can be generally divided into progressive impairments of

language associated with dementing diseases and non-progressive, abrupt-onset aphasia. This article describes the language deficits associated with dementia syndromes and provides a brief review of language deficits in aphasia.

Dementia (*see* Dementia) is an acquired disorder of cognitive and self-management abilities, characterized in many instances by progressive decline of intellectual function involving impairment of memory, judgment, and abstract thinking, as well as changes in personality. Language impairment also accompanies most forms of dementia. Dementia predominantly affects older adults, and its prevalence rises with increasing age. Since a larger proportion of the population of today is older than in the past, and long-term survival is predicted to increase in the coming decades, the number of individuals with dementia is rising.

Different types of dementing disorders have been identified (e.g., dementia of the Alzheimer's type, frontotemporal dementia, vascular dementia), but differential diagnosis of these disorders is still clinically challenging, and the prevalence of the different disorders is not only difficult to ascertain but also controversial. At the present time, dementia associated with Alzheimer's disease is often considered to be the most prevalent form and is often said to account for 55% of all cases of dementia, with dementia with Lewy bodies accounting for about 15%, vascular dementia about 10%, and frontotemporal dementia about 5%. As diagnostic precision improves, these percentages will undoubtedly shift.

Researchers have asked whether dementia accompanies the normal course of growing old (*see* Language and Communication in Aging). If so, one or another form of dementia will necessarily occur, eventually, in any individual who lives long enough. If, by contrast, dementia is related to a disease state superimposed on the course of healthy aging, it would not be expected to occur in all individuals. Research evidence available today points to the latter proposition; that is, despite growing percentages of aging individuals who acquire dementia, the majority maintain most of their cognitive skills over time. Age alone, therefore, despite being a major risk factor, does not explain dementia.

Aphasia (*see* Language Disorders: Aphasia) refers to an acquired, usually abrupt-onset, language impairment resulting from brain damage. In contrast to dementia, behavior, personality, and other cognitive abilities are essentially preserved in aphasia. The leading cause of aphasia is cerebrovascular accident (CVA, or stroke), which results from a sudden disruption of blood flow to the brain, causing cell death. Such a disruption can be the consequence of obstruction of flow in the blood vessel or rupture of the blood vessel with bleeding into the brain. Strokes are the third most common cause of death among adults in the United States, and about two-thirds of all strokes occur in individuals who are 65 or older. About 20% of persons with stroke have aphasia, and it is estimated that approximately one million persons in the United States today have aphasia. Although the behavior and cognitive deficits of individuals with aphasia and dementia are fundamentally different, the term aphasia is sometimes used to refer to the manifestation of language and communication deficits in dementia.

Language in the Dementias

This section outlines the major dementing syndromes that are pertinent to aging and summarizes the language deficits that have been observed clinically as well as experimentally in individuals with these syndromes.

Dementia of the Alzheimer's Type

Dementia of the Alzheimer's type (DAT) is characterized neuropathologically by cerebral atrophy, predominantly in temporo-parietal, anterior frontal, and hippocampal regions, excessive deposition of amyloid plaques and neurofibrillary tangles, amyloid angiopathy, and granulovacuolar degeneration. Behaviorally, individuals with DAT exhibit progressive impairments in memory, attention, and executive function that lead to associated communication deficits. Other cognitive deficits include impairments of judgment and reasoning and are severe enough to interfere with daily functioning. Despite the considerable variability that can be found among individual patients, some generalizations about language and communication skills can, nonetheless, be made. The following sections review the changes in lexical, semantic, syntactic, and discourse skills typical of DAT.

Lexical Skills Lexical skills are those that relate to the production and comprehension of individual words. Even in the earliest stages of the disease, patients with DAT show evidence of lexical impairment but are often unaware of this difficulty. For example, they may replace target words with less meaningful fillers (such as *thing*), confuse semantically related words (e.g., *dog* for *cat*), produce names that would be correct in another context (e.g., *jelly jar* instead of *cookie jar*), or generate a novel expression in place of an accepted noun (e.g., as Alois Alzheimer's original patient did, saying *milk pourer* for *cup*). They

may also show difficulties in elicited word retrieval tasks such as confrontation naming (naming a picture or an object upon request) or word list generation (generating as many words as possible, given a letter or a semantic category, within a given time). Typically, letter-based word list generation is more impaired than semantic-based generation in DAT. Performance differences may exist by response modality. For example, a person who does well at oral naming may have extreme difficulties with written naming.

As the dementia progresses, word retrieval problems become more pronounced. Frequent instances of circumlocution (describing a target instead of using the word itself) often make the language production of individuals with DAT difficult to follow, and their own awareness of their problem tends to diminish as other cognitive skills decline. In even later stages, production errors may include sound substitutions or non-words (neologisms), as well as semantic substitutions. Lexical skills become progressively worse with time, and by the end stages of DAT, some patients are unable to produce their own names.

Problems using words correctly in conversation are thought to be due, at least in part, to short-term memory deficits, as patients with early stage DAT frequently forget what they are saying. However, their lexical problems cannot be fully explained by a loss of short-term memory or loss of semantic knowledge (the knowledge of what things are). Rather, researchers have shown that people with DAT who cannot name an item on their own are more likely to choose a semantically related word rather than an unrelated word, if given several choices. Furthermore, they are often able to identify objects when provided with a name. Researchers have taken these experimental observations as evidence that, at least in the early stages of DAT, many elements of semantic knowledge are intact, but that the ability either to discriminate among several related items or to choose the intended word produces the word-finding difficulty.

Syntactic Skills Syntactic skills are those that enable a person to understand and use conventional rules of grammar. Researchers generally report that the syntactic abilities of people with DAT remain intact. However, by late-stage DAT, patients exhibit spoken comprehension difficulties and can rarely follow multistep commands. Their ability to comprehend written material is difficult to judge because of the difficulty that reading aloud poses for them. Furthermore, some studies have shown that people with DAT may have difficulty understanding and producing syntactically complex structures, such as subordinate clauses (e.g., "The truck that pulled the car was blue."). Memory problems are likely to contribute to these deficits. Although language output may become progressively more fragmented, many speakers with DAT are able to produce grammatically complex sentences through the middle stages of the disease. As with other language skills, syntactic knowledge in DAT does not seem to disappear, but its use appears to be severely hampered by the cognitive problems associated with the progression of the dementia.

Discourse Skills Discourse skills include the knowledge of language use at the conversation level, including verbal aspects of conversation, such as referential coherence (e.g., appropriate use of pronouns), and non-verbal aspects, such as prosody (intonation patterns) and social expectations. In DAT these skills are usually intact until the later stages of the dementia. While turn taking and the prosody of the speech remain normal, individuals with late-stage DAT show an increased tendency to violate conventions of topic maintenance and shifting, abruptly changing the topic or failing to signal their interlocutor appropriately. They are also much more likely than non-demented speakers to mention things that are inappropriate for the setting or to misinterpret the interlocutor's questions (e.g., during a naming test, a patient was asked whether he knew what an object was called; the patient replied "Yes, why do you ask?"). In addition, their discourse may become fragmented due to the impaired use of referring expressions. For example, to the question "Do you remember me?" a patient answered "I've seen it I think, I hope," using the pronoun *it* inappropriately. Similarly, individuals with DAT may refer to the same person as *he* and *she* within a single sentence. These deficits are thought to be at least partially due to memory deficits that prevent the speaker from remembering, and then correctly referring to, his or her utterances over the course of the conversation. Often, individuals with DAT respond to social greetings and are able to give their names when asked, even in advanced stages of the dementia.

Non-Alzheimer's Dementias

Frontotemporal Dementias The frontotemporal dementias (FTDs) are a group of syndromes characterized by progressive degeneration of the frontal lobes, the temporal lobes, or both. A prominent characteristic of FTDs is personality change, manifested in impaired social interaction, loss of insight, and self-neglect. Frontal-executive skills are impaired, and memory retrieval may be impaired, often as a consequence of frontal-executive deficit. Individuals with greater left hemisphere involvement

experience greater language impairment, whereas those with greater right hemisphere deficit show relatively intact language and speech skills (although their affect and communicative facial expressions might be impaired).

Language-related changes associated with FTDs include reduced speech output, repetitive and habitual use of single words or phrases (stereotypy), and an increased use of automatic speech. In later stages of the dementia, the speech production of individuals with FTDs is characterized by involuntary, spontaneous repetition of their own words (palilalia), other speakers' words (echolalia), and previously used words or phrases (perseveration). Also common are repetition of final syllables (logoclonic speech) and rapid reiteration of individual phonemes (festinant speech). Language impairment comprises severe word-finding difficulties (anomia) and reduced verbal fluency. As the dementia progresses, there is often a gradual progression to mutism. Although language comprehension appears less impaired than language production, in many individuals with FTDs, spoken language comprehension can be affected. Research studies of language comprehension have found that on auditory comprehension tests, individuals with FTDs are insensitive to transitivity and thematic agreement. For example, on a word-detecting test, healthy older adults respond faster to a word that is consistent with the thematic constraints of the preceding sentence than to a word that is inconsistent with the theme (e.g., responding to the word *carpet* after hearing: *the plaster falls onto the carpet* as compared to after hearing *the thought falls onto the carpet*). By contrast, individuals with FTDs do not exhibit slower response times with the latter type of sentences (i.e., with incorrect thematic agreement).

A subgroup of individuals with FTDs consists of those with primary progressive aphasia (PPA). In the first 1 or 2 years of this syndrome, a language deficit emerges, but memory and social and behavioral skills are preserved. Speech impairments include articulation difficulties, stuttering, and gradually reduced speech output, often progressing to mutism. Most patients with PPA experience anomia, with verb naming often more severely impaired than noun naming. Furthermore, research evidence suggests that in object naming, both natural kinds (e.g., *horse, tree*) and manufactured objects (e.g., *table, spoon*) are impaired, and there is differential impairment on these different subcategories.

Individuals with PPA can be divided into those with non-fluent aphasia and those with fluent aphasia (also known as semantic dementia). These two subtypes share many aspects of language disturbances but can be distinguished on the basis of their relative difficulty with word list generation (known also as verbal fluency), object naming, and single word comprehension, and the sound substitutions (phonemic paraphasias) they produce, as described in the following.

Frontotemporal dementia of the frontal type Among individuals with PPA, asymmetric cortical atrophy and frontal lobe degeneration can result in progressive non-fluent aphasia (PNA). Initially, PNA causes a slowly progressing language impairment, with little additional cognitive decline. Speech production is often slow, hesitant, and effortful. Articulation difficulties (dysarthria) may be present and are more likely as the disease progresses. The language impairments include phonemic paraphasias and anomia, although the anomia is less severe than that seen in semantic dementia. Utterances tend to be short due to difficulty with complex sentences, such as those containing relative clauses. Language comprehension is relatively preserved. Reading aloud is effortful, and sound substitutions are common. Writing skills are also impaired, characterized by frequent spelling errors.

Frontotemporal dementia of the temporal type Semantic dementia (SD) is the fluent type of progressive aphasia and is primarily associated with temporal lobe involvement. As in PNA, the onset of semantic dementia is insidious and the course of the impairment is progressive. SD is characterized by effortless, fluent, grammatical speech. Repetition and writing skills are basically intact. By contrast, word production (e.g., in picture naming) and word comprehension are impaired. As in fluent aphasia (*see* Language Disorders: Aphasia), speech often appears empty, due to the increased use of vague terms. Word substitutions (semantic paraphasias) are common, especially as the dementia progresses. Researchers have pointed out that the lexical deficit in SD can indicate loss of semantic knowledge. Evidence for this can be found in the semantically based word production errors and in word and object recognition errors produced by individuals with SD.

Individuals with semantic dementia have difficulty producing irregular past tense forms (e.g., *break–broke*) but perform at near-normal levels with regular verbs (e.g., *visit–visited*). This is consistent with research findings suggesting that irregular verb forms are represented as words in the lexicon, whereas regular verb forms are produced by the grammar. Similarly, irregular verb production (but not regular verb production) correlates with the ability to judge verb synonyms (i.e., whether two given verbs have roughly the same meaning), suggesting semantic,

rather than syntactic, impairment. Furthermore, more individuals with SD show greater impairment on naming tests than those with PNA or other subtypes of FTDs. People with SD also show a significant correlation between naming and performance deficits on semantic memory tests as well as impaired performance on word list generation tasks, consistent with a memory deficit basis for the naming impairment.

Movement Disorder-Related Dementias

Parkinson's disease dementia Individuals with Parkinson's disease (PD) are more likely to have dementia (PDD) than are age-matched persons without Parkinson's disease. Reports estimate that the percentage of individuals with PD who exhibit dementia ranges from 15 to 40%. PDD typically develops slowly, often with modest and variable decline. Motor slowing and impaired movement programming associated with PD often affect speech production. Speech deficits include monotonous speech (dysprosody), reduced phrase length, low intensity of speech (hypophonia), and dysarthria.

Generally, language skills have been considered to be intact in early PDD, gradually declining only as the dementia progresses. However, investigators have demonstrated that in language production, individuals with PDD have mild naming and word list generation deficits. As in individuals with DAT, semantic-based production is better than letter-based production. Output is characterized by frequent pauses and hesitations, but few word substitutions. Syntactic skills remain essentially intact in PD, but in PDD, grammatical ability varies with the severity of the dementia. When written language production is examined, using samples of one sentence and measures such as length in words, length in clauses, number of propositions, and number of fragments, individuals with moderate PDD differ from healthy older individuals. By contrast, individuals with PD without dementia or with mild PDD have not been found to decline on any of these syntactic measures. Working memory limitations, reduced processing speed, or visual impairments may contribute to comprehension deficits on tests such as picture identification. When auditory probes are used in a listening comprehension task in people with PDD, participants may have difficulty detecting a missing grammatical morpheme but are able to detect word order errors. They perform well with passive structures and transitive verbs but have trouble with lexical causative verbs (e.g., "The woman drowned the swimmer").

Dementia with Lewy bodies The diagnosis of dementia with Lewy bodies (DLB) is based on the presence of intracellular hyaline inclusions (Lewy bodies), found in cortical and subcortical brain regions of a subset of individuals with PD. The distinguishing characteristics of DLB are parkinsonism, visual hallucinations, and fluctuating cognitive impairment.

Relatively few reports have focused on the language of individuals with DLB. Speech production might be impaired to the extent that parkinsonism is present, with decreased volume and rate of speech. Whereas language itself is not typically impaired in DLB, impaired executive skills and reduced cognitive speed contribute to compromised language skills. For example, individuals with DLB may experience difficulty producing words and phrases during testing, but this difficulty is likely due to executive skills rather than frank language difficulty. Such difficulties include poor performance on word list generation tests, with no greater deficit on semantic- than on letter-based productions, and mild deficits in confrontation naming. Perseverations are also common. Additional limitations include decreased attention and poor search and working memory skills, which might interfere with efficient language use. Fluctuations, which characterize cognitive abilities in DLB, characterize these verbal difficulties as well.

Huntington disease dementia Huntington disease (HD) is characterized clinically by jerky movements (chorea), slow writhing movements (atheosis), repetitive movements, and twitching. As the disease progresses, breathing and articulation impairments disturb speech production and yield dysarthria, dysprosody, and decreased speech volume, rate, and phrase length. In HD, speech is characterized by markedly decreased initiation and short, grammatically incomplete sentences. Clinically, frank language deficits are not typically associated with HD, but communication abilities may be affected due to cognitive impairment, including decreased ability to shift set, impaired attention and memory, and decreased organizational skills. These cognitive deficits have been linked to impaired word list generation, both semantic- and letter-based production (performance is typically better on the semantic-based task), and impaired naming. This is true particularly as the dementia advances, although difficulty on naming tests has been reported even when the dementia diagnosis is mild. Moreover, in studies comparing individuals with late-stage HD and DAT, people with HD do not perform better than those with DAT on measures of language comprehension, speech perception, and vocabulary. As the dementia develops, verbal output is severely decreased, progressing eventually to mutism.

Vascular Dementias The vascular dementias (VaDs) include several dementing syndromes resulting from cerebrovascular insufficiency: multi-infarct dementia, single strategic strokes, multiple subcortical lacunar strokes, white matter lesions, postischemic dementia, and vascular-Alzheimer dementia. Although grouped together, there is great heterogeneity among the differing vascular dementias.

Relatively few studies have examined language deficits associated with the vascular dementias. Existing data suggest that poor executive function might affect planning, sequencing, and attention during task performance. Memory impairment might lead to impaired performance on naming tests, but such deficits are not always found. Little is known about the language of VaDs of the multi-infarct dementia type, primarily because individuals with vascular impairment who are diagnosed with aphasia are normally excluded from studies of vascular dementia, to avoid confounding the focal deficits of aphasia and those of dementia. For individuals with VaDs resulting from a single stroke, the location of the stroke will influence the language impairment that might follow. In individuals with white matter lesions (WMLs), decreased verbal retrieval, reduced spontaneity, and laconic speech with reduced syntactic complexity may be present. Additional frank language deficits associated with VaDs include decreased word list generation, particularly for letter-based production, reduced sentence complexity in language production, and frequent perseverations.

Developmental Disorders and Dementia

Until recently, relatively little had been written about the neuropsychological functioning of individuals with mental retardation (MR) who subsequently develop dementia. With the increasing life span of individuals with MR, clinicians and researchers have begun accumulating data about age- and dementia-related changes in individuals with MR, particularly those with Down syndrome (DS). There is substantial evidence suggesting that dementia, especially dementia of the Alzheimer type, is highly prevalent among individuals with DS. Studies of neuropsychological impairment of individuals with DS who develop dementia demonstrate that their cognitive impairment is similar to that found in the dementia syndromes of the general population. Areas of cognitive decline include memory, naming, semantic fluency, and comprehension skills.

Behaviors associated with dementia, mostly with DAT, may develop in individuals with DS at a relatively early age (as young as 40 or 50 years). It is often difficult to dissociate cognitive deficits associated with the dementia from those that pre-existed in the aging individuals due to their developmental disorder. This difficulty is compounded by the great variability of intellectual abilities found among individuals with DS and MR generally. Furthermore, commonly used tests for dementia diagnosis are usually inappropriate for diagnosis among individuals with MR. Researchers have begun to demonstrate that certain neuropsychological tests, including tests of short-term memory, confrontation naming, and word list generation, can be sufficiently sensitive to distinguish between individuals with MR with and without dementia; however, normative data for cognitive skills and particularly for language skills are still necessary.

Multicultural Aspects

Cultural Considerations Data concerning the prevalence and characteristics of dementia across cultures and languages, especially in developing countries, are sparse. Recent reports suggest that by employing cognitive and language measures adapted to several languages, as well as informant information, clinicians can efficiently assess the dementing syndromes among a variety of communities. These reports are preliminary, and experts agree that normative data from a wide range of cultures and languages are still lacking. This dearth of norms might lead to misdiagnosis.

Whereas the majority of data available in the United States today is about Caucasians, recent work has focused on dementia among non-white Americans, including Asian Americans, Hispanic Americans, African Americans, and Native Americans. Dementia prevalence has been reported to be higher among African Americans and American Hispanics than among Caucasian Americans. Reports also suggest that there might be differences in the prevalence of the various dementia types among the different ethnic groups. Differences may be attributed to environmental, social, and biological factors, and to measurement differences.

People of Hispanic, Asian, and Native American communities may be less likely to be aware of resources for patients and caregivers and may be less likely to seek medical support. Moreover, fewer resources (professionals, diagnostic materials) adapted to the culture and language of minority communities are available. As a result, persons in minority communities are often less informed about the dementing syndromes, their etiology, and symptoms. Furthermore, attitudes toward individuals with dementia vary across cultures. In some cultures, stigmas might be associated with dementia and the symptoms associated with it. They can be considered shameful

or be attributed to 'bad blood,' being punished for previous sins, or mental illness. In some cases, dementia symptoms are attributed to normal aging, and respect for the elderly would prevent seeking external help. Such cultural differences have started to be considered in assessment and treatment of individuals with dementia.

Bilingual and Multilingual Speakers To date, evidence on language disturbances in bilingual dementia is limited. Individuals who speak two languages and acquire dementia have been found to exhibit the same patterns of language impairment found in monolinguals with dementia. For individuals who have high proficiency in both their languages, the two languages appear to be equally affected. But, as in bilingual aphasia, there are individuals who demonstrate differentially impaired skills in their first or second language. Little is known about individuals who use more than two languages (multilinguals).

Those impairments observed among bilingual individuals with dementia include inappropriate language choice and language mixing. For example, inappropriate language choice occurs when individuals (unintentionally) speak one of their languages with an interlocutor who only understands the other language, or reply in a language different from the one in which they were addressed. Language mixing (code mixing) refers to a situation in which the individuals mix words and utterances from both languages, even when the listeners are not able to comprehend both languages. At least in early stages of dementia, bilingual individuals are able to follow a conversation in any one of their languages, even if they reply in another. Preliminary research data suggest that the degree of inappropriate language mixing is not directly related to the degree of the dementia severity. Mechanisms that account for language choice in dementia are not well understood and represent a fruitful area for further research.

Language in the Aphasias

Aphasia (*see* Language Disorders: Aphasia) refers to language-specific deficits resulting from brain damage, usually in the left cerebral hemisphere. In most instances of aphasia, not all language skills are equally affected. Several types of aphasic syndromes have been identified. The classification of aphasia has been based, traditionally, on the type of language deficit observed as well as the location of the brain lesion. Whereas links between the type of deficit and lesion location have been identified, these relations are complex and are still debated.

Language impairment in aphasia may affect predominantly language production or language comprehension, one modality (e.g., spoken language) or all modalities, and may be mild or severe. Most speech-language clinicians and researchers today distinguish between two major categories of language disturbance. Fluent aphasia is typically characterized by fluent but empty (meaningless) speech production, word-finding problems, speech errors, semantic deficits, and impaired comprehension. Non-fluent aphasia is characterized by effortful speech and language production and relatively intact comprehension. In most cases, an aphasic impairment is not progressive, and time, practice, and treatment result in gradual improvement of language skills.

Several epidemiological studies of aphasia in adulthood demonstrate that certain forms of aphasia are associated with particular age ranges. Specifically, non-fluent aphasia has been associated with younger age ranges than fluent aphasia. In one study, for example, individuals with non-fluent aphasia were in their 30s to 60s with a mean age of 52, whereas individuals with fluent aphasia tended to be older, with an age range of 40 to 80 and a mean age of 63. This distribution might be related to brain changes associated with aging. The relation between age of aphasia onset and degree of recovery from aphasia, however, is less consistent. The hypothesis that older adults with aphasia are less able to recover their language skills than younger adults has not received unequivocal research support.

Learning

J S Freund, University of Arkansas, Fayetteville, AR, USA

Glossary

Association – An association between two events is inferred when a subject reliably produces one event when presented with the other.

Conditioned Response (CR) – The learned response conditional upon presentation of the conditioned stimulus (CS), and previous pairings of the CS and unconditioned stimulus (UCS).

Conditioned Stimulus (CS) – Originally neutral stimulus that comes to elicit a response by being paired with the unconditioned stimulus (UCS).

Learning – The process that results in a relatively permanent change in behavior potential due to experience.

Paired-Associate Learning – A learning task involving pairs of stimuli. The subject is presented with the first item of each pair and is expected to produce the second.

Unconditioned Response (UCR) – The response produced by the unconditioned stimulus (UCR).

Unconditioned Stimulus (UCS) – A stimulus that has the ability to elicit a response without prior training.

Introduction

The area of learning encompasses a wide variety of tasks, from motor skills such as driving and typing to verbal tasks such as learning one's native or a new language or simply learning to pair a new friend's face with her name. This article presents a brief summary of research and theory in the area of learning and aging.

Learning is often defined as 'the process by which long-lasting changes occur in behavioral potential as a result of experience with various tasks.' Several of the terms in the definition need further explication. 'Learning' typically refers to the process by which change occurs; memory refers to the outcome of that process. 'Long-lasting' is used to distinguish learning from other more transient changes that may look like learning but are not; fatigue, motivational changes, and changes due to drugs are some examples. 'Behavior potential' is used because non-learning factors (e.g., motivation, opportunity to display the behavior) may not allow the changes to be expressed immediately. 'Tasks' is an omnibus term encompassing a diverse set of activities that can and have been studied, some examples of which are in **Table 1**.

The area of learning must also be distinguished from its companion area, memory, which Anderson (2005:5) defined as "the record of the experience that underlies learning." It should be apparent that the difference between these two areas is often subtle, perhaps arbitrary, and certainly debatable. It is also true that they are inextricably linked: without learning, there would be nothing to remember; without memory, learning would be for naught. A working distinction, to be adopted here, is that one studies learning when the focus of the investigation is the acquisition process itself, whether the material or skill being acquired is novel or familiar. Operationally, learning is the focus when the time period between the study or practice portion and the test portion is equal to, or less than, the time taken for the study phase.

For example, in a typical learning experiment, a list of 35 common words is presented on a tape recorder at the rate of one word every 5 s. After presentation, subjects are given 2 min to verbally recall as many of the words as possible. The list is then repeated, and again recall is attempted. This entire study–recall sequence is repeated five times. Although the list is composed of common words, that is, words already in memory, the focus of the study is the increase in recall (i.e., learning) across the five trials. Adding a sixth recall-only trial 20 min after the fifth study–recall cycle would have introduced a memory component to the task.

Rationale and Theory

Psychologists are interested in the relationship between aging and learning for several reasons. On a practical level, the proportion of the population over 60 is growing, and we need to determine how the learning processes of older adults differ from those of younger adults. Knowledge of these differences will allow us to develop effective ways to teach older people new skills, whether for the workplace, for treatment of various physical or psychological problems, or simply to help people deal with, and get more enjoyment from, their ultimate retirement. In

Table 1 Types of learning and examples of research and everyday responses

Type of learning	*Research tasks and responses*		*Common examples*
	Animal research	*Human research*	
Classical conditioning	Eyeblink Fear Taste, aversion Salivation	Eyeblink Galvanic skin response	Desensitization therapy Phobias Prejudices Food aversions
Operant conditioning	Bar pressing (rats) Key pecking (pigeons)	Key pressing Digit-symbol substitution	Behavior therapies
Instrumental learning	Multiple-choice-point spatial maze	Multiple-choice-point paper maze	Navigate in a new environment
Motor-skill learning	None	Typing Pursuit rotor Mirror tracking	Typing Bicycle riding Playing golf
Implicit learning	None	Artificial grammar learning Serial reaction time	Learning to speak one's native language as a child Skill learning requiring sequenced movement to specific stimuli
Paired-associate	Discrimination learning	Learning a list of noun pairs Learning a list of picture-word pairs	Foreign language vocabulary Face–name learning

addition, there is some concern that the retirement of older, highly skilled people might leave vacancies that could be filled only after extensive periods of training, prompting the idea that these older employees may be asked to remain on the job past their planned retirement time. Thus, additional training might be required for those individuals, especially when methods, materials, or equipment change.

On a more basic research level, one way to understand a process is to compare the process under two conditions: when it is working efficiently, and when it is not. Careful comparison of those two situations may yield insight into how the process works. Studying the effect of the aging process on learning may give us some insight into the learning process in general.

Finally, study of aging and learning allows psychologists to test theories of learning. Many theories of learning make predictions involving individual differences. For example, one theory might predict that physical activity is related to mental alertness. A preliminary test of the theory would be to determine if there were a correlation between some measure of physical activity and a measure of mental alertness. While finding such a correlation would be only modest support for the theory, not finding the correlation would likely doom the theory. Making different theoretical predictions for younger and older adults will allow us to test many different theories of learning.

Over the years, many theories have been developed to explain the fact that elderly adults typically perform more poorly than younger adults on various tasks. There are currently three primary theoretical orientations guiding research in the area of 'cognitive aging' that can be applied to the area of learning. These orientations are briefly described here, and are mentioned where appropriate in the remaining sections. It should be clear that no one approach adequately explains all of the data concerning age-related changes in learning.

Speed of Processing

As organisms age, various parts of the system slow down, including the speed at which nerve impulses are conducted, motor movements are initiated and completed, and mental operations are conducted. Slower responses mean many tasks take longer to complete or can not be completed in the time available. Thus, on tasks that require speeded responses or faster pacing, elderly adults are at a disadvantage relative to younger adults. Speed of processing is usually measured on simple perceptual tasks, and performance is then related to other cognitive tasks. A large body of research indicates that more of the age-related variance on the cognitive tasks is accounted for by the speed factor than by other possible mechanisms, including cognitive capacity. This theory can also explain some age $\times$ complexity interactions. If a simple task requires only one component, then the age-related speed difference on that component will result in a small difference in performance. If a complex task requires three successive processes and each is slowed by the same amount, the result will be a threefold age difference on the complex task relative to the simple task, an age $\times$ task complexity interaction. This approach is often the benchmark against which other theories are measured, but it does not explain all results. In addition, although the studies that support this theory employed many subjects, the data are correlational, making causal inferences problematic.

Limited Resources and Self-Initiated Encoding

Craik and other theorists have argued that age-related differences in various learning and memory tasks are the result of age deficits in the capacity to process information. Because attentional or working memory capacity is limited, those limited resources are allocated to various tasks as required. Some tasks (e.g., extracting frequency of occurrence information) are more automatic and require minimal capacity, while others (e.g., making visual images, learning a list of words) are more effortful and may require substantial cognitive resources. As we age, for whatever reasons, the attentional capacity, or the capacity of working memory, decreases. Thus, an effortful task that requires 80% of the processing resources of a young adult may require 95% of the resources of an older adult. Additionally, reduction of processing capacity results in more reliance on external factors, specifically, the environmental support provided by the task and the encoding and retrieval situations. Because of diminished capacity, older adults are less able to carry out resource-demanding operations, which include self-initiated operations such as mediation, organization, elaboration, or creation of novel connections. Thus, on tasks such as recall or learning new face-name pairs, which require effortful processing, the elderly are at a distinct disadvantage. However, when tasks provide sufficient environmental support, as in recognition of faces, age-related differences are reduced. This orientation also leads to the prediction that elderly will come to use more routinized, less demanding mechanisms for dealing with novel learning situations.

Although this approach has been useful in guiding research, different measures of working memory do

not correlate with other measures of capacity and do not consistently show age differences. In addition, other experimental results are not easily explained by this theory.

Inhibitory Control

Hasher, Zacks, and colleagues have proposed that differences in performance on many tasks can be attributed to age-related differences in "attentional inhibitory control over the contents of working memory" (Zacks, Hasher, and Li, 2000: 296). This approach has as its basis the idea that the performance of many tasks may be complicated by the presence of extraneous, irrelevant, or misleading stimuli, and to perform well on such tasks requires that responses to those stimuli must be eliminated or reduced. These irrelevant stimuli may be external, such as noises or voices, or internal, such as thoughts or feelings. Inhibition reduces the impact of these irrelevant stimuli in one of three ways: (1) by denying them access to working memory, (2) by deleting them from working memory, or (3) by restraining strong but situationally inappropriate responses, thus allowing consideration of less probable, weaker but more appropriate responses. Failure to inhibit attentional responses to these irrelevant stimuli leads to interference and subsequently to degradation in performance. The theoretical assumption, based on research evidence, is that with increasing age comes a decreased effectiveness of these inhibitory processes. Thus, in situations in which these irrelevant stimuli need to be inhibited to foster efficient learning, the elderly would be at a disadvantage. However, in situations in which those previously irrelevant stimuli subsequently become relevant, the elderly might have an advantage.

Non-associative Tasks

Research in the area of learning can be organized in various ways. For the purposes of this article, we will divide research into two primary categories, associative learning and non-associative learning. Associative learning can take various forms, all of which involve two events and the relationship between them. Although non-associative tasks may, on some level, involve two events, they are marked by the conspicuous absence of a relationship. Each category can be partitioned into subcategories, and in each of the subareas, where appropriate, research with both animals and humans is discussed.

Skill Learning

The prototypical example of the skill learning class of tasks is motor skill, or perceptual motor learning. These tasks require coordinating fine motor skills with the perception of sequential stimuli. In many instances these skills are learned in youth and, through continued practice, become very overlearned and automatic. A skill that has become automatic requires very little in the way of cognitive resources and thus can be maintained at reasonable levels even when cognitive resources have been greatly reduced, by either age or illness.

There is no doubt that increasing age brings with it a general slowing of responses. This slowing is evident in simple and choice reaction time tasks, and in other measures requiring speeded responding. Any theory of learning must be able to explain not only the generalized slowing with age, but also the fact that the slowing is even more pronounced for difficult or cognitively demanding tasks.

Research on motor skill learning has used both real-world tasks (typing, computer skills, archery, etc.) and laboratory tasks. As in any area, use of real-world tasks allows for ready generalization of the findings to those tasks, but also introduces a number of potential confounds that may be difficult to remove. Laboratory tasks, on the other hand, provide greater control over potential confounding variables, and also permit component analysis of the task. That is, with appropriate manipulations and theory, one can break a complex skill into its component processes. Examination of the separate processes allows for determination of those processes sensitive to aging and those that might be less sensitive, or even age insensitive.

Research using tasks that are sensitive to knowledge of results and that require discrete and precise movements, such as moving an object or moving one's hand a specified distance, show a main effect of age. The elderly start at a disadvantage relative to young subjects, but their rates of learning are comparable. As might be expected, when no knowledge of results is provided there are no age differences: there is little improvement in either age group. Although examination of task-specific processes may lead to identification of processes or variables exhibiting age-related declines, it is clear from a great deal of research that while many variables exhibit age-related declines, only a limited number of theoretical explanations will be necessary.

Given the increasing importance of computers for everyday living, it is not surprising that there has been research on learning to use computers. Basically, results indicate that the elderly can learn to use computers, but that the learning process takes longer and involves more errors in training than for younger subjects. Because of the complexity of this task, it will take a substantial amount of research to isolate

the important components. While some of the current research on computers and aging has involved skill learning, more attention has been focused on the attitudes of the elderly toward computers and ways to motivate the elderly to take classes or learn the skills. Other research has looked at ways to structure programs and training to facilitate learning and reduce the trepidation involved in approaching a new task.

Laboratory investigations have employed pursuit rotor, mirror tracing, or problem-solving tasks involving motor skills. For example, in mirror tracing, the subject is instructed to trace a figure (often a star) using only the information gained from the view of one's hand in a mirror. Tasks like mirror tracing produce larger age-related decrements than simpler tasks. It seems likely that the large age decrement may be due to the heavy cognitive component of the task. To trace an object using the mirror image requires that the subject mentally rotate the image and then translate that information into a hand movement. Thus, the task is analogous to performing in a dual-task situation, for which it has been consistently found that the age-related decrement on either task is greater than that for each task separately. These results are consistent with the idea that relative to younger adults, the elderly have reduced cognitive capacity to apply to various tasks. Other research has indicated that because aging brings a loss of motor control, elderly adults often take more time to perform various motor actions because they focus on accuracy rather than speed. Thus, the elderly spend longer on a movement or task because they are trying to be accurate and error-free. However, even when controlling for this tendency, elderly still take longer than young adults.

Other research on the effects of expertise are also consistent with the speed of processing explanation. A comprehensive study utilizing skilled typists ranging in age from 20 to 70 years found that when typing rate was measured by inter-key interval, the regression line relating typing to age was essentially flat. There was no relationship between age and typing rate. For the same typists, however, there was a strong positive relationship between age and choice reaction time. The typical age-related slowing was apparent in the choice reaction time task, but not on the typing task. Thus, it appeared that the subject's expertise led to an exception in the area of expertise. Because of the control afforded by the laboratory experiment, it was determined that the compensatory process responsible for this exceptional behavior was that older typists were more sensitive to characters farther in advance. Because the motor skill portion of the task was automated, the older typists were able to commit some of their free cognitive resources to the task of translating letters into movements. Similar compensatory mechanisms may be seen in other areas in which skills can become highly automated, such as reading, driving, or operating some machinery.

Because the typing tasks were performed under controlled laboratory conditions, there were few distractions. It is not clear how the results would have turned out had subjects also had to deal with distractions such as conversations or other noises. To the extent that subjects would have had to use some of their cognitive resources to block out or otherwise deal with the extraneous stimuli, one might expect a decrement in typing speed, with a greater decrement for the elderly. By appropriate design of experimental conditions one could conceivably test different predictions generated by the cognitive resources and inhibition theories.

Implicit Learning

Implicit learning refers to the process of acquiring knowledge about the structure of the environment without conscious awareness, or 'the non-intentional acquisition of knowledge about structural relations between objects or events.' Much of the research in this area has utilized either artificial grammar learning or serial reaction time (SRT) task.

In artificial grammar studies, subjects study letter strings, or in some cases figural sequences, generated by an artificial grammar. After the study phase, they are asked to classify new strings as grammatical or non-grammatical, which both young and elderly are able to do at greater than chance levels.

There are two interpretations for this learning. One is that subjects abstract the rules governing the task from instances of the task, not unlike children learning to speak their native language, without conscious effort. The second interpretation is that subjects learn the covariation of bigram and trigram sequences in the instances, rather than the rules. Because artificial grammar studies require many controls and conditions that have not always been utilized, and because of the interpretation difficulties, many investigators use SRT tasks.

In SRT tasks, subjects are presented a series of symbols, often asterisks, in positions on the computer screen and are required to press a button corresponding to the location of the asterisk. Across the practice trials there may be a series of blocks that contain a repeated pattern of locations and therefore of button presses. When the sequence is random, there is a small decrease in the reaction time, due to practice on the task. However, on the repeated

patterns, both young and elderly show the same increase in speed of responding. Appropriate controls indicate that this increase in speed is due to learning the specific patterns. The fact that there are no age differences on this measure while there are age differences in SRT tasks in which subjects are explicitly asked to predict in advance the location of the asterisk is taken as a measure of implicit learning.

Results of SRT studies indicate that there are age differences when the task is relatively difficult or when subjects are of relatively low ability. Results of some studies are consistent with the interpretation that age-related differences are due to differences in working memory.

Age-related differences in implicit and explicit learning may best be explained by referring to two mechanisms. Age-related differences in efficiency of processing speed may explain age differences in many explicit and implicit learning tasks. Preservation and use of certain mechanisms (e.g., chunking, unitization) may explain the lack of age differences on implicit and explicit tasks that are simple or are well learned or automated.

Associative Tasks

Classical Conditioning

In classical or Pavlovian conditioning, the unconditioned response (UCR) is naturally elicited by the unconditioned stimulus (UCS). For example, an eye blink is elicited by a puff of air to the eye; touching a hot object elicits a hand withdrawal response. Conditioning occurs when control of the elicited response is transferred to a previously neutral stimulus, the conditioned stimulus (CS), so that presentation of the CS (e.g., a tone, sight of the stove) elicits the response (eye blink, hand withdrawal). In a typical laboratory procedure, the CS comes about 500 ms before, and overlaps with, the UCS (puff of air). Both are terminated at the same time. After a number of CS–UCS pairings, the UCR (blink) originally elicited by the UCS would begin to occur at the onset of the CS, and prior to the UCS. (This statement is not meant to imply that the UCR and CR are identical responses. There are many instances in which the CR is very different, in fact the opposite of, the UCR. However, for the types of responses used in aging research, the CR and UCR are similar.)

Although most of the research on aging and classical conditioning has been done with animals, and while generalizing from animals to humans is risky, the results in both areas lead to similar conclusions. Older adults acquire classical conditioning responses more slowly than younger adults. While classical conditioning is sensitive to the effects of variables such as motivation and anxiety, which may be correlated with increasing age, it seems likely that differences in conditioning are not due to these factors.

Current approaches to classical conditioning and the more general category of associative learning characterize associative tasks as a class of tasks that can be viewed as a problem-solving situation faced by the organism. The problem is to determine, or learn about, the relationship between event A and outcome O. Does event A cause outcome O? Is A a reliable predictor of O? Specifically, is the probability of occurrence of O, given that A occurred, greater than the probability of occurrence of O, given that A did not occur? These accounts revolve around the CS–UCS connection. Of particular import is the information value of the CS. When the CS is a reliable predictor of the UCS, that is, the UCS always follows, but does not occur in the absence of, the CS, conditioning is rapid. Reducing the strength of either of those correlations results in poorer conditioning. In fact, if conditions are arranged so that the CS is a reliable predictor of no UCS (i.e., the CS is never followed by the UCS), subjects can learn to withhold the CR when the tone sounds. Current theories stress the idea that subjects are abstracting the information value of the CS or of the relative frequency of occurrence of stimulus events from their environment. Although the details of the theories are not relevant here, the implications for age differences are.

Researchers have been examining the parallels between associative learning (classical conditioning) and attribution of causality in humans. In one study, college students were presented 16 pairs consisting of a compound stimulus and allergic reaction outcome, and were asked to rate the likelihood that each element of the compound caused the allergic reaction. Thus, subjects might have been told that the patient ate shrimp and strawberries eight times, which resulted in eight allergic reactions, while after eight incidents of eating shrimp and peanuts, there were no allergic reactions. Across subjects, the correlation between the compound stimuli and the allergic reaction varied from 0 of 1. After all presentations, the subjects were asked to rate the degree to which each element of the compound stimulus (shrimp, strawberries, peanuts) caused the allergic reaction. Their ratings reflected the correlations, but of more interest was the fact that the results from the humans paralleled exactly those from analogous studies with pigeons. While there has been no aging research in this area, it has potential.

It is possible that the elderly have a decreased ability to learn the informational value of the CS or the nature of the CS-UCS contingency. According to one theory of classical conditioning, contextual stimuli become conditioned as part of the CS, thus reducing the strength of conditioning to the punctate CS, because the total associative strength is spread over all components of the CS. That is, the sights, sounds, and other external or internal stimuli in the situation may become conditioned as part of the CS. If the elderly are not as able to inhibit or suppress responses to these irrelevant stimuli, they will become conditioned as part of the CS, reducing its effectiveness as a predictor of the UCS, thus making learning more difficult.

Operant Conditioning

Responses in operant conditioning, like those in classical conditioning, are of relatively short duration and can be repeated many times without intervention by a researcher. Examples of these types of responses are presented in **Table 1**. Unlike classical conditioning, these responses are emitted by subjects rather than elicited by stimuli, and are followed by the critical stimulus event. The goal of the stimulus event is to alter one or more attributes of the response, such as the rate of emission, frequency, speed, or strength. Modification of the particular attribute may be accomplished by positively reinforcing (i.e., presenting a valued stimulus such as a candy bar, money, praise) when the desired attribute occurs, or negatively reinforcing (i.e., removing an aversive stimulus) when the response occurs. (Negative reinforcement might involve turning off an electric shock or noxious sound.) Another alternative might involve punishment of the response by taking away a desired stimulus (e.g., candy, privileges), or presenting an aversive stimulus (shock, insult, noise).

The limited amount of research involving the elderly has involved enhancing the speed with which tasks such as the digit-symbol substitution are performed, and indicates that both young and elderly benefit from reinforcement. There is some suggestion that the elderly may benefit more from reinforcement than the young. To the extent that basic research on operant conditioning has indicated that the role of reinforcement is a motivational or activational one (i.e., it affects performance rather than learning), these results have no clear implications.

Instrumental Learning

Instrumental learning is similar to operant conditioning in that the behavior of interest is emitted and the desired responses are followed by reinforcement or punishment in order to produce modifications. It differs in that the responses may be more complex or of longer duration, and they typically involve discrete trials. That is, the responses in instrumental learning can not easily be repeated without some external intervention. (In maze learning, for example, the animal can not repeat the maze until it is removed from the goal box and placed in the start box.) Results of animal research indicate that on simple tasks, age differences are minimal, but on complex tasks, young subjects are more proficient (take fewer trials to learn, make fewer errors) than older subjects. These age differences may be reduced, but not eliminated, by factors such as guidance through the maze (not allowing incorrect choices) and individual difference variables such as diet.

Partly because of its applied value, research employing more complex and real-world situations, such as learning to navigate in a new or strange environment, has been more frequent since the late 1980s. Studies using simulated walks (via slides) in novel environments produced the familiar age-related decrement in learning, and also revealed that the age difference was primarily due to a difference in learning route information. There was little age difference in extracting knowledge about landmarks on the trip. That is, elderly adults had more trouble than younger adults in learning the turns in a route, but were about as good at recognizing landmarks.

Verbal Tasks

Paired Associate Learning The classical associationist view that learning consists of the formation of individual stimulus–response (S–R) bonds or associations led to the use of paired associate learning (PAL) as a standard task. In a typical PAL task, subjects are presented a list of pairs of events (often words), with one arbitrarily designated as the stimulus and the second as the response. In the anticipation procedure, the stimulus is presented for some amount of time (e.g., 2 s), during which the subject is to try to produce the response. At the end of this anticipation interval, the response (or the S–R pair) is presented for some amount of time (e.g., 2 s) for study. One trial is competed when all pairs have been presented. After a brief interval a second trial begins, using the same procedure, but with the pairs, not the S-R units within the pair, in a different order. On the second and subsequent trials the subject must try to say the response aloud before it is shown. The entire process is repeated either for a fixed number of

trials or until a preset performance criterion is reached.

To provide a concrete example: suppose you have created a deck of 3×5 cards with a Spanish word on one side of each card and its German equivalent on the other side. As you flip through each card, you look at the Spanish word and try to say the German word out loud. Whether or not you say the correct word, you turn over the card and look at the German word. After going through the entire deck, you shuffle the cards and repeat the procedure.

It is clear from a great deal of research with college students that PAL is composed of a number of different component processes, each of which may play a role in various situations. Because at least some of these processes may be age sensitive, a brief review of them is relevant.

Several processes deal with the stimulus terms. Stimulus differentiation is the process of discriminating among the various S elements in the list. When using meaningful and distinctive items such as words, this process is less important than when the items are meaningless and have overlapping physical features. A related process, stimulus selection, may be invoked when items have overlapping features, but one of which allows each stimulus to be uniquely identified. For example, if the stimuli in a list were JSF, SFJ, FJS, KLW, LWK, WKL, the subject could select the first letter of each trigram as the effective stimulus and essentially ignore the remaining letters.

Similar processes are involved on the response side. Response learning refers to the acquisition of the responses, that is, being able to report the responses irrespective of the S–R pairing. Acquiring the responses may involve response integration, or making each response a unit, especially when it consists of a series of unrelated letters.

The final set of components refer to the associations between stimuli and responses. The S–R, or forward, association is the ability to produce R when presented S. This association may be strengthened by rote rehearsal or mediation. The R–S, or backward, association is the ability to produce S when presented with R. The R–S associations develop incidentally and often augment the S–R associations.

Results of cross-sectional and longitudinal studies indicate that increasing age leads to less proficient PAL. Elderly subjects attain a lower level of learning after a fixed number of trials and take more trials to reach the same criterion. Although early studies suffered from serious methodological problems, more recent studies correcting these problems have produced similar results. Analysis of the learning curves, that is, trial-by-trial performance data, of young and elderly indicates that both the intercept and the slope were affected by age. That is, not only do the elderly learn less on the first trial of PAL (which could be due to non-learning factors), but also their rate of learning (i.e., the number of additional items acquired on each trial) is lower than for younger subjects.

While it is clear that there are substantial age effects in PAL, the more important question concerns the possible locus of those effects. As in motor skill learning, in which cognitive aspects of the task are more age sensitive than other aspects, it may be that some of the component processes are more age sensitive than others.

There is ample evidence that at least part of the age-related decrement in PAL is due to the general slowing seen with age. Consistent with the idea that older adults are simply slower than younger adults is the finding that older adults make more omission than commission errors; they are more likely to not give a response than to give a wrong response, especially at faster presentation rates. Independent manipulation of the length of the study and anticipation intervals in PAL produces a significant age $\times$ anticipation interval interaction, but a nonsignificant age $\times$ study interval interaction. Short anticipation intervals are much more detrimental to elderly than to younger subjects, but there is a constant age difference in performance when the length of the study interval is varied. This pattern of results is consistent with the general slowing hypothesis. Producing a response should be a speed- and therefore an age-sensitive process. Processes involved in forming an association should be less dependent on timing, and thus should be less age sensitive. However, lack of an age $\times$ study interval interaction does not imply that younger and older adults do not differ in the processes or methods used to form associations.

Running parallel to the view that association learning is actually a problem-solving situation to which the subject brings a variety of methods and techniques is a similar view of PAL. In this view, the component processes that have been identified by classical research in PAL can be categorized according to the extent to which they tax the cognitive system. One would then predict that there would be larger age-related differences in effortful or cognitively demanding processes and smaller differences in more automatic processes. It is also likely that the type of material being learned would affect the size of the age differences.

Response learning is an important component in PAL, and research comparing conditions in which response learning is not required to conditions in which it is required greatly reduced, but did not eliminate, the age decrement in PAL. Also, increasing

the difficulty of the responses, and thus the cognitive effort required to learn them, by using nonsense syllable responses increases the age decrement. Related research in free recall learning indicates that age-related differences are most likely to occur when there is little environmental or situational support, or when self-initiated processing is required.

As in studying the role of response learning, one can look at the effect of age on association formation by comparing conditions requiring minimal associative learning with conditions requiring substantial associative learning. Results of studies using various methods and comparisons indicate that acquisition of the S–R association is an age-sensitive process. Interestingly, examination of the associative, or hook-up, stage may allow for differential predictions from the capacity and inhibition theories. Inhibition theory would predict that situations involving many competing responses (high-frequency words, multiple responses) should be more difficult to learn for elderly than for younger subjects, while a capacity theory would not necessarily make similar predictions.

There are two methods of forming S–R associations: rote rehearsal and mediation. While the associations can be learned by rote rehearsal, research indicates that it is a relatively ineffective method and a less preferred alternative, at least for college students. In one study, college students reported using mediators of various types on up to 75% of the pairs they studied. If younger and older adults rely differentially on rote rehearsal or mediational strategies, there will be age differences in PAL. Consistent with predictions from capacity theories, results of two early PAL studies indicated that older subjects were less likely to spontaneously use mediators of any sort, with 36% of the elderly and 68% of the younger subjects reporting mediator use. Also, young subjects reported using imaginal mediation more frequently than verbal, while elderly subjects reported just the opposite. Basic research on mediation indicates that in general, imaginal mediation is more effective than verbal mediation. Thus, part of the age difference in leaning S–R associations may be due to choice of mediational strategy.

Clearly, mediational strategies produce faster learning, and younger subjects are more likely than older subjects to engage in mediation. Researchers have studied the cause of this difference, either an inability to use mediators (mediational deficiency) or a production deficiency, simply not using mediators. Results of this research indicate that not only are the elderly less likely to spontaneously use mediators, but also instructions and training in the use of mediators does not eliminate the deficit. More recent research in the use of mediators indicates that elderly subjects do produce effective mediators during learning, but that they have more difficulty than younger subjects in retrieving those mediators at the time of test.

In summary, research indicates that age-related differences are found primarily in those processes that are effortful, require substantial amount of self-initiated processing, and provide minimal environmental support. There are small differences in stimulus selection and differentiation.

Transfer Transfer effects are found when learning one task either facilitates (positive transfer) or interferes with (negative transfer) learning the second task. Typically, the first list is an explicit list learned in the laboratory, although sometimes the first list is assumed to have been learned as part of the previous language experience. For example, learning the pair table-lamp in the lab might be made more difficult because of the strong association of table-chair that the subject had acquired outside the laboratory. Analysis of transfer in PAL has revealed two types of component processes, non-specific and specific.

Non-specific transfer effects refer to improvements in performance on a second task that are independent of the specific content of the tasks. The only two types that have been identified, warm-up and learning-to-learn, both produce positive transfer. Warm-up is getting used to the particular pacing and timing procedures of the task, and is generally eliminated as a factor after a few trials. Although there is no research on this factor as related to aging, the response slowing hypothesis would predict that it is most likely to become important as the rate of responding or the pacing of the task increases, with older adults requiring more warm-up time than younger adults.

The second factor, learning-to-learn (LTL), is defined as an improvement in performance on successive unrelated tasks. The amount of LTL can be substantial. One study with college students found a 2.75-fold increase in rate of learning as a function of extensive practice. These subjects learned 36 successive unrelated PAL lists (one list per day, every other day). Mean trials to criterion on the 10-item lists dropped from about 11 on the first list to 4 on the last list. No similar studies have been conducted with older adults, although some data do indicate that under self-pacing conditions the rate of improvement due to LTL is comparable for younger and older adults. However, results of other studies indicate that younger adults show a larger increase in LTL across lists than do older adults. Thus, no definitive conclusions are possible at this time.

Table 2 Transfer paradigms in paired-associate learning

Paradigm	*First list (A–B) pairs (stimulus response)*	*Second list pairs (stimulus response)*	*Processes involved and transfer effects*[a]	
A-B, C-D (control)	bug sleepy rug rural vat tranquil hat playful	cot gloomy kin insane gum dirty dam tearful	Warm-up Learning-to-learn	+ +
A-B, A-D	cot sleepy kin rural gum tranquil dam playful	cot gloomy kin insane gum dirty dam tearful	Warm-up Learning-to-learn S-R association	+ + −
A-B, A-Br	cot insane kin tearful gum gloomy dam dirty	cot gloomy kin insane gum dirty dam tearful	Warm-up Learning-to-learn S-R association R-S association	+ + −
A-B, A-B′	cot dingy kin crazy gum sullied dam crying	cot gloomy kin insane gum dirty dam tearful	Warm-up Learning-to-learn S-R association (depends on mediation)	+ + +/−
A-B, C-B	bug gloomy rug insane vat dirty hat tearful	cot gloomy kin insane gum dirty dam tearful	Warm-up Learning-to-learn R-S association	+ + −

[a] + indicates positive transfer; − indicates negative transfer.

The study of specific transfer effects evolved from the component analysis of PAL and research into the effects of various components. Examining these components requires two PAL lists with specific relations among the stimuli and responses. Some of the paradigms used in these investigations are summarized in **Table 2**.

The paradigm used to control for the effects of warm-up and LTL is the A-B, C-D paradigm, where A refers to the stimuli and B to the responses in the first list. The stimuli and responses in the second list (C-D) are unrelated to the first list. Note that because interest is in the learning of the second, or transfer, list as a function of the relationship between the two lists, all paradigms have a common second list. Variation in the relationship between the two lists is accomplished by changing the stimuli or responses on the first list. Thus, there are no possible confounds attributable to the different paradigms having different second lists; all groups learn the same second list.

Negative transfer results from several sources of incompatible or interfering forward associations, backward associations, or both acting together. Each of these sources can be examined by using the appropriate transfer paradigm. As can be seen in **Table 2**, forward associations are the primary source of interference in the A-B, A-D paradigm. The associations formed during A-B learning are elicited during A-D learning and interfere with learning the second list. Results of various studies indicate that younger and older adults show about the same amount of negative transfer in the A-D paradigm, a finding somewhat at odds with what is expected if the elderly have more trouble inhibiting irrelevant responses, that is, keeping them from intruding and interfering. Because this research was not designed to test the inhibition hypothesis, it may not have afforded an appropriate or sensitive test.

The role of the backward association in transfer is assessed through the A-B, C-B paradigm. To the extent that during C-B learning the B term elicits A, the first list stimulus, it will interfere with the acquisition of the new backward association. As mentioned earlier, older adults have weaker backward associations, that is, they evidence poorer R–S learning during acquisition of the A-B list. Thus, during C-B learning there should be less interference from the backward associations, and therefore less negative transfer for the older adults. However, methodological problems in those few studies using the C-B paradigm allow for no conclusions. The A-Br paradigm involves interference from both forward and backward associations, and thus might be expected to produce large amounts of negative transfer. Studies using this paradigm have found that both younger and older adults show large amounts of negative transfer, and that

older adults show substantially more negative transfer than younger adults. These results are consistent with both capacity and inhibition theories but do not provide analytical comparisons to be able to distinguish between the two.

As can be seen in **Table 2**, positive transfer over and above nonspecific transfer effects can be expected only in the A-B′ paradigm. In this paradigm, the second list responses are related (e.g., associatively, semantically, acoustically) to the first list responses. To the extent that the subjects can use the first list response as a mediator during second list learning, transfer should be positive. Inability to recognize or use the relationship would leave a nominal A-D, or negative transfer, paradigm. Thus, one might expect less positive transfer for older than for younger adults. Limited data bear out this prediction, at least as far as initial performance on the second list.

Summary and Comments

Three general conclusions can be drawn from the research on the effects of normal aging on learning. The most general conclusion might be 'You can teach an old dog new tricks; it just might take a little longer.' Normal aging produces decrements in almost all areas of learning, although the amount of the decrements will vary substantially across areas and individuals. Second, research psychologists have identified some of the age-sensitive component processes involved in various learning tasks, which should allow others to develop appropriate compensatory strategies. Finally, current theoretical accounts of age-related differences in learning offer additional insight into the aging process and to a better understanding of the learning process itself.

Research in many areas of cognitive psychology, including cognitive aging, which includes learning, has been utilizing functional neuroimaging technology such as magnetic resonance imaging (MRI), functional magnetic resonance imaging (fMRI), positron emission tomogrophy (PET), and event-related potentials (ERPs). The goal of many of these types of studies is to relate various cognitive tasks and processes to activity in specific brain areas. While research using these techniques clearly has great promise, the studies are yet too few and the results still give only correlational data. It is very likely that by the next revision of this article, the advances in this area will be substantial and significant.

Leisure

N L Danigelis, University of Vermont, Burlington, VT, USA

Glossary

Age, Cohort, and Period Effects – Age effects are attributable to biological, psychological, or social changes in an individual due to chronological aging. A decline in reaction time, for example, is an age effect. Cohort effects are due to differences in birth cohorts. Today's seniors are more active in sports, because they learned to play sports at an early age; their predecessors 50 years ago were too busy helping the family work the farm to learn sports on a large scale. Finally, period effects refer to the result of common experiences that different age groups experience together. An example would be the effect of living through 9/11 and the US war in Iraq, regardless of one's age today.

Busy Ethic – The value of being occupied with productive activity during retirement. The 'busy ethic' is the older retiree's functional equivalent of the 'Protestant work ethic.' A key distinction is the intentional use of the term productive. The busy ethic does not emphasize the kind of activity that often is referred to as spinning one's wheels; rather, it is illustrated by older individuals' calendars that are filled with bridge, golf, volunteering, shopping, looking after the grandchildren, and the like.

Elite and Mass Leisure – Elite leisure includes the kind of recreation that often has been called high brow and that includes activities involving classical music, reading serious literature, etc. By contrast, mass leisure refers to the kinds of free time activities that are commonly associated with the masses: sporting events, movies, and other low-brow activities.

Flow – The concept of engagement in any activity that requires such total concentration on the task at hand that the concept of time becomes meaningless. Such behavior represents an exact fit between the demands of the task and the ability of the individual to complete the task. Flow may be said to occur in any number of institutional contexts. Flow might be exemplified in the rarified atmosphere surrounding a scientist single-mindedly working out a particularly knotty mathematical problem, or in the relatively simpler challenge of a child intensely playing 'Chopsticks' all the way through without error for the first time.

Leisure – Commonly described as free time activity, as recreation or as play, leisure is most fruitfully seen as a complex experience across both time and activity dimensions. Historically it has ranged from conceptualizations like those in ancient Greece (a state of being exemplified by music and contemplation) to those of the early Puritans ('the devil's workshop'). Today, leisure is seen as a multidimensional construct that reflects individual perceptions in the context of societal values and norms.

Play – Usually applied to the child's unrestricted enjoyment of the moment, regardless of the nature of the activity, play generally is accepted to be activity for it own sake without extrinsic motivation. Play often is seen to emphasize exploration as well: exploration of one's environment and exploration of the self.

Recreation – The third member of the leisure/play/recreation triumvirate, recreation emphasizes the restorative nature of the activity that one pursues. Often seen as a way to re-energize the individual in preparation for returning to work, recreation also has been seen to have positive consequences for society as well as the individual.

Time Deepening – The three-dimensionalization of time. Particular characteristics of time deepening include multitasking, speeding up activities, substituting quicker activities for slower ones, and keeping precise schedules for organizing activities. Probably no technological innovation illustrates time deepening better than the personal computer: Often, for example, one has email, a word processor, an Internet search engine, a music download, and perhaps one or two other tasks running simultaneously, as one switches back and forth among them. This multitasking is facilitated by powerful memory that speeds up all the tasks performed on the computer. Finally, for those with dial-up Internet access or who are otherwise tied to time restrictions, scheduling one's work becomes critical.

Introduction

Leisure often has been characterized as nothing more than free time activity. In this sense, it has more in common with recreation than with play – two terms with which it often is confused. At the other extreme, leisure has been asserted to represent a state of being

to which one aspires. Here, leisure has more in common with the self-exploratory emphasis that many scholars attribute to play. Most social scientists, however, consider leisure to be something more complicated than simply free time but also less ambitious than the foundation for a lifelong philosophy of existence. If, as many have argued, leisure is a time-bound activity with a particular self-expressive purpose, then, for our purposes, it becomes important to try to describe the leisure of older individuals and how that leisure compares with their leisure when they were younger and with the leisure of younger cohorts. A major obstacle is the lack of operational definitions of leisure that extend beyond free time measures, so the latter will be used as a starting point. Finally, available evidence on leisure in one's later years can provide some insights into the current state of knowledge reflected in theories about social aging and how one ages successfully.

Conceptualizing Leisure

Leisure was best seen as play in early society, often inextricably mixed up with work activities in a life rhythm that was modulated by seasonal and daily time cycles. In this context, leisure's value was the celebration of work that had been completed. By the time society had become more segmented and a division of labor was forming – even before industrialization, but certainly reaching a peak in industrialized societies – leisure's dominant value was illustrated by its recreational role, which allowed one to become refreshed enough to go back to work. In today's technologically advanced societies, leisure's role is said to be evolving into a major life force with the value being placed on consumption, one aspect of which is illustrated by bumper stickers and T-shirts proclaiming "I shop," "Only one more shopping day till tomorrow," and "Ya gotta have plastic." Given such extremes of perspective, it is not surprising that many students coming into courses on leisure declaim: "Leisure is what I say it is." In an effort to avoid linguistic anarchy, we might consider the following definitional discussion of leisure.

Normative, Nominal, and Operational Definitions of Leisure

Definitions of leisure have run the historical gamut from leisure as a life force that encompasses one's whole being to the empirically friendly leisure that is free or leftover time. As DeGrazia has so ably pointed out, these different definitions of leisure have historical roots in different cultures' normative positions toward leisure. In ancient Greece, leisure was exalted as a state of being to which one aspired – if one was a free male citizen, that is. In the Puritan epoch following the Protestant Reformation, however, leisure became the devil's handmaiden, because free time came to symbolize a break from God and Godly works. As Weber has pointed out with respect to work, however, leisure is a social construct, a product of a society's values, beliefs, and norms; it is, therefore, neither inherently good nor inherently bad. Nash's leisure pyramid stretching from acts that harm society at the bottom to creative activities at the top illustrates the wide range of leisure's reach.

Discussing leisure in the context of aging requires that we take care not to proselytize on the basis of what we think leisure should be for older individuals – or for anyone else, of course. This creates a dilemma of sorts, however, since any definition of leisure that is not a synonym for whatever one does in free time runs the risk of appearing to be normatively based. Further complicating efforts to find useful definitions for leisure is the extent to which definitions of both play and recreation cross over into leisure's realm. Over 40 years ago, for example, the Neumeyers and Miller and Robinson suggested that recreation is behavior in which one engaged during one's leisure. Ten years later, Torbert and Rogers saw the degree of playfulness one exhibited in free time to be a measure of the amount of leisure one had in one's life. A parenthetical note worth mentioning at this point is that this encyclopedia contains no article on either play or recreation.

In order to convey leisure's meaning for contemporary social scientists, the following three nominal definitions differentiate leisure from free time and tend to set leisure apart from recreation and play. They are the International Group of Social Sciences of Leisure definition, which notes the placement of leisure activity as behavior in one's free time after one's normal obligations have been discharged, but which also emphasizes the range of such activities as possibly including simple rest or amusement, or adding to one's knowledge, enhancing ones skills, or contributing to the commonweal; Dumazedier's (1974: 71) interpretation of leisure as "time whose content is oriented towards self-fulfillment as an ultimate end"; and Kelly's (1996: 31) notion of leisure as "activity focused on the experience rather than instrumental outcomes."

If one turns toward the empirical world, definitions of leisure begin to defer to definitions of free time, a concept somewhat easier to manage than leisure. One particularly fruitful approach to finding an operationally useful definition of leisure is Parker's division of life space into time use and activity constraints. Time is used either for work (meaning paid

work) or non-work. Within non-work time are physiological needs such as eating and sleeping, non-work obligations related to family, household, etc., and what he calls leisure. Activity may reflect either constraint or freedom. For paid work, commuting to and from the job is required, but the activities in which one engages during the commute may be freely chosen to varying degrees. These include casual conversations, reading, and listening to music or books on tape. Leisure is even more evident in those work-related recreational activities that sometimes occur in the course of one's work: golf or tennis with clients, for example.

For activities wholly unrelated to paid work, the same dimension of constraint applies. For example, meeting physiological needs such as eating and sleeping is absolutely necessary, but constraint begins to be less obvious with regard to eating snacks and drinking alcohol with friends. The greatest freedom attends those activities we label as leisure: reading for pleasure, pursuing hobbies, playing sports, etc. The pendulum moves back toward greater constraint, however, when such activities are undertaken in a family context with one's children, for instance, and, of course, as part of one's work-related activities.

A second classification scheme is the relatively simpler one used in the Americans' Use of Time Project: paid work, family care, personal time, and free time. This scheme does provide finer breakdowns within each category that build in implicit, if not explicit, activity distinctions. For example, free time is broken down into educational, organizational, entertainment or social, recreational, and communicational activities. A third classification distinguishes primary, secondary, and tertiary activities. Multinational studies of time use as well as US trend data on time use beginning some 40 years ago have utilized the four-category classification scheme described previously, but then have taken the description of time use even further by detailing not only primary but also secondary and tertiary activities undertaken during the same time period. This acknowledgment of multitasking would appear to optimize the ability of researchers to determine whether a particular time period is being devoted to pure leisure or is a hybrid that contains elements of both leisure and non-leisure activity.

Why Do We 'Do' Leisure?

Various accounts have suggested leisure to be a social institution, a social domain, or a social dimension. While some have argued that for leisure to be an institution it must be relegated to industrial society and its aftermath, this appears to be too restrictive a focus. If we consider social institutions to be interweaving beliefs, values, and norms oriented to meet human needs, then the functions of play and play-like behavior in hunting and gathering and horticultural societies would appear to meet this definition. If, as suggested previously, our definition of leisure includes relative freedom and the potential for personal growth, then such early play – even in the context of mimicking war through early sport – should qualify as leisure.

Kelly, in the first edition of this encyclopedia, makes a slightly different argument about leisure's place in life by contrasting leisure as a domain, in which it "has parameters of time and space that are based in the social allocations of society," with leisure as a dimension, which he sees as "more of a theme that may be found in different forms anywhere and any time." This distinction suggests that the domain perspective is more sympathetic to the kinds of operational definitions of leisure described in the previous section, while the dimension focus emphasizes the overarching beliefs and values to be found in a wide variety of different activities, including paid work.

Leisure can also be treated in a multidimensional way. As a social institution, leisure does address basic human needs and desires and thus can serve the larger society as well. Leisure as a domain allows us to measure aspects of behavior in time and space that often are connected to what one normally thinks of as leisure but more often is described as free time activity. At the same time, leisure as a domain reminds us that leisure may not be limited by time and space, as demonstrated by the evidence of kidding around on the job, playing with one's children, and the kinds of activities often associated with older individuals. Such activities as volunteering for non-profit organizations embrace a number of work-related values but are nevertheless suffused with many leisure qualities like freedom, including the freedom to choose where one volunteers, the freedom to continue to volunteer or not, and the freedom to volunteer more or fewer hours. In addition, of course, the possibilities for personal growth embrace yet another important value of leisure (*see* Volunteer Activity by Older Adults).

Understanding Leisure in Later Life

Social Aging

The most relevant perspectives for understanding social aging as it relates to leisure would appear to be those arguments that deal directly with continuities

and discontinuities within aging individuals and how they relate to older people's well-being. The two that fought for primacy in gerontological thinking throughout the last quarter century – the much maligned disengagement theory and its antagonist activity theory – have receded somewhat to the background in favor of continuity theory and its modifiers, which emphasize adaptation by the aging individual. Disengagement theory's assumptions of a rational disconnecting from one's role relationships with co-workers and then family and friends has come under serious theoretical and empirical attack. While it is true that the theory may owe too much to biological reductionism and represent an apologia for the kinds of mistreatments society's representatives have bestowed on aging individuals in the not-too-distant past, nevertheless, there may be a kernel of truth to the idea that aging in some individuals can be seen through a disengagement lens.

Activity theory too has come under attack, primarily because of the lack of demonstrable causality in the many cross-sectional studies that purported to show a high level of activity correlating with a high level of well-being among older individuals. Based on studies employing longitudinal data, the discovery that older individuals who were never particularly socially active in their free time might find themselves to be unhappy at unwanted increases in their social participation levels indicates a more complex association between activity levels and well-being than originally believed. It is possible that the continuation of low levels of activity, as well as high ones, correlates positively with well-being – not high levels per se. Again, for some of the aging population, being active may very well be a key to successful aging. Such individuals illustrate Ekerdt's notion of the busy ethic, which is retirement's parallel to work's 'Puritan work ethic.'

At first glance, continuity theory and its amenders would appear to be the umbrella under which ideas connecting leisure activity to well-being could most efficiently be gathered. Retirement as a discontinuity of major proportions for many individuals, of course, complicates the fit between theory and data. Again, however, the busy ethic idea suggests an ideal way in which the problems produced by this discontinuity can be minimized.

Theoretical Connections between Obligations and Leisure

Even though many would argue that large segments of the population can have leisure without paid work (children, the unemployed, prisoners, stay-at-home moms and dads, and, of course, retired individuals), much thinking in the last half of the twentieth century about the reasons for engaging in various forms of leisure has dealt with paid work. If one were to substitute obligated time for paid work, then the vast majority of children and adults will be covered by the following discussion. Building on arguments about the relationship between paid work and leisure offered by others, one could conceptualize leisure's relationship to obligated activity (mostly paid work, but also school, family, and household obligations) in three general ways. While the arguments usually have been used to illustrate males working at paying jobs, the application of these ideas to older individuals and their obligations – females as well as males and whether or not they are in the labor force – would seem to be an appropriate use as well. Consider the following:

1. First, there may be a positive association between obligations and leisure. There are four ideas represented by this positive association. One suggests that work is so fulfilling that it spills over into one's free time. This phenomenon may be illustrated over the course of the life cycle by the individual whose teaching continues to be so fulfilling that she does not stop but rather uses what would be leisure time in retirement to keep doing what she wants: teach. A spouse may continue to be the primary cook in the household, because it is what he loves to do; he cooks not only for sustenance but also whenever he can for friends and family. In all such cases, one would expect Csikszentmihalyi's idea of flow to be operating – at least some of the time.

A second way in which paid work and leisure may be positively correlated is illustrated by the now-retired teacher whose interests extend from work to leisure and who, therefore, volunteers teaching religious school and reads to her grandchildren as well as to herself for pleasure. Her leisure mirrors her work interests. Again, the opportunities for flow would be increased in such cases. Both spillover and extension may be subsumed under activity and continuity theories and Ekerdt's notion of the busy ethic. Retirement, for many older individuals, means exchanging one set of behaviors and values regarding the productive use of time for a parallel set of behaviors and values.

Third, both one's world of obligations and one's leisure may be unfulfilling, and these realms may in fact feed off one another. The assembly line worker who is so damaged by the monotony of his job may find solace in getting drunk every night to forget. Similarly, when he retires, he may engage in equally damaging behaviors to fill up his free time: more

drinking, mindless television watching, fights with family and friends. The association between obligations and leisure is positive in the sense that negative behavior begets negative behavior. While there certainly is a sense of continuity here, it is not the kind that will produce well-being. Possibly, such individuals will begin to disengage as a way of dealing with their unhappiness; such disengagement may be intentional or unintentional. Finally, what Parker has called neutrality is the situation in which a person is engaged neither by work or other obligations nor by free time activities. These so-called gray people living their gray lives are emotionally disconnected from life, often going through the motions. Again, the association between obligations and leisure is positive in the sense that lack of engagement in one domain is mirrored by lack of engagement elsewhere. We would not expect such individuals in old age to change, unless, like their unhappy compatriots discussed previously, they begin to disengage.

All of the preceding cases would appear to support the basic arguments of gerontology's continuity theory.

2. There also may be a negative association between obligations and leisure. There are two ideas represented here. The first is the opposition of the domains in which one's obligations and leisure fall. Therefore, a businesswoman retires and spends her time learning to be a cabinet maker. She may already have worked with wood as a hobby during her preretirement years, in which case this also illustrates opposition between obligations and leisure. Another illustration is exemplified by the National Parks manager who has spent so many of his working hours outdoors but who relaxes by reading and, when he retires, by preparing to write about his experiences with the public. A second negative association is illustrated by the compensatory use of good leisure for bad obligations. This scenario probably is best captured by the (often apocryphal) example of the individual whose work world is filled with endless dreariness and boredom but who discovers peace and serenity through painting for pleasure, an activity carried into retirement. More likely are the individuals whose work is so alienating that they make career changes to reduce their alienation. Although some empirical evidence exists to show that this has occurred in the past, it may be that the new relationships between employers and employees engendered by downsizing and outsourcing will facilitate such apparently radical changes. If so, old age may arrive after one has made these life-changing decisions and, therefore, represents continuity from one's (recent) work life.

3. The connection between obligations and leisure may be non-existent. Such an argument assumes no strong commitment to one's obligations or leisure; at the same time, individuals described by this argument are not so disengaged from their obligations and free time that they fit the neutrality model described earlier. Instead, leisure takes on a recreational form for the office worker who likes her job well enough and who takes part of her 2-week vacation to travel and see new sights and the rest to putter in her garden. Her retirement years will be filled with a variety of activities, only some of which mirror her work life (e.g., reading) and familial responsibilities (e.g., sewing, quilting); other activities will include activities not related to her world of obligations (e.g., travel, bicycle riding). In historical terms, her leisure might be best understood as recreation in the Roman restorative sense or in the Utopian idea of divided time that did not prescribe what one did when one's obligations were finished. Such individuals may best illustrate continuity theory, because they either will be continuing or replacing with functional equivalent behaviors in which they had always engaged, or because they will have adapted to modifications in their environment in old age (*see* Retirement).

Leisure as Activity, Time, and Money

The analysis of empirical evidence on leisure in later years is fraught with a variety of problems. The first, of course, is the likely disconnect between nominal and operational definitions of leisure for all individuals – regardless of age group. The data that do exist generally measure leisure as a residual term. The three most prevalent measures of residual leisure speak to different dimensions of free time: activity pursued, time used, and money spent. Each has built in advantages and disadvantages, so together they may provide a reasonably accurate view of free time use among older individuals and, by extension, the beginning of an idea of older people's leisure.

The Pursuit of Leisure Activities

Activities pursued have been measured for a wide range of both mass and elite leisure activities. **Tables 1** and **2** present national data on attendance at selected leisure events by event and age group. In **Table 1**, the percentages across the top show that mass leisure activities such as movies (60%), sporting events (35%), and amusement parks (42%) attract the most people. The percentages at the bottom for the two oldest groups also reflect the popularity of movies, but the second-most attended venue for those 65+ is the art museum – an elite culture venue.

Comparison of percentages down each column reflects a clear linear decline in attendance from the

	1992→2002	−19	−1	−7	−2	+2	+2

From US Statistical Abstracts for 1995 and 2004–2005.

youngest age group to the oldest in the cases of movies (83 to 20%) and amusement parks (58 to 10%) and a somewhat more moderate decline for sporting events (46 to 11%). For the last four venues, the percentages actually tend to increase with age until about 45 to 54, and then drop slightly until 75+. In the cases of classical music performance and non-musical plays, in fact, the 65 to 74-year-olds have higher attendance rates than the 18 to 24-year-olds (musical plays, not shown, show the same pattern as non-musical plays).

The participation rate percentages in the top row of **Table 2** reflect a clear bias in favor of physical activity: exercising, gardening, and playing sports. While the rate at which they play sports drops significantly, the two oldest groups generally reflect the rest of the population; although, for those 65 and older, gardening is the most popular endeavor, followed by participating in an exercise program.

Comparison of percentages across age groups shows that exercise, sports playing, and creative writing rates are lower with increased age, and, in the latter two activities, the drops are precipitous. Dancing and photography show slightly higher levels of participation among the young, but the pattern is not as dramatic as in the first three activities. For gardening, however, rates increase as age increase, until 75+ – at which point there is a slight drop.

One problem with the 2002 data in **Tables 1** and **2**, of course, is the confusion of aging, cohort, and period effects. Are the age differences observed due to aging or to some combination of other factors? A partial answer comes from an examination of the percentage changes between 1992 and 2002 reported directly under each 2002 percentage in each of the first two tables. The 10-year time difference is not large enough to make too many generalizations, but a couple of comparisons are illustrative. For example, amusement park attendance shows a drop between 1992 and 2002 both in general and for each age group, suggesting some sort of period effect – possibly the substitute amusements afforded by computer games and the like. In the case of art museums, the relative similarity of percentages across age groups through age 74 tends to obscure the fact that in the 10 years between 1992 and 2002 the rates of attendance fell in the age groups under 45 but rose in the age groups 45 and older, even though the increases were not large. These different trends suggest possible cohort or aging changes at work, although the precise reason is not clear.

Data not presented here on specific sports activities show that for aerobic exercising and tennis, declines between 1992 and 2002 for the youngest age groups were in direct contrast to increases among those 65 and older. Here period effects may be interacting

with aging effects. Again, for each activity and each year, the participation rates among those 65 and older were lower than the rates for young and middle-aged adults, despite the contrasting trends.

The relationship between age and both leisure attendance and participation, therefore, is not so clear-cut. While some measures do appear to show a decline in activity with advancing age, others do not, and, for a few cases, the activity may very well be increasing with advancing age. Finally, cross-sectional data may be hiding patterns relating age to leisure activities that longitudinal or trend data can help uncover. What these and other similar data sources focusing on activity do not do, however, is provide a sense of how important these activities are to each individual. How comparable, for example, is the individual who went to one sporting event in the past year to someone who attends every home game of his or her professional sports teams? The data presented allow no way of distinguishing frequency of attendance or participation.

The Use of Leisure Time

Data on how time actually is used, usually gleaned from the personal diary method, has been shown by researchers in the United States and abroad to provide a wealth of information. Excellent sources of diary information are the Americans' Use of Time surveys that go back as far as 1965 but that unfortunately excluded anyone 65 and older until 1985. Nevertheless, some useful information can be gleaned from the 1985 and 1999 studies.

Using the residual definition of leisure as time not devoted to paid and household work, childcare, obtaining goods and services, and personal needs and care, the Americans' Use of Time investigators have divided free time into five categories, as shown in **Table 3**. Reading across at the top, one can see that free time takes up nearly 1 in every 4 h of each 24-h day (22.1%), and that nearly two-thirds of that free time is devoted to what the investigators call communication – a category that includes television watching, listening to the radio, reading, and conversing with others. Among those 65 and older, the proportion of time that is free increases to nearly one-third (30.8%), while the part of free time that is allocated to communication likewise increases to over three-quarters.

A comparison of age groups shows that for those under 65, the percentage of free time is more or less the same; only after the nominal retirement age of 65 is there an increase. By contrast, the percentage of free time devoted to communications activities steadily increases from youngest age to oldest. For the other free time categories, different patterns can be observed. Education, as expected, takes up a larger portion of younger people's time; for those over 35, very little time is devoted to education. Organizational activities, including volunteering and religious and political organizations – what Dumazedier calls semi-leisure – appear to be unrelated to age. Finally, recreation, which includes the kinds of activities in **Tables 1** and **2**, shows very few age differences, the only exception being a slight drop for the 65 and older group.

Table 3 US free time use by age group by time period, 1985–1999

Age group	*Year*	*Free time (percent of total time)*	*Free time allocated to (%)*				
			Educational activities	*Organizational activities*	*Entertainment/ social activities*	*Recreation*	*Communication*
All	1999 ($N=1151$)	22.1	3.6	4.9	14.9	13.8	62.8
	1985→1999	−0.6	−1.1	+0.4	−0.3	+2.2	−1.3
18–34	1999 ($N=330$)	21.1	12.1	4.2	20.8	13.3	49.6
	1985→1999	−0.8	+2.7	+1.3	+2.0	+2.6	−8.5
35–49	1999 ($N=366$)	18.6	0.7	5.4	16.6	15.8	61.7
	1985→1999	−0.6	−1.7	−0.6	+2.5	+4.5	−4.6
50–64	1999 ($N=216$)	21.5	0.6	4.4	10.3	14.3	70.2
	1985→1999	−1.5	−0.4	−1.5	−3.2	+2.4	+2.7
65+	1999 ($N=170$)	30.8	0.0	4.5	10.1	9.3	76.1
	1985→1999	+1.6	−0.4	−0.5	+0.9	−3.1	+3.1

From Americans' Use of Time Series Data Files for 1985 and 1998–9 (ICPSR numbers 9875 and 3191, respectively).

This last result underscores another significant weakness of the kinds of activity measures in **Tables 1** and **2**, if they are taken alone: attendance and participation rates appeared to be strongly negatively correlated with age in several instances, yet the diary data show that the amount of time devoted to these kinds of recreation activities is not nearly so different across age groups. Indeed, recent research shows that, while they may participate in fewer recreational activities than younger cohorts, middle-aged and older individuals are participating more frequently and for longer periods at a time.

If free time use differences between 1985 and 1999 are contrasted, age group differences appear to be patterned in three areas. Time spent on education increases for the 18 to 34 age group but declines for each of the others. Recreation time increases for all but the oldest age group, which shows a decline. Finally, those under 50 show a decline in communication, while those 50 and older show an increase. It's not clear whether these differences, small though they are, represent cohort or aging effects.

Two footnotes on the communication category. The first has to do with the single biggest user of communication time for all age groups: television viewing. Data not in **Table 3** show two important facts: The first is that television takes up two-thirds of all communication time and nearly half of all free time – regardless of age group. Second, over time, television viewing as a percent of all free time increases from 47.5 to 53.1% for those aged 65 and older but declines for each of the age groups under 65. Again, the cohort that is 65 and older by 1999 may be viewing more television because of their birth cohort's experiences with television, or there may be some other explanation. In any event, the increase in television viewing for older individuals calls into question the notion of an increasingly leisured senior population. The aged are a population with increasing free time perhaps, but does the television enhance a leisure lifestyle, or does it discourage self-growth and self-awareness? With the proliferation of cable television channels, the nature of the programs becomes a key to answering this question.

The second communication footnote deals with the emerging importance of cell phone usage. As an emergency standby, a means of social communicating with friends and family on the spur of the moment, and a source of experimentation with new technologies, the cell phone has insinuated itself into the workplace, school, home, and points in between. As of 2005, less than half of individuals 65 and older had cell phones, while over two-thirds of those under 65 had one. As younger cohorts age and older ones climb on to the cell phone bandwagon, its ubiquitous nature will render cell phones an important determinant of time use in general, and leisure use in particular, for older Americans.

Spending Money on Leisure

Probably least related to the notion of leisure is the expenditure of discretionary income on activities that take up one's free time. **Table 4** provides age comparisons with respect to expenditures on what is labeled entertainment, which overlaps many of the activities illustrated in **Tables 1–3**, reading, and education. Reading across the table, it is clear that entertainment takes up the bulk of the expenditures. All told, about $1 in $14 (7.3%) is spent on entertainment, reading, and education, and, of that dollar, two-thirds is spent on entertainment.

Reading down the table, one can see that the age group with the highest expenditure on entertainment is the 65 to 74 group. The group spending the highest percentage of discretionary monies on reading is the oldest. Not surprisingly, the group spending the highest percentage on education is the youngest. When all such discretionary expenditures are added together, it is the youngest that have the highest percentage, due primarily to their spending on education. After them, there is essentially no difference in percentage of discretionary expenditure on entertainment, reading, and education for the next five age groups; only among those 75 and older is there a measurable drop.

Change over time between 1984 and 2003 is relatively modest when it comes to spending on entertainment and the like. Noteworthy perhaps is the fact that entertainment expenditures rose slightly as a percentage for the older age groups but declined slightly for the younger. Reading declined very slightly for all, while education showed an increase for all but the two oldest groups. It's not clear what explains these results; but the only dramatic pattern is the education figure for the youngest age group. Not surprisingly, the youngest are spending a larger percentage of their discretionary expenditures on education, thus reflecting a contradiction to the continuity argument described previously – but at the beginning of one's adulthood, not the end.

One final point about leisure expenditures as they compare to leisure time used: leisure types of activities, defined on the basis of free time and its component categories of time use in **Table 3**, suggest that leisure is an important part of the life course at all stages. By contrast, money spent represents a small fraction of one's overall expenditures. There probably are several reasons for this, starting with the large proportion of time spent watching television and pursuing other activities in the communications

Table 4 US consumer expenditures for entertainment, education, and reading, 1984–2003

Age of householder	*Year*	*Average annual expenditure*	*Percent entertainment*	*Percent reading*	*Percent education*	*Percent entertainment plus reading plus education*

category and ending with the relative inexpensiveness of television viewing, radio listening, book reading, conversing, and the like.

Leisure's Meaning for Aging

The arguments describing possible conceptual ties between leisure and obligations and the data on leisure activities, time, and spending over the life course have raised a number of questions. This last section addresses a central one: Why does leisure matter for the aging individual?

Leisure and Well-Being in Later Life

A review of the research on leisure and aging in the United States and elsewhere uncovers several cross-sectional studies, as well as some longitudinal research that confirms positive associations between leisure activities and various measures of well-being. Three themes emerge from the more than two dozen studies focusing on leisure in later life. First, leisure and well-being are positively associated, and this association probably is not spurious. As before, cross-sectional data show a positive correlation between various measures of leisure and subjective representations of well-being, including lowered stress and higher levels of self-esteem. In addition, however, longitudinal evidence in the United States, Sweden, and Germany has shown participation in leisure activities to have a beneficial effect on older individuals' well-being in a variety of ways. Specifically, leisure activities increase the psychological adjustment necessary after loss of spouse or functional impairment, reduce the risk of dementia (including Alzheimer's), and reduce the risk of mortality.

Second, the particular value of leisure appears to be directly related to the number of activities in which one engages as an older individual in some cases, but the picture is complicated. For one thing, engaging in a new activity that may be a functional equivalent for one that has been taken away or given up voluntarily seems to help older individuals' sense of well-being. For another, reducing the number of leisure activities while increasing one's energy devoted to the ones that remain has a beneficial effect for those older persons who are resource rich (but not for those with limited resources).

Finally, some of the research described previously has found important contextual differences by gender. For example, having a partner appears to enhance the leisure of older men but to decrease that of older women. In another instance, participating in leisure activities reduces the mortality risk of older men, but not older women, when health factors are controlled. These findings suggest several fruitful

areas of inquiry regarding leisure and aging. Researchers not only might examine gender as a context for examining leisure's place in aging, but also should treat other important background factors in a similar way. As Kelly has described, privations associated with being female, non-white, or poor have negative consequences for one's leisure and for one's well-being in later life. An important next major step should be a systematic separate examination of men and women, Whites and people of color, poor and non-poor individuals as they age in order to describe potentially different leisure patterns and to ascertain the ways in which leisure may or may not associate with well-being for each of these subpopulations.

The Busy Ethic, Flow, and Time Deepening

Earlier, downsizing and outsourcing were mentioned as potential new sources of discontinuity for today's work force. It will not be very long before large numbers of workers who have known only a work world in which these values exist will be retiring and heading into later life activities. Simultaneously, we have seen a cybernetic explosion this past decade that has put a personal computer and an Internet connection in over half the households in the United States and that has encouraged over half of those in their 60s and about one-quarter of those 70 and older to use a computer.

Both the world of paid work and the availability of personal computers and their technological offspring raise serious questions for those concerned with the role of leisure in later life. As succeeding cohorts enter the later stages of life, will the busy ethic paradigm continue to describe older individuals, or will there be an evolution of behavior in later life leisure of which we have seen only glimpses? The dominance of the new business model and the omnipresence of computer technology suggest that the busy ethic may continue to describe individuals in later life. Time deepening, including especially multitasking but also the speeding up of various behaviors, fits with the idea of multiple jobs over the course of one's work life and the computer as a mediator of simultaneous, speeded-up activities. In this respect, future generations of aged individuals may find the transition from the frenetic work world to the life of frenetic leisure a seamless one. Indeed, some of the research connecting leisure with well-being appears to support the idea that more is better.

By contrast, Csikszentmihalyi's notion of flow suggests the kind of more focused leisure that sacrifices quantity in favor of quality. The implied slowdown behind the idea of flow would appear to work directly against time deepening. True, both concepts stretch the meaning of time. Time deepening does it by stuffing as much activity into any given time slot, however, while flow makes time irrelevant, as the individual becomes caught up in the task. The evidence on older individuals engaging in fewer leisure activities but spending more time on leisure suggests that there is a functional alternative to the popular tendency to time deepen.

Successful Aging and Later Life Leisure

The recipe for aging well – living a long and happy life and dying after only a brief illness – is certainly consistent with the ideological definitions of leisure described at the beginning of this article. The evidence on leisure as discretionary time, however, raises the question as to precisely how aging individuals will engage in those activities that afford rest, amusement, and the potential for self-growth. For some of these older individuals, a life filled with a variety of discretionary activities may be the perfect recipe for successful aging. For others, however, a life devoted to a limited number of discretionary activities pursued in depth may make more sense.

Theoretically, recent evidence from longitudinal studies on the relationship between leisure and well-being appears to support activity theory. The mere number of leisure activities seems to have a direct, positive effect on well-being. At the same time, the evidence that resource-rich elders limit the scope of discretionary activities in their major leisure domain suggests support for another argument that is related to the basic ideas of continuity theory but that emphasizes adaptation to change. This argument comes from the SOC model, named for the three adaptation strategies of selection, optimization, and compensation. More research is needed to determine how well the model works in different cultural contexts for different populations of elders, but the ideas behind adaptation appear to be based on solid evidence.

In the near future, a mobile workforce, increased computerization, and time deepening will continue to encourage new experiences and communication across a wide range of personal networks that know no geographical boundaries. They also potentially will make it more difficult to focus one's attention on singular tasks that create tremendous self-satisfaction from being caught up in the moment and thus having rendered time irrelevant. Whether the two scenarios can co-exist peacefully will have a profound effect on the role that leisure plays in later life.

Life Course

D Dannefer and L Falletta, Case Western Reserve University, Cleveland, OH, USA

Glossary

Cohort – The subpopulation of individuals who are born within the same time frame.

Cohort Effect – Historically specific circumstances that leave a distinct imprint on a particular cohort.

Life Course – A set of analytical perspectives designed to apprehend several key aspects of human development and age-related change. In biographical terms, it may refer to a sequence of roles and transitions embedded in a particular sociohistorical context, or as a trajectory of lived experiences. It may also refer to a set of social practices and ideas about how individuals should appropriately change as they move through time.

Life Cycle – The generational pattern of birth, growth, reproduction, and death, linking individual development to intergenerational dynamics and to the reproduction of the species.

Life Span – The maximum length of life of an organism.

Life Stage – A period of time that is part of a reliably recurring set of developmental stages in a species.

Introduction

The life course refers to a set of analytical perspectives designed to apprehend several key aspects of human development and age-related change. From its beginnings in the 1960s and early 1970s, the life course perspective has emphasized the impact of social structure on social change and on the organization of experience and individual opportunity, thus providing an important corrective to traditional assumptions of development and aging as universal, transhistorical, and transcultural processes. The life course perspective was first established as a field of study in the United States, where its primary focus, prominently articulated by Glen Elder, has examined the impact of early-life experience on subsequent outcomes. Several other theoretically distinct questions and issues have also been introduced within the domain of life course studies. For example, analysis of the historical shifts in the transition behavior of entire cohorts helped to define what Martin Kohli and others have termed the institutionalization of the life course, a process that can also be traced through the study of historical change in age norms and the meaning of age. Each of these perspectives and the attendant theoretical issues are reviewed here.

The Emergence of the Life Course as a Field of Study

The life course as a field of study is only a few decades old, yet it has increasingly been recognized as an area of considerable promise not only in the study of gerontology, but also in other substantive areas of social science inquiry such as family, education, work, and crime.

The beginnings of life course studies are generally traced to a series of independent lines of sociological scholarship in the 1960s in the United States. This work became visible beginning with Leonard Cain's

foundational paper on the life course, published in 1964. The following year, cohort analysis was introduced to the social and behavioral sciences by the classic articles of Ryder and Schaie. Cohort analysis contributed the recognition that social change produces differences in development, so that each historical period leaves a distinct imprint on the development and aging processes of its members. The social context of an actor's formative years is especially important, since it inevitably provides experiences and influences development in early-life that will reverberate across the adult years.

The discovery that individuals growing up in different historical conditions as successive cohorts age differently on many presumably stable characteristics such as age-related physical change and cognitive performance compelled the recognition that patterns of individual age-related change could not be reliably inferred from the longstanding practice of making cross-sectional age comparisons. It also gave a new importance and urgency to tracing individual lives through time, in order to gain an understanding of how the specific features of a historical period and social change create cohort effects by shaping early experience and subsequent life course outcomes.

Thus, the discovery of cohort analysis was a conceptual and analytic breakthrough that was codified in several fresh theoretical approaches developed across the social and behavioral sciences in the late 1960s and early 1970s. These included the life span psychology approach developed by Schaie, Baltes, and associates and in sociology the age stratification model introduced by Riley and associates. These developments also provided a fertile intellectual context for a flurry of studies identified as life course research, heralded by Glen Elder's classic study, *Children of the Great Depression*, first published in 1974 and printed in a second edition in 1999.

Meanings of Life Course and Related Concepts

It is generally useful to begin by defining terms and clarifying the scope of phenomena covered by a concept. This is perhaps especially so with a term as broad in scope and as widely used as that of life course. The term life course should first be distinguished from three similarly familiar, but not interchangeable terms: life cycle, life span, and life stage. These three terms are derived from the organismic model of the biological sciences, and, while allowing for varying degrees of environmental influences, they generally refer to the enduring and largely determined trajectories of growth and decline associated with development and aging. The life cycle refers to the generational pattern of birth, growth, reproduction, and death, linking individual development to intergenerational dynamics and to the reproduction of the species. Life span generally refers to the maximum length of life of an organism, which is regarded as a species-specific characteristic based on relatively fixed, biologically anchored processes of temporal change. Although it is a term that can refer to socially constructed as well as naturally occurring stages, life stage also derives from the organismic paradigm, more specifically, from the reliably recurring sequences of stage development that are observable in the life stages of many species of plant and animal life.

By contrast, the life course is anchored in biography and in history. These domains intersect the biological imperatives of the organism, but they are not reducible to it and are not determined by it. History and biography introduce distinctly human temporal dynamics that entail complexity, contingency, and change deriving from the diversity, flexibility, and culture-specific self-production of the human species. Thus, the life course implies human openness and social contingency. Life course scholars thus often speak of pathways, not predetermined life consequences, and of life history – the accumulation of events that occur over the lifetime of the individual.

Cohort, a term central to the logic of life course studies, refers to the subpopulation of individuals who enter a system within a specified time period. In studies of the life course, the system is usually society as a whole, and the defining entry event is birth (hence the term birth cohort). However, cohorts are not always defined by birth. They may also be defined by entry into a particular social system (e.g., school, military, work organization) or status (e.g., marriage, retirement).

A set of historically specific circumstances that leave a distinct imprint on a particular cohort is called a cohort effect. Cohort effects can take many forms. To take a familiar example, cohorts that enter adulthood during wartime are confronted with special, memorable, and, for many, fateful consequences. In this sense, cohort effects are closely related to what Elder has termed the life stage principle, which asserts that changed conditions have differential effects on people of different ages or stages. Such effects have generally been assumed to be most decisive for children, youth, and young adults, but they can affect trajectories throughout the life course and outcomes in later life. Other applications of the idea of cohort effects are based on the analysis of long-term trends. For example,

educational expansion has meant that, at least through the twentieth century, youth had far more education than their parents. Of course, this is not because the offspring were more talented or inherently motivated; it simply reflects the long-term societal trend toward increasing educational investments. Thus, the educational differentiation (and attendant differences in, e.g., cognitive test performance) between young and old is considered a cohort effect.

Cohort effects are often discussed in conjunction with two other categories of postulated causal factors: age effects and period effects. These are analytically distinct from, yet empirically confounded with, cohort effects. Age effects refer to the presumably transhistorical and enduring aspects of aging and development, such as puberty (of course, even the age of onset of fecundity has manifested a historical trend of change in late modern societies). The term period effect describes a historical event or period that has effects that cut across all cohorts. For example, large-scale disasters impact entire populations and markedly affect every age category. Whether or not the effect is entirely uniform across age or other individual characteristics is a secondary consideration in discussions of period effects.

It is important to distinguish between the concept of cohort and the concept of generation. Generation is a less temporally precise concept, implying position in relation to parents, sib or cousin groups, or other points of kin reference. Again, the intersection of individual lives with military institutions illustrates the relevance of the cohort–generation distinction. Consider the fate of young men in the United States during the Vietnam era. In some cases, cousins or even brothers belonging to the same generation but differing in birth years had dramatically different chances of being drafted for military service, based on cohort membership. For example, in 1969 the Vietnam draft applied only to young men born between 1944 and 1950. Therefore, those born after 1950 were not subject to being drafted in that year, but their older brothers were. Thus, members of the same generation encountered differential constraints and life chances based on cohort membership.

The term life course itself is not restricted to a singular meaning. It has been applied to respected lines of scholarship involving several types of individual and supra-individual phenomena. It has often been defined in biographical terms, as a sequence of roles and transitions embedded in a particular sociohistorical context, or as a trajectory of lived experiences that may be characterized by more or less continuity and punctuated by social transformations or individual life events. Such definitions seem to imply the tracing of individual-level patterns, and the concept is applied at the individual level. However, these characteristics can also be applied to entire cohorts and can be analyzed as features of culture as well.

Thus, Dannefer and Uhlenberg classified life course outcomes into three broad categories, representing different levels of analysis: the individual level, population level, and sociocultural or symbolic level. Individual-level analyses focus on individual-level outcomes; most frequently these are understood as having been influenced by the prior experiences of individuals that are carried forward through time in the form of, e.g., coping strategies, personality characteristics, or accumulated resources. Population-level analyses consider outcomes for collectivities, typically birth cohorts. These analyses consider the significance of social-structural factors encountered by populations as they move through the life course (such as age-graded or age-defined school experiences and Social Security or workplace pension programs). Finally, sociocultural or symbolic analyses define the life course not as a set of features of individual characteristics or change over time, but as a social construction – a symbolic representation of the movement of an individual through a sustained period of time. From this perspective, life course refers to a set of social practices and ideas about how individuals should appropriately change as they move through time. In other words, different cultural groups may have different publicly shared meanings and expectation for the course of human lives. Both the population and symbolic levels of analysis are especially important to the idea of the life course as a social institution, advanced by Martin Kohli. Examples of each of these three categories of life course outcomes are presented in the following section.

Principles of Life Course Analysis

In addition to the life stage principle described previously, Glen Elder proposed several other principles to consider while seeking to understand life course dynamics: These include (1) developmental aging, the idea that development and change are lifelong possibilities; (2) linked lives, the idea that each life is interdependent with others; (3) the principle of time and place, referring to sociohistorical specificity of experience; and (4) agency, which asserts the choice-making power of individuals. These principles enunciate important temporal and contextual dimensions that are essential for life course analysis. Nevertheless, others have offered extensions and amendments. For example, Hagestad and Dannefer argued that limiting the scope of interest in

linked lives to those with whom one has personal relationships can entail microfication – reducing a needed analysis of large-scale forces to the individual level. The lives of modern consumers are intimately linked to, e.g., the lives and work of farm and factory workers who live far away, and globalization has extended and strengthened these linkages. It has also been cautioned that a too-easy declaration of choicefulness must not be allowed to obscure the real and powerful constraints within which agency is exercised and choices are made.

Since the contingency of the life course is predicated on distinctive features of the human species, principles drawn from developmental biology and from symbolic interaction and social constructivism have also been identified as providing important foundational elements for life course theory. These principles emphasize the exceptional plasticity and adaptability of the human organism, the irreducible fact that individual identity and personhood are always formed in a specific time–space context, and the necessity of social interaction and cultural participation (e.g., language learning) to develop, sustain, and accomplish a life course. These principles thus provide a clear empirical basis for the importance of the life course not as reducible to developmental universals or constants that are sometimes emphasized by organismic approaches, but as contingent and specific. Human organisms require social interaction to become human beings, and thus are profoundly dependent on contextual dynamics from prenatality onward. Thus, the life course can never be reduced to normal or universal human patterns, only to social patterns. In every society, interaction is patterned and organized by broader features of social structure, including language. Such patterns are generally taken for granted and treated as natural within a given society. When viewed across societies, however, they reveal both the diverse potentials of the human life course and the active role of social forces in creating and sustaining each culture's definition of the life course.

Three Levels of Life Course Analysis

In this section, the three levels of life course analysis described previously, individual, collective, and symbolic, are discussed in some detail.

Life Course Outcomes at the Individual Level

The dominant mode of life course analysis is focused at the individual level, taking the individual as the unit of analysis. Such research typically proceeds by examining particular outcomes of interest at some particular point in the life course – usually midlife or later – and then identifying factors that may account for variation in each of those outcomes. Mental and physical health and socioeconomic status or achievement are among the more widely studied classes of outcomes. Research in this tradition has focused heavily on the role of early experience in shaping later outcomes, thus generating a time 1–time 2 (or $T_1 \ldots T_n$) design. Elder's *Children of the Great Depression*, described previously, is still the exemplar of this style of life course analysis. In the 1960s, Elder surveyed individuals who had participated in the Oakland Growth Study in the 1930s. These participants included individuals born 1920–1921 and their parents. In *Children of the Great Depression* and in scores of subsequent articles, Elder demonstrated that the effects of whether or not an individual was deprived during the Depression predict later outcomes. For example, among those who originated from the working class, those who were deprived during the Depression experienced significantly more behavior disorders than those who did not experience deprivation. The opposite is true for those whose parents were of the middle class.

A variant of this general logic is provided by the studies of John Clausen, who also employed the basic logic of the time 1–time 2 design, and who also used data from the Berkeley and Oakland studies began in the late 1920s and early 1930s. Unlike Elder and others, however, Clausen did not build historical events and change systematically into his framework and analysis. Rather, he argued for the importance of a psychological factor – a personality characteristic that he termed planful competence, which is formed by adolescence, as a significant predictor of later successes.

These studies used context as an explanatory variable in the sense that specific features of early-life experience were hypothesized to be predictors of health or status in later life. In some cases, the same logic has been fruitfully applied in examining the development of lives from midlife onward. In further analysis of the Oakland data, for example, Elder and Liker found that adult women's circumstances during the Depression had a predictive effect on their mental health decades later. In this case, class and hardship interacted. The best outcomes were achieved by middle-class women who experienced deprivation during the Great Depression. Working-class women and middle-class women who did not experience the challenges of deprivation did not fare as well. Based on these findings, they proposed that mastery of early-life struggles enhances adaptive capabilities in later life. Scrutiny of this research tradition has yielded some discussion of how the concept of time is

used in the life course literature. One relevant issue concerns the relation of time with another central life course term, context. As several observers have noted, the relevance of contextual factors as operative variables here are limited to their role at or prior to the earlier (time 1) point in the life course upon which time 2 outcomes are predicted. The role of context after time 1 is silenced. For this reason, Dannefer and Uhlenberg term this style of analysis personological. Since this term can be taken to imply that only individual-level factors are at play and since early-life context is typically part of the predictive model, use of this term generated some controversy.

Especially recently, some life course studies focused on individual-level outcomes have examined the importance of contemporaneous social-structural variables in addition to those from the past. This is important, because it provides a basis for assessing the relative importance of early-life factors versus temporally proximate ones, and it also elaborates the nature of the causal mechanisms through which early experience operates. Two examples of this approach are provided by the recent work of Sampson and Laub and of Crosnoe and Elder. Sampson and Laub accomplished this in their re-examination of a classic data set from a longitudinal study of juvenile delinquency and adult crime. In addition to recognizing the importance of early-life context in delinquency and the continuity between childhood/adolescence and adult criminal behavior, their framework assumes that social circumstances encountered in adulthood are also significant in understanding persistence of antisocial behavior, desistance from criminal behavior, and adult-onset criminality. In this study, 500 White male delinquents and 500 nondelinquent matched controls were interviewed first between the ages of 10 and 17 and then 15 years later, when they were between ages 25 and 32. Consistent with other research and with the premises of the life course perspective, Sampson and Laub found that early experience had a predictive effect, but to an important degree it was mediated by other adult experiences. The effect of adult social bonds was substantial and was identical for the two groups when earlier delinquent careers were controlled. Specifically, weak social bonds related to employment and marital attachment were strongly related to crime and deviance among both delinquents and controls, net of earlier influences, demonstrating the importance of current context to individual outcomes.

Crosnoe and Elder also included contemporaneous variables in their study of how early family experiences relate to adjustment and functioning later in life in an analysis of the Terman sample of talented children. They found strong effects upon current health and well-being of early-life antecedents, but they also found that these early experiences largely operate through current objective circumstances.

This kind of analysis is important in helping to specify the mechanisms through which the effects of early-life experience on later outcomes are accomplished. These studies appear to support the importance of adult circumstances as having an independent causal effect on adult outcomes. This is an issue that has implications for policy as well as for research and theory. If positive change in circumstances in adulthood makes no difference in the patterns already established by one's life history, interventions to improve circumstances may have little return in health or lifestyle improvements. On the other hand, if improved objective conditions are found to improve adult well-being, it lends support to arguments that a social return may be realized from improving the circumstances of adults. Like most studies, those described here are rather specialized, but they do suggest hypotheses to be tested on more representative samples.

Life Course Outcomes at the Population Level

Population-level analyses are concerned with collective outcomes. Collective outcomes are properties of the cohort that cannot be reduced to the individual level. One obvious feature of any population (or, in this case, cohort) is its distribution on a given characteristic – the size and shape of the distribution of its members around the mean or other measures of central tendency. Concern with the distribution relates to issues of diversity and inequality among cohort members. Viewed in temporal perspective, it also relates to the degree of age-graded conformity or homogeneity with which cohort members complete key life transitions.

Conformity in life transitions has been assessed by a number of analysts, using demographic measures such as spread or the interquartile range. For a given transition (such as entry to adulthood or the transition to retirement), spread refers to the length of time it takes for a specified proportion of the population to go through a particular transition. Similarly, the interquartile range is based on a record of the age at which each cohort member undergoes the transition in question. It reports the number of years it takes for the middle half of the cohort to complete the transition (the 26th to the 75th percentiles). Applying this measure to cohorts of young men born in the United States between 1907 and 1952, Hogan found a steady trend toward a reduction in the interquartile range applied to the transition to adulthood. Reduction in the interquartile range means a reduction in

the age variability of transition behavior and, correspondingly, an increasing level of age-graded conformity in successive cohorts across the first half of the twentieth century. As time passed, the age-graded behavior of young men became increasingly similar, as each successive cohort completed the transition in fewer and fewer years. Over the second half of the twentieth century, the transition to retirement appeared to reflect a similar trend toward greater age homogeneity.

These dramatic historical shifts toward greater levels of homogeneity and age-graded transition behavior have been given two kinds of interpretations, one based at the individual level and one more sociological. Some have suggested, paradoxically, that greater conformity in transition behavior reflects a higher degree of individual prosperity and hence economic freedom, which allowed young men to marry earlier. Such an interpretation implies a natural or at least culturally preferred age for marrying. Others have seen this historical trend as an indication of the increasing institutionalization of the life course. This term requires a conceptualization of the life course as a social institution, a notion that has been extensively discussed by Martin Kohli and others. Both of these interpretations point toward the development of age norms and the increasingly precise expectations for age-graded behavior that they imply. The related concepts of age norms and the institutionalized life course are discussed in the next section.

Premised on observations about the extraordinary diversity and inequality that are observed in older age strata of the population over the life course, some analysts have focused on the question of how intracohort variability changes over the life course of a cohort, giving rise to the concept of trajectories of variability. While this question is in principle applicable to many characteristics, most such analyses have relied on income data, for several reasons. Population and other macro-level data on income are relatively accessible, and income is regarded as an index of resources that is likely related to health and to other forms of resources. Analyses of trajectories of inequality for income show a remarkably robust pattern of steadily increasing inequality within each cohort as its members age. Most of these analyses have been conducted in the United States, and whether the same pattern exists across societies or only in certain societies remains to be clarified.

Two major explanations of this phenomenon have been advanced, which may be termed accentuation and cumulative advantage/disadvantage. Accentuation begins with features of the individual, such as personality and decisive early events, which may shape the individual's habits and aspirations that then become accentuated as he or she moves through the life course. In contrast, cumulative advantage/disadvantage emphasizes the operation of stratification processes within social systems, examining how they organize the opportunity structures that individuals experience while they are growing up and throughout the life course. The stratification of opportunity has been studied in schools and in the dynamics of the labor market and the workplace, but it also has roots in an individual's family of origin.

While few would dispute the relevance of both kinds of dynamics, how much causal force to attribute to individual-level accentuation and psychosocial development processes on the one hand, and to sociogenic cumulative advantage/disadvantage and opportunity structure processes on the other, remains a matter of interpretation and debate. Whatever the interpretation, the matter of resource inequalities is important for theory and also for social policy, since a strong and enduring relationship exists between resources and health. A number of significant recent analyses of health and resources have placed great emphasis on the role of social stratification processes and outcomes in accounting for health differences. This includes research in the sociology of health, epidemiology, and related areas and is well represented in the work of Michael Marmot and others working in these areas. Applying this general proposition to life course trajectories, researchers such as Mirowsky, Ross and Wu have shown that the health of individuals also tends to diverge over time along social class lines.

Life Course As a Feature of Social Organization and Culture

The life course is also embedded in social arrangements and practices and in their legitimation by ideas, or sets of ideas, that have force and legitimacy in a given social system. Its focus is not the empirical life course of actual individuals, but the life course as it is variously inscribed in social institutions, in social policies, and in popular culture. Of course, the characterizations of the life course in social institutions and in popular culture are not independent of each other.

The nature and significance of the life course as a symbolic construction can be readily illustrated by considering the institutionalization and force of public retirement pension schemes (such as Social Security in the United States and *Gesetzliche Rentenversicherung* [legal pension insurance fund] in Germany). These programs have complex political and cultural histories, but what is common to all of

them is the notion that there is an age-qualified time of life when people should be freed from work. This is a matter of social policy and practice, and it is also a symbolic construction – an idea – that is part of each society's cultural system and that has become an important part of what Berger and Luckmann termed the world-taken-for-granted experienced by the members of that society. Thus, it becomes an idea that influences many aspects of the lives of individuals: everyday behavior, life planning, relationships, etc. It also contributes to the formation of a definition of what is normal in a specific segment of the life course, the segment that is known as old age.

The analyses of historians, demographers, and other social analysts have clearly demonstrated that the public establishment of an age-graded life stage of retirement is just one manifestation of the general historical process of what Martin Kohli and others have termed the institutionalization of the life course. This process, which tended to follow the industrial revolution and the expansion of government bureaucracies, in part reflects an increasing reliance on age as a criterion of social organization. In the United States and elsewhere, this practice first developed with the expansion of public schooling. Universal public education was soon followed by the implementation of age grading as a general educational practice. More recently, focus by educational and health professions and by the popular media on normal developmental issues, whether in very early childhood or in turning 30, the midlife crisis, or the empty nest stage, have encouraged the continuing development of what historian Howard Chudacoff has called age consciousness and, with it, age norms. These developments entail an increasing reliance on age as an index of individual characteristics and appropriate social relationships and more generally as a basis for determining status, aspirations, and behavior.

The institutionalization of the life course refers to more than the organization of individual lives by social institutions such as school and retirement. It also has produced a bureaucratically organized, age-graded normative organization of society. This age-stratified social organization entails age segregation – the separation of individuals into age-homogeneous groups that are relatively insulated from each other. Age segregation is experienced as a normal part of everyday life and is sanctioned and reinforced by widespread institutional arrangements from the school years onward. Thus, it is experienced as a taken-for-granted aspect of social life, supported by the notions of normal life course development supplied by the institutionalization of the life course.

The idea that the nineteenth and twentieth centuries comprised a historical moment of institutionalization in modern bureaucratic states has more recently been called into question. The contemporary trends of postindustrialism, globalization, and so-called postmodern cultural developments have suggested the hypothesis that the life course is now being deinstitutionalized, as diversity in the transition to adulthood and in patterns of marriage and parenting have emerged, and as changes in the economy and in corporate organizational structures have led to announcements of the demise of the traditional one-career imperative. Current efforts at pension reform in the United States and elsewhere can be taken as further evidence of destandardization and increasing variability in life course processes. Others argue that, despite these developments, the policies and structures that support the components of the institutionalized life course (e.g., pension policies that support retirement, school and school-to-work programs, and family support programs) remain popular and strongly entrenched, especially in Europe. The economic challenges related to the globalization of production combined with the demographic challenges of graying populations will ensure the relevance of questions of the extent and shape of life course institutionalization for some time to come.

Change/Stability and Structure/Agency: Enduring Problems of Life Course Analysis

Like any lively field of research, the study of the life course has been characterized by a number of ongoing debates and unresolved conceptual and methodological problems. Some problems concern the design of research, especially with issues surrounding longitudinal data analysis. Until recently, few longitudinal data resources were available, but with the recognition of the need to follow individuals over time, that situation has changed. Still, the tasks of matching research questions to appropriate data and the analysis of longitudinal data raise thorny questions for life course researchers.

Beyond these methodological issues, some important issues of design and interpretation confront researchers working in the life course tradition. Two such issues entail the tensions between change and stability and structure and agency. Each of these is briefly discussed in the following sections.

Change/Stability

As noted previously, the reality of social change has been central to life course analysis from the beginning. The recognition that changing social conditions produce different patterns of aging in midlife and later

life and that unique events can play a decisive role in shaping subsequent life outcomes was central to the establishment and expansion of the life course perspective in the behavioral and social sciences. Thus, change and history are familiar and prominently featured ideas in much of the writing on the life course.

At the same time, it is important to be aware that the significance of social forces in shaping life course outcomes in no way depends on the degree of change that is occurring. Under conditions of stability as well as change, individual selves, individual personhood, and the individual life course are constituted in interaction with a social and cultural environment that supplies relevance structures that provide a context for values, interests, and aspirations to be formed and opportunity structures that regulate individual life chances. Change does nothing to create such pervasive social forces; it only makes them more visible. Under conditions of stable and strongly legitimated social systems, such constantly recurring, multilevel interactions and life course dynamics tend to be thought of as normal. This psychosocial process, sometimes called naturalization, can lead to a misspecification – attributing causal phenomena that originate in the realm of social forces to individual volition or temperament.

Structure/Agency

From the beginning, the idea that social structure, change, and other dimensions of context both direct and constrain the direction of individual lives has been central to the life course perspective. At the same time, life course analysts have frequently emphasized individual choice making, action or agency, as one important factor or node of analysis of life course outcomes. This contrast has set up a tension between structure (which is sometimes mistakenly associated with a fear of social determinism) and agency (sometimes erroneously assumed to be synonymous with free will). In the life course literature, as elsewhere, terms such as choice and agency on the one hand, and context and structure on the other, have been used to mean quite a range of different things and are often used without clear definition. Marshall identified at least eight distinct ways that the term agency has been used in the life course literature and provided a critical analysis of their assumptions.

An important theme in several recent analyses of agency is that the common assumption that structure and action are inherently opposed concepts is inappropriate. The interactionist traditions of social theory, as articulated in the writings of Weber or as synthesized in Berger and Luckmann's modern classic, *The Social Construction of Reality,* make clear that human agency is always operative in social life, true even in situations of extreme constraint. At the same time, social-structural processes are also always operative, often at levels that are so pervasive and fundamental that they are barely discernible. For example, it is through social processes that the linguistic, cultural, and political contexts of everyday life are defined. These contexts inform intentional human action and provide the field in which individual agency can express itself.

The debates of stability/change and structure/agency resonate far beyond the domain of life course studies. Indeed, they are fundamental to the social and behavioral sciences. Yet the multileveled, dynamic, and temporally extended subject matter of the life course ensures that researchers in the life course tradition will be confronted with them. It is not yet clear whether or not life course studies can contribute to advancing a more general understanding of problems such as these.

Summary

The life course emerged as a field of study in the 1960s and since then has offered promise of a means to understanding how history and social structure interact with individual experience to produce commonalities and patterned diversity in human experience. Beginning with the logic of cohort differences and cohort analysis, conceptual and analytical breakthroughs have brought a new appreciation of the important roles of history and context in the development and aging of individuals and entire populations. More recently, the roles of systematic social-structural processes and individual processes in producing intracohort differentiation and stratification have been elaborated. Research on the life course can be considered to occur at three levels of analysis: the individual level, the population level, and the symbolic/cultural level. At each, both individual-level (e.g., psychological) and social (e.g., structural and interactional) explanations have been proposed to account for many kinds of life course outcomes. While recent advances in theory and methodology have enhanced the study of the life course, problems remain in life course analysis, including the tensions between change and stability and agency and structure. A challenge for current and future scholars of the life course will be to determine how to best approach these issues.

Life Events

K E Murray and A J Zautra, Arizona State University, Tempe, AZ, USA

Glossary

Intracategory Variability – The differences that may exist between any two reports of the same event.

Life Event – Any change in lifestyle routine that prompts a need for readjustment. Four major domains of life events among the elderly include social losses, illness events, changes in social roles, and shifts in the patterns of everyday life events.

Introduction

Studies of stress and adaptation began the journey into the investigation of life events at the start of the twentieth century when Walter Cannon wrote of his observations of the bodily changes that followed a stressor. Adolf Meyer introduced the life chart into medical offices, linking life events to physical and psychological outcomes in the mid-1900s. Others

also explored the relation between stressful life events and the physiological, emotional, and behavioral responses that ensued, but did so anecdotally. The development of standardized measures in this domain began in the 1960s with the introduction of the Schedule of Recent Experiences (SRE) by Thomas Holmes and Richard Rahe. Over the past 50 years, there have been many advances in theory and measurement. Indeed, life events research continues to be a dynamic and exciting field.

There is no universally accepted definition of a life event, but the definition proposed by Holmes and Rahe is used most frequently. They defined a life event as any change in lifestyle routine that prompts a need for readjustment. Within that definition, there are two aspects that must be addressed: what constitutes an event, and what constitutes change? Life events range from relatively small daily events, such as being stuck in traffic, to major sociopolitical events, such as a major flood or a declaration of war. Change may range from small disturbances, such as altering the path one takes to work that day, to major changes, such as moving in with a romantic partner and the impact of that change on one's coping strategies. The wide spectrum of possible events and consequences raises a difficult issue for researchers.

Life event research has primarily examined the consequences of events by charting their impact on life course trajectories and health outcomes. A longstanding focus has been the relation between negative life events and decreases in quality of life, as measured by symptoms such as physical decline and psychopathology. Consistent links have been drawn between negative social interactions and depression, anxiety, and mortality among older adults. However, recently research has begun to focus on desirable events such as positive social interactions with friends and family and personal achievements such as competing successfully for an award and their impacts on health and well-being.

Why should we study life events among the elderly? Do older adults have different types of stressful experiences than younger adults, and do they struggle with resolving problems of adjustment that follow the occurrence of these events to the same degree? Older adults typically report fewer change-producing events on standard life event inventories than do their young or middle-aged counterparts. However, biases in measurement and recall may be leading culprits of differences in reports rather than overwhelming stability in the lives of the elderly. Common events among the elderly do not include those developmental tasks of early and mid-adult life such as childbirth or beginning a new job, which are included on standard inventories. For elders, retirement, change in work responsibilities, and bereavement, illness, and episodic pain are more likely, but not all of the events associated with developmental challenges of older adult life are found on standard inventories. Earlier reviews of the literature have identified four major domains of life events among the elderly: social losses, illness events, changes in social roles, and shifts in the patterns of everyday life events.

This article focuses on inventories for the assessment of life events for older adults, with special attention given to advances in theory and measurement made over the past 50 years. It discusses these advances in four critical areas of life events research: dimensions of life events, method and measurement issues, consequences of life events, and future directions. The goal is to inform the reader of existing research and methodological issues in assessment and provide a framework to guide future applications in theory, research, and interventions with older adults.

Dimensions of Life Events

There are several dimensions of life events addressed in the literature (**Table 1**) that are critical to understanding and assessing them.

Change

The magnitude of the life event, or the extent to which it causes a change in daily activities and prompts a need for readjustment, is a fundamental property of life events. Early inventories scaled events according to the degree of readjustment required by using magnitude estimation procedures. In the original SRE by Holmes and Rahe, they assigned Life Change Units (LCUs) that were developed by a panel of outside raters to each of the 43 events on their inventory. The sum of all LCUs was then taken as an indicator of overall stress. Another approach is to predefine events by setting a cut-off score at which an event will qualify as either major or minor. The use of weights to scale the stressfulness of events has not proven to be effective at improving the score's correlation with other measures of change. There is

Table 1 Dimensions of life events

Major	Minor
Desirable	Undesirable
Low threat	High threat
Independent	Dependent
Congruent with developmental and social contexts	Incongruent with developmental and social contexts
Recurring events	New events

ongoing debate on how to improve the assessment of change in the inventories. One recommendation is to expand assessment to obtain information about some of the following dimensions.

Desirability

Whether the event is a desirable experience, undesirable experience, or both, is perhaps the most fundamental attribute of an event. There has been a longstanding emphasis on negative life events and their impact on functioning and health, showing consistent links between negative life events and physical illness. Undesirable (negative) events have also been shown to be related to higher rates of depression, anxiety, and somatic complaints. However, recent research examining desirable events, which also may facilitate change, suggests that they may also play a distinct and important role. Studies indicate that positive events are common among older adults and may offset the effects of negative life events, protecting against feelings of anhedonia and loneliness. Positive events, although shown to be significant predictors of well-being, have not been thoroughly addressed in the literature. Positive associations have been found between desirable events and quality of life and psychological well-being. However, desirable events play a lesser role in predicting psychological distress, suggesting that desirable and undesirable events should be assessed separately rather than as opposite ends of a single continuum. To understand the complex interactions in an individual's daily life, a complete matrix of both desirable and undesirable events must be examined.

Ratings of desirability of an event can be obtained by self-report or by consensus scores established by objective raters. Some researchers have also obtained profiles of the individual's plans and goals independent of event ratings and determined the extent to which that event interferes with those goals. Therefore, undesirable events would be those that interfere with the achievement of or advancement toward goals.

Contextual Threat

Brown and Harris introduced the dimension of contextual threat in their measure, the Life Events and Difficulties Schedule (LEDS). Contextual threat takes into account the circumstances surrounding a life event, such as other recent events and life conditions that provide a backdrop for the current event of interest. For example, the loss of a spouse or partner may be very different when the loss was unexpected, left a person with little to no other social support, and generated significant financial strains. In the LEDS approach, the degree of threat is rated by consensus of a group of persons not involved in the interview on a four-point scale from marked to little or no threat. The ratings are based on the event and extensive background information on the event, but not on the respondent's subjective reports of threat, therefore reducing an important source of potential bias in life event assessments.

Control

Another important dimension is the controllability of the event. Research has shown that uncontrollable events are related to greater levels of distress than controllable events. Methods have been developed to assess whether an event is fateful, that is, occurs independently of the behavior of the person. Uncontrollable events have been linked to greater psychological distress than controllable events, which tend to be more desirable. Among older adults, death and illness of family members are generally considered the most stressful fateful life events. In theory, injury and illness are also fateful; however, those illnesses and ensuing treatment can also influence outcomes directly, rather than through their life stress effects.

Some research studies suggest that seemingly fateful events are not necessarily random; rather, individuals may play a role in creating the interactions in their lives. In individuals, the experience of positive and negative events has been shown to be rather stable over time and event categories (e.g., financial, interpersonal relationships), and individuals experiencing negative interactions with one set of relationships tend to experience negative interactions in other relationships as well (e.g., with family, friends, children). Indeed, individual characteristics, such as neuroticism and affective reactivity, may influence the likelihood of positive and negative events and the magnitude of the readjustment required. The use of daily process paradigms presents an exciting opportunity to better tease apart the issues of cause, effect, and independence between individual characteristics and life events.

Event Congruence

Some events are likely to occur and may even be expected given the person's stage in life. Other events may be highly unusual. The degree to which an event may be thought to fit, or be congruent, is an important dimension in life event research, particularly among the elderly. Across the life span, various events are more or less common given societal and developmental norms. For example, the death of a

spouse is much more likely in late life than in the first few decades of life. Events that are incongruent in the given developmental period are perceived as more stressful for the individual.

Recurring Events

Similarly, given an individual's experiences over the life course, there are few types of events an older adult will experience that he or she has never faced before. Older adults may be better able to navigate the adaptational demands from those events they have faced in the past. However, other dimensions would likely influence this effect, such as the magnitude or desirability of the life event that is recurring. The impact of new versus recurring events on outcomes has yet to be thoroughly assessed.

Cumulative Effects

Other research has examined whether there are cumulative effects; that is, are individuals who experience more life events at greater risk for poorer physical and mental health outcomes? Some research has shown that as the total number of events increases, so do levels of major depression. The extent to which the cumulative events are capable of overwhelming the individual's capacity may be the driving force behind these correlations. More rigorous research is needed to examine the long-term trajectories of individual adaptation following experiences of clusters of life stress events. There are two major theories driving research on stress and adaptation among older adults. First, the theory of inoculation proposes that direct and cross-tolerance will build up one's immunity and further one's ability to tolerate other stressors. Through experience, therefore, one is better able to handle stresses in the future. Alternatively, the opposite reaction to stress may occur. That is, when individuals experience stress they then have heightened vulnerability to subsequent stressors. There has been support in the literature for both models. The thoroughness of recovery from the life stress and the timing of subsequent stressors are likely to define whether greater or less vulnerability to future stressors results. Further research needs to be done that more clearly discriminates between these different patterns of vulnerability and invulnerability as a consequence of life events.

Method and Measurement Issues

Many life event inventories have been developed over the past 50 years since the SRE was introduced by Holmes and Rahe. These inventories vary in their comprehensiveness. Some inventories reference only major events; others assess only daily events. Some inventories have been developed to assess events that are most relevant to specific populations, special circumstances, or age groups. For example, special inventories have been developed for veterans of war, refugees, victims of assault, children, and adolescents, among others. **Table 2** lists commonly used life event measures. Rather than enumerating a comprehensive list, it identifies frequently used scales that are representative of the range of approaches used to assess life events. There have been several life event measures developed for use with older adults, such as the Research Inventory of Major and Small Life Events for Older Adults, the Pleasant and Unpleasant Event Schedules for the Elderly, and the Louisville Older Persons Event Schedule.
