In the development and evaluation of life event inventories, there are several criteria that may enhance the reliability and validity of event measures. First, in concordance with the definition of a life event, an event ought to be observable, have a discrete beginning, and signify a change in ongoing activities. Second, inventories must be able to tease apart other components of life stress so that spurious associations are not identified. Life event items should not include dimensions that are related to the presence of a disorder or influenced by a person's mood state at the time of evaluation. For example, there are considerable confounds in assessing illness events such that it may be difficult to distinguish properly between health events that are signs of the illness and those that are clearly independent of the disorder. Likewise, current depressive mood may influence self-ratings of desirability and stressfulness of an event. Well-constructed life event inventories minimize such confounds.

Issues of redundancy and comprehensiveness are also important to consider. There are often several items in an inventory that overlap and assess the same experience. Items can be linked, as in 'car broke down' and 'had an automobile repair expense,' or they may describe a pattern of events that nearly always co-occur, such as 'marital infidelity' and 'marital conflict.' It is preferable for inventories to count each event only once. On the other hand, there are limits to the degree of comprehensiveness of any measure. Comprehensiveness can be improved by using open-ended probing for additional events not included on the investigator's list. Moreover, most event inventories thoroughly cover undesirable events but inquire about relatively few desirable events. Older adults generally report considerably more desirable events than undesirable events; adequate measurement of desirable events among this

Table 2 Commonly used inventories of life events

Measure	*Format*	*Dimensions and/or subscales*	*Reference*
Schedule of Recent Experiences	Checklist	43 items ranging from major to minor events	Holmes TH and Rahe RH (1967) The Social Readjustment Rating Scale. *Journal of Psychosomatic Research* 11: 213–218.
Life Events and Difficulties Schedule	Interview	Eight domains (e.g., changes in role, personal health, other's health, goal fulfillment)	Brown GW and Harris TO (1989) *Life Events and Illness*. New York: Guilford.
Research Inventory of Major and Small Life Events for Older Adults	Checklist	Thirteen life domains (e.g., work, social, financial, crime, transportation)	Zautra AJ and Guarnaccia CA (1988) Research inventory of major and small life events for older adults. Paper presented at 41st annual meeting of the Gerontological Society of America, San Francisco, CA.
Structured event probe and narrative rating (SEPARTE)	Interview	Life events, ongoing situations, and personal dispositions	Dohrenwend BP, Raphel KG, Schwartz S, Stueve A, and Skodol AE (1993) The structured event probe and narrative rating (SEPARTE) for measuring stressful life events. In: Goldberger L and Bresnitz S (eds.) *Handbook of Stress: Theoretical and Clinical Aspects,* 2nd edn., pp.174–199. New York: Free Press.
Life History Calendar	Interview	Residence, marriage, children, education, work, other events	Caspi A, et al. (1996) The life calendar: a research and clinical assessment method for collecting retrospective event-history data. *International Journal of Methods in Psychiatric Research* 6: 101–114.
Pleasant and Unpleasant Event Schedules for the Elderly	Checklist	Frequency, impact score (enjoyable or aversive), mean cross-product (amount enjoyable/aversive over previous month)	Teri L and Lewisohn P (1982) Modification of the pleasant and unpleasant events schedules for use with the elderly. *Journal of Consulting and Clinical Psychology* 50: 444–445.
Checklist of Life Events	Checklist	Positive life events Negative life events	Krause N (1986) Stress and sex differences in depressive symptoms among older adults. *Journal of Gerontology* 41: 1–39.
Geriatric Social Readjustment Rating Scale	Checklist	35 items ranging from major to minor	Amster LE and Krauss HH (1974) The relationship between life crisis and mental deterioration in old age. *International Journal of Aging and Human Development* 5: 51–55.
Louisville Older Person Event Scale	Checklist with follow-up probes	56 items ranging from major to minor	Murrell SA, Norris FH, and Hutchins GM (1984) Distribution and desirability of life events in older adults: population and policy implications. *Journal of Community Psychology* 12: 301–311.
The Elders Life Stress Inventory	Checklist	Egocentric Nonegocentric	Aldwin CM (1990) The Elders Life Stress Inventory: Egocentric and Nonegocentric Stress. In: Stephens MAP, Crowther JH, Hobfoll SE, and Tennenbaum DL (eds.) *Stress and Coping in Later-Life Families,* pp. 49–69. New York: Hemisphere Publishing.
The Geriatric Adverse Life Events Scale	Checklist with follow-up probes	Six domains (e.g., financial/work difficulties, interpersonal conflicts, disruption in living situation)	Devanand DP, Kim MK, Paykina N, and Sackeim HA (2002) Adverse life events in elderly patients with major depression or dysthymic disorder and in healthy-control subjects. *American Journal of Geriatric Psychiatry* 10(3): 265–274.

Modified from Zautra AJ, Affleck G, and Tennen H (1994) Assessing life events among older adults. In: Lawton MP and Teresi JA (eds.) *Annual Review of Gerontology and Geriatrics*, pp. 324–352. New York: Springer.

population may be particularly salient. The absence of desirable events may be particularly diagnostic of difficulties that would not be detected through probes of undesirable experiences alone.

In general, there have been two major approaches to inquiry of life events: self-administered checklists and semistructured interviews. Checklists provide an economical approach, whereas interviews provide greater detail and accuracy at the cost of efficiency and resources. The majority of studies have used self-administered checklists to obtain information on life events. Checklists have the marked advantage of being economical, requiring fewer resources for training, administration, and scoring. In addition, this format has been shown to increase response rates to more sensitive topics, such as abortion or sexual assault. However, reliability has been shown to be a significant limitation of the checklist approach. Over brief periods of time, checklists are reasonably reliable; however, significant issues arise when tests are administered a mere 2 weeks apart. Attempts to counterbalance these deficits have been to provide more detailed definitions of the event or to follow up positive responses with additional open-ended questions.

The second major approach entails more detailed interview formats in response to the major shortcomings of the checklist format. In the interview approach, individuals are asked a series of open-ended questions or follow-up probes to get greater detail about the events and the dimensions surrounding them. Individuals may be asked about when the event happened, circumstances surrounding the event, details of the event itself, and their reactions to the event. The advantages of this approach include greater test–retest reliability, reduction in the biases induced by current mood states, and greater ability to predict outcomes. The significant improvements in reliability and validity, however, come at the cost of significant amounts of time spent training interviewers as well as collecting and scoring each interview.

Intracategory variability appears to be a major factor that has been driving inconsistencies in the study of life events. Intracategory variability refers to the differences that may exist between any two reports of the same event. For example, the loss of a friend may be a very major or very minor event depending upon whether the person was an integral member of the person's social network. Little systematic research has been done to examine the differences in affirmative responses across individuals or even across the same person's repeated experiences of an event; however, the existing research suggests that intracategory variability is alarmingly high. That is, people endorsing the same item are often reporting very disparate experiences. This variability can be minimized by using an interview approach, or by obtaining subject ratings of stressfulness and/or the undesirability of the event.

Another issue in measurement is the reliability of event recall. Inventories differ in the time periods they assess. Some inventories assess lifetime or cumulative events, whereas others assess events that have occurred within a specified time period, often within the past 6 months or year. The time period of assessment brings up several critical issues regarding the reliability of life event measures. Inventories that attempt to capture events across the life span typically provide a calendar or use other techniques to prompt recall and help individuals to better establish time sequences. In general, there appears to be relatively good test–retest reliability when measured over brief periods of time. However, there seem to be significant limitations in long-term recall, biases in reporting (e.g., fluctuations in mood or public opinion that influence report responses), and problems with reporting an event in different categories with repeated measurement.

In the assessment of life events among older adults, problems with long-term recall may be particularly apparent, as individuals may be asked to recall events that happened several decades ago. With that in mind, long-term recall studies have focused on major life events given that recall of minor life events is not viable. Studies on cumulative negative life events have shown that older adults report fewer total negative events. This may be due to cohort effects, but it may also be due to limitations and biases in recall. Cognitive processes may be at work to significantly impair the accuracy of the retrospective recall of life events. A phenomenon called the fading affect bias suggests that the affect associated with negative events fades more quickly than the affect associated with positive events. This is a clear limitation of retrospective recall that has not been adequately resolved.

Two alternative approaches that are better able to accommodate the causal limitations and challenges in measurement are the use of longitudinal analyses and daily diary studies. Both of these approaches provide the opportunity to document and assess actual changes, rather than retrospective perceived changes, surrounding life events. In addition, the use of hierarchical linear modeling provides the opportunity to examine differences within and between individuals in their responses to life events. That is, are there differences across individuals or circumstances under which certain individuals will experience positive or negative consequences of life events? Longitudinal analyses allow researchers to examine

life trajectories and other critical aspects of this research such as the impact of cumulative life events. Daily diary studies provide a method of assessing the nuances of everyday experiences, examining in detail both stability and change, typically over a 30- to 60-day period. Diary studies minimize the problems associated with recall and enhance understanding of the immediate impact of life events within the context of everyday life. The advancement of these methods and statistical analyses has introduced important opportunities to further develop life event research.

Consequences of Life Events

The assessment of life events has been consistently linked to physical and mental health outcomes. In particular, negative life events have been linked to depression, anxiety disorders, speed of recovery from illness, and onset of medical disorders. Positive events have small but consistent effects, predicting enhanced well-being and higher quality of life.

Existing life event research on the elderly has focused on life events and rates of depression. Research shows that negative life events have a modest but significant relationship with depression. In particular, the degree of threat to one's identity is a better predictor of rates of depression than the magnitude of total stress associated with the event. Research has shown multiple pathways between stress and depression, in which depression both precedes and follows life events. Researchers in this domain have examined the role of attachment, appraisals, and cognitions in the generation and response to life events across individuals.

Research assessing the link between life events and depression suggests variable outcomes depending on whether an individual has experienced a prior episode of depression. The kindling hypothesis suggests that prior episodes of depression lower the threshold at which major life events impact health and well-being. This hypothesis posits that as the number of previous episodes increases, a person's vulnerability to stressful events also increases. Several studies have supported this hypothesis, whereas with previous episodes of depression the risk of a depressive episode following a major life event is significantly greater. However, research has shown that when the number of previous episodes is greater than nine, there is little additional impact from subsequent episodes.

Lab and daily diary studies have begun to distinguish some of the short-term effects of events as well as the mechanisms that underlie those outcomes. In particular, this research has focused on physiological responses to traumatic and other major, negative life events. Studies have looked at changes in the hypothalamic–pituitary–adrenocortical (HPA) axis, such as levels of cortisol, immune system dysregulation, and changes in structure and activation in the brain, via brain imaging techniques. Research in this domain has flourished over the last decade and advancements continue to be made. However, the physiological response to stress is incredibly complex, involving a number of hormones and systems with bidirectional influences. Therefore, research to date has produced several inconsistent findings, and current understanding of these mechanisms is limited.

One finding that has been relatively consistent is a link between stress and autoimmune dysfunction. Research has shown faster disease progression of chronic illnesses among individuals reporting greater levels of stress in their daily lives. Given autoimmune and other physical health concerns among the elderly, this is a particularly important field of research that continues to evolve. In addition, it appears that the type of event, either chronic or acute, has a differential impact on the immune system's ability to ward off illnesses. Sheldon Cohen and colleagues found that individuals experiencing chronic stressors (>1 month) are more susceptible to developing a cold than healthy adults experiencing acute stressful life events (<1 month).

In similar lab paradigms, individual differences in cortisol reactivity and antibody response influence susceptibility to developing upper respiratory infections. For example, research has found that individuals who have a greater cortisol reaction to lab-induced stress and who experience higher numbers of stressful life events have higher rates of upper respiratory infections than individuals with high cortisol reactions experiencing fewer stressful life events and higher rates than individuals with lower cortisol reactions regardless of the number of life events they experience. That means an individual's natural physiological response to stress may be an important factor that influences the likelihood of ill-health outcomes in the face of negative life events. Similarly, individual differences in antibody response to infection, basal levels and reactivity of other hormones (e.g., prolactin), and other physical health factors may influence individual differences in the impact of life events on physical health. Much more is needed to understand this complex web of interactions.

The few studies of long-term effects of life events have primarily focused on the effects generated by childhood trauma and traumatic events over the course of the lifetime. Although assessment strategies to date for long-term effects have been compromised

by reliance on retrospective accounts, this body of research has consistently found that exposure to trauma predicts vulnerability to later psychological and physical health problems. For example, studies of World War II and Holocaust survivors have shown that they have higher rates of post-traumatic stress disorder (PTSD) and other anxiety disorders than others their age who did not directly experience those traumatic events. Many theories suggest that trauma endured during childhood may be particularly detrimental, altering developmental processes and neural pathways and laying the basis for physiological responses to stress throughout the lifetime. This is a rapidly growing area of research, but much more must be done before a better understanding can be reached of the complex interactions of stress, trauma, and life events across a lifetime in predicting physical and psychological health.

Women have been shown to experience greater emotional responses to negative life events, with rates of PTSD two times higher in women exposed to trauma than in men. Theories abound about why there are gender differences in rates of psychological distress, ranging from predispositions to role-related stress. A well-designed study by Kessler and McLeod found that the tendency of women to be emotionally invested in the lives of those around them was a considerable source of higher psychological distress.

Among older adults, the relation between life events and cognitive decline is particularly salient. Cognitive decline is a natural part of the aging process; therefore, causal links between life events and cognitive impairment are particularly problematic. Not only do these changes influence recall limitations and biases, but changes in cognitive functioning may also be an outcome in life event research among the elderly. Cognitive impairment associated with PTSD has been well documented, showing problems with immediate and recent recall among diagnosed individuals. The magnitude, degree of threat, and duration associated with the event are probably critical factors influencing short- and long-term effects on impairment. In fact, some research has shown that acute stressors may enhance cognitive functioning, whereas chronic stressors may be detrimental.

The impact of life events may be moderated by (depend on) an individual's social resources, such as marital status, social connectedness with friends and family, and/or other ties with religious or community organizations. That is, the impact of life events on outcomes will be different depending on whether an individual has high or low levels of those factors. Other moderators may include personal characteristics, such as self-esteem, perceptions of control and mastery, self-identity, emotional complexity, and an individual's ability to regulate his or her emotions. Research has shown that individual coping and attributional styles may also interact with various types of life events to produce different effects across individuals. For example, individuals who have an internal locus of control (believe their own actions determine outcomes) may have a more difficult time coping with an uncontrollable negative life event than individuals with an external locus of control (believe their own behavior does not matter much). Unfortunately, a complete review of potential moderators that impact the effects of life events on outcomes is outside the scope of this article.

Future Directions

Although the field has come a long way over the past 50 years, many questions remain. In assessing life events among older adults, the literature is relatively sparse in comparison to research with other age groups. In addition, the numerous life event inventories that have been developed for children and adolescents outnumber the tailored inventories for assessing the elderly. It is critically important that research uses inventories that tap the types of events encountered by this distinct population. As the elderly become a much larger percentage of the US population, research within this field must be enhanced.

As previously mentioned, the interaction between individual characteristics and the experience of life events is an exciting and potentially fruitful area of research. The use of daily process paradigms to examine daily fluctuations and interactions between life events and individual behavior and outcomes is increasingly commonplace. The ability of this research to examine individual experiences within the context of daily life and the individual's psychosocial world has been significantly enhanced with statistical advances in recent years. This research advances the understanding of why, when, and for whom life events have the greatest impact.

In addition, more research is required to fill in the biopsychosocial model and provide a better understanding of how cognitive, behavioral, emotional, and physiological responses to events are all interconnected. For example, lab and diary methods have begun to assess the physiological substrates thought to be related to daily life events and individual responses to stress. However, research examining sympathetic response, the HPA axis and cortisol secretion, and autoimmune markers has been mixed, varying across samples and procedures. This is a particularly important domain among the elderly, given autoimmune and physical vulnerabilities experienced

within this population. Additional research in this domain will help fill in the gaps in understanding that currently exist.

Questions remain as to how life events intersect with developmental processes. Several theories suggest that the goals and emotional processing of older adults are markedly different than those of their younger counterparts. The types of events that were threatening at the age of 20 may no longer seem important. As older adults experience changes in their daily roles, purposes, and goals, they also experience and are influenced by positive and negative life events in different ways. Recent applications of dynamic systems theory to developmental psychology may provide tools to better understand the interactions between developmental changes, life events, and health outcomes.

There should be an increased focus on resilience in the study of older adults' reactions to life events. Resilience research seeks to explain why and how individuals are able to recover from stressful situations. Several fields are currently examining the growth-producing effects of events, such as posttraumatic growth. This literature is plagued with the issues in measurement and study design that were highlighted previously. Thoughtful and thorough prospective research designs and measures are imperative for advances in the understanding of how people recover.

The inquiry into events continues to evolve and holds considerable promise in the study of the lives of older adults. It is hoped that this article may serve to prompt new research on life events that will help to advance the current understanding of many challenges that have come to define the lives of older adults.

Life Expectancy

K G Manton, Duke University, Durham, NC, USA

Glossary

Active Life Expectancy – The period of time that one can expect to live free of functional impairment.

Life Expectancy – The average number of years a person in a population could expect to live after age x.

Morbidity Compression – The rate of improvement in life expectancy relative to active life expectancy.

Introduction

Life expectancy is the average number of years a person in a population could expect to live after age x. It is the life table parameter most commonly used to compare the survival experience of populations. The age most often selected to make comparisons is 0.0 (i.e., birth), although, for many substantive and

policy analyses, other ages such as 65+ and 85+ are more relevant and may be used (e.g., for determining person-years of Medicare and Social Security benefit entitlement). To calculate life expectancy at age x (e_x), age-specific mortality and population counts are needed to determine the age-specific mortality rates (i.e., the q_x) and survival probabilities (l_x) used in life table computations. Life expectancy is determined by multiplying the sequence of the probabilities of survival at each age to determine the proportion of a population expected to survive to age x. The number of persons expected to be alive in each single year of age category after age x is summed to determine the total number of years left to be lived after the index age (L_x). The total number of person-years to be lived after age x divided by the expected number of survivors to that age yields the life expectancy at age x.

Common Forms of Life Expectancy Calculations

Life tables may be calculated in abridged (e.g., rates calculated for every 5 years of age) or complete (rates calculated for single years of age) forms. Life expectancy is a realized biological trait of a given birth cohort (all persons born in a given year) – though most often life table computational strategies are used to combine data from the survival experience of multiple birth cohorts observed at different ages at a point in time. Such cross-sectional or period life tables reflect the experience of the synthetic cohort constructed from the period-specific experience of multiple birth cohorts. Thus, such statistics do not describe the experience of a real population unless there are no differences in age-specific mortality rates between the cohorts observed for the period of interest.

Cohort life tables are calculated by following a population born in a given year to extinction. Thus, true cohort life tables, and life expectation calculations for current human populations, are rare due to the scarcity of high-quality survival and death data for a cohort followed 100 or more years from birth to extinction. Cohort life tables, survival and hazard modeling, and life expectancy calculations are often applied to animal and insect experimental populations. In those much shorter-lived populations, it is easier to gather accurate data by direct observation to calculate cohort life expectancy statistics.

An alternate type of life table used in studying human mortality to late ages involves forming a synthetic population by summing deaths occurring in a given calendar year back over age from the oldest observed age at death to birth (age 0). Life table age-specific mortality rates are formed from the synthetic population counts for each age and the observed number of deaths in the age interval. Such extinct-cohort life tables may be used to examine mortality at very late ages, since this does not require accurate population counts at late ages (only accurate age-specific counts of death made for the calendar year observed). A confounder in extinct-cohort calculations is that the number of deaths at each age comes from cohorts initially different in size due to cohort differences in fertility. An age-specific growth factor can be used to adjust for initial cohort size differences.

The life table calculations used to determine life expectancy are generally assumed to be nonparametric in form; i.e., no assumptions are made about the distribution of deaths across age category boundaries. This is feasible when life tables are calculated for large national populations where age is reported with little systematic error. Often, however, populations are not large enough for age-specific mortality rates to have negligible uncertainty, and, in many populations, age is not precisely reported at extreme ages (e.g., ages 95+). In these cases, biologically based models (e.g., the Gompertz or Weibull hazard functions) of age changes in mortality risk may be used to smooth rate estimates over higher age categories. For example, in the life tables calculated by Social Security Actuaries, a Gompertz-type hazard function is used to calculate mortality rates at ages over 95. This strategy, however, involves imposing assumptions about how mortality changes at advanced ages. Since many studies question the biological validity of the Gompertz hazard function above age 85 (possibly due to mortality selection of a heterogeneous population at younger ages), this procedure is problematic. The National Center for Health Statistics (NCHS) uses Medicare mortality data for life table calculations for ages 85 to 99. Manton et al. showed that, even after adjusting for errors in age reporting in Medicare data, mortality rates plateau (or even decline) above age 95. Thus, there is debate about how to estimate life expectancy at ages 95+.

Other life expectancy calculations involve determining the life expectancy of people observed to die from specific causes of death (e.g., cancer, heart disease, or diabetes) or groups of causes of death (i.e., multiple-cause-of-death data). These calculations require assumptions about how various causes of death biologically compete with one another at specific ages – usually using the artificial assumption that causes of death are generated by independently operating disease processes.

To avoid assuming independence of competing risks, analyses must be made of the nature of the dependence of cause-specific mortality rates over time/age. One approach requires assessing the nature of the individual cause-specific hazard functions to determine the structure of correlations between those hazard functions. An alternate approach is to analyze the risk of death in longitudinally followed study populations in which measures are made of multiple health factors (e.g., disability measures in the National Long Term Care Survey, chronic disease risk factors in the Framingham Heart study) at multiple points in time before death. Measurements made before death can be used to describe health factor dynamics in the population, with the correlation of individual risk factor trends providing empirical evidence on the correlation of cause-specific mortality functions.

A second important form of life expectancy calculations is determination of active life expectancy, i.e., calculating the period of time that one can expect to live free of functional impairment. To calculate active life expectancy, ancillary data are needed on the age-specific prevalence of disability (e.g., determined by whether a person has a chronic impairment of an activity, or instrumental activity, of daily living) from population health survey data. These measures may be more informative about the health status of an economically highly developed country with a high life expectancy than classical life expectancy at birth measures, which do not describe the quality of life before death. The World Health Organization (WHO) has recently emphasized the importance of such measures in describing health improvements in developed countries over standard life expectancy calculations that describe only mortality differences.

Active life expectancy calculations also are frequently used in economic and policy analyses of human capital changes at late ages in aging populations. For example, in historical studies of Civil War veterans' health compared, for example, to the health of World War II veterans, the age at onset of various chronic diseases and disabilities was found to have significantly increased. Analyses of human capital, as might be used to study Social Security and Medicare benefits, require determining a life table function not only for persons surviving to a given age, but also for the subgroup who survive in a relatively intact functional state to that age. This type of calculation can help determine the potential labor force population at later ages, i.e., the proportion of the elderly population capable of performing socially and economically productive roles. Congressional debate in the United States now centers on further increasing the normal Social Security retirement age (e.g., to age 69 or older) from the currently programmed level (i.e., to age 67 in 2027; for persons born in 1960 and later).

Important in these analyses is the rate of improvement in life expectancy relative to active life expectancy (i.e., morbidity compression). This ratio reflects the efficiency of public health measures and medical therapeutic innovations in increasing human capital, as opposed to simply increasing length of life. For example, an analysis of this ratio starting in 1935 at Social Security inception, at 1965 at Medicare inception, and at various dates at which major biomedical breakthroughs have occurred showed a tendency for the proportion of life expectancy remaining at age 65 and 85 that is spent in functionally intact states to increase faster than total life expectancy after 1982 (**Table 1**). **Table 1** also projects these quantities to 2080. This suggests that recent health-care investments in Medicare and biomedical research have caused health to improve faster than survival.

These calculations also demonstrate a critical flaw in actuarial evaluations of the Social Security and

Table 1 Life expectancy (LE) and active life expectancy (ALE) at ages 65 and 85, US population

Year	*Age 65*				*Age 85*			
	Difference			*Ratio ALE to LE (%)*	*Difference*			*Ratio ALE to LE (%)*
	LE	*ALE*	*(disabled years)*		*LE*	*ALE*	*(disabled years)*

Medicare programs. Specifically, changes in life expectancy projected for Social Security are not calculated by taking into account changes in the level – and nature – of Medicare investment in improving health outcomes. Social Security Administration (SSA) life expectancy projections should reflect the effects of Medicare expenditures in changing US health and functioning – especially in an era of rapid innovations in biomedical technology. The longer term the projections, the greater the potential accumulated effects of this model misspecification.

One use of life expectancy measures is to compare the relative efficacy of health-care expenditures across countries. Such comparisons are often done to show the advantage of the Japanese and European health-care systems over that of the United States. In 2004, Japan's life expectancy was the highest among major economic powers, with an estimated male life expectancy of 77.9 years and female life expectancy of 84.6 years. Sweden, Switzerland, and France were close. Official US life expectancy estimates are currently several years behind those countries. More detailed analyses suggested that much of those differences are due to the greater size and heterogeneity of the US population.

The highest recorded human life expectancy observed to date is for the small European country of Andorra, with a male life expectancy of 80.6 years and a female life expectancy of 86.6 years. In the case of Andorra and Japan, the theoretical limits to life expectancy postulated by Olshanky et al. and Fries of 80 to 85 years have been materially exceeded.

These observations highlight the difficulty of inferring longevity, a theoretical potential of the human organism, from trends in the empirical measures of life expectancy, which reflect the interactions of a heterogeneous human physiology with a highly variable and dynamic environment. Fogel and Costa argued that longevity is a function of multiple environmental factors generated through a process they call techno-physiological evolution. In this model, human life expectancy will evolve far more rapidly than could be expected under a genetic model. Such a model may explain, for example, why the recent obesity epidemic failed to have the serious health implications its proponents argued.

The United States often fares poorly in life expectancy comparisons because it is larger ($\sim$293 million) and more ethnically, socially, and economically heterogeneous than the Japanese ($\sim$127 million) and Swedish populations. Adjusting for the heterogeneity of the US population and related measurement problems (e.g., for the extremely high mortality of undocumented Mexican farm workers) shows the United States to have a much higher life expectancy at birth (80.6 years) for the large majority of persons who are more fully integrated into the US health-care system (e.g., persons covered by private and public health insurance, Medicare and Medicaid). This is much closer to the life expectancy currently observed in Japan (i.e., less than a year's difference at birth).

Life Expectancy Calculated Conditionally on Physiological Covariates and Their Dynamics

A major concern in estimating life expectancy is to perform calculations for persons in specific health states in which health states may change over time. Health states can be discrete, described by a set of continuous covariates, or a mix of discrete and continuous changes. One approach uses a multivariate stochastic process model to describe changes in the distribution of a longitudinally followed population on j health variables. This model, to include covariates, requires that two sets of equations be estimated. One, of j autoregressive equations, represents the change over time of the j risk factors for individuals in the population. Those dynamic equations describe the rate of change in risk factors as a function of the individual's prior health status and a stochastic or error term. Mortality is described by a quadratic hazard function in which each coefficient in the hazard function is an explicit function of chronological age. This type of model may more accurately transfer effect estimates across populations since (1) it has the health effects appropriately modeled over time/age and (2) it better describes risk factor interactions. Estimation of the parameters for the two sets of equations requires longitudinal data in which persons are followed over a significant period of time prior to death and are assessed on multiple variables at multiple points in time during follow-up (e.g., 50-year follow-up of the Framingham Heart Study; Honolulu Heart Study).

The additional parameters in the two sets of equations enhances the ability to describe the biological mechanisms driving changes in mortality, health, functioning, and life expectancy, making them more useful for health forecasting and health policy evaluation purposes. Such models are also of benefit in comparing the health consequences of particular medical innovations (e.g., use of progenitor cell transplants to reverse atherosclerotic changes in adults compared to interventions in more traditional risk factor interventions). Olshansky et al. critiqued the use of mortality forecasting models that did not contain measures of health status or describe disease mechanisms as extrapolation. Mechanism-based

models are more likely to detect cause-specific mortality trend turning points, such as observed for cancer in 1990.

One limitation in the use of health-state models is that many of the longitudinal study populations that could be used to parameterize the models are in small geographic areas (e.g., in Framingham, Massachusetts) so that they do not represent the experience of the US population (e.g., in Framingham there are few Hispanics or African Americans). Furthermore, such studies often have limited follow-up periods (the initial Framingham population study is exceptional in having followed the sample for over 50 years). As a consequence of limitations in longitudinal study data, it is often necessary to combine data from multiple studies. Use of more detailed health-state models is a benefit in combining data. With a more detailed parametric structure, differences between populations can be more completely and precisely adjusted when combining model parameters estimated from individual data sets. For example, using data from four of the WHO Monica studies of cardiovascular disease and risk factors, comparative studies could be done by modifying parameters to control for differences in the distribution of risk factors in China, Germany, the United States, and Russia.

There are a few US longitudinal survey series, such as the 1982 to 2004 National Long Term Care Survey (NLTCS) and the 1960 to 2000 National Health and Nutrition Examination Survey (NHANES) series, which are nationally representative and in which a range of risk factors and social and economic variables are measured. By applying health-state models to such longitudinal data sets, it is feasible to produce national estimates of survival and life expectancy adjusted for risk covariate distributions and their change.

Future uses of life expectancy measures will likely require their calculation to better reflect the dynamics of multiple covariables measured in multiple data sets. Unfortunately, this has often been attempted using non-linear regression models that did not satisfy the dynamics of conditions represented in the data. For example, though Cox proportional hazard models were used to assess the benefits of hormone replacement therapy in the Heart and Estrogen/Progestin Replacement Study (HERS) I and II study, these data did not fulfill the model assumption that the time-dependent hazards in different groups were proportional over time, calling into question the conclusions of those analyses. Specifically, there were concerns that accumulating benefits of the hormone replacement therapy on circulatory disease were hidden by an early increase in circulatory disease risk, possibly due to early pro-inflammatory states.

This raises other concerns about the mathematical form of models used to relate covariate dynamics to survival outcomes and life expectancy. Specifically, logistic models do not naturally describe the long-term behavior of stochastic processes. Thus, logistic functions are generally not satisfactory for calculating life table functions and life expectancy in the presence of the effects of multiple dynamic (non-fixed) covariates for studies with measures made at different time intervals. A model mathematically appropriate for such calculations is described in Woodbury et al., in which the model with separate risk factor dynamic and mortality equations was used to calculate life table parameters (including life expectancy) conditional upon the trajectories of the means and variances of multiple covariates using a system of five differential equations.

Life Expectancy: Current and Future Values Based on Death Dynamics

Problems can occur in calculating life expectancy when assembling mortality data in various meta-analytic studies, especially when studies involve very different age ranges. This is sometimes due to inconsistent use of proportional and attributable risk calculations. Such errors were made when epidemiologists at the Centers for Disease Control (CDC) tried to demonstrate that obesity had nearly overtaken smoking as the number one risk factor for mortality in the United States. In Flegal et al., the methodological errors in the earlier CDC calculations leading to the declaration of an obesity epidemic were identified. It was determined that there was an error of between 17 and 100% due to such methodological errors. Furthermore, the calibration of the survival functions used in the model was based, in part, on old data on the relation of mortality to body mass index (BMI). In more recent data, the relation of BMI to mortality was found to have significantly attenuated – probably due to improvement in the medical management of major risk factors (e.g., hypertension, hypercholesterolemia, elevated blood sugar), especially in high-risk groups such as those with elevated BMI and adult diabetics.

In analyses of survival data from several recent NHANES, it was found that (1) the BMI range (25–30) called overweight was associated with a large reduction (86 000) in the number of expected deaths relative to the so-called normal weight category of 18.6–24.9; (2) underweight, especially at later ages, was an unhealthy state associated with significant mortality; and (3) the net effect of changes in BMI in the United States was, as a consequence,

small – ~25 000 deaths (i.e., the seventh ranked cause of death). Over 40 years (1960 to 2000), cardiovascular disease risk factors (smoking, hypertension, cholesterol) declined in all BMI categories, with risk factor declines in the population of obese persons being more rapid than in normal-weight persons – a finding consistent with the faster reduction in risk factors observed among diabetics.

Arguments about life expectancy changes and obesity trends (i.e., those finding adverse health effects of an obesity epidemic versus those finding lower excess mortality risks) do not reflect the theoretical, historical, and empirical arguments of Fogel and Costa about the effects of economic and social development on life expectancy and BMI trends – and possible changes in trends in the future. Their arguments suggest that the normal body weight (implying the healthiest BMI) has changed over time (e.g., since the Civil War in the United States) due to public health and other improvements in health care that changed health risks at various BMIs. Specifically, Fogel and Costa, analyzing a wide range of historical data sets (especially a study of Union Army Civil War veterans assessed for pensions and the separate, more medically detailed, Gould study of 23 785 persons assessed at entry to the army during the Civil War), found that the BMI optimally associated with survival and health grew after the Civil War to levels that the CDC currently categorizes as overweight; i.e., the current Waaler surface for US males had a minimum mortality rate at a BMI of 26.4, which can be compared to the 25–30 range categorized by CDC as overweight. Fogel's calculations are supported by new data and analyses of increases in BMI by Flegal et al. and others showing that the overweight category (BMI of 25 to 29.9) was associated with a large decrease in expected deaths (86 000 fewer than expected) using recent NHANES data and related BMI-specific mortality follow-up. The reductions appear due to the better medical management of risk factors in various overweight and diabetic groups. Costa found that the historical (100 year plus) increase in average BMI in males was correlated with a decrease in abdominal body fat, improved vital capacity, and an increase in lean body mass.

These and other long-term observations led Fogel and Costa to posit the theory of techno-physiological evolution, i.e., that environmental and technical changes (e.g., improved nutrition and sanitation) lead to epigenetic modification of physiological parameters controlling metabolism, energy production, and organ dysfunction manifest as chronic disease at late ages. If such a theory were valid, the use of model life table functions at advanced ages to deal with imprecise data over time would be invalid (i.e., potentially tautological) if the shape of hazard function could theoretically change as a function of the environmental changes.

Deaton, evaluating the implications of the techno-physiological evolution and its effects on life expectancy dynamics, suggested that one factor underrepresented in the Fogel model is the recent benefit of biomedical innovations on the range of therapeutic options now available. Deaton cited the work of health economists such as Cutler and McClellan, which indicate that – for specific medical problems – there have been rapid increases in the number of productive life years due to improved medical therapies and that these contributed to the growth of human capital (i.e., more rapid active than total life expectancy increases) at later ages. Manton et al. estimated what increases in investment in basic biomedical research are optimal relative to increasing productivity and expanding human capital (active life expectancy) in a population experiencing rapid aging. These models, based on the work of Romer and Jones and Williams, suggest that even the recent doubling of the National Institutes of Health (NIH) budget leaves research investment far below the optimal level of investment in medicine and related biomedical research areas (e.g., nanotechnology; development of new biological materials) to best stimulate (US) economic growth and increase active – as well as total – life expectancy.

Life Expectancy and Longevity

One critical use of life expectancy analyses in studies of aging is to determine how aging relates to the longevity – and senescent processes – of a given species. Life expectancy is a statistical quality determined from data. Longevity has a relation to life expectancy similar to that of fecundity to fertility. That is, life expectancy and fertility are observed. Both fecundity and longevity are theoretical latent biological traits of individuals in a population. Life expectancy calculations may be used to infer the trajectory of the unobservable trait longevity only by using additional data on physiological changes before death or biological theory. The analysis becomes complex when longevity changes – in addition to life expectancy – in response to environmental factors as in the techno-physiological evolution model of Fogel and Costa. This emphasizes the conceptual problems, as well as methodological and measurement difficulties, in relating longevity and life expectancy, which are partially resolvable by measuring health changes prior to death. A complete resolution, however, is necessary to successfully project long-term life expectancy trends for determining future

population growth, rate of population aging, and the structure, fiscal stability, and performance of programs like Medicare and Social Security.

Life Review

R N Butler, International Longevity Center (US) of the Mt. Sinai Medical School, New York, NY, USA

Glossary

Autobiographical Memory – Memories of specific events occurring in an individual's daily experience that are stored without the benefit of conscious memory goal activities on the part of the individual.

Guided Autobiography – Topical approach to the collection of autobiographical data. Life review in a systematic manner.

Narrative (or Experiential) Gerontology – The field of study by which the inner perspective of aging can be revealed.

Oral History – Individual account that becomes a source of history.

Reminiscence – The process of recollecting past experiences and events, or the experiences or events recollected. One-on-one and group reminiscence can be therapeutic but not evaluative, thereby distinguishing reminiscence from life review.

Introduction

The life review is a normal developmental task of the later years characterized by the return of memories and past conflicts, which can result in resolution, reconciliation, atonement, integration, and serenity. It can occur spontaneously or can be structured.

Structured evaluative life review is practiced for research and therapeutic purposes.

One key goal of early work on life review was to demonstrate that the process of life review in older people is not a pathological condition, but rather is a normal developmental task of the later years that may in certain cases contribute to psychological dysfunction and in other cases to psychological growth, including resolution of past conflicts, reconciliation with significant others, atonement for past wrongdoing, personality integration, and serenity.

The concept of life review was used originally to refer to the older person's process of review and evaluation of their lives within the context of intensive psychotherapy and research interviews. The life review concept is distinguished from reminiscence. A related concept is guided autobiography.

Origin of the Theoretical Concept

In 1961, R. N. Butler postulated the universal occurrence in older persons of an inner experience or mental process he called the life review. He proposed that life review helps account for the increased reminiscence in the elderly, contributes to the occurrence of certain late-life disorders, particularly depression, and participates in the evolution of such characteristics as candor, serenity, and wisdom among certain older persons.

Allusions to a life-reviewing process have been common in the literature of various historical periods, from Aristotle to Somerset Maugham. G. Stanley Hall adumbrated a somewhat similar idea in his 1922 work, *Senescence: The Last Half of Life,* and intimations of the life review can also be found in Gordon W. Allport's 1937 book, *Personality: A Psychological Interpretation,* in which he emphasized the continuity of personal memories.

In contrast to the prevailing tendency, which at that time was to identify reminiscence in the elderly with psychological dysfunction, and, thus, to regard it essentially as a symptom, Butler saw the life review as a naturally occurring, universal mental process characterized by the progressive return to consciousness of past experiences, particularly the resurgence of unresolved conflicts. Simultaneously and normally, these revived experiences and conflicts can be surveyed and reintegrated. Presumably this process is prompted by the realization of approaching dissolution and death and the inability to maintain one's sense of personal invulnerability. It is further shaped by contemporaneous psychosocial experiences, and its nature and outcome are affected by the lifelong unfolding of character.

The life review potentially proceeds toward personality reorganization. Generally, the more intense the unresolved life conflicts, the more work remains to be accomplished toward reintegration.

The life review is not synonymous with but includes reminiscence; it is one level or type of reminiscence. It can occur silently without obvious manifestations. In mild form, the life review is reflected by increased reminiscence, mild nostalgia, and mild regret. In severe form, it includes anxiety, guilt, despair, and depression. One case study presented by Butler describes a woman who in the course of reviewing her life became remarkably abusive, violent toward others, and physically damaging to herself. It became clear that past actions justified her sense of guilt. In such a case, a simple reassuring response is valueless. Discussing the events or situations that provoked the guilt reactions and confronting the feelings that are prompted by the life review are more productive responses (*see* Reminiscence).

In the extreme, life review may involve the excessive preoccupation of the older person with his or her past, and it may proceed to a state approximating terror and result in suicide. Thus, although the life review process may be universal and normative and contribute to a reconstruction of personality, its outcome can in extreme cases include psychopathology. The more severe affective and behavioral consequences tend to occur when the process occurs in isolation in those who have been deeply affected by increasing contraction of life attachments and notable psychosocial discontinuities such as forced retirement and death of a spouse. The most tragic situation may be that of the person whose increasing but only partial insight into the past leads to a sense of total waste. Just as one is about to die, one may experience the horrifying feeling that one has never lived or may see oneself realistically and in some sense as inadequate.

Samuel Beckett's one-act play, *Krapp's Last Tape,* is a most compelling modern existential illustration of the life review. An old man listens uncomprehendingly to recordings he made as a young man in happier times. He is listening to a total stranger. The play asks, can he be regarded as the same human being in youth and in old age? Novelists and poets have, of course, used reminiscence or life review in their works, for example, the writings of Marcel Proust, James Joyce, Joyce Cary, and many others. Writers, poets, and teachers have deliberately used life review in their teaching, writing, and filmmaking (*see* Literary Representation of Aging). Referring to the 1980s to the early 2000s, and given the growing number of autobiographies and memoirs,

Patricia Hampl has called the memoir "the signature genre of our age."

People of all ages review their pasts at various times in life, especially when confronted with a crisis. Life review is common, for example, in middle age when one begins to see death at a closer distance. The philosopher Schopenhauer even remarked that middle age is that point in time when one begins to count backward from death rather than forward from birth. However, one may ask, do all life reviews serve the same functions, regardless of when they happen? Does life review in old age have particular characteristics, especially when it occurs in the face of death? As originally formulated, life review is defined as the latter.

The Nature of Memory

Memory is a complex amalgam of the senses, perception, integration, and cognition. Memory, reminiscence, life review, autobiographical memory, life story, narrative, oral history, and related concepts may one day be understood from the neurophysiological and molecular-cellular perspectives. The neurotransmitter acetylcholine is especially crucial to memory, but memory, so important to adaptation, does not depend upon one neurotransmitter alone. Memory is apparently located in the hippocampus and the amygdala. The latter is associated with memories of fear. Gender may play a role in memory function, because estrogen and other hormones affect the brain. Corticosteroids have been associated with stress and 'brain aging.' In the 1940s, neurosurgeon William Penfeld and others at McGill University in Canada demonstrated the human brain's information storage and retrieval capacity. With electrodes, they stimulated exposed temporal brain lobes of neurological patients under a local anesthetic. The process evoked vivid memories of isolated and even insignificant past events (*see* Brain and Central Nervous System; Endocrine Function and Dysfunction). Eric Kandel's work has revealed the molecular basis of memory using a snail, Aplysia, as the animal model.

Researchers still have much to learn about how the brain integrates and organizes information into categories. In *Remembering,* British psychologist Sir Frederick C. Bartlett argued that all new learning builds upon existing knowledge. A single stimulus can bring forth myriad memories, a fact novelist Marcel Proust poignantly illustrated in the 'Combray' section of his book *Remembrance of Things Past,* when the protagonist experiences a flood of memories of his youth triggered by eating a cake he enjoyed as a child. However, there may not be a single bank or library of stored information that can be called up at any time. Special stimuli might be required to reveal what may be deeply repressed. On the other hand, some information might be easily recalled or retrieved when specific stimuli are provided. One researcher distinguished six types of reminiscence: integrative, instrumental, informative, narrative, escapist, and obsessive. Instrumental reminiscing, for example, was reviewing past experiences to solve present problems. Age and life stage may also be factors in memory (e.g., childhood amnesia) (*see* Memory). Memory can be uncertain and faulty, and may vary at different stages of life and under varied circumstances in healthy individuals. When brain disease occurs, as in Alzheimer's disease, many functions, including memory, are directly impaired.

Life Review as Psychotherapy

The life review and similar autobiographical concepts have been suggested as psychotherapeutic techniques. The Martin Method, in which the client is asked to relate his or her life history in detail; life review therapy; guided autobiography; and reminiscence and structured life review therapy are among the therapeutic techniques related to or using life review.

One can use family albums, scrapbooks, cherished possessions, and other visual images to evoke crucial memories. Genealogy, reunions, pilgrimages to one's ancestral home, and family archives have also been used therapeutically. Memories can involve all of the senses – taste, smell, vision, hearing, and touch – and each may be exploited to evoke memories of the past. For Charles Dickens, for example, one whiff of a paste would bring back the anguish of his early years. Music is also a powerful stimulus for the flow of memories. The Hebrew Home for the Aged in New York City created in 1995 a lovely garden intended to trigger positive memories from the past. A porch swing evokes a bygone era, as does a water fountain made from a fire hydrant. The guided biography method proposed by Birren consists of creating a composition responding to topics such as 'my family of origin.'

Life review therapy or guided autobiography has been used with those who may not spontaneously report reminiscences. In structured life review, specific questions about one's life and conflicts are explored. Life review therapy may be conducted in group settings. For example, the family as a whole can participate in life review therapy. Such family life review has therapeutic advantages because it may lead to consensus and clarification of specific family issues.

Life review therapy has been used with institutionalized and demented older persons. Remote memory is not as affected in the early stages of dementia as much as recent memory is. Life review and reminiscence techniques are widely used by nurses in nursing homes and as part of hospice care. The life review has been used in caring for terminally ill young adults with AIDS as well as older people. The National Hospice Foundation has used the concept of the life review and created a comprehensive guide for persons of all ages. Such a review should be available for those dying patients who wish to receive therapy that offers personal, existential, and spiritual help as well as palliative nursing and medicine (*see* Hospice).

Professionals in nursing, social work, occupational therapy, physical therapy, arts and music therapy, psychology, medicine, and psychiatry have advocated reminiscence and life review as ways to help patients achieve self-esteem. The life review may aid people to resolve conflicts in their lives. Part of the therapeutic value of life review therapy in older persons may be the simple fact that someone is listening to them and that approaching death, affording them little time, is a potent incentive for positive change, such as improvement in mood, increased self-esteem, and so on (*see* Self Esteem). Forgiveness of others is an important element in reconciliation.

There is a moral dimension to the life review because one looks evaluatively at one's self, one's behavior, one's guilt. One stands in judgment of the life one has led. Atonement, expiation, redemption, reconciliation, and meaning in life are powerful potential positive outcomes of the life review. It is necessary to explore guilt, confess, and not deny it, as well as experience atonement and reconciliation, especially at the end of life. With suffering may come resolution, new insight, and self-discovery.

Fears about time running out may be reduced and replaced with a sense of immediacy, or the here and now. The elemental things in life – children, friendship, nature, human touching (physical and emotional), colors, shapes – gain significance as people sort out the more important things in life from the less important.

The Validity of the Life Review

Although the concept of life review has become entrenched in both the literature and the practice of gerontology, nursing, social work, and to some degree psychology and psychiatry, aspects of the life review have been called into question, and many questions remain unanswered. For example, how does one determine whether memories have a factual basis or are defensive distortions? How effective or even possible is external verification of memories? Studies show, for example, that mothers' memories of the timing of the most simple events in their children's development, such as toilet training, are not always accurate. What are the interconnections between emotions and memories? Personal myths emerge from childhood and may be held throughout life, affecting one's self-image and most certainly influencing reminiscences. How do self-representations change over time? What are the connections between memories and identity or self-definition? What is more important, that which is remembered or that which is forgotten, or both? How does one confirm findings that people regret most the things that they failed to do rather than the things they did do?

The life review helps both uncover and stabilize one's past selfhood. Tolstoy at age 81 said, "I remember very vividly that I am conscious of myself in exactly the same way now, at 81, as I was conscious of myself, my 'I' at five or six years of age." Consciousness is immovable. Due to this alone there is a movement that we call time. If time moves on, then there must be something that stands still; the consciousness of my 'I' stands still. This is a common feeling, substantiated by extensive work at the National Institute on Aging's Baltimore Longitudinal Study of Aging.

Some careful studies have demonstrated the effect of life review on dependent variables, such as depression and life satisfaction. It is true that much work still needs to be done to effectively operationalize outcome measures. But how does one 'measure' meaning in life, guilt and expiation, redemption, and reconciliation?

It has been said that the life review may be specific to Western society because of its focus on individualism. However, there is an active program on reminiscence in Japan, for example, and meditation on death and the end of life is common in other Asian countries.

Is the life review a universal occurrence? Studies report that between 49 and 84.1% of older persons have reviewed their lives or are currently reviewing them. Of course, this does not preclude the possibility that all persons might eventually do so. One study showed that those closer to death showed significantly less reminiscence activity and significantly less introspection when compared with matched controls, but this could be consistent with the original theoretical formulation that suggested post-review serenity or ataraxia. Subjects in these studies were not always followed through to the time of death. Some individuals may review their lives only

on their deathbed. A further complication is the difficulty of determining whether the life review has already occurred, because the process is not always a conscious one. The life review often occurs over a considerable period of time and only after a significant relationship has been established with either a mental health professional or a trained empathic listener.

One study reported asking questions such as the following: 'Some people review and evaluate their past in order to get an overall picture of their life. This is called the life review. Have you reviewed or are you currently reviewing your life?' This question does not always give access to the life review, and it might not be immediately answerable by all individuals. Such a literal, objective, or conscious approach also contrasts with the context of intensive psychotherapy and intensive research interviews that led to the original formulation. This formulation assumed the existence of the unconscious, the division of the mind in psychoanalytic theory that contains memories or repressed desires, not subject to conscious perception or control but often affecting conscious thought and behavior.

The Value and Use of Oral History and Autobiography

The need to engage in life review has prompted the writing of many major memoirs, autobiographies, and treatises summarizing the authors' life work, especially since the seventeenth century. People maintain diaries and write memoirs and autobiographies because they value their lives and feel that they have important ideas or information to convey to others or want to 'set the record straight' or gain revenge against their enemies.

There are life review and family history training manuals and guides to help people collect on audio- or videotape their life stories to leave to their families and others. Businesses have been created to sell audio- and videotapes and books made from interviews. Several aging organizations have developed materials to help people create their autobiographies or life reviews. In Britain, Age Exchange, The Reminiscence Centre, has developed *A Practical Guide to Reminiscence*. Age Exchange focuses on 'making memories matter.' Its goal is to "improve the quality of life for older people by emphasizing the value of their reminiscences to old and young through pioneering artistic, educational, and welfare activities." Age Exchange has the only professional Reminiscence Theatre company in the United Kingdom, to which Londoners have given their memories of living through the blitz in World War II. StoryCorps is a project created to tape the stories of everyday people and store them at the Library of Congress.

Autobiography is one literary genre that potentially gives everyone the opportunity to become 'someone.' This democratic process gives one the chance to speak about oneself, which can, of course, lead to reinvention of the self, self-indulgence, shameless vanity and egotism, and defense and revenge, or offer a sensitive, valid portrait of oneself. In some measure whatever one writes, however biased or fabricated, provides, to a degree, information about the individual or his or her personality. External historical observations and the memories and commentaries of others may be available to evaluate the validity of the contents of autobiographies. Some public life reviews can be painful and controversial, such as Robert S. McNamara's *In Retrospect: The Tragedy and Lessons of Vietnam,* published in 1995. His life review was also provided in the film documentary 'Fog of War' in 2004.

Behaviorism brushed aside various subjective sources of information about personality. However, oral histories and autobiographies constitute a rich source for information in such fields as anthropology, history, and literature. For example, the popular *Foxfire* books of Eliot Wigginton, which recorded the lives of people living in Georgia, preserve cultural history as well as the lives and skills of everyday people. Another example, the 1993 oral history *Having Our Say: The Delany Sisters' First 100 Years* by Sarah L. Delany and A. Elizabeth Delany with Amy Hill Hearth, was a best-seller and was made into a Broadway play. It provides a first-hand account of what it has been like to live as an African American in the United States in the twentieth century.

Life Review and New Directions in Psychiatry

What will happen now that psychiatrists have moved further away from psychodynamics and the inner life to the use of psychoactive medications in their practices? Perhaps more people will feel good and healthier faster. Painful feelings will be assuaged. But if medications were utilized in the context of ongoing psychotherapy, self-understanding might also grow. There need not be a dichotomy here, for both psychoactive medications, such as antidepressants, and psychotherapy should be concurrent and reinforcing.

What about the fact that relatively few gerontologists and psychologists have spent significant

amounts of time being with and listening to older people? They will lose opportunities to better understand the inner life if they depend upon drugs alone and if psychologists and gerontologists do not explore human personalities in depth. Researchers do not know how lasting either psychopharmacological or psychotherapeutic approaches are, but it is hard to believe that a pill gets to the bottom of genuine guilt due to acts of commission or omission. Is there no place for some measure of human suffering? Is there not also a time for celebration when painful issues are successfully resolved?

The life review concept has contributed to a better understanding of late-life and end-of-life development as well as development across the life span. It has helped demonstrate the therapeutic value of reminiscence for older people and helped eliminate prejudice against those who reminisce. But people and their life stories are more complex than any presently available methods for their study allow. Therefore, researchers must encourage further study of life span developmental psychology.

Summary

Memory is a great force for human adaptation in general and is important to social evolution. The survival value of memory both to the individual and to society cannot be denied. Life review is important in itself; in a sense, it is analogous to undifferentiated, basic research. It adds to self-knowledge per se, independent of consequences. And, by extension, one learns of the lives of others and how lives might be led. As virtue is its own reward, so, too, is the life review, for as Socrates said, "The unexamined life is not worth living." Put more positively, there are chances for pain, anger, guilt, and grief, but there are also opportunities for resolution and celebration, for affirmation and hope, for reconciliation and personal growth.

Although a majority of persons may undergo a life review, it may not be accessible and reportable in a significant minority. Memories may be deeply repressed. Moreover, life reviewers may be more introspective than those who do not appear to review. Studies of subgroups might help us to better understand such differences in personality.

It has been suggested that the life review might not be universal or even exclusively precipitated by approaching death. Yet it is remarkably common among older people, and the prospect of death is one of its most common triggers. Only in old age with the proximity of death can one truly experience a personal sense of the entire life cycle. That makes old age a unique stage of life and makes the review of life at that time equally unique.

Life Satisfaction

R C Mannell and S Dupuis, University of Waterloo, Waterloo, ONT, Canada

Glossary

Affect – A broad class of emotional processes, including feelings and moods.

Cognition – A general concept comprising all forms of knowing, including perceiving, imagining, reasoning, and judging.

Happiness – The extent to which positive feelings outweigh negative feelings. The relatively temporary affective feelings of the present moment. Often, the time period of the 'past few weeks' is used to anchor the assessment.

Morale – A future-oriented optimism or pessimism regarding the problems and opportunities associated with living and aging. Morale refers to how well people feel they fit into their social and physical environments and their acceptance of those things they can not change.

Psychological Well-Being – A general concept representing positive psychological functioning. The extent to which people are happy, experience positive affect, and do not experience depression and anxiety.

Quality of Life – A broad concept referring to overall population and/or individual-level well-being, assessed with a wide variety of objective and subjective indicators. There is some controversy about whether the quality of life concept can be defined precisely enough to serve as a legitimate social scientific construct.

Satisfaction – Implies an act of judgment, a comparison of what people have to what they expect in terms of their whole life or some specific part of it. The more their achievements fall short of their aspirations, the greater the level of dissatisfaction. Satisfaction has a past orientation, an evaluation of how things have gone up to the present.

Introduction

The quality of life for a society or group is often determined by using objective indicators such as gross national income, frequency of high-risk health behaviors, quality of the environment, and levels of crime, suicide, public violence, and family disintegration. An individual's quality of life can also be characterized on the basis of these types of objective factors. Alternatively, measures of subjective well-being have been developed based on the belief that the psychological quality of a person's life can not be understood simply from knowledge of these objective circumstances. Life satisfaction is a popular subjective well-being measure of quality of life. People are typically asked to rate their satisfaction with life as a whole or some aspect of it.

Focus of Life Satisfaction Research

Life satisfaction is one of the oldest research issues in the social scientific study of aging. Initially, this research focused on pathology and coping, but later the issue became perceptions of quality of life. Life satisfaction and other subjective well-being measures have been of considerable importance in gerontology. Researchers and policy makers are attempting to better understand the impact on quality of life of disability, changes in health status, caregiving, bereavement, retirement, role transitions and loss, diminishing social networks, modifications in activity involvement, and personality development over the life course.

Two issues have dominated research on subjective well-being in the field of gerontology. The first concerns how best to conceptualize and measure subjective well-being. Life satisfaction is only one of several competing subjective well-being constructs, and researchers continue to work at developing appropriate measures. The second issue involves the identification of those factors in people's lives that influence their subjective well-being. A substantial amount of research focusing on this issue and using the life satisfaction construct has been reported. The impact on life satisfaction of various interventions, programs, and policies directed at older adults has also been of recent interest.

Constructs and Measures

In addition to life satisfaction, other popular constructs used to conceptualize subjective well-being in the study of older adults include happiness, psychological well-being, and morale. Paper-and-pencil scales have been developed to measure these constructs. Standardized scales used for measuring life satisfaction include Cantril's Self-Anchoring Scale, the Neugarten Life Satisfaction Index and modifications

of it by Wood and colleagues, the Andrews and Withey Delighted-Terrible Faces Scale, and the Satisfaction with Life Scale developed by Diener and colleagues. A variety of single-item measures of life satisfaction have also been used in many studies. The most frequently used happiness and psychological well-being scale is the Bradburn Affect-Balance Scale, and morale is typically measured with The Philadelphia Geriatric Center Morale Scale.

A major problem with the subjective well-being research in gerontology has been the lack of consistency in defining, measuring, and using the terms psychological well-being, happiness, life satisfaction, and morale. In fact, these concepts and their measures often have been used interchangeably. However, they appear to differ on a variety of dimensions. First, there is time orientation. Satisfaction is seen to have a past, happiness a present, and morale a future orientation. Second, these constructs and measures vary in how enduring or temporary the state of subjective well-being is thought to be. Life satisfaction and morale scales measure more enduring and stable cognitions, while happiness scales measure more temporary and transient affective states. Third, the measures of these constructs differ to the extent that their items allow the assessment of both positive and negative life experiences as distinct aspects of subjective well-being. Some research evidence suggests that the positive and negative aspects of well-being are not opposite ends of a continuum, but rather separate dimensions that reflect satisfaction with different components of life (e.g., external social conditions such as friends and activities versus inner psychological conditions such as self-esteem and health, respectively). Finally, the various measures used differ in terms of whether they assess global well-being or well-being in specific domains of life (e.g., work, family, leisure, and neighborhood). By examining satisfaction with each of these domains, some researchers believe that a more accurate picture of well-being can be obtained. Researchers examining different domains of life have primarily used satisfaction measures, and specialized areas of research have been developed on single domains, such as job and leisure satisfaction.

Substantial correlations have been found to exist among the satisfaction, morale, and happiness scales, suggesting that they measure different facets of the same underlying construct. These findings are not too surprising given that the most popular measures share a number of scale items in common. However, these constructs and scales are not completely interchangeable. Research has shown that various well-being constructs are related differently to a wide variety of predictors of subjective well-being.

Although researchers continue to examine empirically the internal structure of these measures and fine-tune them for use in specific studies of older adults, other measures have been developed. For example, the Memorial University of Newfoundland Scale of Happiness and a shorter version, the Short Happiness and Affect Research Protocol, are used to measure both the enduring cognitive and the more immediate transitory affective dimensions of subjective well-being among older adults. In addition, these scales allow the systematic assessment of both the positive and negative content of life experience.

Another approach to conceptualizing and measuring subjective well-being in later life also has been suggested. Several authors have proposed breaking with past work and reconceptualizing subjective well-being, successful aging, and aging well by defining it as personal development and adjustment. They argue that measures of well-being based on the notions of satisfaction, happiness, and morale are too tied to concepts that were developed independently, and that attempts to integrate them into some superordinate subjective well-being construct fails to provide a strong theoretical basis for the development of better measures and future research. A few studies have been reported that use measures that reflect a more developmental view of psychological health and well-being (e.g., generativity, self-acceptance, autonomy, environmental mastery, purpose in life, and personal growth) based on major personality and life span theories such as those of Erikson, Rogers, and Maslow. Feelings of having lived up to one's potential and identity development earlier in life have been found to predict life satisfaction later in the life course.

In spite of the difficulties of conceptualization and measurement, a great deal of research has been done on the factors that influence subjective well-being. In much of this research, subjective well-being has been conceptualized as life satisfaction. Also, survey methodology has been predominantly used to examine a wide variety of predictors of life satisfaction. Consequently, the psychological and social factors or mechanisms linking these predictors and life satisfaction have not been explored. The rationale for the linkage is often quite speculative. As will become apparent, many of the predictors are themselves linked in complex ways that make it difficult to sort out likely causes and effects. For example, research done on the influence of housing and living environment on life satisfaction suggests that older adults living in their own residences experience higher life satisfaction than older adults living in long-term care settings such as nursing homes. Little research has been reported that explores the reasons

this relationship exists, though we can speculate that being in familiar and meaningful environments in close proximity to friends and neighbors may have something to do with the relationship. However, this relationship also is likely linked to other factors that have been found to be important. Older adults who live in their own residences are likely younger, healthier, more physically independent, and wealthier – all factors that predict higher levels of life satisfaction. With these qualifications in mind, the major predictors and correlates of life satisfaction among older adults are identified and discussed.

Predictors and Correlates

Health Status and Functional Ability

Research with community and clinical populations has consistently demonstrated that individuals in poor physical health are less satisfied with their lives than those in good health, and subjective health perceptions are a better index of life satisfaction than number of actual health problems. Health has also been found to influence people's estimates of their future life satisfaction and changes in life satisfaction over time. Though the limited cross-cultural research reported suggests that the physical health and life satisfaction relationship is fairly universal, health status may affect life satisfaction for some groups more than others. For example, perceived health is the best single predictor of life satisfaction for elderly Whites but may not be for elderly African Americans. Health problems also appear to have a greater negative impact on females than males, and on older than younger elderly adults.

Certain health problems are more strongly related to life satisfaction than others. Functional limitations that complicate daily living and interaction with others (e.g., control of bladder/bowel, visual and hearing impairments, limitations in mobility) have been found to be more strongly negatively correlated with life satisfaction than chronic disorders with established treatments. Longstanding illnesses or chronic health problems may have an indirect effect on life satisfaction by reducing activity levels. Declining health may lead not only to difficulties in performing everyday chores, but also to difficulties in maintaining social contacts and continuing valued leisure activities. However, it remains unclear how variables such as type of illness and time of onset influence life satisfaction.

Researchers have begun to identify factors (e.g., support systems, treatment programs, coping strategies) that may play an important role in buffering the effects of decreased health status on life satisfaction. Although more attention has been given to the impact of caregiving on the caregiver than the person needing care, research has suggested that older adults who require assistance with the activities of daily living have lower levels of life satisfaction. Consistent with these findings, formal support but not informal assistance has been found to reduce the deleterious effects of perceived health problems on life satisfaction. Involvement in adult day programs has been found to lead to significant improvements in life satisfaction for older adults with disabilities or illnesses and their informal partners in care. Adult day programs may be most effective when they are used consistently starting early in the caregiving career and over longer periods of time. Positive cognitive coping (i.e., modifying the meaning of the problem) rather than direct action coping (i.e., behavioral approaches) has been shown to buffer the effects of health problems on life satisfaction. Emotion-oriented coping (i.e., becoming angry, minimization of the threat, or resignation) has been found to be associated with lower levels of life satisfaction.

Although researchers have explored the relationship between physical health and life satisfaction, the relationship between psychological and cognitive health and life satisfaction remains largely unexplored. Several studies have suggested that psychological well-being (e.g., happiness, lack of depression, positive self-esteem) is positively associated with life satisfaction. With respect to cognitive functioning, even a mild decline may represent a substantial loss of capacity and may diminish overall life satisfaction, though ways may be found to positively adapt to these circumstances. Yet people with cognitive impairments or who take medications that interfere with cognitive functioning are often excluded from studies of life satisfaction. Such sampling practices imply that constructs such as life satisfaction are unimportant for persons with cognitive impairments, or that persons who are cognitively challenged are unable to make sense of or express their perceptions, experiences, and feelings. Nonetheless, recent evidence suggests that cognitive functioning is positively related to life satisfaction.

Financial Satisfaction, Security, and Strain

Overwhelming evidence from both cross-sectional and longitudinal studies suggests that adequacy of income, especially satisfaction with financial security, plays an important role in the life satisfaction of older adults. Wealthier, older adults in a number of countries report higher levels of life satisfaction than individuals experiencing financial strain. Financial problems appear to be a much more important factor

in the well-being of older adults than younger adults, and of older men than women. Socioeconomic status in general appears to be a more important predictor of satisfaction for Whites than for African Americans, and for North Americans in comparison to other national groups. Preliminary evidence suggests that older adults who utilize the life management strategies of selection (choosing specific focused goals and opportunities) and optimization (maximizing the use of their internal and external resources to achieve these goals) experience financial strain to a lesser degree and, consequently, have greater life satisfaction.

Education and Employment/Occupational Status

Evidence for the influence of education and employment status on life satisfaction is inconsistent and relationships tend to be weak, often disappearing when other factors are controlled. Some researchers have found that the relationship between education and life satisfaction differs for various age groups. Others have found that education may be more important to non-White population groups. Although some research suggests that education may play a more important role for women than for men, the opposite has also been found. Education likely has an indirect effect on life satisfaction through its influence on such things as retirement plans, current financial difficulties, and satisfaction with finances as well as perceived health. There is also some suggestion in the literature that the primary advantage of education accrues to those who finish high school and not from further participation in higher education or lifelong learning. Lower educational attainment, besides negatively impacting occupational opportunities and income, is thought to contribute to stable levels of negative affectivity over the life course, which then has an adverse effect on health practices and expectations regarding satisfaction later in life.

Employment status appears to be more strongly related to life satisfaction than to occupational status. Employment continuity has been found to be the most important factor, after health, in assessments of both present and future life satisfaction. Older workers, both male and female, exhibit higher life satisfaction than homemakers or retirees. Being employed part-time is positively associated with life satisfaction among the urban elderly, and involvement in volunteer work has been found to positively influence life satisfaction among community-living elderly persons by enhancing available social support. Nonetheless, the relationship between employment status and life satisfaction tends to be weak and present among only specific groups of older people in the population. For instance, employment status has been found to be more important to life satisfaction for middle-aged women than for older women. However, it is unclear whether this difference holds for men. Past patterns of employment and homemaking do not appear to be related to current life satisfaction.

Age

Early studies found weak negative correlations between age and life satisfaction. However, once other variables associated with aging (e.g., declining health, decreasing financial resources, widowhood, loss of friends, and decreased activity) were introduced, the relationship between age and life satisfaction disappeared. Longitudinal studies tend to demonstrate the stability of life satisfaction over time, though some studies suggest a peak at age 65 with a subsequent gradual and very moderate decrease. When asked to assess the most satisfying decades of their lives, a minority of older adults chose decades during the period of old age. However, the pattern of life satisfaction over the life span is complex and may vary significantly as a function of gender. Further, although different age groups may show similar life satisfaction scores, there may be important qualitative differences among them in the factors that affect life satisfaction. For example, the factors that contribute to the life satisfaction of older adult women have been found to be different from those that contribute to the life satisfaction of middle-aged women.

Gender

Few consistent patterns in life satisfaction can be attributed to gender alone, and the life satisfaction of widows and widowers has not been found to differ. When direct relationships are found, they are generally weak and disappear when other variables are controlled. For example, in a number of populations studied, women had lower educational attainment, less favorable employment opportunities, and lower financial satisfaction, which, as already noted, are associated with lower life satisfaction. However, gender differences may interact with other factors such as race, socioeconomic status, and age. Much work is still needed to determine how these variables interact with and influence life satisfaction.

Marital Status

Marital status appears to be more strongly related to life satisfaction for older adults than for younger adults. Married older adults typically have higher levels of life satisfaction than non-married groups.

Many studies, however, combine for analysis never-married, widowed, divorced, and separated older adults despite the fact that never-married older adult women have been found to report higher life satisfaction scores than widowed women. Never-married older women may have greater involvement in careers in comparison to widows, and this career involvement may account for some of the differences in life satisfaction attributed to marital status. Being married provides social support and companionship that enhance life satisfaction, and older adults who are married typically have higher financial satisfaction and health, which also are associated with higher life satisfaction. Loss of a spouse during old age is associated with a decline in life satisfaction, particularly for men, and older adults who get married appear to have higher levels of life satisfaction. When considering the relationship between marital status and subjective well-being, researchers have not examined the influence of the quality of the marital relationship on life satisfaction.

Leisure Activity, Social Interaction, and Community Involvement

Positive relationships between leisure activity patterns and the life satisfaction of older adults have frequently been found. In fact, some research has suggested that activity levels may be better predictors of life satisfaction than health and income. Frequency and diversity of leisure participation show a stronger relationship with life satisfaction than amount of time spent participating, particularly for those activities that enhance opportunities for self-determination, competence, and challenge. The negative impact of declining health with age on frequency and diversity of activity participation can be offset by the maintenance of high levels of leisure satisfaction through continued participation in a few highly valued activities. Activity levels and hence life satisfaction also may be indirectly or directly influenced by such factors as income, health and functional ability, education level, perceived social competence, and opportunity.

Participation in some activities is associated more strongly with life satisfaction than participation in others. Social, outdoor, and sports activities have been shown to have the strongest associations with life satisfaction, and hobbies the lowest. Engagement in active leisure pursuits has been found to act as a stress coping resource for older adults who are caregivers. Formal activities such as voluntary association memberships also show a positive relationship to life satisfaction for older adults. Nonetheless, the types of activities that are significantly related to life satisfaction have been found to vary by age. Researchers have found that sports, travel, and outdoor activities were the most important predictors for those 55 to 64 years old. Involvement in community organizations, culture and art activities, and travel were the most important activities for young older adults (i.e., 65–74 years). Home-based activities and informal social activities were the most important contributors for those over 74 years of age.

Research has demonstrated the importance of social activities, networks, and support for life satisfaction among older adults. There is evidence that social involvement is more important to older adults than younger adults. For example, social involvement appears unrelated to life satisfaction among those aged 40 to 54 years but is an important positive factor in the life satisfaction of older adults. Life satisfaction appears higher for people with larger social networks and who participate in them more frequently. This finding is particularly true for older adults with disabilities. The quality of social interactions has been found to be more important to life satisfaction than objective factors such as the frequency of contacts. Further, it has been suggested that spending time with family, particularly a spouse, may be more related to global life satisfaction, whereas spending time with friends may have a strong influence on immediate happiness and affect. Again, differences in these relationships have been found among various groups of older adults. For example, social support may be far more important to the life satisfaction of widowed older adults than the never-married.

Role Loss

Older adults who experience greater amounts of change and role loss in their lives have been found to have lower levels of life satisfaction, though this association may be stronger for men than women. Supporting the activity and continuity theories, much of the research suggests that role consistency, particularly a continued sense of usefulness in old age, is related to life satisfaction, as is the number of roles occupied. Participation in social roles has also been found to have a deleterious effect on life satisfaction if more important or central roles engender stress.

Personality and Coping Styles

Research on the links between more enduring dispositions such as personality differences has only just begun to be reported. Neuroticism and extraversion have been found to be positively and negatively correlated with life satisfaction, respectively. Competence and achievement motivation, which are stable

individual differences, are positively correlated with life satisfaction, as is the capacity to experience intrinsic satisfaction in leisure activities.

Coping style, the typical strategies with which people respond to negative external events, also may affect life satisfaction. Empirical studies indicate that coping style, much like stable personality traits, changes little during adulthood. The evidence suggests that there are few significant age-related differences in overall level of coping effectiveness. The influence of coping styles on subjective well-being among older persons has not received much attention. Among older patients with cancer and orthopedic pain, coping style is significantly related to quality of life, even after accounting for the duration and severity of illness. Passive and emotion-focused coping strategies are associated with negative responses to physical illness among older patients. Perceived control and health locus of control have been found to be indirectly (through their influence on activity/exercise levels) and directly related to life satisfaction. Higher self-efficacy in a number of areas of functioning predicts life satisfaction among widows and widowers, though the important domains for men were financial, instrumental, and health. For women, the important functional domains of life in which higher self-efficacy contributed to life satisfaction were interpersonal, emotional, social, and spiritual.

Race, Ethnicity, and Cultural Differences

Race has been found to be more strongly related to life satisfaction for middle-aged compared to older adults. Some studies suggest that older African Americans have significantly higher levels of life satisfaction than older Whites. Others have found the opposite. It has been suggested that race differences in life satisfaction may be better explained by the influence of socioeconomic factors (i.e., educational attainment, economic retirement planning, present financial circumstances). Alternatively, Black and White American life experiences may vary, and, therefore, the predictors of life satisfaction may differ by race. For example, some research suggests a significant negative relationship between race-related stress (i.e., due to racism) and life satisfaction. Social support and integration appear to be important determinants of life satisfaction for Black Americans. Religious participation and religiosity have also been found to be more important contributors to life satisfaction for Blacks than for Whites. In addition, there may be cultural differences in the factors that influence life satisfaction when North Americans are compared to other cultures. For example, family and having love and affection appear to be more important contributors to life satisfaction next to health for West Germans compared to North Americans. More research on aging and life satisfaction is emerging from East Asian countries; however, little cross-cultural research has been reported in which the mechanisms or factors underlying similarities and differences are explored.

Assessment and Prospects

Overall, the research demonstrates that subjective rather than objective indicators are better predictors of life satisfaction. This finding in part may be due to common method variance, that is, to similarities in the ways in which life satisfaction and the subjective indicators used to predict it are measured using paper-and-pencil self-report measures. Also, findings using subjective and objective indicators of the same phenomena do not always agree, as suggested by research in which both subjective and objective measures of the same predictors have been employed. For example, the link between the qualities of the physical living environment and life satisfaction has been examined. The relationship appears to differ depending on whether the indicators are objective assessments or subjective perceptions of these environments. Clearly, researchers need to examine the factors that mediate the relationship between the objective conditions of people's lives and their perceptions of the quality of those conditions. After all, interventions to improve the quality of life of older adults are typically aimed at changing objective living conditions. We should know how changes in these conditions translate into perceptions of satisfaction and quality of life.

Although most of the life satisfaction research has been cross-sectional, longitudinal studies are being employed more frequently, and modeling and trend analyses are being employed to explore changes in life satisfaction over the whole life course as well as the latter years of human life. These approaches are an important step if the determinants of life satisfaction over the life span are to be successfully examined. Further, in spite of the growth and widespread acceptance of qualitative approaches for the study of human behavior, such studies are still infrequent in research on aging and life satisfaction, though a few studies have been reported. For example, the different factors that married and single older adults associate with life satisfaction (e.g., having something meaningful to do, contentment with present circumstances, marking milestones), the different aspects of daily life that people in various stages of later life find meaningful and satisfying,

and the impact of feelings of generativity on life satisfaction have been examined. The detailed scrutiny that these types of qualitative studies can provide would help to improve our understanding of those aspects of people's lives that contribute to life satisfaction.

Researchers also have begun to investigate the nature of the relationship between global life satisfaction and satisfaction with different domains of life using 'bottom-up,' 'top-down,' and 'bidirectional' models. The top-down approach assumes that global life satisfaction is a dispositional trait or personality characteristic that influences a person's evaluation of satisfaction in specific domains. Bottom-up approaches maintain that global life satisfaction is the sum of satisfactions in various domains. Evidence suggests that relationships between global and domain specific satisfactions are bidirectional; however, they may vary across different types of life domains. This line of research seems to hold some promise.

Another line of research that has emerged in recent years, and that has the potential for application, has focused on the evaluation of the impact of various types of interventions designed to improve the life satisfaction and quality of life of older adults. For instance, studies have examined the impact of health promotion and leisure education programs as well as initiatives to provide opportunities for older adults to become involved in altruistic activities. These types of interventions have been shown to enhance the life satisfaction of older adults under some circumstances.

Finally, most of the aging and life satisfaction research has treated life satisfaction primarily as a dependent variable. A useful strategy might be to treat life satisfaction as an independent variable as well. For example, a 4-year study found that older adults with higher levels of life satisfaction had lower mortality rates during the study period regardless of health status. Also, the relationships between life satisfaction and the various factors that researchers have examined are much more complex than the simple bivariate relationships often examined suggest. Fortunately, research is beginning to be reported that is based on more sophisticated multivariate and trend analyses to determine the variables that are directly and indirectly related to life satisfaction and the direction of such relationships.

Life Span Theory

W J Hoyer, Syracuse University, Syracuse, NY, USA

Glossary

Development – The outcomes of the accumulation of experiences and of time-related biological processes that affect behavior and physiology throughout the life span of individuals.

Metatheory – Theorizing about theories. Life span theory is a metatheory in the sense that it involves macro-level integrations and syntheses of observations and theories that bear on the understanding of aging and development throughout the life span.

Personal Control – A person's influence on how events are experienced and how tasks are carried out. For example, one important topic in life span theory is the role of the person's deliberate actions in the selection and implementation of strategies for managing situations and making decisions across the life span.

Plasticity – The extent to which change is possible within an individual. For example, one index of plasticity is the extent to which cognitive or physical functions can be improved by practice or intervention.

Primary Aging – A composite of time-related biological processes that affect neuro-anatomical structures and function, and physiology throughout the body, in all organisms. The effects of primary aging on physiological functions and behavior are universal. The course of primary aging is relatively predictable for members of a particular species. In contrast to disease processes, primary aging is insidious and affects all biological systems.

Psychological Aging – Age-related changes in behavior that are generally the dynamic product of past organism–environment interactions, present organism–contextual transactions, and age-associated changes in brain integrity. Psychological aging includes primary aging, secondary aging, individually controlled trajectories within the ranges of plasticity, and dynamic organism–context transactions throughout life.

Reserve Capacity – The range of effective function that is available to the individual for responding to physical or psychological challenges. The amount of reserve capacity available for restoration of homeostasis in response to challenges and insults (e.g., stress, physical illness) is diminished in the oldest old, but not necessarily in young old adults.

Secondary Aging – A variety of moderating factors that serve to negatively influence the course of development and aging. For example, factors such as stress, trauma, and disease serve to accelerate aging processes.

Introduction

Life span theory is concerned with the description and explanation of how individuals change throughout the life course. The study of human aging from the perspective of life span theory is informed by considering the cumulative influences of experiences and biological events that have already transpired for the individual. Individual development and aging is a complex product of past and current biological and sociocultural influences, and thereby draws on many sources of data and theory bearing on individual change. The study of aging from a life span perspective involves the study of age-related interindividual differences and age-related intraindividual change. Life span theory assumes that development occurs along multiple dimensions and that there are both gains and losses in function along different dimensions throughout the course of life. It is also assumed that the interactions among some biological, historical, and sociocultural influences vary for different dimensions of development and aging at different points in the life span. Particular combinations of influences are known to have either more optimal or more negative consequences in regard to effective functioning than others. It is also assumed that there are age-related interindividual and intraindividual differences in the plasticity of function throughout the life span, and in the extent to which the individual can personally control the course of aging along some dimensions. Advances in life span theory depend on a well-equipped arsenal of research methods, including micro-level, age-comparative studies and macro-level longitudinal studies measuring relations across a wide range of biological, cognitive, personality, and sociodemographic phenomena.

Emergence of Life Span Theory

Life span theory represents a way of thinking about the development of individuals as they change

throughout the life span. The view that development is a lifelong process is probably the most general and the most accepted model in the developmental sciences and gerontology. Theorists and researchers have increasingly recognized the view that development is lifelong and that particular phases or eras of the life span are best understood by looking at them within the context of the entire life of the individual.

Data suggesting longitudinal consistencies or continuities are of special interest to life span theory. For example, archival records of Scottish school children allowed researchers to show a relation between the occurrence of late-onset dementia and lower intelligence test performance at age 11. Similarly, in another study of long-term continuities using archival records, researchers showed a relation between higher linguistic expressive ability in young adulthood and reduced incidence of dementia in later life.

Any phase of development may have its own distinctive characteristics and significance, but there are also similarities and continuities with earlier and later periods of the life span. In fact, one of the important questions in the study of life span development is the extent to which there are continuities and discontinuities across the life span. Life span theory has as its core focus the understanding of development per se, not just the cataloging of the changes associated with selected periods within the life span. For example, life span theorists are interested in how the processes and mechanisms of development in the early years of life are different from the later-life processes.

The life span perspective has stimulated new insights into the nature of human development. Some of the major theoretical advances in the developmental sciences can be attributed to the life span view. But an appreciation of the limitations of the life approach also benefits our understanding of human development and aging. Informal, early, and superficial conceptions of the full course of the human life span reinforced the stereotypical idea of development as mostly gain during the early phases of life and as mostly loss in the later years. Innovative contributions by Charlotte Buehler, Erik Erikson, and others that took issue with the stereotypical view of the life course paved the way for late twentieth century writers, especially Paul Baltes, James Birren, Bernice Neugarten, Matilda Riley, and K. Warner Schaie, to make major advances in the conceptualization and application of life span theory. In the early twenty-first century, life span theory has had a positive impact on the science of gerontology by aiding the correction of negative stereotypes associated with particular age periods, such as overly pessimistic views of aging and the elderly. It is anticipated that the life span approach will continue to evolve in light of new observations and theory-building efforts in the developmental sciences and gerontology.

What is Aging?

The term development refers to the accumulation of experiences and the consequences of time-related biological processes that affect behavior and physiology throughout the life span. For individuals attaining normal longevity, development in the later two-thirds of the life span is about aging. Primary aging refers to a composite of time-related biological processes that affect neuro-anatomical structures and function, and physiology throughout the body, in all organisms. Many of the outcomes of these processes are so predictable that they seem controlled by a 'biological clock.' One of the major aims of current research in aging is to describe and explain the relations between primary aging and the contexts in which it takes place. A second major aim is to describe and explain the extent to which there is plasticity, reserve, and personal control in development. That is, a distinction can be made between neurogenic and psychogenic age effects. Neurogenic age effects refer to changes in behavior that are largely the result of primary aging, whereas psychogenic age effects refer to effects of behavior on brain function. For example, age-related atrophy in the prefrontal regions of the brain may lead to inefficiencies in recollection and working memory, and reciprocally, long-term selective disuse of effortful cognitive strategies may lead to atrophy of prefrontal regions. A good example of neurogenic effects is the established relation between physical fitness and cognitive and cardiovascular health.

In contrast to the consequences of forms of disease that are relatively abrupt and affect primarily one system or organ, the consequences of primary aging are more gradual, cumulative, and insidious or system-general. For example, there are gradual but inevitable changes in all physiological systems and sensory-perceptual systems. Further, it is well established that the speed of basic processes or operations becomes gradually slower with advancing age and that such slowing has general or broad-reaching consequences for higher-order functions.

Despite the ubiquity and universality of primary aging processes, one of the most remarkable characteristics of human aging is the wide range of heterogeneity in the expression of the consequences of aging. Secondary aging factors such as stress, trauma, exposure to toxins, and disease negatively influence primary aging or neurogenic effects. In addition to interindividual heterogeneity in the

expression of the negative consequences of primary aging, there are also interindividual differences in the interactive effects of aging, health, and lifestyle. For example, studies have shown robust effects of physical fitness training on cortical plasticity and a cognitive vitality. Such benefits are the result of increased blood flow to particular regions of the brain or to increased synaptic interconnectivity in the frontal lobes as a result of cardiovascular fitness. Further, the circumstances and consequences associated with particular events (e.g., DDT use, 9/11, the AIDS epidemic, the Internet) could be distinctly influential in producing interindividual differences for particular birth cohorts.

In addition to large interindividual heterogeneity, there is also considerable age-related intraindividual variability across various dimensions of biological and behavioral function. Individuals become more unique as they grow older, in part because of their particular histories of life experience. During the life course, the repertoire of an individual is shaped by how that person invested time and energy in work and in human relationships. By deliberate selection and circumstance, the developing individual is both a producer and a product of a myriad of developmental influences. The description and explanation of how individuals change as they grow older and how different individuals show different patterns of change with aging are signature characteristics of a life span approach to the study of aging.

The study of aging has as its major goal the understanding of the orderly or regular time-related or age-related transformations that occur in representative organisms living under representative conditions. The main purpose of theory in the study of aging is to provide a context for organizing the available data bearing on the description and explanation of such transformations. Theories serve the process of articulating meaningful patterns from observations that would otherwise be disconnected pieces of a puzzle and hence less meaningful. In the study of aging, theories are frameworks for connecting laboratory research findings as well as informal everyday observations with emerging themes in the field.

The study of aging can be approached in many different ways. For example, aging can be seen as a complex mix of interacting time-linked biological processes, and/or as a sequence of age-ordered sociocultural prescriptions. In gerontology, one of the aims of life span theory is to capture the full range of individual differences in age-related intraindividual change in functions that characterize the older population. Life span theory is usually considered to be a 'metatheory' in that it is a set of themes for approaching the study of development and aging. Basically, life span theory offers a broadened approach to the study of aging.

Characteristics of the Life Span Approach

The characteristics of the life span approach are summarized in **Table 1**.

The notion that aging is multidimensional and multidirectional is one of the basic tenets of a life span orientation to the study of aging. Consistent with evidence suggesting increased interindividual differences with aging in healthy adults, the experience of aging seems to produce cumulative differentiation within individuals along multiple dimensions. The fact that gain, or growth, as well as loss, or decline, can be observed throughout the life course has provided a general framework for researchers to explore some of the positive attributes of aging. For example, the study of the characteristics of wisdom and creativity in late life, the maintenance or continued evolution of exercised cognitive skills and cognitive expertise in the later years, and the emergence of emotional maturity in late life are areas receiving increased research attention. However, efforts aimed at describing the positive aspects and potentials of late life functioning must be objective

Table 1 Summary of the major characteristics of a life span approach to the study of aging

1. Aging is a cumulative, lifelong process.
2. Aging is multidimensional and multidirectional in that there is variability in the rate and direction (gains and losses) of change for different characteristics within individuals and across individuals.
3. There is plasticity and resiliency in function throughout the life span, but less so in very late life.
4. There are age-related differences in the extent to which the individual is or can be active in determining the course of aging along some dimensions.
5. Aging is a product of the interactive effects of neurogenic processes and the historical and sociocultural contexts in which change takes place; the contributions of environmental and biological influences vary for different dimensions at different points in the life span. Some combinations of neurogenic and environmental influences may be uniquely synergistic.
6. The study of aging involves the integration of multiple theoretical perspectives across multiple disciplines and professions (e.g., anthropology, biology, medicine and nursing, psychology, sociology).

and take into account the realities of loss and decline. In their efforts to dispel overly negative views of aging, life span researchers have considered the pragmatics of aging. That is, one line of evidence in support of a more balanced view of aging is based on observations of ordinary lives in progress in real settings in contrast to age comparisons based on standardized tests and measures that are indigenous to youth and insensitive to the unique qualities of older adults. Another line of research evidence in support of a more balanced view is derived from studies that distinguish between the characteristics of normal aging, illness-free aging, and successful aging. Research on successful aging has as one of its aims the identification of the personal attributes and contextual characteristics of individuals who minimize or escape the debilitating consequences of aging and disease. From a gains vs. losses perspective, there is a complex array of human capabilities; some show decline, some improve, and some remain the same across selected time periods. A third line of research leading toward a more balanced view calls attention to the differences between the young old and the old-old, such that the vulnerabilities of very late life are distinguished from the potentials of the young old. The advancement of a balanced view of the potentials and limits of aging is a main theme of life span theory.

Another main theme in life span theory, as illustrated in **Table 1**, is associated with the terms plasticity, reserve capacity, and personal control. Plasticity refers to the potential for intraindividual change. Intraindividual plasticity is evident when there is variability in levels of performance across different kinds of tasks or when there is variability in carrying out the same task at different times or under different conditions. Life span researchers are interested in understanding developmental differences in the gap between observable behavior and underlying competence or potential. It is assumed that the potential for optimization is present throughout most of the life course, but plasticity and reserve capacity are constrained near the very end of the life span, such that the individual is vulnerable to a variety of circumstances associated with mortality at that point. The term reserve capacity refers to the individual's resources for responding effectively to challenging conditions. The term resiliency is similar in its meaning, and refers to a capacity for successful adaptation and recovery in response to stressful life events. Individuals exhibit varying capacities to protect themselves from impairment and insult associated with aging and disease, and to adapt effectively to the demands of stressful situations.

Successful development and aging also involve the ability to deliberately or actively influence the course of one's own development in various ways. Personal control refers to the person's ability to affect how events are experienced or how tasks are carried out. For example, personal control might involve emotional selectivity, cognitive optimization, and strategies for managing situations and making decisions. Personal control is associated with frontal lobe functions such as planning, ordering and sequencing of information, cognitive flexibility, stimulus selectivity and inhibition, and working memory and executive control functions. Control functions are also mediated by interactions between the frontal lobes and other brain regions that are engaged depending on the nature of task. Although there are age-related inefficiencies in the performance of complex tasks, individuals can control task selection and strategies so as to optimize behavior.

The concepts of plasticity and personal control hold promise for improving our understanding of the relationship between aging and behavior. Analogous to cardiovascular function, or muscular efficiency, healthy older adults usually function quite effectively in everyday non-stressful conditions, but their functioning is likely to be impaired under stressful conditions. That is, age-related deficits in behavioral efficiency are most prominent when systems that are critical to maintaining performance are challenged or stressed. The study of reserve capacity is useful for describing the effects of aging on a wide range of functions under stressed conditions. However, studies of reserve capacity and resiliency do not address how development can be enhanced in situations in which there is optimal support.

Another main characteristic of a life span view is the idea that development and aging are continuously and simultaneously influenced by a wide range of neurogenic and social processes. Although it seems trivial to point out that aging has multiple causes, most theories of aging underemphasize the malleable aspects of aging. As previously mentioned, many of the antecedents and consequences of aging are universal and species determined (e.g., graying hair, menopause), whereas other antecedents and consequences of aging are idiosyncratic or cohort specific, culture specific, or specific to a segment of historical time (e.g., happiness, wisdom).

Methods in the Study of Life Span Development

Perhaps one of the most important methodological issues in developmental research involves the

distinctions among age, cohort, and time of measurement as potential sources of influence on development. It is now well known that many observations of age differences in behavior are attributable to cohort factors (influences associated with time of birth) rather than to age factors per se. Cohort factors account for more of the variance than does chronological age in some ability domains. The validity of inferences drawn from cross-sectional comparisons of different age groups is confounded by variability associated with chronological age differences and cohort differences. Further, the validity of longitudinal comparisons across multiple times of measurement is confounded by variance associated with chronological age change and the influences of changing sociohistorical circumstances.

Another important methodological theme in life span theory has to do with the specification and meaning of the age variable. Although age-related change is usually described in terms of years since birth or calendar time, chronological age often does capture or accurately correspond with the course of some time-related phenomena. One theme of the life span approach is to replace chronological age with index measures that more accurately represent the course and underlying sources of time-related or age-related change (e.g., brain imaging measures). Further, the effects of aging on behavior are sometimes irreversible, analogous to the irreversible consequences of chemical or nuclear reactions. The effects of aging on behavior can also be quantitative and continuous rather than qualitative, and reversible rather than irreversible. It should also be noted that markers of elapsed time are insensitive to the meaning of time as a relative and subjective dimension. Indeed, the experience of the passing of 365 days is likely to not be the same at different ages. There are also biological clocks based on biomarkers or measures of physiological time, and social clocks based on the socialization of age prescriptions.

Since age and time are not causes of change per se, an aim of aging research is to identify the mechanisms that are primarily responsible for age-related change. Successful explication of the mechanisms that produce aging would enable researchers to replace chronological age (measure of time since birth) with the real index variables and the real causal variables for which it is proxy. For example, there is some evidence suggesting measures of brain reserve capacity can serve as more accurate measures of the effects of aging than chronological age.

It should also be mentioned that the multicausal and multidirectional themes in life span theory have driven the development of new methodologies and methods for the analysis of multiple antecedents and multiple outcomes across age and time. The life span approach has led to a number of significant advances in the way researchers think about the analysis of change.

Implications for the Interdisciplinary Study of Aging

One consequence of acknowledging the multidimensionality and multicausality of aging is that life span researchers try to be both specialists and multidisciplinary generalists in their outlook. Although a high degree of disciplinary specialization is usually required in order to contribute meaningfully to the advancement of scientific knowledge about aging, life span researchers find it useful to be informed about findings across related specializations. Occasionally, such linkages lead to major changes in how we think about aging processes. For example, the idea that aging consists of multiple antecedent mechanisms and multiple outcomes is now generally taken for granted. Further, from the gains vs. losses perspective, to the extent that lifelong experience contributes to the construction of distinctive systems of knowledge for particular cohorts, the aging individual thinks and acts in ways that expand some opportunities and at the same time restrict other opportunities.

Some of the most significant advances in the study of aging reflect multidisciplinary integrations and inferences drawn from comparisons and contrasts across widely different age groups and cohorts. For example, quantitative work in developmental behavioral genetics has shown that there are unique combinations of nature and nurture that produce synergistic or optimal outcomes for development. Further, much of the variance is shared between genetic and environmental factors, leaving ample room for personal control.

Finally, it should also be mentioned that a life span orientation complements the aims of research and practice in developmental and clinical intervention. How the aging individual compensates for age-related decrements is an important practical theme in life span theory. Some life span researchers maintain a focus on the optimization of aging in everyday situations. Several of the prevailing models of cognitive development in adulthood and aging emphasize such notions as knowledge encapsulation and selective optimization. Some life span researchers also give emphasis to the idea that individuals are active in constructing and controlling their own development throughout the life span.

Summary and Conclusions

In conclusion, life span theory provides a basis for describing both gains and losses associated with aging. Life span theorists give emphasis to the potentials as well as limits of intraindividual change across the life span. Due to a combination of influences, many developmental outcomes are possible for each person: some outcomes are more likely than others, some outcomes can be made more likely, and some outcomes are not possible. The study of aging from a life span orientation gives emphasis to the idea that our understanding of human aging across domains (biological, biomedical, cognitive, social) can be advanced by research that views aging as both a cause and a product of interactions among biological and sociocultural factors across time and age.

Literary Representation of Aging

A M Wyatt-Brown, University of Florida, Gainesville, FL, USA

Glossary

Swan Songs – Narratives written when their authors knew that their time on earth was limited.

Overview and History of Literary Representation of Aging

Just as in youth, aging is affected by issues of class, race, gender, health, family dynamics, and genetic good fortune. As we age, we discover how variable later life can be. Some older psychiatrists have compared the stresses of this time of life to those of adolescence. The unpredictability of that stage, they

maintain, is an important marker. Therefore, if writers fail to recognize the sometimes confusing transitions of their older characters' lives, they are most likely engaged in sentimentality or stereotyping.

Why are some portrayals of aging convincing and impressive whereas others are less so? E. M. Forster in *Aspects of the Novel* (1927) distinguished between what he calls flat and round characters. His categories can be applied to depictions of aging. As readers, we hope to be entertained and informed about the human condition. Flat characters, such as Mr. Smallweed, a vicious moneylender in Dickens' *Bleak House* (1852–1853), startle and amuse us, but do not teach us what it feels like to be in the body and mind of an elderly protagonist. To some extent, the ability to empathize with aging characters depends upon the age of the writer. Younger poets, novelists, and playwrights may assume erroneously that the elderly have little potential for emotional growth or the capacity to surprise the reader. Fortunately, some relatively youthful writers have the empathy and curiosity necessary to comprehend and display the complexities of later life. In general, however, by the time most writers reach late middle age, they can more easily draw upon personal experiences – both their own and those of friends and relatives.

In prior centuries the life course was generally shorter than it is today. Until the middle of the twentieth century few writers had productive late years. Still, some remarkable portraits of aging appeared. For example, Homer, who traditionally has been depicted as a blind, elderly bard, presented a range of older characters in the *Iliad*. Nestor, an aging Greek leader, is much too garrulous to be an effective counselor. On the other hand, Priam and Hecuba, Hector's aging parents, respond to his death and the destruction of Troy with great dignity and courage. Aging characters in Greek comedies traditionally were blocking figures, determined to complicate the lives of their youthful charges. That formula also appeared in medieval poetry. Chaucer (ca. 1343–1400), however, presented a range of older characters. These include the vital wife of Bath, who has married five times but seeks yet another husband if luck should be on her side. In contrast, the hapless January in "The Merchant's Tale," the merchant insists, deserves the cuckolding he endures for the sin of marrying a much younger wife.

Of course, characters grew old at an earlier stage of life than they do nowadays, just as their authors felt old at a relatively early age. It is not entirely clear how old King Lear is, for example, when he resigns his throne, but whatever his age, Shakespeare (1564–1616) portrayed his voluntary retirement as premature and even foolish. Despite his many mistakes, however, Lear, like his friend the Earl of Gloucester, matures dramatically in the course of the play. Beset by his enemies, he yet endures to achieve a dignity that suffering had taught him.

Written at about the same time *King Lear* was composed (1608, the first quarto), Cervantes published sections of *Don Quixote* between 1605 and 1615. The novel begins as a satire on honor and chivalry. Quixote, the elderly knight, has addled his brain by reading too many romances, tales that were very popular at the time the novel was written. After several adventures, however, Quixote begins to develop heroic qualities. Readers gradually become very fond of the old man, despite the absurdity of some of his adventures. Cervantes makes us almost wish that the world were more like the one Quixote imagines.

The change in Quixote's reception is similar to that of Shakespeare's Falstaff. This famous aging character was also conceived to satirize the concept of honor. In *Henry IV,* Part I (1597) Falstaff organizes outings and encourages Prince Hal and his retinue to drink, gamble, and wench, all diversions from the duties of valorous warfare. A complication in audience reaction comes when Hal rejects Falstaff in *Henry IV*, Part II (1598). Of course, casting out the old knight is a sign that the prince has repudiated his rebelliousness and is now ready to become king. Nonetheless, he dismisses Falstaff in such a cruel fashion that playgoers sympathize with the plight of the foolish old knight. His death is reported in *Henry V* (1599), but he also appears in *The Merry Wives of Windsor* (1597–1600) as Sir John in love – absurdly so. The dates are approximate.

In the nineteenth and mid-twentieth centuries, some poets and novelists admire older people almost as if they long for a premature old age. For example, Wordsworth (1770–1850) not only wrote with sympathy and affection about the ancient leech-gatherer, but also insisted in "Tintern Abbey" (1798) and "Intimations of Immortality" (1807) that old age is a richer stage than youth. Given the early deaths of Wordsworth's parents, one can speculate that melancholy rather than enthusiasm accounts for the youngish poet's insistence on the compensations of age. Unfortunately, the poetry of Wordsworth's middle years lacks the spontaneity of his early verses.

Some poets and playwrights of the late nineteenth and twentieth century have also created impressive portraits of aging figures. The plays of Henrik Ibsen (1828–1906) and Anton Chekhov (1860–1904) feature some arresting older characters, such as in Ibsen's *The Master Builder* (1892) and in Chekhov's *Uncle Vanya* (ca. 1899–1900) and *The Cherry*

Orchard (ca. 1904). At 68, William Butler Yeats (1865–1939) published several poems about aging. One is "Crazy Jane Talks To the Bishop" (1933). Jane is a ragtag old woman who talks back to the bishop, a disapproving authority figure. An especially moving short poem is "After Long Silence" (1933), a reunion of lovers in old age, who conclude that physical decline brings wisdom; youthful love lacks experience of the world. Moving on to recent times, poets Virginia Adair (1913–2004) and Stanley Kunitz (1905–2006) have published in old age. Adair issued her first collection, "Ants on the Melon" (1996), at 83. Many of the poems were written earlier, but after her husband's suicide she had put aside thoughts of publication. After a long and successful career, Kunitz published a collection at 90. The collection, "Passing Through: The Later Poems, New and Selected" (1995), won the National Book Award. On the whole, however, poets and playwrights have written less about aging than recent novelists and short story writers.

Nonetheless, the influence of poets such as Wordsworth can be found in some stories and novels. In the nineteenth century, two women writers combined a sympathy with the aged with an understanding that women need to be tough to survive. Maine author Sarah Orne Jewett (1849–1909) wrote with nostalgia about elderly women and men in *A Country Doctor* (1884) and the days of ship captains and their wives in *The Country of the Pointed Firs* (1896). In *The Country Doctor*, the old doctor helps his orphaned young ward find her way as a woman physician. Fourteen years later, in *The Country of the Pointed Firs*, Jewett described a once-active seafaring town filled with elderly folk who yearn for the days of their youth. Fortunately, the sentimentality is leavened by Jewett's careful observations of the dialect and behavior of each character. Even more tough-minded and equally observant are the short stories of Massachusetts writer Mary Wilkins Freeman (1852–1930). Her collection, *A New England Nun and Other Stories* (1891), highlights the plight of aging women, marooned in New England. An economic decline had caused younger folk to desert for more promising areas of the country. Despite their poverty and lack of power, some of these elderly women surprise the rest of the town folk by insisting that their lives matter, too.

A more modern example of the Wordsworth phenomenon can be found in the novels and journals of May Sarton (1912–95). In her youth and middle age, Sarton idealized strong older friends or others like those whose lives she depicted in her novels, such as *Mrs. Stevens Hears the Mermaids Singing* (1965), published when Sarton was 53. Unfortunately, Sarton's old age did not follow the desired script. Given her ill health following her stroke in 1986, it is not surprising that Sarton created a final protagonist, Harriet Hatfield (1989), who at 60 was younger and spryer than the 77-year-old author herself. Despite disability and depression, Sarton kept on producing journals, but as gerontologist Harry Berman has pointed out, one sees more unpleasant glimpses of the sacred monster of melancholy as Sarton aged.

Categories of Literary Representations of Aging

Besides the preceding works, fictional narratives can in general be divided into various categories depending on how aging is depicted. The categories are the following: idealized parent figures; midlife crisis and opportunity; late-life love; grandparents; disability and degrees of decline; retirement; retirement communities; life reviews; death, dying, and rituals of grief; and swan songs.

Idealized Parent Figures

Idealized mothers and fathers abound in early twentieth century modernist works, as well as in more recent fiction. In his early 30s, English novelist E. M. Forster (1879–1970) created an enigmatic older woman, Mrs. Wilcox, in *Howards End* (1910). Energetic, powerful males surround her. In the end her spirit dominates, however, for the ill health and misjudgments of the men diminish their control. Fourteen years later Forster created Mrs. Moore, a mystically powerful old woman, in his masterpiece *A Passage to India* (1924). Mrs. Moore has the ability to reach across barriers of ethnicity, religion, age, and class when the other characters find these chasms unbridgeable. When in her mid-40s, Virginia Woolf (1882–1941) wrote *To the Lighthouse* (1927), which contains moving portraits of her father and mother, the latter having died when Woolf was in her teens. Like Mrs. Wilcox and Mrs. Moore, Woolf's Mrs. Ramsay is the guiding spirit of the household in death as well as in life.

Later in the twentieth century, strong male figures emerged. During the civil rights era, Harper Lee (b. 1926) published *To Kill a Mockingbird* (1960). Her hero is a middle-aged lawyer, who willingly defends a black man unjustly accused of raping a white woman. In 1991, English novelist Pat Barker (b. 1943) published the first volume of her Regeneration trilogy of World War I (1991–95). Although many of her young characters are important, the emotional center is W. H. R. Rivers, the psychiatrist

who in real life had treated World War I officers suffering from shell shock. He is 53 years old and his patients are in their 20s, so they tend to think of him as a father figure.

Midlife Crisis and Opportunity

Willa Cather's (1873–1947) *The Professor's House* (1925) is in many ways the archetypal midlife crisis novel. Professor St. Peter, like Cather herself at the time of publication, is 52. He has successfully completed his life's work, having written eight volumes of *Spanish Adventurers*, a prize-winning work. Depressed by thoughts of the future, he mulls over the past and the death of his favorite student, the brilliant Tom Outland, who was killed in World War I. Mourning the lost vitality of his youth, St. Peter realizes he no longer finds his wife and daughters of much interest. After talking to a down-to-earth seamstress at the novel's end, however, he gathers the strength necessary to return to the life that he no longer desires.

In contrast to Cather's melancholy work, English academic novelist David Lodge's (b. 1935) *Therapy* (1995) and Scottish writer Alexander McCall Smith's (b. 1948) seven novels about Botswana (1998–2006) offer more hope to their middle-aged protagonists. Lodge's hero, Laurence Passmore, at 58 suffers from an unexplained depression. As his situation deteriorates, he recalls his first girlfriend, Maureen, out of his adolescent past. Eventually he finds her on a pilgrimage to Santiago de Compostela. The two complete the journey, and although she returns to her husband, their continued friendship in London brings him some degree of peace.

McCall Smith's series about the No. 1 Ladies' Detective Agency features older women and men who are busy living active lives in Botswana. Precious Ramotswe, a middle-aged woman of size, decides to start her agency, drawing upon her knowledge of human nature and upon Clovis Anderson's *Principles of Private Detection*. Not only does she solve the problems brought to her by troubled women and men, but in time she is also able to confront some of the ghosts of her past. After marrying the kindly Mr. J. L. B. Matekoni, a skilled but sometimes depressed automobile mechanic, she finds the courage to outwit Note, the man who abused her when she was young and vulnerable.

Late-Life Love

Unlike Chaucer's *The Merchant's Tale*, in which the aging January is punished for his lust for the nubile May, Vita Sackville-West and Jon Hassler showed sympathy for an older person's desire for love. English novelist Sackville-West (1892–1962) wrote about the short widowhood of Lady Slane in *All Passion Spent* (1931). Her husband, the first Earl of Slane, dies at 94 while she is merely 88. Having done her duty to her husband and children, she decides to move to Hampstead, near the Heath, and away from her family. This freedom allows three old men to fall under her spell. For the first time since girlhood, she is able to bask in the approval of her landlord, the builder who repairs the house, and Mr. FitzGeorge, a friend of her son Kay.

In his early 50s Jon Hassler (b. 1933) wrote compassionately about Miss Agatha McGee in *A Green Journey* (1985). Miss McGee is a Catholic of the old school and is most dismayed by the changes of ritual first brought about in Vatican II. A school teacher in her late 60s, she starts a correspondence with James O'Hannon, believing him to be an Irish school teacher about her age. For many years a formidable presence in her community, Miss McGree discovers that she yearns for love and understanding. Hassler shows great respect for the intelligence and strength of the elderly woman and for O'Hannon, who, to Miss McGee's dismay, turns out to be a priest. In a sequel published eight years later, *Dear James* (1993), we learn that Agatha has been devastated by his deception. Fortunately they reconcile. Her parish priest approves. He realizes that these two elderly people have much in common with Saint Francis of Assisi and Clare, being passionate but completely celibate. At the novel's end, Miss McGee feels reconciled to her community and capable of living on her own once again.

Grandparents

Several narratives highlight the lives of grandparents. Five years before *Regeneration* (1991), Pat Barker published *The Century's Daughter* (1986), about the last days of an 84-year-old woman. In many ways it was a tribute to her grandmother, who, along with her grandfather, had bought her up in Yorkshire and encouraged her to get an education.

In two short stories Peter Taylor (1917–94) and Gish Jen (b. 1955) emphasized the differences between generations. "In the Miro District" (1977), published when Taylor was 60, depicts a grandfather and grandson who can find no common ground despite the assumption of the boy's parents that they will be friends. In fact, the grandson seems determined, as one critic has pointed out, to debase his grandfather's space by having sex with his girlfriend in the grandfather's bedroom. That act of ritual desecration convinces the old man that he can no longer

stave off the ravages of age. Instead, he moves in with his daughter's family and becomes like all the other Confederate War veterans, who dress up in uniform and accept repeated promotions in rank.

In Gish Jen's "Whose Irish?" (1999), a 3-year-old Americanized half-Irish granddaughter provokes her Chinese grandmother and babysitter into spanking the child in a vain effort to tame what the grandmother considers to be wild and un-Chinese behavior. The outraged parents force the old woman to leave their house. No reconciliation takes place, but, the Irish paternal grandmother asks the Chinese one to move in with her to provide some feminine company. Middle-aged herself, Jen employs a detached and wry tone.

A remarkable story about grandparents is Gloria Naylor's (b. 1950) *Mama Day* (1988). Naylor's intergenerational novel has occasional touches of magic realism. It takes place on an island offshore of Georgia and South Carolina, inhabited entirely by African Americans and ruled by Miss Miranda "Mama" Day. The story begins when Mama Day is in her 80s and ends when she is almost 100. The Day family descends from Sapphira Wade, who, they remember, was never a slave. In the third generation three daughters experience tragedy. As a result of untimely deaths, Miranda and her sister Abigail have but one grandchild between them to rescue from premature death, Ophelia, also known as Baby Girl or Cocoa. Mama Day, who is a midwife and local herbalist, is blessed and cursed with second sight. The townspeople of all ages turn to her whenever they are in trouble, despite her advanced age.

Besides these novels, there are three additional intergenerational immigrant novels with touches of magic realism, written by young women in their 20s and 30s. Hiromi Goto's (b. 1966) *Chorus of Mushrooms* (1994) features a Japanese grandmother who lives in Alberta but has learned no English. Nonetheless, she becomes very important to the granddaughter once she leaves the family's house for an epic journey. Cristina Garcia's (b. 1958) *Dreaming in Cuban* (1992) portrays a close relationship between a Cuban grandmother and her Cuban American granddaughter. Despite Castro and the distance of time and space, the two speak to each other for many years until at last the granddaughter thinks she has enough of her forebear's story to continue on her own. The heroine of Edwidge Danticat's (b. 1969) *Breath, Eyes, Memory* (1994) also has a close relationship with her Haitian grandmother. For many years the grandmother and aunt take care of Sophie Caco in Haiti. Her mother Martine moves to New York in the vain effort to forget how she was raped by a *Tonton Macoute*, one of dictator Duvalier's paramilitary thugs. Fortunately for Sophie and her infant daughter, the extended family creates a sustaining community of women and rituals that help Sophie recover from the pain of ensuing loss.

Disability and Degrees of Decline

Disabilities in the following novels include the effects of ill health, depression, stroke, and dementia, but the characters with the disabilities display great energy. Anzia Yezierska (ca. 1881–1970), an immigrant novelist from Eastern Europe, wrote popular novels in her 30s about aspiring immigrant women. In her 60s she wrote an autobiography with more than the usual amount of fictional elements. She composed "The Open Cage" (1979), a posthumously published story, in the 1960s when she was in her 80s. In it, an elderly woman energetically complains about failing eyesight, faulty memory, and impoverished surroundings. Despite the problems of old age, Yezierska's narrator identifies with a bird who accidentally flies in her window. She celebrates when the bird is released to the wild, but mourns that she, alas, must return to her room, a place of confinement for the aged, marked by poverty and loneliness.

An even earlier novel about disability is *Mrs Palfrey at the Claremont* (1971), composed by English writer Elizabeth Taylor (1912–1975). Mrs. Palfrey is an elderly widow who suffers from arthritis. She lives in an inexpensive hotel with other old people but dreads the thought of a nursing home. She knows, however, that she will have to move against her will if the arthritis becomes crippling. Taylor had the gift of close observation and empathy. She took seriously the lives of her older characters and treated their problems as worthy of attention.

Alison Lurie's (b. 1926) *The Last Resort* (1998) combines social satire with a hopeful attitude about the capacity of some characters to start their lives afresh in midlife. This amusing intergenerational novel is set in Key West, which is inhabited by elderly artists, the young and middle aged, gays and straights. Wilkie Walker, an aging writer and naturalist, is convinced that he will soon die of cancer. To avoid that fate he attempts to drown himself, but every effort fails for absurd reasons. Although he has had a successful career, in old age he has become a complaining egotist. Other older characters are more stoical than Wilkie. Not surprisingly, his younger wife, Jenny, who has served as his acolyte for many years, finds serving a withdrawn old husband less than compelling. She discovers the pleasures of genuine affection in her new friendship with Lee, an attractive lesbian.

In his early 40s Brian Morton (b. 1955) wrote *Starting Out in the Evening* (1998), a novel with a

compelling portrait of an artist in old age. Leonard Schiller in his 70s is struggling to write yet another novel, despite the lack of interest shown in his earlier work. A young student seeks him out, hoping to write a master's thesis that might rehabilitate the old novelist; Schiller grants her interviews. Toward the end, however, the novel takes an unexpected turn. The thesis writer shows little respect for Schiller's later work, and the old man has a stroke, leaving him in need of caretaking. His feckless and immature middle-aged daughter proves capable of meeting the challenge. The old man returns to his unfinished novel while accepting the necessary assistance of his daughter and her boyfriend, both of whom prove equal to the task.

Two experimental novels are J. Bernlef's (b. 1937) *Out of Mind* (1984) and Howard Engel's (b. 1931) *Memory Book* (2005). Bernlef (Hendrik Jan Marsman), a Dutch novelist, wrote about the onset of Alzheimer's from the point of view of the sufferer, a Dutch immigrant to America. In the beginning, 71-year-old Maarten seems somewhat absentminded. His thoughts are represented by complete sentences and paragraphs. His decline, however, is very swift. It is not long before his wife, Vera, decides to hire another woman to help her manage her husband. To Maarten it seems as if Vera has withdrawn from him, and his condition deteriorates dramatically. By the time he is put into a nursing home, he has no idea where he is. He thinks he is in Holland during World War II under German occupation. Toward the novel's end the paragraphs are short, the sentences full of ellipses, and the ideas disconnected. Howard Engel, a Canadian detective story writer, suffered a stroke in 2001 that caused alexia, the inability to read. Nonetheless, in 2005 he published *Memory Book*. In it his middle-aged sleuth, Benny Cooperman, experiences the same kind of stroke. Not surprisingly, his disability complicates his ability to solve crimes, but, like his author, he finds a way of coping.

Retirement

Problems and advantages of retirement are featured in several novels. When in her early 60s English novelist Barbara Pym (1913–1980) wrote *Quartet in Autumn* (1977), which was shortlisted for the prestigious British Booker Prize. When she began a draft of the novel, she was facing early retirement herself, having had a stroke that followed a mastectomy. For several years she had refused to quit her job until her doctor insisted on it. Fortunately, her reality turned out to be far happier than she had anticipated. The characters in the novel face some of the health problems and isolation that she had feared, but all but one find it possible to renew their friendships and find muted pleasure in their lives.

Jon Hassler at midlife wrote a comic novel about premature retirement, *Simon's Night* (1979). Simon is an emeritus professor of English who becomes depressed and loses confidence in himself when at 76 he begins having some memory problems. He decides that he is not fit to take care of himself and moves into a small retirement home. So little stimulation exists in the home that he is warned by a young doctor to leave as soon as he can. The home is a soul destroyer, but Simon turns out to be surprisingly resourceful.

Tony Hillerman (b. 1925) has been writing detective stories about a Navajo Police lieutenant, Joe Leaphorn, for many years. In recent novels Joe has retired from the force, but whenever a knotty problem arises, young Sergeant Jim Chee needs his help. At nearly 80, Hillerman published *Skeleton Man* (2004), in which once again Joe Leaphorn plays a role. In fact, Leaphorn's telling of the story provides its narrative frame. Leaphorn reacts wryly when he revisits the station that he had run for many years only to discover that few remember him. Hillerman is hardly the only aging detective story writer still active. On May 15, 2005, the National Public Radio program "All Things Considered" aired a piece on aging writers of detective stories. As writers, such as Elmore Leonard and Tony Hillerman, are aging, their detectives are aging with them.

Retirement Communities

Two novels describe very different retirement communities. A youthful Gregg Kleiner wrote a lively fantasy about aging solidarity in *Where River Turns to Sky* (1996). The hero, George Castor, at 80 finds out that his old friend Ralph has died alone in a nursing home while George was off fishing, despite having promised that he would not desert his friend. George hates the home for its lack of humanity. In his anger he buys a big house in town, paints it red, and spirits some of the inmates out of the home to join him in the effort to make a genuine community. The group grows robustly and survives the death of some of the residents, including that of George himself, who has cancer. In the end new people join the old residents, and the survival of the group is assured.

James Michener's (1907–97) *Recessional* (1994) is based on solid research. It was published when he was 87 years old and had already published 38 books. *Recessional* takes place in a retirement center in Tampa, Florida, called the Palms. Most of the residents are rich, for the fees are steep. The plot has elements of soap opera. Just about every possible

scenario unfolds. By far the biggest headache for Andy Zorn, the young director, has to do with end-of-life issues. Some residents lack valid advance directives and to his dismay are kept alive artificially on life support. Unlike Kleiner, Michener does not suggest that the Palms is a place of horrors. The residents he describes are vital individuals whose life stories are of interest.

Life Reviews

Characters in five novels reconnect to the past in different ways. The earliest of these is John P. Marquand's (1893–1960) *The Late George Apley* (1937). In its time the novel was regarded as an amusing satire, but it is far sadder than that. The narrator describes a man who is reared to conform. In youth he longs to marry an Irish woman named Mary Monahan, but his parents would have none of it. Instead, he marries Catharine Bosworth, whom he does not love, and as a result his life has many dreary moments. When he knows he is gravely ill, for a moment he reflects honestly upon his life. He realizes that pleasing others has made it impossible for him to recognize his own true feelings. Even so, he fails to understand that his children have moved far away to avoid having to follow in his footsteps.

Wallace Stegner (1909–93) published *Crossing to Safety* in 1987. It is a compelling story of four friends who meet in youth but maintain their friendship into the beginning of old age. Like many novels of life review, much of the plot reconstructs their early lives. After many years of friendship, some of it by long distance, the Morgans, who are in their 60s, are called back to the Lang family compound in Vermont. Charity Lang, who in many ways has dominated the lives of the four, is dying of cancer and wishes to orchestrate her end, just as she has tried to control the rest of her life. Unfortunately, Charity's desire to mastermind her final days pains her husband deeply because it represents yet another vote of no confidence in his manhood. The four renew their friendship, but their crossing is perilous.

Peter Pouncey's (1938) *Rules for Old Men Waiting* (2005) describes an 80-year-old man who is grieving the loss of his wife and somewhat passively awaiting his own death. He recognizes physical symptoms that need medical care, but instead of taking charge of his life, he uses his flagging energy to construct some fascinating stories. These narratives combine elements of his own life, including his service in World War II, with a fictional story of trench warfare in World War I. The war plot, which features a villain, is an outgrowth of MacIver's (and Pouncey's) research in military history. As the novel progresses, the reader begins to realize that the villain's own uncontrolled emotions have their counterpart in MacIver's lifelong struggle with anger.

The final two novels break new ground in the genre of life review. At age 80, English novelist Stanley Middleton's (b. 1919) *Necessary Ends* (1999) chronicles a year in the life of an 81-year-old man. Like several other older writers in recent years, Middleton is not afraid to discuss death and dying, but perhaps surprising is his interest in old age sex and desire. Although Samuel Martin thinks a lot about the past, he is such an outgoing person that he quickly makes new friends during his first year in a seaside village. He begins to have a surprising relationship with Alice Jeffreys, a woman in her 60s, whose husband has cheated on her repeatedly. Alice controls their relationship, but permits him liberties. In one wonderfully orchestrated scene in bed, the old man strokes her hair and touches her breasts while she continues to discuss her musical interests in vivid detail. Sam feels completely rejuvenated for a time. At the novel's end, however, a new acquaintance of Sam dies unexpectedly. The death saddens him in unexpected ways. He has little fear of his own demise, he muses, but the death of friends shatters his self-confidence.

Marilynne Robinson (ca. 1944) won the 2005 Pulitzer Prize for *Gilead* (2004). John Ames, a preacher in Kansas, is facing death from heart disease at 76. Because the novel is set in 1956, his doctors can do little to extend his life. Recognizing that his beloved son is only 6, he writes an extended letter to the boy about his family history and his thoughts about life in the present. The novel is unusual for its theologically serious discussion of religion and the religious life. Moreover, Ames's life review incorporates unresolved feelings of jealousy and sadness about his imminent death. Like the best of these novels on aging, *Gilead* appeals to our intellect and our emotions.

Death, Dying, and Rituals of Grief

Death is described as a natural process, with little pain and unhappiness, in Willa Cather's *Death Comes to the Archbishop* (1927). Like Sarah Orne Jewett's dying characters, the archbishop suffers a short decline and peaceful end. Contemporary novels rarely have characters slip away so easily, even in situations in which the figure is not hospitalized. Memoirs that confront death with all its horrors include Madeleine L'Engle's (b. 1918) *Two-Part Invention* (1988), published when she was 70. In her earlier memoir, *The Summer of the Great-Grandmother* (1974), L'Engle's family takes care of her 90-year-old mother in order to keep her out of a nursing

home. The demented old woman's dying exhausts the family, even though they willingly have taken on the burden. In contrast, 14 years later L'Engle's husband, Hugh Franklin, develops bladder cancer. He spends much time in the hospital, for the physicians hope to cure him. Unfortunately, every procedure causes further trouble. In the end the family unanimously decides to write no code in the chart so that nothing further will be done. In both memoirs the pain of loss is increased by the sense of helplessness. Still, L'Engle realizes how lucky she is. She is surrounded by loving friends who give support during and after the ordeal, and the church offers her companionship and solace.

A. G. Mojtabai's (b. 1937) *Autumn* (1982) and her short stories in the collection *Soon* (1998) describe people caught in liminal states between life and death. These threshold moments are bewildering and not always subject to human will. *Autumn*, published when Mojtabai was 45, is a sensitive study of Will Ross, a man of 66, in mourning for his wife. He thinks he has things under control, but he does not. Troubled by the unresolved conflicts in his life, he believes that his tree house contains a comatose young man. At one point he recalls sleepwalking through his own youth. At the novel's end the boy disappears, and Will thinks he hears someone calling him. He answers, but the novel ends shrouded in ambiguity.

Autumn's ending has much in common with Mojtabai's short stories in *Soon: Tales from Hospice*, published 16 years later. They are based on the novelist's work as a volunteer in a hospice, where she longed to fill in the missing details of the patients' lives. Unable to ask them pertinent questions, she invented her own answers. The stories depict patients and families who are awaiting the moment that they or their relative will die. The stories employ different perspectives, sometimes that of the patient, the family, or members of the staff. Death is taken seriously, as are questions of religious belief and skepticism.

English novelist Graham Swift's (b. 1949) *Last Orders* (1996), winner of the Booker Prize, describes the effect of one man's death on his four friends and their families. Written when Swift was in his mid 40s, the novel interweaves events from the past and the present. The four friends and Jack Dodds' adopted son take turns describing their journey to Margate, where they must scatter Dodd's ashes. The trip is arduous because each person has unfinished business with Jack and the other survivors.

Swan Songs

In this context, swan songs are narratives written when their authors knew that their time on earth would soon end. For three novelists, Barbara Pym, Carol Shields, and Paul Scott, writing was a lifeline that none of them wished to abandon. Death, however, is not necessarily a topic that they chose to pursue in their final novels. Instead, Pym and Shields wrote obliquely about life's end, whereas Scott approached the subject more directly.

Barbara Pym began *A Few Green Leaves* in 1978 at age 65, before she learned that she had a new malignancy that would shorten her life. Still, when she wrote the final draft, she did not make it lugubrious. Instead, she maintained such an objective stance that the casual reader would not guess that the author was facing her own death. Although images of death permeate the novel, death is not always treated with great seriousness. On one occasion, her youngish heroine, Emma, makes fun of the subject, unable to imagine her own demise. When Miss Lickerish, an elderly village eccentric, dies, Pym describes the church service in considerable detail, taking pleasure as if she were stage managing her own funeral. Ritual was comforting to Pym even in extremis.

American-born Canadian novelist Carol Shields (1935–2003) published *Unless* (2002) after she had been told she had stage four breast cancer, for which no cure exists. The 44-year-old main character, Reta Winters, suddenly has her life shattered when her eldest daughter drops out of university. She sits in the street holding a sign saying Goodness, begging from those who emerge from a subway stop in Toronto. Although Reta clings to her writing life, the loss of her daughter makes her feel as if her heart is breaking. Not surprisingly, the novel has melancholy overtones, and at times the novelist expresses anger at the treatment of women and women novelists in particular.

English novelist Paul Scott (1920–78) wrote *Staying On* (1977) while he was gravely ill. Scott was working on another novel when *Staying On* won the Booker Prize. Many regard the novel as the coda of *The Raj Quartet* (1966–75), his four-volume epic of the last days of English rule in India. In it, two minor characters from the early novels, Lucy and Tusker Smalley, become the chief protagonists. They have stayed in India after partition, but their situation becomes more tenuous even before Tusker dies. Mrs. Bhoolabhoy, who owns their dwelling, an old hotel, the only place the Smalleys can afford, is determined to sell it. Like the other swan songs, this one leavens the grimness of death and loss with humor and with rich descriptions of life in India. Lucy and Tusker may be losers, but Scott portrays them with great sympathy and affection. The novel begins and ends with Tusker's death, but only at the end does one know how desperate Lucy's life will be. She tries to be brave but ends by calling out to her dead husband, asking how can he desert her in an alien land.

Conclusion

In conclusion, aging has become such an important topic in modern life that even some comic strips feature older characters. Not only do grandparents play supporting roles in mainstream comics, such as Lynn Johnston's (b. 1947) "For Better or For Worse," but they also dominate strips such as Aaron McGruder's (b. 1974) "The Boondocks" and Brian Crane's (b. 1949) "Pickles." The grandfather in "The Boondocks" shares the stage with his young grandsons and their friends. Their disparate perspectives provide intergenerational humor and conflict. In contrast, "Pickles" is devoted to the daily life of an elderly couple. In it, their daughter and grandson appear as minor figures. Unlike American movies and television, which desperately seek a young audience, comics, like fiction, can appeal to people of all ages. In the future, as populations age, we will see even more literary works devoted to aging characters and themes, written from a variety of perspectives.

Loneliness

L C Mullins, Auburn University at Montgomery, Montgomery, AL, USA

Glossary

Emotional Isolation – The lack of person(s) to whom one feels attached (i.e., emotionally committed).

Loneliness – A psychosocial emotional condition that may stem from many factors, but that is usually related to either social isolation or emotional isolation.

Social Isolation – The lack of, or a deficit in, the quantity of a social network.

Introduction

This article first looks at loneliness from a social problems perspective and examines whether loneliness in old age is a myth. Next, the focus shifts to a general examination of the two broad conceptual and theoretical approaches that have driven the examination of loneliness. One perspective focuses on a micro-social, or social psychological, framework, while another perspective emphasizes a sociological and cultural orientation. Also, the primary trends in

loneliness research with special emphasis on social relationships and health are examined. Further, there is a discussion of the two primary measures of loneliness. Finally, an overview of intervention strategies that can be used to reduce loneliness is presented.

Loneliness, especially in old age, is a condition and a concept that on the surface appears to be understandable to everyone. We have all heard such statements as 'her husband died last year; she is lonely,' or 'he has been living alone for six years; he must be lonely.' The reality is that loneliness is a theoretically and conceptually complex idea, which in its social, psychological, and behavioral effects can be emotionally and perhaps physically debilitating.

Loneliness as a Social Problem

One such issue concerns whether loneliness is viewed as a social problem, i.e., the focus is on the magnitude of the problem. In 1986, Revenson argued that loneliness in old age is simply a myth that should not be continued. The 1974 NCOA (National Council on the Aging) Survey showed that among those under age 65, 61% viewed loneliness as a very serious concern for those over 65. In 1981, the comparable figure was 65%. In 2000, the same type of evaluation indicated that 38% of those under 65 saw loneliness as a very serious concern for those over 65. The general American public under age 65 certainly does not view loneliness in old age as a myth, though the perception of it as a problem is declining.

What about the elderly themselves? Among those age 65 and under, 38% in 1974 and 21% in 2000 viewed loneliness as a very serious or somewhat serious problem. It could be concluded that loneliness is still a problem among older persons, but the extent of the problem is decreasing. Still, 21% of those 65 and over represents more than a fifth of the 35 million older persons in the United States in 2000, i.e., more than 7.3 million older persons.

Whether such figures indicate that loneliness is or is not a social problem is a conclusion for others to draw. The figures presented here, however, do lend credence to the focus that has been placed on the examination of the causes and effects of loneliness among the elderly over the past 30 years.

The growth in the number of older persons worldwide, especially in developed countries, has stimulated much interest in their various needs and conditions. Loneliness is one of those conditions that has generated considerable examination. Much of the focus in loneliness research has come from a micro-level of analysis. Researchers have typically focused on variables at the individual level, especially looking at issues of individual health characteristics, gender, age, and, most particularly, the quantity and/or quality of contact and relationships with friends and/or family.

Micro-Social Perspective of Loneliness

The theoretical foundation of loneliness research from a micro-social perspective began in the 1950s and 1960s. The best review of this foundation comes from Marangoni and Ickes. They point out that the theoretical approaches can be broadly classified as one of several categories: (1) the behavioral approach, represented by the behavioral problems and social skills deficits perspective; (2) the personality explanations; (3) the cognitive processes approach; (4) the social needs approach–neo-Freudian; and (5) the social support perspective. An examination of these approaches leads to an identification of several common themes: (1) loneliness is a subjectively experienced emotional condition with no necessary association with social isolation; (2) loneliness is an aversive psychological condition; and (3) the underlying cause of loneliness results in some way from deficits in social relationships. The various theoretical orientations essentially differ in how and why social deficits lead to the experience of loneliness.

The importance of a phenomenological, *qua* existential, approach is clearly seen in the classic distinction made between feeling lonely and being alone. A person may live alone and have relatively few social contacts, but still seldom feel lonely. Conversely, persons may have chronic feelings of loneliness even when in a crowd or surrounded by others. The objective fact of social isolation and the subjective experience of emotional isolation are by no means equivalent.

It is important also to distinguish among different types of subjective loneliness. Young identified three distinct types: chronic loneliness, transient loneliness, and situational loneliness. Chronic loneliness concerns persistent deficiencies that people experience in their social relationships for at least two or more consecutive years. Transient loneliness refers to occasional feelings of loneliness, such as those that many people experience from time to time, that are not persistent for more than brief periods of time. Situational loneliness results when individuals are confronted with a specific crisis or loss, such as the death of a spouse.

The lines between these types of loneliness are not absolute. For example, a person may experience situational loneliness as a result of a particular loss from which recovery does not occur; thus, situational loneliness gradually transforms into chronic loneliness. Or episodes of transient loneliness may become

more frequent, ultimately resulting in chronic loneliness. The reasons for such increases in loneliness could be traced to social or psychological changes that are associated with the process of growing old.

Under normal circumstances, there are gradual changes, such as the gradual reduction of social contacts, that can trigger the transformation of transient or situational loneliness to chronic loneliness. Among the chronically lonely, however, there may be brief interludes when the acute pain of loneliness is lifted temporarily, e.g., when there is an overwhelming but temporary increase in social contacts at a family reunion.

Macro-Social Perspective of Loneliness

While much of the attention, both theoretically and empirically, has been given to the micro-level of examination, more emphasis needs to be placed on the macro-level, i.e., the examination of sociological and cultural variables in their impact on explaining both isolation and emotional loneliness.

Additionally, cross-cultural comparative work would be invaluable in furthering understanding. Cross-cultural comparative analysis is needed to sort out what is culturally specific and social psychologically general. A comparative perspective is not necessarily limited to the general cultural or subcultural environment, however. It can also deal with the relationship between subjective feelings of loneliness and the social networks in which older persons are involved. These networks, also, can be affected by the type of living arrangements in which older persons are involved, their health, their socioeconomic status, their family structure, and various other indicators of opportunities for social contact.

The basic approach underlying this type of examination can be summarized as follows. (1) People with differences in basic personality structures vary in terms of their social needs, especially needs for sustained or intense intimate interaction with others. (2) Individuals' basic personality structures are formed in large part by the type of basic cultural value system that they have internalized. (3) Because societies differ in terms of their basic cultural value orientations, personality patterns, especially needs for social interaction, will likewise vary in different societies. (4) The crucial importance of cultural variations for personality formation also applies to subcultural variations within a complex and pluralistic society.

While these basic principles focus primarily on the subjective level, objective variables may readily be incorporated into the model. The importance of such variables and their relationship to the subjective level can be expressed as follows. (1) Societies differ in terms of the opportunities provided to older persons to develop or maintain a desired level of social contacts. (2) Similarly, within a complex or pluralistic society, different segments of society vary in the same way. These variations in objective opportunities for social contact are no doubt influenced by numerous other social structural variables, including, for example, the preferred social role for older persons, density of communities in which older persons live, specific living arrangements, marital status, health and mobility skills, socioeconomic status, and so forth.

However, in order for us to understand the problem of loneliness among older persons, these variations in objective opportunities for social contacts must be related to individuals' subjective needs and desires. Accordingly, the following basic principle is pertinent: for any particular level of opportunity for social contacts, a person's evaluation of its adequacy or deficiency is based on a subjective comparison (not necessarily conscious) of that level with the level of social interaction that is expected, needed, or desired within the culture. Expectations, needs, and desires, in turn, result in large part from basic personality structure. Because of the difference among people in this regard, the concept of the 'loneliness threshold' is a potentially crucial consideration. The loneliness threshold is the minimal level of social contact that is needed for a person to avoid the subjective experience of loneliness. Although individually specific, it is heavily influenced by the basic cultural or subcultural value systems that the individual has internalized.

Trends in Research

Loneliness and Social Relationships

A key question in loneliness research, to paraphrase Dykstra, is 'What is it about social relationships that influences loneliness?' When the impact on loneliness of different forms of relationships is examined, the conclusions reached are quite varied. For example, research on the spousal relationship has often focused on examining loneliness among persons who were married, but are now widowed. Widowhood, i.e., the loss of a significant other, is shown to be a major risk factor in the manifestation of loneliness among older persons. This perspective assumes the loss of both a social and emotional companionship. More research, however, needs to focus on the development of loneliness while the marital relationship still exists. That is, among married older persons, how does the level of emotional commitment

between the partners influence the loneliness experienced?

Adult children, of course, are important to the well-being of older persons, e.g., providing financial assistance, emergency assistance, and help with health care. Those older persons without children are more likely to live alone and, if alone, are less likely to have had recent social contact. Research does not show, however, that childless older persons are any more lonely than those with children.

An area neglected by loneliness research is the contact and emotional relationship older persons have with grandchildren and with siblings. Grandchildren provide a potential source of emotional intimacy that has not been fully examined. The facts that three-quarters of all older persons in the United Stated have living grandchildren and that half have contact with grandchildren every day or so indicate an emotional and social context important to well-being.

The impact of sibling relationships on loneliness has also been a neglected area of study. Cicirelli observed that the sibling relationship can be of the longest duration and may be the most egalitarian of kin relationships. The limited research findings, however, are mixed. There are indications that sibling relationships can either reduce loneliness or not influence loneliness.

The greatest emphasis in loneliness research has been on the friendship relationship. Hochschild indicated that friendships foster a kind of belonging based on proximity and conviviality. Unlike family ties, which remain consistent through old age, contact with friends can be more varied. Friendships are not formally prescribed, as are kinship roles, and require both initiative and sustenance by both parties to be successful. Although some conditions associated with aging may change, e.g., health or economic conditions and geographic distance, many older adults maintain some friendships for many decades.

Research has shown that friends, especially close friends, exert a positive influence on the emotional well-being of older persons. Friends provide numerous forms of social and emotional support that are valued and appreciated especially because the support is non-obligatory. Friends clearly are important in preventing or reducing loneliness. Generally, older persons who have sufficient contact with friends, especially those residing near them, and who are satisfied with those relationships, experience less loneliness.

The Impact of Health and Selected Other Characteristics on Loneliness

Though there are both objective and subjective components to health consideration, previous research has not systematically made a distinction of the influence such variables would have on the experience of loneliness. The health of older persons consistently has been shown to be related to their emotional well-being. Considerable consistency in loneliness research indicates a strong association between poor health, especially subjectively assessed poor health, and loneliness. A lingering issue, though, is whether greater loneliness leads to poor health, or whether poor health leads to greater loneliness.

There are a number of other characteristics that need to be further examined with respect to loneliness. Some of the more obvious are age, gender, race and ethnicity, rural and urban settings, education and income, place of residency within the continuum of care, and religious background and religiosity. Each of these has been examined with respect to loneliness, either specifically or as a control variable in studies focusing on other issues; a brief overview of this research follows.

Studies do not show a clearly identified gender-specific effect on loneliness. However, the research suggests that either gender is not important, or women are more lonely and men are more isolated. The examination of differences by race and/or ethnicity does not show any particular difference in loneliness. There is some evidence that those living in rural areas are more likely to experience loneliness, due to factors associated with social isolation. There is no particular conclusive finding that education or income is related to loneliness. The adequacy of income, a subjective measure, does show some relationship to loneliness.

There is a general indication that loneliness increases for persons residing in increasingly restrictive levels of care. Research in the Netherlands, however, shows a decline in loneliness upon admission to a residential facility. Also, while there has been no work comparing loneliness experiences with respect to religious denominations or tenets of faith, there is evidence that the associational or communal aspect of church attendance is related to loneliness, while the subjective element of religious commitment is not.

Measurement of Loneliness

While there are a number of scales that measure feelings of loneliness, there are two that have received the most use and attention. Both measures are based on a cognitive approach to loneliness. The UCLA Loneliness Scale, originally developed by Russell, Peplau, and Cutrona, has been utilized in several forms, i.e., a long and a short form. The 'revised' scale, consisting of 20 items and published in 1980,

examined concurrent and discriminate validity. The scale consists of 10 positively and 10 negatively scored items. An example of a positively scored item is 'I feel isolated from others.' The scale has shown consistently high internal consistency, with a coefficient alpha of greater than 0.90. An example of a negatively scored item is 'I do not feel alone.' The scoring is based on a four-point scale with higher scores indicating a greater expression of loneliness.

Another measure that has been used extensively is the Loneliness Scale developed in the Netherlands by DeJong-Gierveld and associates. Originally a 34-item multidimensional scale, the final scale consists of 11 items. It can be used in face-to-face interviews or as a self-administered test. It also consists of positively (five items) and negatively (six items) specified items. A positive item is, for example, 'There is always someone I can talk to about my day-to-day problems.' An example of a negative item is 'I experience a general sense of emptiness.' Scale scores, ranging from 0 to 11, are based on summing dichotomous item scores. The total loneliness score can be categorized as one of four levels: not lonely (0–2), moderate loneliness (3–8), severe loneliness (9–10), and very severe loneliness (11). This scale also has reasonably high internal consistency – alpha coefficients in various studies range from 0.80 to over 0.90.

A caveat about these scales concerns the positive and negative nature of the items. An examination of the factor or content structure of these scales usually shows two dimensions. One dimension consists of the positive items, which assess feelings of belonging, while the other dimension consists of the negative items, which seem to relate to missing relationships.

Of course, whether the UCLA Scale, the DeJong-Gierveld Scale, or another is used is at the researcher's discretion. The essential issue of which is best is based on the needs of the research conducted.

Intervention Strategies for Loneliness

Intervention strategies for the amelioration of loneliness can take many forms. Broadly conceived, these approaches can take three forms: those that are individually oriented, those that are group oriented, and those that are environmentally focused.

Individual Approaches

The interventions targeting individuals include interpersonal therapies, psychodynamic therapies, cognitive-behavioral therapy, and friendly visitor programs.

Interpersonal Therapies In a Rogerian and humanistic framework, interpersonal therapies consider loneliness as a result of the person's belief that without conformity to social norms social rejection will result. In effect, the self is unlovable. The therapeutic approach is to develop a client–therapist rapport, which, through free interchange, will reduce the individual's fear of rejection and provide a new experience with interpersonal relationships.

Psychodynamic Therapies Similar to the interpersonal strategies, the psychodynamic approaches look at the lonely client–therapist relationship. Through the transference between the lonely individual and the therapist, the childhood conflicts and difficulties that have made adult social bonding ineffectual are identified. Such issues as dependency, hostility, and intimacy are examined with regard to their impact on the manifestation of loneliness.

Cognitive-Behavior Therapies This approach suggests that negative cognitive presumptions regarding interpersonal relationships can lead to emotional isolation. For example, it has been found in several studies since the mid-1970s that those who experience greater cynicism, mistrust, and negativity of peer ratings and who are vigilant and hyperalert to threats in social encounters tend to experience loneliness. The therapeutic rationale is focused on influencing the lonely person's perception of interpersonal relationships. In effect, the person is trained to recognize and change what are presumed to be inaccurate perceptions of social interchange.

Friendly Visitor Programs Probably the most straightforward therapeutic approach is the provision of friendly visitors. In this approach, programs typically are aimed at persons who are considered to be socially and physically isolated. While such programs do have at least short-term effects, they are usually broadly sweeping with little attempt at targeting the particular social relationship most in need of change, or in ameliorating other considerations, e.g., health and economic condition.

Group Approaches

Similar to the individual approaches to the resolution of loneliness are the group approaches. In group approaches, the focus is on specific target groups. Professional interventions using a cognitive approach in combination with group process techniques have been useful in maintaining self-esteem and in facilitating emotional adjustment. Most interventions within this context emphasize the development of skills needed to initiate social contact, e.g., social

skills training for the socially isolated, those who are shy, or those who have inhibitions of social risk taking. Particularly effective within the group context is the ability to capitalize on the often-noted association between depression and loneliness. Group therapy procedures that prove effective in alleviating depression would likely reduce the distress associated with loneliness.

Environmental Approaches

The two preceding approaches to loneliness reduction attempt to educate or change the person in some way in order to increase the satisfaction the person experiences with social ties. The alternative approach is to design the environment in such a way as to facilitate social interaction and (either intentional or unintentional) network building. Enhancing, as Hochschild described, the 'web of sociability' is viewed as a positive approach to cooperative task development.

Senior centers, congregate programs, home-delivered meal programs, adult day care programs, and transportation programs would be well-served by looking into creative ways to design their programs in order to facilitate social integration and emotional attachment, opportunities to give and receive support, and enhance feelings of personal worth.

In sum, there are many varied approaches that may be useful for the alleviation and/or prevention of loneliness. Much work needs to be done that systematically addresses the emotional condition of older persons within the context of not only their interpersonal relationships, but also the sociodemographic situations and health conditions within which they find themselves. Treatment and therapeutic regimens must be developed that are understandable, developed for specific groups based on needs, and testable.

Long Term Care

S Zimmerman and P D Sloane, University of North Carolina, Chapel Hill, NC, USA

Glossary

Culture Change – A transformation in long-term care that is bringing control to older adults and those who work closest with them, such that care is becoming more person-directed and focused on relationships, rather than on the task of care provision.

Dementia – A progressive, irreversible, organic brain disease that involves a reduction in memory and multiple other categories of cognitive ability, with the impairment being sufficient to interfere with self-maintenance, work, and/or social relationships.

Nursing Homes – Facilities with three or more beds that provide 24-hour nursing care services. More narrow definitions require the facility to be certified by Medicare or Medicaid.

Quality of Care – The structure and process of care that result in outcomes, with the understanding that quality care increases the likelihood of desired outcomes.

Quality of Life – The essential conditions beyond survival that are needed for individuals to have experiences that provide meaning and joy to their time.

Residential Care/Assisted Living – Facilities that are not licensed as a nursing home; house two or more unrelated adults; provide room, board, 24-hour oversight, and personal care; and can respond to unscheduled needs for assistance. More narrow definitions consider assisted living to be those residences that have apartments rather than rooms and/or that embrace a distinct philosophy of care.

Introduction

Long-term care is the broad range of personal, social, and medical services that assist people who have functional or cognitive limitations in their ability to perform self-care and other activities. With the growth of our older population, long-term care has become a major component of the United States health-care system. These services are provided in a multitude of locations, including private homes, adult day-care settings, residential care/assisted living facilities, and nursing homes. This article focuses on those last two settings, both of which constitute residential long-term care. In 2005, there were approximately 17 000 nursing homes in the United States, with 1.9 million beds, serving 1.6 million persons. Almost one-half of the nation's population aged 65 and older will spend at least some time in a nursing home, and in many states, nursing home care consumes over 50% of the Medicaid budget. Furthermore, nursing homes are only a portion of the residential long-term care system; nationwide, residential care/assisted living facilities have proliferated since the 1990s, to the point that the number of beds in these residences rivals that in nursing homes. In 2005 there were approximately 36 000 residential care/assisted living facilities in the United States, housing as many as 1 million older adults.

Nursing Homes

Overview

Since the inception of Medicare, nursing homes (also referred to as skilled nursing facilities) have been the predominant form of residential long-term care in the United States. They provide 24-hour nursing care, supervision, help with activities of daily living, meals, and medication administration to people who cannot manage independently. They also provide rehabilitative services, including physical, occupational, and speech therapy, to assist those recovering from acute conditions such as stroke or hip fracture. The vast majority of nursing home residents are elderly, and in general, nursing homes have consistently housed approximately 5% of the US population age 65 and older.

The predominant model of nursing home care is medical, ordered by physicians, planned primarily by licensed nurses, and delivered by certified nursing assistants and other professional or paraprofessional staff. Because nursing homes are tightly controlled by federal regulations, much of the administrative structure, staffing, and physical characteristics of one facility are similar to those of any others. However, as discussed later in this article, the field of long-term care is embracing a culture change movement, which may allow for more diversity, and improved quality of care, in these settings.

Clientele

Reflecting the demographics of the population, the majority (almost 75%) of nursing home residents are women. The average age at admission is 84, and

approximately one-half of residents are 85 years of age and older. Overall, an estimated 75% of nursing home residents require assistance in three or more activities of daily living, such as bathing, dressing, eating, transferring from a bed to a chair, and using the toilet. Approximately one-third of admissions are for short-term rehabilitation after hospitalization (e.g., for a stroke or hip fracture), although those receiving rehabilitation occupy less than 10% of nursing home beds. One-half of new admissions have dementia (this condition being one of the primary reasons for admission), with 'long-stay' residents displaying a higher dementia prevalence – up to 75% – as well as disabling chronic medical conditions. Reflecting the long-term care needs of the population, of all those in a nursing home at any one time, fewer than 20% have been there for less than 3 months. Overall, the average length of time since admission among all residents currently living in a nursing home is 2.5 years.

Regulation

Most federal regulations of nursing home care are linked to federal funding of services through Medicare and Medicaid programs. The primary elements of regulation consist of establishing standards for providers, assessing compliance, and imposing sanctions for non-compliance. The Nursing Home Reform Act of 1987 created the most far-reaching changes in nursing home regulation since Medicare and Medicaid were created in 1965. It focuses on numerous components of care, including resident rights, quality of life, and quality of care; staffing and services; resident assessment; federal survey procedures; and enforcement procedures. The survey (and certification) process is conducted annually under contract by state agencies, and uses observation, record review, and interviews with residents, family members, and facility staff. Facilities that do not meet standards are given a deficiency of varying levels, depending on the severity of the infraction. Enforcement of regulations has resulted in a decline in the number of deficiencies, but weaknesses in the system remain, including variation across states and concerns that the survey process does not always detect serious quality of care problems such as falls, restraint use, infection, and even death.

Funding

The average annual cost of nursing home care is about $56 000, or $153 per day, with total national expenditures reaching $78.6 billion (1998 dollars). For those receiving rehabilitation after a hospital stay, Medicare covers 100 days of skilled care per benefit period. Given that the majority of residents are not receiving nursing home care under this condition, it should come as no surprise that Medicare supports only a limited amount of nursing home costs (13%; the equivalent of $10.4 billion in 1998). Medicaid funds 40% of nursing home costs ($31.4 billion) followed closely by private, out-of-pocket payments (36%, $28.5 billion).

Table 1 overviews some of the components of nursing homes, allowing for a comparison with residential care/assisted living facilities.

Table 1 Comparison of nursing homes and residential care/assisted living facilities

	Nursing homes	*Residential care/assisted living*
Number of facilities in the United States	17 000	36 000
Number of beds in the United States	1.8 million	1.0 million
Average size	120 beds	9–65 beds (depending on type)
Predominant model of care	Medical	Social
Involvement of licensed nurses	24 hours/day	Variable, often as supervisors rather than direct care providers
Physician visits	Typically occur in the facility; required every 60 days	Typically occur in the physician's office; required once a year
Nursing procedures, physical therapy	Provided by facility staff	Provided by facility staff, home health personnel or not at all
Help with activities of daily living, e.g., dressing, grooming, eating	Provided by facility staff	Provided by facility staff
Payment sources (approximate)	Private pay, 44% Medicaid, 40% Medicare, 13% Other public funds, 2%	Private pay (including Social Security Disability), 85% Medicaid and other public funds, 15%
Percent of facilities with majority of beds in private rooms	11	55–75 (depending on type)

Residential Care/Assisted Living

Overview

While nursing homes have been the primary source of institutional care for older adults since the inception of Medicare and Medicaid, the combined impact of increasing numbers and the overall better health of new cohorts of older adults, a shortage of nursing home beds, rising costs of care, and dissatisfaction with nursing home care made evident a gap in the continuum of care between independent housing that caters to those without any impairments and nursing homes that caters to the chronically ill. As early as the 1940s, board and care was the model of housing and services that fit into this gap. In recent years, however, residential care/assisted living became the fastest-growing segment of the senior housing market, such that a variety of residences now exist. Despite wide variations, these residences have in common the fact that they all provide room, board, 24-hour supervision, and assistance with medications and activities of daily living. Facilities also tend to provide some degree of coordination of and access to medical and nursing services, although the extent of services varies widely.

In a purist sense, the term assisted living initially referred to a specific model of care based on principles of individuality, independence, privacy, dignity, and choice; it embraced homelikeness, with individual sleeping spaces, full baths, kitchens, doors that locked, individual temperature controls, and personal furnishings; and it introduced concepts such as customized care plans and managed risk contracts. By the mid-1990s, however, it became evident that the term assisted living was being used broadly to refer to a diversity of facilities regulated by the states under a variety of designations, including board and care, residential care, personal care, foster care, domiciliary care, and congregate care – and not all of which subscribed to these principles. Because of this broadened use of the term assisted living, it is more clear to refer to all such settings as residential care/assisted living facilities.

Residential care/assisted living facilities range from private, converted houses with fewer than 10 beds to multilevel campuses with more than 1400 beds. Some have private apartments, whereas others have four residents per room. Rates range from less than $400 to more than $6000 per month. Given this diversity, typologies to create an organizing framework for residential care/assisted living have been suggested. Some typologies address differences in structure and access (public housing, units in continuing care retirement communities, freestanding facilities), differences in services (institutional board and care, housing and services, purely service-oriented), differences in the combination of services and privacy (low/minimal privacy and service, high privacy and low service, high service and low privacy, high privacy and high service), and differences across a combination of size and medical needs/services (residential care/assisted living facilities with fewer than 16 beds, traditional facilities, and new-model facilities that provide medical services to an impaired population). To illustrate the differences across facility types, some components of facilities categorized using this latter typology are shown in **Table 2**.

Clientele

Over time, residents in residential care/assisted living facilities have come to resemble nursing home residents of the 1980s. Like the residents of nursing homes, the majority (75%) are female. Depending on the type of residential care/assisted living residence, as many as 40% of residents are impaired in performing activities of daily living, have moderate or severe dementia, or display behavioral symptoms. The exact composition of the resident profile is somewhat dependent on state regulations, however, as admission and retention criteria define the client population and the limits to which residents are allowed to age-in-place. Across the states, state regulatory restrictions range from none (as is the case in Alaska, for example) to very specific exclusionary criteria such as the number of activities of daily living with which a resident can need assistance (as is the case in Illinois). The intent of these regulations is to restrict resident need to the services that a residence is able to provide or secure – although in some states (including New Jersey), acceptable levels of need may be as high as those necessitating 24-hour nursing care. In addition, variability is allowed within states, if a residence can meet additional regulations to care for more impaired residents.

Regulation

The regulatory environment in residential care/assisted living is dynamic; regulations will continue to evolve as this field emerges as an alternative to other forms of long-term care. Unlike nursing homes, however, there is no overarching federal regulatory body for residential care/assisted living; instead, individual states are empowered to define, license, regulate, fund, and oversee it. Between the years 2000 and 2002, virtually every state addressed issues of residential care/assisted living regulation, doing so with regulatory models ranging from those that are highly defined and prescriptive with detailed criteria

Table 2 One typology of residential care/assisted living

	Type		
	< 16 beds	*Traditional*	*New-model*
Facilities			
Distinguishing characteristics	< 16 beds; often in converted private homes in residential neighborhoods	> 16 beds; older; fewer medical services	> 16 beds; newer; more medical services
Common licensure names (vary according to state)	Adult foster care Family care Senior group homes Sheltered housing Assisted living	Board and care Congregate living Domiciliary care Residential care Assisted living	Assisted living Homes for the aged Residential care
Average number of beds	9	46	65
Mean facility age (years)	13	23	5
Average number of employees	5	21	33
Percent for-profit	91	65	73
Residents			
Mean age of residents	83	85	85
Percent of residents with:			
Dementia	40	21	34
Impairment in ≥ two activities of daily living	56	34	46
Percent of non-white residents	9	4	3

to those that are broad and general, using criteria as non-specific as 'meeting resident needs.' To further complicate the issue, approximately one-third of states do not even use the term assisted living in their licensing regulations. Further, only slightly more than one-half of the states describe their philosophy of care as part of their regulations.

Funding

The average cost of residential care/assisted living is approximately $30 000 a year. To date, residential care/assisted living facilities has been mostly private pay; however, with the growth of the industry and increased provision of services to impaired older adults, there has been a trend toward public subsidies. By 2003, 41 states provided funding for residential care/assisted living services. Methods of payment are diverse, however, with states providing payment as a flat rate (32%), tiered rate (27%), in accordance with care plans (24%), or resident case mix (<1%). Twelve states allow room and board to be covered, but this constitutes an ongoing controversy. That is, because assisted living is considered to be a residential setting providing services based on a social model rather than medical model of care, the implication is that room and board is a primary service; however, room and board traditionally have been (and continue to be) excluded from Medicaid coverage. Thus, despite some public support, private sources (i.e., resident and family funds) continue to provide the majority of payments (75%), with trivial additional amounts from long-term care insurance (<2%) and managed care (<2%). The remaining costs are covered through a combination of Medicaid waivers, state funds, and Supplemental Security Income (SSI).

Current Issues in Long-Term Care

Nursing homes and residential care/assisted living facilities are complex settings that provide for the care of frail, chronically ill persons. Not surprisingly, numerous issues exist regarding the optimal provision of care in these settings and the extent to which it is in need of improvement. Those issues that are reviewed here are the relative roles of nursing homes and residential care/assisted living, dementia care, quality of life, access to and disparities in care, rehabilitation services, medical management, physician services, end-of-life care, family involvement, staffing, abuse and neglect, the quality of care, and culture change in long-term care.

The Relative Roles of Nursing Homes and Residential Care/Assisted Living

The variability of residential care/assisted living has resulted in two differing perspectives on its role in the system of long-term care: one is that it lies along a continuum between home care and nursing home care, and the other is that it constitutes an approach and philosophy that can apply to all persons, regardless of their level-of-care needs. Consequently, there

has been some dynamic tension between the residential care/assisted living and nursing home industries, with the former being viewed as competing with nursing homes for many of the same individuals. Furthermore, although reliable data are not plentiful, there is evidence that residential care/assisted living facilities may be able to serve some (but not all) individuals as well as and at a lower cost than nursing homes. Overall, the matter seems to be resolving itself such that nursing homes are caring for an increasingly rehabilitative and frail population, while residential care/assisted living caters to those with functional and cognitive limitations.

Dementia Care

Even as residential care/assisted living takes care of an increasing number of persons with dementia, the prevalence of this condition is such that significant numbers of nursing home residents will continue to be impaired as well. In the 1990s, almost one-quarter of nursing homes responded to this need by developing and marketing special dementia care in the form of units dedicated to the care of persons with dementia. These units were thought to be a superior treatment environment for persons with dementia because they were purported to specially select, train, and supervise their staff; provide activities specially designed for the cognitively impaired; involve the family in treatment; and have a physical environment designed for safety and segregation. However, much as the philosophy of assisted living is not always practiced, these components of special care were not always evidenced. In addition, the provision of special care did not consistently relate to better care, in terms of resident outcomes (e.g., cognition, function, behavior, mood, discomfort, hospitalization), staff outcomes (e.g., stress, burnout), and family outcomes (e.g., depression, satisfaction). Specialized dementia care is growing in residential care/assisted living, but of the total number of people with dementia in long-term care, the vast majority are not treated in special units. Thus, dementia care has become the province of all long-term care providers.

Quality of Life

One of the most important changes that has begun and will continue to impact the future of long-term care is the understanding that those who live there are not merely waiting to die. Instead, despite their need for care and support, they remain able to experience joy, accomplishment, meaningful relationships, a sense of comfort, and other pleasures that jointly are referred to as quality of life. Thus, as the focus of long-term care evaluation and research has gradually shifted from how care is delivered (process of care) to how care affects residents (outcomes of care), accompanying this shift has been the recognition that the primary outcome of interest should be the quality of life achieved by its residents. Even nursing homes are being recognized as providing more than medical and nursing care, and all long-term care settings are being called upon to attend to the conditions that are necessary for individuals to have experiences that provide meaning and joy to their time. One manner in which this philosophy is being operationalized relates to resident autonomy, self-governance, and the right to make decisions about care and to take responsibility for risks that may result from those decisions. This concept of negotiated risk suggests that even while individuals are residents of group settings, they have the right to live a life of their choosing.

Access to and Disparities in Care

The current trend is for long-term care in the United States to be increasingly segregated by payment status, with nursing homes primarily serving a Medicaid clientele and residential care/assisted living facilities serving those who can pay privately. Early board-and-care type residential care/assisted living served low-income older adults who could not live independently and relied on Medicaid, SSI, or other state and federal government funds. As the field grew and the business community recognized residential care/assisted living as a profit-making opportunity, a schism developed between modest facilities catering to residents of lesser means and more upscale facilities serving residents able to afford substantial private pay rates. Consequently, the industry is now largely private pay-based and unaffordable for low- or moderate-income persons. Due to this economic and other social factors, the proportion of residents who are minorities is minimal. Indeed, between one-half and three-quarters of residential care/assisted living facilities have no African American residents. This distinction contrasts with northern European models of long-term care, which have emphasized serving the broad range of the community through the generous use of public revenues. Such a solution appears unlikely in the United States, but a variety of states are experimenting with creative models of financing to provide affordable assisted living. Offering residential care/assisted living to persons who cannot afford to pay is an important policy issue, and not doing so further compounds the disparity in nursing home care that currently exists and is reflected in the proportion of those receiving Medicaid.

Rehabilitation Services

Persons who have been hospitalized for an acute medical or surgical problem often need a period of therapy and recuperation before they can return to their homes in the community. A few who meet very strict criteria are admitted to special rehabilitation hospitals, but the majority of these individuals (including most of the elderly) are cared for in nursing homes. Rehabilitation is the only instance of long-term care provision for which Medicare and most private insurance plans will pay for room, board, and treatment; in the case of Medicare, a rehabilitable condition (e.g., stroke or hip fracture) and a 3-day hospital stay are required to receive reimbursement. Nursing home rehabilitation personnel include physical therapists, occupational therapists, and speech therapists, who work with physicians to plan and implement treatment aimed at improving and maximizing function. Barriers to successful rehabilitation at home include severe cognitive impairment (causing problems learning or re-learning needed skills), severe medical impairment (such as dyspnea at rest or a stroke with complete paralysis on one side), and an unsuitable discharge residence (one that lacks necessary supports). In such situations, the long-term care facility may become the individual's permanent home.

Medical Management

A variety of medical problems are quite common among residents of nursing homes and residential care/assisted living residences. Dementia and less severe cognitive impairment are present in the vast majority. Other conditions include arthritis and osteoporosis (often with a history of compression fractures of the spine), leading to a high prevalence of chronic pain, especially upon movement. Hearing loss and visual impairment are also common, with as many as one-third of long-term care residents having severe impairment in one or both of these senses. Other common medical conditions in this population include congestive heart failure, diabetes, chronic lung disease, hypertension, and urinary incontinence. Thus, it is not surprising that the average long-term care resident takes between five and ten medications and that monitoring health status and medications is a major issue for facility staff. A particularly common and challenging medical problem for long-term care providers occurs when a resident undergoes an acute change in function due to a medical problem such as fever, a fall, an exacerbation of arthritis, or syncope. Such problems require rapid assessment by a skilled professional, because progressive worsening and/or the development of permanent impairment can occur rapidly in this frail population. Ideally, the following services should be available to help manage such situations: a rapid on-site evaluation by a physician, nurse practitioner (NP), or physician's assistant (PA); portable X-rays, electrocardiography, and laboratory testing, with results sent by fax transmission to the facility; and, if hospitalization is needed, an electronic record system that allows for seamless transfer of information between the facility and the acute care setting.

Physician Services

Families of long-term care residents are often surprised at how infrequently physicians visit and assess the residents. Medicare and Medicaid require one physician visit per month for persons undergoing nursing home rehabilitation, one physician visit every 2 months for other nursing home residents, and one physician visit every year for residential care/assisted living residents. More frequent visits are reimbursed only when a specific medical problem is documented to need more than routine care. Given the burden of illness in the long-term care population, this arrangement necessitates a high level of autonomous assessment by nursing staff, and much communication between the facility and the physician. As a result, numerous daily fax and telephone communications between the facility and physicians are the norm, and at times create undue burden for both. There are several other unresolved issues related to physician services in long-term care, as well. One debates whether or not it is preferable to have a small number of physicians, who serve as long-term care specialists, provide the majority of the care. Another issue is whether, and to what extent, the quality of care is improved by having an NP or PA. Most data to date suggest that both of the above care arrangements do improve the quality of care. Other, less well-researched issues involve the importance of continuity of care in this setting, and whether it is preferable to have care rendered in the physician's office or on-site in the facility.

End-of-Life Care

With high proportions of older adults living in long-term care, it should come as no surprise that increasing numbers of older adults are dying there, as well. In fact, as many as two-thirds of nursing home residents die there rather than in hospitals or private homes. Overall, the proportion of US deaths occurring in long-term care is 23%, and it is expected to increase to 40% by the year 2040. One of the issues relevant to end-of-life care in long-term care is the presence and adequacy of available medical services. As noted previously, physician presence is

not common in either setting, and long-term care providers may not be sensitive to changes in resident status that suggest impending death and so indicate the need for palliative care. Similarly, when families are not present on a daily basis, it is challenging to know when to contact them so as to assure their presence at the time of death. Fortunately, these types of issues are receiving attention, and one historic limitation of end-of-life care in long-term care – insufficient use of hospice – seems to be resolving.

Family Involvement

It is the norm rather than the exception that older adults who live in long-term care settings were cared for by family before their admission, and that caregiving does not end after admission. In fact, families visit residents an average of twice a week, for approximately 4 hours. They constitute an important resource to staff because they have knowledge of the resident's history, and they are important to the resident for emotional connectedness and psychosocial health. Indeed, family presence improves resident psychological and psychosocial well-being, as well as the accuracy of diagnoses and thus the resultant care. Also, family members are called upon to make decisions regarding care for cognitively impaired residents and to provide continuity that may otherwise be lacking due to staff turnover. However, the value of family members as a resource in long-term care is only beginning to be realized, and efforts have begun to consider how to integrate them into the fabric of long-term care provision – albeit while not overburdening them and creating tensions.

Staffing

The long-term care workforce is one of the major challenges to the provision of consistent, high-quality care. Already, the workforce is in short supply of crisis proportion, a problem that promises to worsen as the population continues to age. Between 2000 and 2030, the demand for paraprofessional workers (referred to as nursing assistants in nursing homes and as personal care aides in residential care/assisted living) will increase by 200% as the Baby Boomers reach age 85. In contrast, the supply of these workers is expected to increase only modestly: projections indicate that the availability of direct care workers will grow by approximately 2% in nursing homes and 5% in residential care/assisted living per year between 2000 and 2010. Because these paraprofessionals provide 80–90% of the direct care, they constitute a crucial component of the workforce. Coupled with an insufficient number of staff are turnover rates exceeding 100%, reflecting the poor pay, challenging work, and scarce rewards that accompany this job. Turnover compromises the quality of care and is costly to facilities already struggling to provide optimal care with fixed resources. Considering the expenses of overtime pay, hiring outside agency staff to cover shortages, and the time required for training, the cost of replacing a worker averages three to four times the monthly salary of the employee being replaced. More important, however, is the effect of turnover on the quality of care and the unfortunate fact that those workers who are the most motivated and capable are the most likely to leave for better jobs elsewhere.

Abuse and Neglect in Long-Term Care

Residents of long-term care facilities are especially vulnerable to abuse, due to their physical and cognitive limitations, dependency on others, inability to report abuse or neglect, and fear that if they do, their reports may result in retaliation or other negative consequences. While there are no good estimates as to the prevalence of abuse in long-term care, there is evidence to suggest that it is a notable problem. There is also evidence that abuse is inflicted not only by staff on residents, but also by residents on staff (such as pushing, shoving, and slapping during receipt of personal care) and by residents on residents. Landmark work convincingly indicates that the prevalence of staff abuse toward residents in long-term care is not related to facility characteristics such as size or proprietary status, nor to staff characteristics such as age, education, or experience. Instead, it is the quality of staff–resident interactions that predict abuse. This is not to say that the staff want to have poor relations with the residents; on the contrary, most workers choose long-term care because they want to help older adults. Unfortunately, staffing shortages necessitate that relationship building and maintenance take a back seat to performing visible and immediate tasks, such as making beds and changing soiled clothing – clearly, not the type of work that enticed the staff into this field. In fact, workers typically have only 15 min a day to actually talk with residents.

The Quality of Care

Problems in care have plagued the long-term care system for decades, and continue; for example, untreated pain, reports of neglect and abuse, medication errors, and urinary incontinence have been identified as recent and ongoing problems. Some of the problems in the quality of care relate to staffing. Staff turnover is associated with poorer resident function and increased risk of resident infection

and hospitalization. The exact mechanism through which care is affected is unknown, but it is suggested that turnover impedes training and supervision and reduces the familiarity between staff and residents that is central to detecting change in resident status and incident events. Other staffing factors that relate to the quality of care include training (the requirements of which are minimal), temporary versus permanent assignment, staffing ratios, and staff–resident relationships. Of course, some of the problem also relates to the nature of long-term care itself: it provides care for frail and chronically ill residents and does so with limited resources. Overall, however, the quality of long-term care is gradually improving. Rates of preventable problems, such as decubitus ulcers, are declining; awareness and appropriate treatment of dementia is increasing, along with reduced use of chemical and physical restraints; newly built facilities are more attractive than those built decades ago; and private rooms and bathrooms are more common. Some of the credit for improved care is due to the Nursing Home Reform Act of 1987, which specified, in part, a resident-focused, outcome-oriented survey process and a standardized assessment and care-planning process known as the Resident Assessment Instrument (RAI). A version of the RAI has been developed for residential care/assisted living, but as this setting does not have federal oversight, its use is optional, and it is not widespread.

Culture Change

Despite the advances that have occurred, consumers and providers of long-term care remain dissatisfied with many aspects of the present system. Within the long-term care industry itself, a growing movement believes that new models of care that focus more on resident quality of life within the context of quality of care are necessary and possible. These efforts include a greater emphasis on consumer involvement, the growth of residential care/assisted living, increasing attention to physical environments, and efforts to bring about 'culture change' – care that is person-directed and focused on caring for people and relationships, rather than on the task of care provision. Spearheaded by a small but growing group of providers, culture change is a grassroots movement that seeks to develop new, more resident-centered models of care through empowerment of both residents and front-line staff. Among the innovations promoted by culture change proponents are smaller, decentralized facilities, involvement of nursing assistants in all aspects of decision making and care planning, offering more choices to residents (e.g., dinner buffets), and individualized approaches to bathing and other activities of daily living.

Trends in Long-Term Care

A number of societal forces characterize and will guide changes in long-term care during the coming decade. Demographic factors, combined with changing societal attitudes, will lead to both an increased need for long-term care and a desire for more varied and higher-quality forms of care. Chief among the demographic changes are the aging of the Baby Boomers, many of whom are currently serving as caregivers for parents and are also beginning to enter the retirement years, and the nation's increasing multiculturalism. In addition, advances in health care are leading to the survival of significant numbers of persons with congenital disorders and chronic illnesses and to increased numbers of persons living to advanced ages. In part as a result of the aging of the Baby Boomers, attitudes toward long-term care are beginning to change. While the public, the media, and to some extent the research and regulatory communities continue to concentrate on negative issues and outcomes related to long-term care, more general acceptance of the necessity of such care is beginning to emerge. With this acceptance, however, comes higher expectations, a desire for alternative housing options, and increased interest in consumer directedness and choice.

The face of long-term care will be affected by events within the health-care system, including innovations in medical practice and technology, changes in the organization and provision of care, workforce shortages, and trends in financing and regulation. Health care of people with chronic illness will continue to become increasingly complex and include heightened use of complementary care practices, more emphasis on quality of life, and the need to incorporate continuing breakthroughs in treatment. Advances in technology, such as robotics, informatics, standardized data, integrated electronic health records, and more clearly articulated low-tech interventions, will increase the effectiveness of long-term care staff. Additional new and innovative approaches to care will increasingly appear, building upon what is already occurring through the culture change movement, various forms of residential care/assisted living, other residential models of care, and greater use of home- and community-based services. Against this backdrop of progress in the ability to provide care will remain major challenges to care provision, including the aging of the existing physical structures of nursing homes, tensions between

clinical and social models of care and between safety and autonomy, and workforce shortages.

The increasing long-term care needs of the growing population and the potential for the field to become more sophisticated will not necessarily translate into increased allocation of resources, however. It is widely believed that the recent growth in health-care costs is not sustainable and that there will continue to be funding cutbacks and further drift toward a disparate system of care based on ability to pay. A countervailing trend, however, is that of increasing openness to innovation on the part of the Center for Medicare and Medicaid Services (CMMS). This openness has in part taken the form of involvement of the Quality Improvement Organizations (QIOs) in long-term care, including a major emphasis on encouraging person-directed care during 2005–07.

Thus, the field of long-term care is undergoing rapid and exciting change. Use of service is high, and certain to grow. The quality of care is being tackled through significant activities of individuals and groups on the practice, regulation, and research fronts. These concerted efforts are sure to result in ongoing improvement, toward the ultimate outcome of improved quality of life for future cohorts of long-term care residents throughout the nation.

Longitudinal Studies

S M Hofer and A M Piccinin, Oregon State University, Corvallis, OR, USA

Glossary

Age-Homogeneous Studies – Studies in which single or narrow age birth cohorts are sampled.

Ergodicity – Age differences between individuals and age changes within individuals are equivalent.

Longitudinal Design – A study that measures characteristics of the same individuals on at least two, but ideally more, occasions over time.

Introduction

A study with a longitudinal design is one that measures characteristics of the same individuals on at least two, but ideally more, occasions over time. Longitudinal studies are essential for understanding

aging-related changes because, in addition to providing information about between-person differences, they permit direct analysis of within-person change over time. An emphasis on understanding aging in terms of within-person changes is required for making valid inferences about aging-related changes.

Importance of Longitudinal Studies

Remarkable efforts around the globe have produced numerous major longitudinal studies of individuals 50 years of age and older. These represent an enormous wealth of information on within-person changes with age. Longitudinal studies are expensive in terms of both time and money, but they provide many significant advantages relative to cross-sectional studies and contain information relevant to significantly more levels of analysis. The between-person age comparisons that come from cross-sectional data cannot provide a basis for disentangling changes due to aging from, for example, stable individual characteristics, average between-person age differences, population selection, or mortality effects. Within-person change information is available only in longitudinal data. Recent developments in statistical methods facilitate the direct analysis and modeling of these within-person changes over time. Whereas several challenges to doing this persist, including the effects of repeated testing and population inference that take proper account of attrition and mortality, the latter remain inaccessible in a cross-sectional framework.

Potential Levels of Analysis in Longitudinal Research

For understanding aging, longitudinal studies provide many advantages compared to cross-sectional studies. Longitudinal data permit the direct estimation of parameters at multiple levels of analysis, each of which is complementary to understanding population and individual change with age. Whereas cross-sectional analyses permit between-person analysis of individuals varying in age, longitudinal follow-up permits direct evaluation of both between-person differences and within-person change.

Information available in cross-sectional and longitudinal designs can be summarized in terms of seven main levels of analysis and inferential scope. These can be ordered, broadly, in terms of their focus, ranging from the population to the individual. The time sampling generally decreases across levels of analysis, from decades for analysis of historical birth cohort effects to days, minutes, or seconds for individual-level processes such as within-person change, variability, and covariation (e.g., stress and health).

These levels of analysis are based on a combination of multiple-cohort, between-person, and within-person designs and analysis approaches, and all are represented by recent examples in gerontological research. Between-cohort differences (1), the broadest level, can be examined to evaluate whether different historical contexts (e.g., indicated by birth cohort) have lasting effects on level and on rate of change in functioning in later life. Population average trends (2) describe aggregate population change. They can be based on between-person differences in age-heterogeneous studies (confounded with cohort and selection/attrition/mortality) or on direct estimates of within-person change in studies with longitudinal follow-up, in which case they can be made conditional on survival. Between-person age differences (3) can be analyzed in terms of shared age-related variance in variance decomposition and factor models. This approach to understanding aging, however, confounds individual differences in age-related change with average age differences, cohort influences, and mortality-selection, among other effects.

Longitudinal models permit the identification of individual differences in rates of change over time (4), which avoids making assumptions of ergodicity – that age differences between individuals and age changes within individuals are equivalent. In these models, time can be structured in many alternative ways. It can be defined as time since an individual entered the study, time since birth (i.e., chronological age), or time until or since occurrence of a shared event such as retirement or diagnosis of disease. Elaboration of the longitudinal model permits estimation of between-person differences in within-person rates of change (5), in other words, using multivariate associations among intercepts and change functions in order to describe the interdependence of change functions. In shorter-term longitudinal designs, researchers have emphasized within-person variation as an outcome (6) and have examined whether individuals who display greater variability relative to others exhibit this variation generally across different tasks. Within-person correlations (7; i.e., coupling, dynamic factor analysis) are based on the analysis of residuals (after removing intraindividual mean and trend) and provide information regarding the correlation of within-time variation in functioning across variables. Each level of analysis provides only partial information regarding aging-related change, and the inferences and interpretations possible from any single level of analysis have distinct and delimited ramifications for

theories of aging. Each level provides complementary evidence for important characteristics of aging populations and individuals and provides alternative means for the development and evaluation of theories and models of aging.

Time Sampling and Alternative Longitudinal Designs

The levels of analysis described previously correspond roughly to different temporal and historical (i.e., birth cohort) sampling frames and range from longer to shorter intervals of assessment. The interpretation, comparison, and generalizability of parameters derived from different temporal samplings must be carefully considered and require different types of designs and measurements. The temporal characteristics of change and variation must be taken into account, as different sampling intervals will generally lead to different results requiring different interpretations for both within- and between-person processes. For example, correlations between rate of change over time in two variables will likely be quite different for short temporal intervals (minutes, hours, days, or weeks) compared to change across years, the typical intervals of many longitudinal studies on aging. Measurement interval is also critical for the prediction of outcome variables and for establishing evidence on leading versus lagging indicators. The typical design has relatively equally spaced intervals, with variance in spacing due largely to chance or to difficulty contacting participants. An alternative, the measurement burst design, in which repeated assessment bursts are obtained at each longer-term interval, is a compromise between single-case time-series and conventional longitudinal designs and permits the examination of within-person processes (within measurement burst) and change in processes (across measurement bursts) over time.

Chronological age (time since birth) is most commonly used to operationalize the construct of aging. Other approaches treat time as an ordinal variable (e.g., study wave) and model age as a covariate predicting individual differences in level and rate of change. However, we can also use alternative time structures in order to provide a more interpretable basis for individual change. For example, a longitudinal process-based model involves centering time on an event or state of a process of interest in order to compare individual change relative to a common organizing time structure. Such time specifications could be based on the occurrence of particular events or processes (i.e., morbidity, mortality; e.g., time prior to or since diagnosis of dementia or death). A key objective for any of these approaches is to distinguish changes as a consequence of aging processes from changes due to health or other change processes that are merely associated with age. This is similar to separating normative from non-normative influences. Whereas normative processes and events are strongly age graded and occur in all or nearly all individuals, non-normative processes and events are individual specific or subsample specific (i.e., the majority of individuals will not experience them) and tend to not be well predicted by chronological age. Structuring time based on non-normative events for subgroups of individuals permits analysis of change pattern and aggregate individual-level processes. Non-normative events are, by definition, low-frequency events, and are best evaluated in longitudinal studies with relatively long follow-up in order to capture the events and the preceding and subsequent change processes, concomitants, and predictors. Additionally, accounting for the myriad non-normative events permits, and is almost required for, an evaluation of normative patterns of change with increasing age.

Population Sampling, Attrition, and Mortality Selection

In observational studies, representative sampling is very important, as random assignment to conditions is not possible. However, attrition and mortality selection processes complicate both the definition of an aging population and the sampling procedures relevant to obtaining representative sample in studies of later life. Nevertheless, a major advantage of longitudinal studies is that they contain information necessary to examine the impact of attrition and mortality selection on the observed data. This information, ignored and inaccessible in cross-sectional data, is essential for valid inferences and improved understanding of developmental and aging processes.

Attrition occurs when an individual drops out of a longitudinal study. This can occur due to lack of time or interest, a residential move out of the study area (unrelated to the outcomes of interest), or failing physical or mental health. In many cases, the processes leading to non-response or attrition may not be of direct interest. For example, the moving away of participants from a longitudinal data collection project is unfortunate in terms of the study but is not necessarily related to study variables or participant characteristics, nor is it a natural result of developmental and population aging processes. However, attrition in studies of aging is often nonrandom (i.e., selective) in that it is likely to result from morbidity

and is likely to include declining physical and mental functioning of the participants over the period of observation. This is problematic because these are often the outcomes of direct interest.

Mortality is a distinct type of attrition because the definition of the population (i.e., all individuals currently living, conditional on age) changes with mortality. Population selection (i.e., mortality) is a natural population dynamic related to chronological age and a dynamic that is accessible only in longitudinal studies in which previous measurements have been obtained. In terms of population descriptions, inferences regarding change and causal processes may be obscured if mortality and selection processes are not properly taken into account, as such inferences must be made conditional on age and survival. It is important to note that the mortality selection dynamic cannot be understood in typical cross-sectional age-heterogeneous designs because such population sampling is based on single occasion sampling of survivors of different age and birth cohort groupings that have undergone differential mortality selection. Longitudinal data provide the opportunity to measure and address directly the processes of attrition and mortality selection – characteristics that define populations of aging individuals and that are necessary for understanding aging-related changes in health and cognitive outcomes conditional on both age and survival to particular ages.

Heterogeneity in terms of chronological age and survival poses analytical challenges for both cross-sectional and longitudinal data and is a particular challenge to studies that begin with age-heterogeneous samples. In studies on aging, the primary issue is that there is often no single well-defined target population but rather multiple populations that must be defined as conditional on both age and survival. Because attrition and mortality selection processes are inaccessible in age-heterogeneous samples, it is not possible to include these variables in a statistical model in order to obtain conditional estimates regarding populations defined by age and survival. A symptom of the challenges in age-heterogeneous sample selection is the fact that, at a particular age, it is easier to retain people with faltering physical or cognitive health in an ongoing study than it is to recruit them into a new study. As such, cross-sectional studies of older aged individuals will obtain more selective samples of this age range than longitudinal studies of the same age range that are ongoing from a younger age.

Age-homogeneous studies, in which single or narrow age birth cohorts are sampled, do provide an initially well-defined population that can be followed over time, permitting conditional estimates based on subsequent survival. Longitudinal follow-up of age-heterogeneous samples, the most typical longitudinal design, permits analysis of change over time but must be sensitive to the confounds associated with initial sample selection inherent in age-heterogeneous designs. In general, the analysis of longitudinal data on individual and population aging-related change processes can be properly evaluated and interpreted when the population parameters are estimated conditional on morbidity, mortality, and other attrition processes.

This lack of a single, accessible population in the data has consequences for the techniques for analyzing incomplete data. Whereas methods have been developed and are in relatively wide use in multilevel and structural equation modeling software, their application to longitudinal samples in late life remains problematic, both conceptually and computationally. These methods and their corresponding assumptions are based on the notion of a single, accessible population. At each new wave of a longitudinal aging study, however, the sample becomes less representative of the population from which it originated, and generalizations from the sample of continuing participants to the initial population become difficult to justify. Whereas some forms of non-participation can logically permit inference to a single population, such inference is impossible in the case of mortality because individuals have left the population of interest. Therefore, inferences regarding change must be defined as conditional on the probability of surviving or remaining in the study, in interaction with chronological age. In addition, the incomplete data mechanism in studies of aging is not likely to be missing at random (i.e., the probability of missing being dependent on measured covariates or prior states), an important assumption of current methods, because aging-related outcomes are known to be related to mortality and study non-participation.

Statistical approaches for dealing with mortality and ignorable non-response separately and that permit conditional separation of aging-related changes from other decline processes (mortality, disease-related change) are increasing in their application. Conditional selection related to mortality in longitudinal studies can be dealt with statistically in three ways: by ignoring missing values in maximum likelihood analysis, by modeling change conditional on a covariate representing mortality status or a time-varying covariate representing years to death, or by simply treating the data as complete within age-defined blocks of survivors. These methods alleviate some of the concerns with current state-of-the-art approaches for the analysis of incomplete data that

provide inferences to a single population of aging individuals.

Effects of Repeated Testing

Retest (i.e., practice, exposure, learning, reactivity) effects have been reported in a number of longitudinal studies on aging that focus on cognitive outcomes. The concern is that estimates of longitudinal change that might otherwise indicate decline may be attenuated due to gains resulting from repeated testing and potentially persisting over long intervals. Complicating matters is the potential for improvement to occur differentially, related to ability level, age, or task difficulty, which may be due to any number of related influences, including warm-up effects, initial anxiety, and test-specific learning, such as learning content and strategies for improving performance. Differential retest gains confound the identification of differential age-related changes (e.g., in older adults, retest may not be manifest as an increase in performance, but as an attenuated decrease in performance).

Although several statistical and design solutions have been proposed, conceptual difficulties arise in the consideration of whether retest or learning effects are a problem that can be solved statistically. Learning is a fundamental feature of repeated testing and of development in general and reflects important individual characteristics, relevant to aging and long-term change. Conceptual issues arise when learning effects are treated as nuisance parameters or artifacts of the study design. At the individual level, is it reasonable to correct an individual's change slope to what would have been obtained if repeated testing had not been performed? And if such a correction is reasonable, how should the slope be corrected? In most longitudinal sampling designs, exposure to test and within-person age are perfectly confounded, necessitating the use of between-person age differences to anchor the aging effects. Whereas retest effects are essentially within-person changes, this method of statistical identification leads to inferences regarding aging drawn primarily from between-person differences. In general, design-based and statistical approaches for dealing with retest effects rely on the performance of previously untested individuals who differ in age or birth cohort. This yields results that are strongly weighted toward cross-sectional estimates of age differences rather than within-person change and, therefore, suffer from the problems associated with age-heterogeneous sampling and selection issues.

Alternatively, retest effects might be considered an outcome of interest, with evaluation focused on changes in learning processes over time and emphasis on relative comparisons across individuals with similar testing experiences. Widely spaced occasions of measurement, typical of many longitudinal studies, may not be conducive to this perspective of learning as outcome, which requires intensive measurement bursts spaced over longer periods. Considering long-term change as conditional on previous testing experience certainly complicates inference to aging-related changes, with the potential for interaction of age, ability level, prior exposure, and retest effect. However, treating retest or learning effects as predictors or outcomes may provide a more realistic framework for understanding change in constructs influenced by learning gains, making use of individual differences in short-term gains for the prediction of long-term changes.

Generalizability across Cultures and Cohorts

Currently, published results from longitudinal studies are largely based on different analytic approaches, restricted or selective reports of results, and outcomes and covariates that differ in measurement instrument or coding procedure. Such differences hinder comparison of results across studies and limit attempts to assess generalizability. Focused efforts for data integration and evidence synthesis based on optimally comparable cross-study results would be a powerful addition to longitudinal work in aging, in which replication of previous studies may be more difficult. Collaborations across research teams will lead to the harmonization of measurement operations and development of common analysis protocols in order to maximize comparability, permitting both synthesis of results and sensitivity analysis within and across studies.

Overview of Existing Longitudinal Studies

Table 1 lists a sample of major longitudinal studies on aging selected on the basis of the availability of information on cognitive, physical, and mental health on more than two occasions (or with a plan for more than two occasions). Though each involves collection of data on similar constructs, these longitudinal studies fall into three main groups: large-scale epidemiological or survey studies, more focused psychologically based studies, and more intensive medical studies. The former are more likely to have a population-based sample but less in-depth measurement, for example, including little more than a screening measure of cognitive function, whereas the smaller studies are more focused on detailed measurement in their respective areas. Virtually all at least

Table 1 Longitudinal studies on aging with cognitive, demographic, health, lifestyle, and psychological data

Study title	*Start year*	*n (T1)*	*Age (T1)*	*Follow-up (years)*[a]	*Occasion interval (years)*	*Current number of occasions*	*Sample type*
Aging in Manitoba	1971	8950	60+	30	5 to 12	5	Stratified random sample
Asset and Health Dynamics among the Oldest Old	1993	7447	70+	9	2	6	HRS screening sample, Medicare enrollment, minority oversample
Australian Longitudinal Study of Aging	1992	2087	70+	13	1–3	8	Stratified sample of community dwelling and institutional care facilities
Baltimore Longitudinal Study of Aging	1958	260	20–96	46	2	24	Volunteer (men only pre-1978)
Berkeley Older Generation Study	1968	94	59–79	14	14	2	Participants of Berkeley Growth and Guidance Studies
Berlin Aging Study	1990	516	70–100+	15	2–4	7	City Register, Former West Berlin
Betula Project	1988	3500	35–80	10	5	3	Stratified
Caerphilly Cohort Study of Older Men	1979	2512	45–59	25	4, 5	6	Electoral register plus GP lists, male only
Cambridge City over 75 Cohort Study	1985	2616	75+	20	1	20	Population based
Canadian Multicentre Osteoporosis Study	1996	9423	25+	5	1	6	Random sample
Canadian Study of Health and Aging	1991	10 263	65+	10	5	3	Representative sample with oversampling of very old
Canberra Longitudinal Study	1990	897	70–93	12	3.5	4	Community sample (electoral role), institutional care, oversampling of very old
Cardiovascular Health Study	1989	5888	65+	10	1	10	Medicare eligibility list, noninstitutionalized, no proxy needed
Duke Longitudinal Study of Normal Aging[b]	1956	267	60–94	21	8 months–4 years	11	Volunteer
Duke Longitudinal Study of Normal Aging II	1968	502	45–69	8	2	4	Volunteer
Einstein Aging Studies	1980	488	70–90	20	1	20	Volunteer sample
English Longitudinal Study of Aging	2002	12 100	50+	2	2	2	Representative of 50+ English population
Established Populations for Epidemiologic Studies of the Elderly	1981	14 456	65+	12	2	7	Random, cluster and stratified sampling

Fredericton 80+ Study	1998	387	80	6	1	7	Population based
Gender Study of Unlike-Sex DZ Twins	1995	500	69–81	8	4	3	Opposite sex twins in Sweden born between 1906 and 1925
Gerontological and Geriatric Population Studies in Göteborg, Sweden	1971	1000	70	30	4, 5	12	Representative
Groningen Longitudinal Aging Study	1993	753	57–99	2	1	3	Patient population with physical limitations
Health and Retirement Study	1992	12 600	50–60	12	2	7	National sample, minorities oversampled
Health, Aging and Body Composition Study	1997	3075	70–79	6	1	7	
Healthy Older Person Edinburgh Study	1990	597	70+	4	4	3	Medical registry
Honolulu-Asia Aging Study	1991	3734	71–93	6	3	3	Japanese men only
Interdisciplinary Longitudinal Study of Adult Development	1996	1384	45, 65	8	4	3	Former East and West Germany
Italian Longitudinal Study on Aging	1992	5493	65–84	8	3, 5	3	Population-based
Kungsholmen Project	1987	327	75+	12	2 to 4	5	Population from Kungsholmen district, Stockholm
Long Beach Longitudinal Study	1978	509	55–87	21	Varies	4	Recruited from Health Maintenance Organization
Longitudinal Aging Study Amsterdam	1991	3107	55–85	9	3	4	Urban and rural municipal registries
Longitudinal Studies of Cognitive Change in Normal, Healthy Old Age	1982	6187	49–96	14	Varies	4	Community volunteer
Lund 80+ Study	1988	211	80+	10	5	3	Population of Lund 80+ years old
Maastricht Aging Study	1992	2000	24–81	6	3	3	Recruitment from Registration Network Family Practices
McArthur Studies of Successful Aging	1988	1192	70–79	3	3, 4	3	Selected from three cohorts of Established Populations for Epidemiologic Studies of the Elderly

[b] Life style data not available.
[c] Only two occasions planned.

touch on the areas of sociodemographics, physical and psychological health, cognitive function, and activity/lifestyle, though there is a large amount of variability in the detail with which the different areas are measured. Some of the longest running studies are approaching 50 years of follow-up. A number have more than 10 occasions of measurement. One has as many as 30. Currently, the available information in most of these studies far exceeds what has reached publication. With continued developments in the methods to analyze these data, and with concerted efforts to make use of the available information, this wealth of data holds the potential to greatly contribute to the development of theories of aging and a basis for intervention and prevention efforts.

Summary

Longitudinal studies have direct implications for explanatory theories of development and aging. Evidence obtained thus far from long-term longitudinal and intensive short-term longitudinal studies indicates remarkable within-person variation in many types of processes, even those once considered highly stable (e.g., personality). From both theoretical and empirical perspectives, between-person differences are a complex function of initial individual differences and intraindividual change. The identification and understanding of these sources of between-person differences and of developmental and aging-related changes require the direct observation of within-person change available in longitudinal studies.

There are many challenges for the design and analysis of strict within-person studies and large-sample longitudinal studies, and these will differ according to purpose. The challenges of strict within-person studies include limits on inferences given the smaller range of contexts and characteristics available within any single individual. Of course, the study of relatively stable individual characteristics and genetic differences requires between-person comparison approaches. In general, combinations of within-person and between-person study designs are necessary for comprehensive understanding of within-person processes of aging because people differ in their responsiveness to influences of all types and the breadth of contextual influences is unavailable in any single individual. The strength of the many existing longitudinal studies is that they permit the simultaneous examination of within-person processes in the context of between-person variability, between-person differences in change, and between-person moderation of within-person processes.

Markers of Aging

G E McClearn, The Pennsylvania State University, University Park, PA, USA

Glossary

Biomarker – A term for a descriptive or predictive variable intended to measure some aspects of some aging processes.

Gerometric – Biometric, psychometric, and sociometric applications to gerontology.

Reliability – The proportion of variance in a measured variable that is attributable to variance in true scores as contrasted to error variance.

Validity – The degree to which a measured variable represents the construct that it is intended to represent.

Introduction

The term biomarker, which is encountered with increasing frequency in the gerontological literature, is used with a variety of implicit or explicit definitions. In some contexts, a biomarker is expected to predict longevity; in other usages, it is expected to be correlated with physiological age; in still other, it is expected to be descriptive of a fundamental aspect of aging, and so on. This breadth of usage is so great that an argument can be made that the phrase, 'biomarker of aging' is simply synonymous with 'age-related variable'.

When understood in this broad sense the only advantage of the label biomarker over the term 'variable' might be the specific emphasis on biology provided by 'bio' and the reminder provided by 'marker' that the variable in question is a proxy or surrogate variable. In the final analysis, whether it be labeled biomarker or age-related variable, it is being used because one cannot measure biological age or aging directly.

In some contexts, the term biomarker is employed in a more restricted sense to refer specifically to variables being used in a multivariate attempt to define biological or functional age. In another, specialized usage, the biomarker label is reserved for outcome variables appropriate to assess the efficacy of an intervention designed to affect some aspect of aging processes. The desirability of a standard reference set of biomarkers in the letter sense has motivated a major program initiative of the National Institute on Aging.

In a recent evaluation of biomarkers, Arking has provided the following (paraphrased) list of desiderata, which may be regarded as a representative summary of current thinking in the field. Biomarkers should

1. Change with time at a rate that reflects the rate of aging,
2. be monitoring some basic, important process,
3. be non-lethal, and preferable non-invasive and minimally traumatic,
4. be highly reproducible,
5. reflect physiological age,
6. display change over a relatively short period,
7. be crucial to the maintenance of health,
8. be measureable in a variety of species,
9. serve as a predictor of life span, and/or
10. serve as a retrospective marker of aging.

As a further summary, it might be suggested that the desired attributes of biomarkers fall into three classes: pragmatic, ethical, and methodological. Pragmatically, biomarkers should be simple and inexpensive to measure. Ethically, they should be minimally intrusive, causing the least possible pain and stress. Methodologically, it is desirable that they be non-destructive (permitting longitudinal research); capable of demonstrating change over a relatively short portion of the life span; insensitive to effects of previous measurement; and robust over a large range of laboratory and experimental conditions. Of utmost importance is that they measure aging validly and reliably. The meaning of this last statement engages subtle issues, some of which will be elaborated later.

The Diversity of Biomarkers

In the broadest usage described above, every attribute measured in a study of aging could reasonable be regarded as a biomarker. The range of applicability is nearly as great when more constrained definitions are used. In a conference reviewing the state of research at the onset of the biomarker initiative of the National Institute of Aging, genetic, molecular, cellular, tissue, and whole-organism variables were discussed. A few years later, the First International Congress on Biomarkers of Aging: Expression and Regulation was convened. Titles from the proceedings of that congress reveal a similarly wide array of measures. A sample of the domains within which putative biomarkers were investigated include neuroendocrine systems, degradation of altered protein molecules, lateral mobility of cell membrane proteins, DNA repair, molecular myocardial changes, membrane cholesterol, blood–brain barrier permeability, immune system alteration, heat shock proteins, activity levels, and cognitive functioning.

In a book on preventive intervention oriented to ward the general reader, Evans and Rosenberg identified the following as pertinent biomarkers: muscle mass, strength, basal metabolic rate, body fat percentage, aerobic capacity, blood sugar tolerance, cholesterol or high-density lipoprotein (HDL) ratio, blood pressure, bone density, and ability to regulate internal temperature.

Obviously, neither a comprehensive review nor an evaluation of the degree to which each of these biomarkers meets the specified criteria is within the scope of the present article. What follows is, therefore, a discussion of some principles that have general applicability.

Biometric Considerations

The definitions of biomarkers are quite varied, but all refer in one way or another to the measurement of age or aging. An appreciation of the purposes and requirements of biomarkers requires consideration of some basic issues of measurement in gerontology. Obviously, biomarkers must meet the same biometric, psychometric, and sociometric requirements as any other variable in biological, behavioral, or social sciences. In the dynamic context of change in aging there are some special, gerometric issues.

Limitations of Chronological Age as a Metric in Gerontological Research

At a cursory glance, gerontologists might be thought to possess a superb measurement instrument in the form of the calendar, for it is possible in principle to determine the chronological age of most human beings and animal subjects to a high degree of accuracy. For some purposes, this sample statement of chronological age – the number of days, months, or years that the individual organism has been alive – may suffice. For example, if the geronotological question concerns the relative longevity of different species, the relevant information may be provided by the average ages at death of people and mice, for example. Such facts of species differences in life span engage fundamental issues of evolution. For many purposes, however, calendar age is an unsatisfactory index, principally because, within species, individuals of the same chronological age may differ markedly in respect to a number of attributes that we associate with the aging process. Thus, there must be a process(es) at work that is somewhat, but not too closely, related to the passage of time, but that differs from individual to individual. To assign the same age value to a number of individuals, all of whom where born on a particular day in 1920, say, would omit information on the huge differences existing among them in functional competence, cognitive performance, memory capability, glucose tolerance, aerobic capacity, pulmonary functioning, cardiovascular health, body composition, and so on.

The facts of intraspecific variability in aging processes are of basic biological interest equal to those of interspecific differences. These individual differences are, of course, central to societal concern over the health and welfare of an aging population; it is expected that elucidation of the determinants of individuality in rate and pattern of aging will powerfully inform efforts to promote 'successful aging' and extend the healthy life span.

If, as we have seen, individual differences reduce the descriptive and predictive value of chronological age, then measures must be employed that are capable of characterizing the individual differences of these features. The functional age of an organism may then be considered to be its relative rank among comparable individuals of the same chronological age with respect to these measures. Aging comes to be defined then, as change with respect to these measures as a function of chronological time. The crux of the matter becomes the section of measures, or, it may be said, of biomarkers of age and aging.

Validity: What Does a Biomarker Measure?

Perhaps the simplest definition of the concept of validity is that it is an index of the extent to which any empirical measure actually measures what it is alleged to measure. Under some circumstances, the entity or property under investigation could actually

be measured directly, but the measure used is a substitute (or proxy, or surrogate, or marker, or indicator) for it. In some cases, the marker is employed rather than the real thing because the marker is more convenient or less expensive. Though it might require considerable effort in practice, the determination of validity in these instances is conceptually straightforward. The concurrent validity of the marker can be evaluated by obtaining the correlation between it and the definitional 'real thing' measured at the same time.

In other cases, the real thing will only exist in the future, and the objective is to predict it from the surrogate measurement. A familiar example of the latter situation is the attempt to predict success in college or in graduate school from standardized tests. Determining the correlation between the marker variable and the outcome variable (when it later becomes available) is described as the predictive validity of the marker. Validity of this type is implied by the above-cited definitions of aging, which refer to the ability to predict longevity as a major criterion of biomarker status. Indeed, some investigators maintain that longevity is the ultimate validity criterion for a biomarker. A major difficulty in accepting age at death as the defining variable in gerontology is the loss of information concerning the highly variable differences in trajectory and pattern by which individuals arrive at the point of death. Thus, whereas longevity has high 'face validity' (on the face of the matter, it seems that length of life must be related to aging), any claims that it enjoys superordinate status as the fundamental validity criterion for biomarkers of aging must be carefully and skeptically examined.

Circumstances abound in the life sciences where explanation invokes hypothetical constructs for which no single, unambiguous measure is consensually accepted by scientists as telling the truth, the whole truth, and nothing but the truth, about it. For constructs of this nature, of which age and aging are widely regarded as examples, there are several approaches to assessment of validity. Content validity, for example, refers to the extent to which a measure (or panel of measures, collectively) samples the domain under investigation. Obviously, to judge content validity, one requires an already highly developed understanding of the domain itself. Another approach is that of construct validity, which is the extent to which the biomarker behaves as predicted by formal theory or by expectation derived from a coherent body of empirical data. For example, although the limitations of chronological age have been discussed, it certainly appears that a valid biomarker of aging should have some relationship to it. Traditionally, this age relevance has been sought in the form of mean differences among groups of different chronological age, or of mean changes in longitudinal studies. The examination of mean values in this context is conceptually direct, but may overlook data of great value. For some purposes, systematic change in variances, covariances, kurtosis, and skewness should qualify a purported biomarker as age-relevant as definitively as would the conventional change in means.

From the perspective of construct validity, it might also be expected that a nominated biomarker of age should respond appropriately to an intervention, such as dietary restriction, which has been shown to increase life span. One problem in applying this criterion arises from the complexity of aging, discussed in more detail below. Different subprocesses of aging may proceed relatively independently and may be differentially susceptible to interventions. For example, research has shown that an antiaging treatment beneficial in one genotype may be harmful in another. Thus, legitimate measures of some aging processes in some animals might be rejected as biomarkers if tested with a different group of subjects. This observation epitomizes the general principle that the validity of a model system is a function not only of the biomarker employed, but also of the total context of its measurement, including the genotypes of the animal subjects.

Generalizability of Animal Model Results to Humankind

The types of validity discussed above concern the extent to which the measurement of some attribute of, for example, a mouse, is really assessing what it is intended to, in the mouse. In research that has the ultimate goal of illuminating aging processes in humankind, there is another level of concern about validity – the generalizability across the phyletic scale from animal model to human beings.

For some biomedical phenomena, the homology of human to animal condition may be apparent – blood pressure, glucose tolerance, renal function, muscle anatomy, body composition, immune system parameters, and so on. Even in these cases of high 'face' validity of the animal model, however, there are often subtle differences that must be carefully evaluated.

In the realm of behavior the homology of animal to human phenotype is usually more difficult to demonstrate. The mouse equivalent of a test of fluid cognitive ability is not obvious, for example. However, this difficulty should not be regarded as totally prohibitive. Typically, the hope in utilizing the animal model is that there exists in the animal some system that has properties sufficiently similar to the human system that the former will be informative

about some aspects of the latter. Of particular relevance to the topic of behavior are the parallels in the neurochemistry and neuroanatomy of humankind and research animals that have contributed immensely to the current understanding of the workings of the central nervous system (CNS). The existence of these parallels in CNS function justifies reasonable expectations that animal models can be valuable in the study of human behavioral aging (*see* Models of Aging: Vertebrates).

Reliability of Measurement

A fundamental principle of measurement is that nothing can be measured with absolute accuracy. It is thus important to ponder the level of uncertainty associated with any biomarker measurement. The statistical model usually employed in such considerations posits the existence of a true value of the variate, with error-producing factors generating a normal distribution of measured values around the true value. That is to say, it is assumed that on any particular measurement occasion, for any given individual subject, there exists a real value of the attribute being measured. Inevitably, however, the measurement process will be affected by factors that cause the observed value to deviate from this true value. The model is particularly applicable when dealing with simple errors of observation – change in angle of view of a meniscus level, or parallax effects on a meter reading, or misscoring an item on a cognitive test, or misrecording of a value on a data sheet, or inaccuracy in mixing a solution. Within each discipline, standardized measurement protocols are intended to reduce such error. It is axiomatic that such error can only be reduced but cannot be eliminated.

Any particular single measurement must, therefore, be regarded as a single sample observation from a distribution of possible values. If the error distribution is narrow, then the number obtained on any one occasion of measurement will be close to the real, 'true' value. If the error distribution is broad, the measure obtained for a single individual on one occasion might be quite far from the true value, and the particular value obtained will not be a very accurate representation of the true state of affairs. An obvious tactic in such a case is to take multiple measurements; the mean of such series will be a more accurate estimator of the true value than will any single measurement. The direct course of action is not possible for many markers, however, which, by their nature, can only be measured once. The recourse usually sought is to shrug off the uncertainty about the precision of individual values and rely on reduction of the sampling error by employing larger numbers of subjects.

The general model of a true score with an error distribution is also useful in circumstances involving factors that influence the measurement outcome but cannot be regarded as genuine error. Consider a biomarker employed to test the efficacy of some intervention in a rodent model. In addition to the effects of the intervention variable, the biomarker might be influenced by season of the year, time of day, temperature, time since last meal, constitution of the diet, techniques of the technician, previous measurements, time since importation into the laboratory, and so on. Each of these factors is, by definition, an independent variable that has influence upon the dependent variable whose value is being sought. In another context, each of these factors might be the object of investigation in its own right, but in the particular research context they are considered to generate unwanted variability. Thus, they are identified as contributing 'error.' The existence of such factors is well recognized within each discipline, of course, and procedures for minimizing their influence constitute the methodological lore of controlled variables within the disciplines. Naturally, these control procedures are effective only for 'error' producers that are known.

There are logistical constraints on the amount of manipulated control that can be exercised in any experiment. Thus recourse to randomization is frequent. The effects of the randomized variables will add to the uncertainty generated by real error, increasing the aura of inconclusiveness to be associated with any empirically obtained measurement.

The concept of reliability addresses the issue of the proportions of variance in empirically obtained values that can be attributed to the variability of the true scores and to the magnitude of the error effects. If the locations of individuals in such an empirical distribution are mostly attributable to their true values, with little error (i.e., if the measurement is highly reliable), then a very similar distribution would be expected if all of them were measured again. The correlation of scores obtained on successive occasions is, in fact, one of the standard methods for estimating reliability.

Biomarkers as Elements of Complex Systems

Appropriately for so dynamic a field of inquiry, many issues of gerontology are unsettled. There is good agreement, however, that aging is a complex process or set of processes. The consensus is well represented by Baker and Sprott (1988: 231): "It is also quite

evident that there may be many processes of aging and that various systems (physiological, biochemical, and/or molecular-genetic) undergo alterations at differential rates."

It is apparent that a comprehensive view of aging will require representation of biological or functional age in terms of a complex nexus of interrelated variables constituting a system. Such a representation has important implications of what one can and cannot expect of biomarker variables.

Conceptual and analytical models for dealing with complex systems have long been the subject of intense intellectual effort. This effort has burgeoned in recent years, and considerations of complexity, dissipative structures, self-constructing systems, and so on, appear in an increasing range of both physical and life sciences. Yates and colleagues have urged and pioneered the application of systems principles to gerontological issues. It is probably accurate to observe, however, that gerontology has only begun to reap the benefits of systems perspectives.

A defining characteristic of a system is the interrelatedness of its elements. These interconnections can be hierarchical, with a one-way flow of influence. On the other hand, there may be feedback. Indeed, some sort of feedback is implied in any system or subsystem that is subject to homeostatic or other types of regulation. The feedback loop blurs the meaning of cause and effect and severely limits interpretations based upon models of Newtonian, unidirectional causality.

A major consequence of network causality is that the influence of any element of the system is context-dependent. Whether or not some particular factor is influential, even the direction of its influence, is dependent upon other elements in the causal network. It may be somewhat discomfiting to conclude, therefore, that the significance of a biomarker may differ from one individual to another. The case cited earlier by Harrison and Archer will serve as a useful example here as well: the efficacy of dietary restriction is dependent upon genotype.

Another clear implication of great importance for the present topic is that no one marker can characterize a system; searching for a marker for all purposes is futile and misguided. The image of blind men describing an elephant is rather overworked, but is particularly apposite. A comprehensive representation emerges only when the diverse perceptions of tail, trunk, legs, ears, and so on are collated and interrelated. Inevitably, gerontology will require increasing sophistication with, and use of, multivariate (multibiomarker) methods as the limited information from each individual biomarker contributes to our understanding of age and aging.

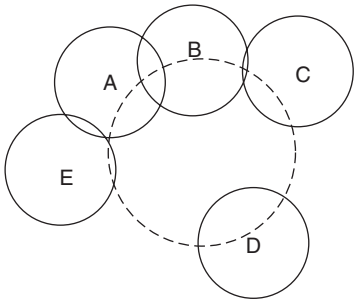

Figure 1 Partial representation of age or aging (dashed circle) by specific biomarker variables (solid circles labeled A–E).

It may be useful to reiterate by a Venn diagram as shown in **Figure 1**. Assume that the dashed circle represents all meaning of the concept of aging. No one has ever measured aging; they have simply been able to measure various manifestations of it. Assume a number of these operational measures of 'aging': A, B, C, D, and E, shown in the figure as closed circles. It may be seen that all of these biomarkers tap some part of the 'aging' system, and that none of them exhaustively assesses the total domain encompassed by the dashed circle. Furthermore, none of them measures only aspects of the domain; that is to say, some of the area of all of the closed circles lies outside the domain. (This means simply that there are things other than the aging processes that influence the biomarker.) Most measures are correlated (i.e., overlap) with others, but one (D) is completely independent. In one case (A and E), the correlation is only for elements outside the domain and is therefore meaningless with respect to aging. Relating this representation to the discussion of systems, it can be imagined that the degree of overlap of the Venn circles represents the extent to which the biomarkers share membership in 'causal' routes within the 'causal field.' Inclusion of all of these empirical measures in an assessment of 'aging' would tap much, but not all, of the total meaning of the concept. Some parts of the domain would be overmeasured, in that three of the measures overlap within the domain, but some would be left without representation.

Biological systems are usually composed of subsystems, often organized into hierarchies and subhierarchies. In a network or causal field of this sort, some elements will have more 'connectedness' than other, in the sense that relatively more than average of the other elements of the system are related to them. The hoary notion of the 'final common path' describes one type of such convergence of influences. Quite obviously, a biomarker that taps into such central 'soft spots' can likely contribute more richly to description, understanding, or prediction than can a less well-connected element.

Biomarkers in Changing Systems

A system of the type discussed above cannot be maintained statically, but only dynamically. Thus, if some element in the system is perturbed, processes are set in motion to return the element to a set point or set range. This system responsiveness is familiar as homeostasis. Variants of the idea involve set points that are changing in development processes (homeorhesis or programmed rheostasis) or in response to environmental factors (reactive rheostasis). In a complex network, any such dynamic action can have widespread ripple effects, with elements of the same subsystem oscillating for some time before settling down. The interactions of a living organism with its environment (including others of its species) assure that at least some subsystems will be in an almost continuous process of displacement from set range and recovery toward it. In addition to the problem of error and uncontrolled variable sources discussed above in relation to reliability of measurement, there is this additional problem that an effort to characterize a biomarker is faced with a moving target. A biomarker of a labile system such as this might give different values on measurement occasions hours or even minutes apart. Somewhat paradoxically, if perfect or near-perfect reliability (in the sense of high test–retest correlation) is required of biomarkers, labile systems, which may be of high biological relevance, will be exempted from examination (*see* Homeostasis, Homeodynamics and Aging).

Intervals of sufficient duration to permit the occurrence of aging changes require a distinction between reliability and stability. If all individuals change at the same rate in respect to some biomarker, then, providing that the measurement is reasonably reliable, their ordinal ranking on occasion $n+1$ will be about the same as that on occasion n, yielding a high correlation between occasions. If, however, there are individual differences in rate of change, the rank orders will differ on the two occasions, and the correlation will be attenuated, even though the biomarker is measured with high reliability. A high correlation between occasions will reflect both high reliability of measurement of the biomarker and stability of the aging process of which it is a marker. A low correlation between occasions may not be a condemnation of the biomarker from a gerometric point of view, but simply a reflection of individual differences in the pertinent aging subprocess. Rejecting candidate biomarkers because of low test–retest correlation across these longer intervals might foreclose on the examination of important processes.

In principle, it is remotely possible that all elements in the changing system would change in proportional ways in the same direction and at the same rate. Given the evidence for differential changes in age-related variables, this prospect is most unlikely for gerontologically interesting system. Thus one may expect that aging of a system will be characterized by changes in the interrelationships among elements in that system. Accepting that the meaning of a variable can only be described by its relationships to other variables, the simple but profoundly important implication is that the meaning of a particular biomarker variable can change over the life course. It might be describing central aspects of some aging subprocess at one stage of the life trajectory and be less related or even unrelated to that same subprocess at another stage.

In multivariate research, through such issues as degree of invariance in factor structure, the possibility of change in the meaning of a biomarker is thrust unmistakably to the fore. In univariate research, unfortunately, there is no obvious way to observe such a change. Ignorance of changes in biomarker meaning does not obviate their effects, however.

Scale

A generally ignored matter, but one of substantial methodological import, is the nature of the scale of measurement of the biomarker. Four types of scale are usually defined: normal, ordinal, interval, and ratio. The distinction among them is an important one because the type of statistical analysis that is justified depends upon the level of measurement that generated the data. For the lowest level of measurement – nominal – the data serve merely to identify individuals or to assign them to groups. Numbers on football jerseys are often pointed to as exemplars of the former application of a nominal scale. Assignment of individuals to the categories of male or female is an example of the latter usage. Assignment of numbers on a nominal scale is an arbitrary matter, and, indeed any distinguishing symbols will work equally as well as numbers. About the only statistical procedures that can be employed with nominal data are frequency analyses of various sorts.

For a scale to be ordinal, there must be an implication of 'greater than' or 'less than' associated with assigned numbers. For many, perhaps most, biomarkers in contemporary use, persuasive arguments can be made that this requirement is met. Qualifying as an ordinal scale permits the use of the median, percentiles, order correlations, and similar non-parametric statistical operations.

Unless a further criterion is met, however, one is not entitled to the use of means, variances, product–moment correlations, *t*-tests, analyses of variance,

and similar parametric statistics that constitute the bulk of statistical treatment in gerontological science. This additional requirement is that the numerical difference between two values of the scale should reflect the same magnitude of difference of the attribute being measured at all positions on the scale. A scale for which this attribute can be demonstrated is said to be an interval scale. Consider the phenotypic domain of mouse activity, of which numerous operational measures have been utilized as biomarkers of aging. The interval-scalar criterion requires that the difference in underlying trait being assessed (energy level, activity propensity, lack of inhibition, degree of fear, or some combination of these or other processes) between a score of 0 and one of 100 is the same as the difference in underlying trait represented between a score of 5000 and one of 5100. In cases where the biomarker is one of convenience, substituting for a more expensive or difficult-to-obtain gold standard measure, appropriate comparisons between the two measures may demonstrate this equality of intervals. For those cases where no such gold standard exists (and such cases must be the rule rather than the exception in the gerontological literature), then demonstration of interval-scale status may be very difficult, if not impossible.

An even higher status of scalar adequacy is that of ratio scales in which there must be, in effect, a meaningful zero on the scale. Under such circumstances, it becomes possible to make comparisons such as twice as much as, one-third as much as, and so on. For ratio scales, one can legitimately utilize coefficients of variation and geometric means. Ratio scales are very rarely encountered anywhere in biological, behavioral, or social sciences.

Lack of interval scale status may affect interpretation of life span differences or changes. Suppose that a change of x units in the lower ranges of a biomarker scale of 'vitality' represents a greater change in the underlying attribute than does the same numerical change higher on the scale. If older people tend to have lower mean values than do younger people, it is impossible to determine if a change late in life is equivalent in magnitude to one earlier in life. Rarely is the function known by which the numerical scale maps onto the underlying variable. Usually, then, and strictly speaking, only ordinal inferences are warranted when relating biomarker status to chronological age. These same considerations suggest the logical difficulty of assessing whether different individuals are changing at the same rate if they differ in mean value of the biomarker.

Addressing issues of this sort requires systematic attention to scale properties, but scalar adequacy criteria are not universally recognized. Even when recognized, explicit demonstrations of scalar adequacy are seldom undertaken. The empirical robustness of parametric statistics in the face of failure to meet interval scale criteria is not very well known in respect to specific biomarkers of aging; much of what is regarded as reliable information about them should, therefore, be regarded with some reservation.

Summary

This review of biomarkers has recognized that there are multiple meanings of the term, but argues that all usages engage two central questions of measurement, which might be informally phrased as follows:

1. What is being measured?
2. How accurately is it being measured?

The theme has been one of caution. It has been asserted that there is no gold standard definition of age or aging, for the philosophically crucial reason that no one knows what aging is, only certain manifestations of it. Any single biomarker, it has been argued, can measure only some (probably very small) part of the total meaning of age and aging. Furthermore, the numerical value obtained for a biomarker must be considered as an approximation, no matter how exquisite the care with which the measurement is made. How crude the approximation will be depends not only upon error but also on the parameters of the regulatory system that responds to displacement of the biomarker from its set range. Even more important, the fundamental meaning of a biomarker will depend upon the values of other components of the subsystem of which it is an element, will almost certainly differ therefore from individual to individual, and may change from one part of the life trajectory to another. In short, at the present stage of gerontological science, it is (1) difficult to say definitively what a biomarker measures, or what it should be measuring, and (2) any particular measurement outcome is surrounded by an aura of indeterminancy, the magnitude of which is usually unknown.

But it must be made clear that the limitations and shortcomings dwelt upon here apply as well to the marker variables of any other biological, behavioral, or social science. Gerontology is not less well served by its variables than are other areas of investigation. Indeed, it must be concluded that they are quite robust to have supported the enormous strides that have occurred in the study of aging in the past few decades. Obviously no biomarker can be flawless in all respects. Equally obviously, consideration of the gerometric issues identified here might improve their incisiveness and utility.

Marriage and Divorce

B A Mitchell, Simon Fraser University, Burnaby, British Columbia, Canada

Glossary

Divorce – The legal dissolution of a marriage before the death of either spouse.

Group Marriage – The marriage of two or more men to two or more women.

Marriage – A socially legitimate sexual union typically marked by a public announcement, commitment, and a written or verbal marriage contract.

Monogamy – The preferred form of marriage within Western cultures, in which there are only two spouses.

Polyandry – A marriage involving one wife having two or more husbands.

Polygamy – The practice of having more than one husband or wife.

Polygyny – A marriage type formed when one husband takes on two or more wives.

Serial Monogamy – Having more than one partner in sequence; is becoming more prevalent in cultures with high divorce and remarriage rates.

Introduction

Throughout human history, the institution of marriage has taken on a variety of shapes, functions, and meanings. Yet, marriage has almost always remained a sociosexual institution and a fundamental feature of family life and kinship structure. As such, it pertains to a specific social and sexual order with functions that are historically and culturally specific. In Western societies, it has traditionally been defined as a union between a man and woman, although same-sex marriages are legally recognized in some areas. In other parts of the world, polygamy, especially the marriage of a man to two or more wives, has been a more common form of marriage. Moreover, marriages are not always permanent – some end through the death of a spouse, while others end through divorce, separation, or annulment. Indeed, divorce, which is the legal dissolution of marriage, has become increasingly prevalent throughout many parts of the world. This emergent trend has significant implications for societies, family patterns, and relationships over the life course and in light of significant increases in life expectancy.

This article reviews patterns of marriage and divorce, beginning with an overview of marriage types and functions in selected Western and non-Western societies. Legal, social, and religious elements relevant to marriage and divorce are also reviewed. And wherever possible, attention is paid to

summarizing current knowledge on this subject from a gerontological perspective. This includes coverage of information that highlights dominant trends and implications for aging individuals and families in mid- and later life.

Defining Marriage, Religion, and Types of Marriage

Although precise definitions of marriage vary historically and cross-culturally, it can be defined as a state-sanctioned, socially legitimate union that occurs between two adults who cooperate sexually, economically, socially, and emotionally. Marriage is typically marked by a public ceremony, ritual, or announcement, such as a wedding, which provides a symbolic expression of the new social status of the bride and groom. Ceremonies range across and within cultures from very elaborate ones to the simpler act of acting married.

Religion often plays a role in these ceremonies and in most cultures. Generally, many religions provide extensive guidelines and teaching with respect to marriage. Christian churches tend to give blessing to a marriage, and the wedding ceremony usually includes some type of pledge by the community to support the couple's relationship. In Judaism, marriage is highly recommended, since it helps in the pursuit of spiritual perfection. It is viewed as the joining of two families, and it helps to perpetuate the religious and cultural heritage of the Jewish people. Hinduism conceives of marriage as a sacred duty that involves both social and religious obligations, while Buddhism tends to focus on how one can lead a happily married life. In the Eastern Orthodox church, marriage is viewed as an ordination and martyrdom.

Marriage is typically assumed with a written or verbal marriage contract, and this contract varies in the degree to which it can be broken. This contract also involves some idea of permanence, obligations to the family, and reciprocal rights. It is traditionally defined as a union between a man and a woman, although it has broadened in some jurisdictions to include same-sex marriage. Same-sex marriages are legally recognized in countries such as The Netherlands (2001), Spain (2005), Canada (2005), Belgium (2003), and the state of Massachusetts in the United States (2004). Some regions, such as Vermont, US, allow couples to apply for civil unions through which they receive virtually all of the legal benefits and protections given to married heterosexual couples.

There is wide variation in the form that marriage takes throughout the world. There are four types of marriage: monogamy, polyandry, polygyny, and group marriage. In Western cultures and countries such as China and Australia, monogamy, in which there are only two spouses, is the preferred form of marriage. In the twenty-first century, bigamy and sexual relations outside marriage are generally socially or legally frowned upon. However, since divorce and remarriage have become increasingly common, the practice of serial monogamy – or having more than one partner in sequence – has become more prevalent.

Polygamy, or plural marriage, is the practice of having more than one husband or wife. There are three forms of polygamy: polygyny, polyandry, and group marriage. Most societies permit polygyny, in which a man can have multiple wives, and it is generally a sign of wealth and power. The status of multiple wives varies from one society to another. This practice is found in many cultures throughout the world, such as the Middle East, Asia, and Africa, and in some fundamentalist Mormon groups in the United States (e.g., in rural areas among Utah's borders with Arizona and Colorado) and Canada (e.g., Bountiful, British Columbia). It is commonly sanctioned by religion, for example, in chapter 4 of the Qur'an, it is stated that in certain situations a man is allowed up to four wives. Although polygyny is preferred in many of the world's societies, preference does not necessarily translate into practice. This is because the number of men and women of marriageable age in most cultures does not create enough extra women to be available as second or third wives.

Polyandry is the practice of having two or more husbands. It is very uncommon, although considered to be the ideal marriage form in societies such as the Toda of India and the Marquesians of the Polynesian Islands, and among some Tibetans. Group marriage is relatively rare and involves the marriage of two or more men to two or more women. It tends to be found in societies in which plural marriage in the form of polygyny or polyandry already exists.

Free Choice and Arranged Marriage

In the West, the choice of a marriage partner is largely voluntary and depends upon the attachment between the partners. For example, in the United States, Canada, and many European countries, the most common reason for marrying is love, based upon a mutual emotional and/or physical attraction and the desire to form a lifelong commitment. In many parts of the world, such as many parts of Africa, Asia, and the Middle East, as well as within some cultural groups in Western societies, the choice of mates is deemed too important to be left to the individual and is often arranged.

Arranged marriages generally involve the role of an intermediary, through the involvement of two sets of parents or through negotiations with professional marriage brokers with prospective families. In most societies, the prospective bride and groom are consulted and they may have some power to reject the potential mate. Arranged marriages are practiced in order to preserve family resources, protect the economic well-being of the couple, and provide family continuity from generation to generation. Potential choices are usually limited to people of the same race and ethnic group and the same religion and class, and love and compatibility may be considered in order to provide the best possible match.

Rules, Regulations, Rights, and Obligations

In many parts of the world, marriage is a legal contract, with the state regulating economic and sexual exchanges between the couple. For example, in the United States, most states specify that individuals must be a certain age to marry, they must marry only people of the opposite sex, and they cannot marry someone with whom they hold certain kin relationships. Throughout history, societies have always placed restrictions on marriages. In particular, marriages to immediate relatives, such as between brothers and sisters, have generally been taboo and restricted (although ancient Egyptian royalty is a rare exception).

The institution of marriage unites people in emotional, social, legal, and economic ways that confer certain rights and obligations. These rights and obligations relate to children, holding property, sexual behavior, kinship ties, tribal membership, relationship inheritance, and intimacy. They sometimes establish the legal father of a child, give spouses sexual control over their partner's sexual services, establish a joint fund of property for the benefit of the children, and establish a relation between the families of the husband and wife.

Marriage Patterns and Family Relations

Marriage has traditionally been a prerequisite for starting a family. However, an increasing number of individuals (especially in Western cultures) are choosing to delay marriage or never marry, which means that the marriage rate is declining. More couples are also having children outside of legal marriage. Most individuals marry in young adulthood, although the average age of first marriage has increased steadily over the past century in most developed nations. Living together in cohabiting or common-law marriages is also on the rise and contributes to a decline in the marriage rate. This living arrangement is relatively common in countries such as Sweden and Canada and in other Western societies. Its roots can be found in a European tradition that marriage contracted between two adults was their own or their family's business and required neither civil nor religious sanction. In contemporary society, this practice is becoming very popular as a first conjugal union for young adults. For example, in the United Kingdom, about 60% of all marriages are preceded by unmarried cohabitation. Cohabitation is also becoming more common in mid- and later life, particularly following the end of a prior legal marriage. These relationships are different than legal unions since they are not contracted on the basis of a state's rules and regulations. As such, these unions are not always socially and legally recognized.

With rising divorce rates in many countries, individuals often remarry, although this is more prevalent at younger ages than in later life. Older adults, compared to younger adults, experience more negative social pressure about their decision to remarry. This negative social pressure sometimes originates from peers or adult children, the latter of whom may have concerns over such issues as inheritance. Adult children in Eastern cultures may also be afraid that they will be ridiculed for not taking their filial responsibility seriously, as observed in some Chinese families. In mid- and later life, men are more likely than women to remarry. The primary obstacles to remarriage for older women are the disproportionate number of women over age 65 and the cultural stigma against women marrying younger men, which is common to virtually all societies. The desire to remarry in later life may also be lower among divorced women than widowed women, which could be related to past negative experiences with marriage.

Remarriage introduces new complexities in aging family relations, since it is often described as an incomplete institution, without clear role boundaries and normative guidelines. For example, children may experience divided loyalties and difficulty coping with a step-parent family environment. Furthermore, among those who do remarry, a significant number are estimated to divorce again, creating complex stepfamily relationships among divorced adults in old age.

Marriage, Health, and Well-Being

Most research on marriage, health, and well-being has been conducted in the United States, although some cross-national research has been done. Generally, married people (with good marriages) report

higher life satisfaction and well-being and adjust to aging better than divorced, separated, and widowed individuals. Marriage is also linked to longer life expectancy, reduced stress, and better physical and mental health, especially for men. Older married adults also show lower rates of hospitalization. Generally, compared to those who are not married, married individuals eat healthier diets, engage in better self-care practices, and live more stable and scheduled lifestyles. Married individuals can also pool financial resources, which can buffer hardships linked to poorer health. Overall, a stable, long-term marriage provides a built-in support system, companionship, sexual intimacy, emotional stability, and a sense of security.

Most elderly men are married and live with a spouse, whereas the majority of elderly women do not. These gender differences lead to differential needs for support in the face of poor or failing health, since older men have a spouse to rely on. Older women often rely on their children, usually daughters, and more on public services. The absence of a spouse (and children) also increases the chance of being placed in a long-term care facility.

Termination of Marriage: Patterns in Divorce

Divorce, or the dissolution of a marriage, is the ending of marriage before the death of a spouse. It can be contrasted with separation and annulment, the latter of which is a declaration that a marriage is void due to certain circumstances (e.g., one spouse is already married). A divorce must be certified by a court of law in order to dissolve the legal act of marriage. The terms of the divorce are usually determined by the court and may consider prenuptial agreements, or terms that the spouses have agreed upon privately.

Divorce rates have risen dramatically over the past century in many developed countries of the world, especially in the United States, Canada, and many European countries, such as the Czech Republic, Belgium, Denmark, and the United Kingdom. Developing Latin American countries such as Cuba and Puerto Rico also have very high rates of divorce. Indeed, internationally, the United States and Cuba have among the highest divorce rates. For example, it is estimated that approximately half of all first marriages and 60% of remarriages in the United States end in divorce. Although divorce has also risen dramatically in many other societies, many countries continue to retain a relatively low divorce rate, such as Japan, Italy, and Vietnam (see **Table 1**). Divorce appears to be relatively rare (although increasing) in countries such as Turkey and Brazil and some parts of Africa, although data from civil registries are incomplete or unknown.

Table 1 Selected international crude divorce rates, 2003

Country	*Divorce rate*[a]
Australia	2.67
Austria	2.44
Belgium	3.03
Canada	2.24[b]
China	1.03
Cuba	3.02
Denmark	2.93
Dominican Republic	0.98
France	2.14
Iran	1.09
Israel	1.67[b]
Italy	0.73
Jamaica	0.61
Japan	2.22
Mexico	0.62
Netherlands	1.94
New Zealand	2.62
Seychelles, Africa	1.52
Singapore	0.83
Slovakia	1.99
Spain	0.75
Sweden	2.39
Uruguay	2.04[b]
United Kingdom	2.80
United States	3.80
Vietnam	0.50[b]

Sources: All data are from the United Nations, except for US data, which are drawn from the National Center for Health Statistics.

[a] Rates are the number of final divorce decrees granted under civil law per 1000 mid-year population.

[b] Only 2002 data were available.

In Western societies, divorce often occurs within the first 5 years of marriage, with youthful age of marriage being a consistent predictor of divorce. A substantial proportion of divorces also occurs after 5 to 15 years of marriage. Divorce rarely occurs once a couple has remained married for more than 20 years. In most cultures, the percentage of those who are divorced is higher for all age groups under 65 than for those over 65. Yet, the growing number of older adults who are divorced indicates the growing acceptance of divorce as an option among all age groups.

Legal, Sociocultural, and Religious Issues

From a historical perspective, divorce is a relatively recent phenomenon in virtually all societies. Many developed countries did not recognize divorce, and it was not until the middle of the twentieth century that many countries broadened divorce laws, which made it easier to obtain a divorce. Many of these societies

have moved toward no-fault divorce laws. For example, since 1970, beginning with California's Family Law Act, 48 US states have adopted no-fault divorce, while still providing for legal grounds divorce when applicable. This process eliminates fault-finding and the adversarial process such that the bases for settlement are equity, equality, and need rather than fault or gender.

Similar to marriage, different religions have different beliefs with regard to divorce. In the Roman Catholic church, for instance, divorce is traditionally not permitted because marriage is forged by God. Thus, many Catholic countries such as France and Italy have prohibited divorce since it is believed that couples should not and cannot be separated. Annulment is permitted in some special cases. Islam allows divorce, although it is discouraged and only the husband can decide to have no-fault divorce. In Judaism, divorce has always been accepted as a fact of life, and it is generally maintained that it is better for a couple to divorce than to remain together in a marriage that is in a state of constant strife.

Divorce, Aging Families, and Social Networks

The decision to end a marriage has significant implications for family members. To date, most research has assumed a deficit perspective – that is, that divorce has a negative effect on families. However, cross-cultural studies are beginning to show some positive outcomes, such as an increase in self-confidence and well-being and relief from a bad marriage. For women in particular, divorce can be positive if the marriage was abusive. Research also documents that adult children of divorce are more likely to divorce themselves compared to those raised with non-divorced parents. The quality and nature of the intergenerational relationship also change when parental divorce occurs later in children's lives, especially for young adult children. For these children, custody, visitation, and child support are no longer issues affecting the relationship. Yet parental divorce can lower the quality of the intergenerational relation and patterns of contact, especially for the father–child relationship. Generally, divorce can weaken kinship ties and obligations when it occurs later in life.

Studies also reveal the consequences of a child's divorce on the aging family system. One area that has received growing attention is the effect of divorce on grandparent–grandchild relations, since divorce can lead to a change in contact patterns. For some grandparents, the divorce can lead to a loss of contact, especially if their child becomes the non-custodial parent. In other situations, grandparents appear to have more contact, particularly when the adult child requires additional assistance and support with the raising of their children. A minority of grandparents become primary caregivers of their grandchildren when their divorced child is unable or unwilling to care for their children. This situation contributes to the formation of 'skip generation' households, since the middle generation is absent in the home.

Turning to the effect of divorce on couples, studies establish that divorce poses a crisis for some divorcing adults that results in a temporary decline in well-being, from which most individuals recuperate. However, for other individuals, divorce can set into motion a number of other stressful events, such as moving to another neighborhood, ongoing conflict with the former spouse, and economic hardship. However, adjustment to divorce largely depends upon characteristics of the individual (e.g., age, socioeconomic status, emotional stability, attachment to former spouse) and contextual factors (e.g., social support networks, custody status). Legal contexts can also shape adjustment processes, such as no-fault divorce laws, which can make divorce less emotionally painful to obtain.

Cultural factors are also integral to adjustment, since in some societies there may be a great deal of stigma associated with divorce. Opportunities (socially and economically) and legal contexts also vary from society to society. For example, in India and Japan, divorce is associated with more social stigma, and social opportunities are more limited. In India, divorced women are often isolated following divorce, due to the principle of *pativratya*, or the notion that a woman should devote herself completely to her husband's needs, even at the expense of her own. Divorced Indian women also find it challenging to find other single mothers with whom to develop social networks, while men retain both their household and the support of their extended families. Women are also more reluctant to seek friendships with Indian men since it might be misinterpreted. As a result, they are less likely to remarry than US women, which increases their social isolation. In Japan, divorced women traditionally experience discrimination in employment opportunities due to the impurity that divorce introduces into their family registry. The effect of this impurity can even spill over to their children. Generally, divorced individuals who reside in countries where divorce is less common are more stigmatized and fare worse socially and economically.

Overall, divorce tends to erode social support networks, especially ties to married friends. Retaining relationships with former in-laws is also fairly

unusual. However, friends and other family members often provide assistance to the divorced individual, particularly to older divorced women in Western societies. Older divorced men have relatively small social networks in comparison. This situation reflects their lesser involvement with their children and the tendency of men to rely on their spouses for emotional support. Also, since women are more likely to be kin keepers, divorced men lose this valuable resource, which is integral to the maintenance of social ties.

Divorce, Health, and Economic Well-Being for Aging Adults

Most research on divorce, health, and well-being has been conducted in Western societies, particularly the United States, although similar findings are observed across numerous societies and among various social and demographic groups. These studies have established that divorced individuals manifest more health problems and greater mortality than married or never-divorced individuals. A consistent finding in psychiatric epidemiology is that the highest rates of mental disorder are found among the divorced and separated, whereas the lowest rates are among the married and intermediate rates are among the single and widowed. Divorced individuals may also exhibit greater risk taking, such as elevated rates of drug and alcohol use and abuse. The recently divorced are at a particularly high risk for illness, possibly due to a weakened immune system as a result of the stress associated with divorce.

Divorce both in midlife and after midlife also influences a person's economic standing. Negative influences are generally more pronounced for older women, which may partly be a function of a more limited range of options. Many older women lack the requisite education, skills, and employment experiences that provide them with the ability to either reenter the labor force or advance their current positions. Although the financial responsibility to one's children decreases with age, many aging parents may continue to assist their young adult or adult children financially. When divorce occurs, the cost of maintaining two parental households may prohibit some of this assistance.

Summary

Marriage is a universal social institution that has historically and culturally unique forms and functions. Marriage and divorce laws regulate the marital agreement that two people make with each other and govern when a marriage can be dissolved. Social and religious contexts also shape these behaviors and experiences. The traditional view that marriage is a socially legitimate sexual union between a man and a woman is increasingly being questioned, such that legal definitions are expanding to include same-sex unions. The increasing popularity of cohabitation or common-law marriage also raises the question of this status as compared with legal marriage.

Marriage and divorce affect the lives of individuals and their families. Married individuals, in general, are found to experience a number of health and economic benefits over the life course, especially compared to divorced individuals. Divorce tends to erode social networks, particularly for older men, although older women often experience a decline in economic well-being. Older women may also experience stigma and isolation, although this may depend upon individual and cultural factors. Midlife and older women are also less likely to remarry relative to their male counterparts.

In the future, the institution of marriage is expected to remain highly valued and to persist in virtually all societies, despite the fact that marriage rates are declining and divorce among older age groups is rising. Undoubtedly, marriage will continue to transform and shape aging family life and social structures in significant ways. And given continued divorce, remarriage, and increases in life expectancy, there is the distinct possibility that we will witness more serial monogamy – that is, having more than one committed partnership in sequence – as well as marriages that will last for 50 years or more.

Medicare and Medicaid and Economic Policy of Health Care

R N Butler and M Schechter, International Longevity Center (US) of the Mt. Sinai Medical School, New York, NY, USA

Glossary

Medicaid – The largest American program covering long-term care. Beneficiaries are defined as poor under state rules or qualified as low income recipients of a federal assistance program for the aged, blind, and permanently disabled.

Medicare – The largest American health insurance program for older persons, covering 35 million persons aged 65 and older.

Medigap – Supplemental coverage from private insurers to pay for expenses not paid by Medicare.

Introduction

The main focus of this article is Medicare. It examines its provisions and relationships to a cluster of programs for the health care of older Americans. In this cluster are included private insurance for some of the gaps in Medicare coverage (Medigap insurance), private insurance for long-term care (which Medicare does not cover directly), and Medicaid, federally supported state programs of assistance (charity) for medical and long-term care costs.

A major addition to Medicare is an outpatient drug benefit, conspicuously absent from the program for 40 years. The new program represents a departure from governmental administration seen in the traditional program. The new program, Part D, is an insurance market, with private insurers having great latitude in shaping the benefit, with options and sign-up procedures that confuse beneficiaries.

Medicare and Medicaid are mainstays of the American older population. Medicare is the largest American health insurance program for older persons; it covers virtually all 35 million persons aged 65 and older. In 1972, disabled workers on the Social Security disability rolls for at least 2 years were brought into Medicare. (In the same year, Medicare was extended to patients with end-stage renal disease.) Counting disabled workers, Medicare has 41 million beneficiaries.

Medicaid is the largest American program covering long-term care. Its beneficiaries are individuals defined as poor under state rules or qualified as low-income recipients of a federal assistance program for aged, blind, and permanently disabled persons (Supplemental Social Insurance, which uses income limits). Medicaid covers 53 million children and young and old adults, making it the largest American program of health insurance.

About 6 million individuals are 'dual eligibles' of both Medicare and Medicaid. They qualify for Medicare benefits because of their social insurance contributions and qualify for Medicaid benefits because they are poor. Counting the dual eligibles only once, Medicare and Medicaid together covered about 88 million persons in 2005.

Major aspects of the 2003 Medicare Prescription Drug, Improvement, and Modernization Act – particularly attempts to improve thrift and quality of care – are touched on in this article.

An Economy within an Economy

In 2005, Medicare and Medicaid spent over $620 billion of the $1.8 trillion spent on health care in the United States. If the programs funded a complete and

universal system instead of huge fragments, they probably would be hailed as one of the developed world's largest programs of national health insurance. Attempts to forge a national health insurance program in the United States have failed because of sharply divided opinion about the roles of government, private insurance, and market-based strategies.

Despite this enormous spending on health care, there were 42 million persons under age 65 in the United States in 2005 without health insurance. Many lost private coverage when they lost their jobs. Some became eligible for Medicaid because of poverty. The costs of their care plus the costs of care for the elderly poor in nursing homes and home-care programs strained state budgets and prompted calls for cutting Medicaid costs, particularly by going after beneficiaries who supposedly transferred assets in order to qualify as poor.

Despite its enormous spending, Medicare covered less than half of the health-care expenses of average beneficiaries in 2005. The largest item not covered by Medicare was long-term care. The Kaiser Commission on Medicaid and the Uninsured reported in 2006 that 1 million elderly persons were at high risk of needing care in a nursing home: they were age 85 or older, had no spouse, and needed help because of functional and cognitive impairments. With the annual cost of staying in a nursing home averaging $70 000, 62% of these individuals would exhaust their assets within 1 month of admission.

Research indicated that appreciable reduction of Medicaid spending was unlikely if targeted on higher penalties for transferring assets. The penalties were increased waiting periods before Medicaid payments to nursing homes would start. A patient who could not show the nursing home that he or she could pay during the penalty probably would not be admitted.

Taking a larger and larger bite out of the economy, inflation in health care and health insurance costs threatened the financial stability of young and old households as well as government budgets and corporation profits. According to a policy brief by the Brookings Institution, if historical trends persisted, the share of gross domestic product (GDP) going toward health care would climb from 15% to more than one-third by 2040. Such a proportion was considered politically and fiscally unacceptable. The author of the brief, Henry Aaron, noted that "with medical technology advancing at an ever-increasing rate, the potential for spending on procedures not worth their costs is growing. But there are few good ideas for reining in medical costs without hurting patients." (Henry J. Aaron (2005) *Health Care Rationing: What it Means*. Washington, DC: Brookings Institution. Policy brief #147 [abstract]).

Some American businesses complained that their health insurance costs undercut their ability to compete well in international markets; foreign businesses were said to bear lighter burdens under national health insurance. The blame for higher US costs is sometimes laid unfairly at the door of the older American population and its financial and health-care supports. What should be noted is that developed countries with larger proportions of elders in their populations had lower health-care costs as a percentage of GNP than the United States.

Both Medicare and Medicaid do have problems controlling costs. They are embedded in an extravagant health-care system. Both have deficiencies in range of benefits and quality of care from a geriatrics viewpoint, where the preference would be for a seamless system of preventive, acute, long-term care and social services. The health system that exists and changes slowly is marked by waste, inadequate and uneven population coverage, and a heavy bias toward acute care.

History and Philosophy

Medicare payment patterns – ranging from public or social insurance to the use of market and private insurance mechanisms – reflect political philosophies in vogue at various times before and since Medicare's enactment in 1965. The emphasis at the start was primarily on social insurance concepts and dedicated payroll taxes formulated by the Democratic Party and brought to fruition in 1965 when Lyndon B. Johnson was president. In 2003, during the administration of George W. Bush, a Republican, Medicare introduced an outpatient drug benefit grounded on market strategies rather than social insurance. The 2003 act intensified Medicare's promotion of managed care systems sponsored by private insurers. Mirroring the President's desire to privatize Social Security pensions, the reigning belief in Medicare administration was that program economies could be effected more or better by markets than by government administration.

Medicare and Medicaid are rooted in the Social Security Amendments of 1965. Title XVIII of the act was Medicare for retired workers, and Title XIX was Medicaid for the poor. Medicare emerged in the law in a form that differed from its original focus on hospital benefits backed by compulsory payroll taxes, a pattern opposed by organized medicine. In search of a broad consensus, the House Ways and Means Committee under its Democratic chairman adapted a Republican proposal for subsidized voluntary insurance acceptable to organized medicine,

Medicare Part B. This plan focused on physician services financed through beneficiary payments (premiums, deductibles, and coinsurance) and federal general revenues rather than a dedicated payroll tax allied with Social Security. Contrary to the desire of organized labor to minimize the use of private insurers, the final legislation placed day-to-day administration in the hands of insurance companies familiar to hospitals and physicians, with overall control by the Social Security Administration.

Medicaid was administered by another unit of the Department of Health, Education, and Welfare (HEW). Later, both programs were lodged in the Centers for Medicare and Medicaid Services (CMS) of the Department of Health and Human Services (HHS), successor to HEW. Placing both programs in one administrative agency seemed to make sense inasmuch as the programs dealt with many of the same providers of service and dealt also with an overlapping population of beneficiaries. For poor Medicare beneficiaries on Medicaid, the latter paid for Medicare deductibles, premiums, and coinsurance. Actually, Medicaid offered older persons a broader slate of health benefits than Medicare; for example, Medicaid covered long-term care, outpatient drugs, routine dental care, and preventive health care, all of which were not included in the original Medicare program.

An erroneous belief that Medicare included long-term care persisted for many years. What misled many persons was that Medicare made use – but only limited use – of nursing homes and home-care programs identified with long-term care. The Medicare law spoke of extended care, a benefit allowed for convalescent and rehabilitative services in a nursing home or home-care program after a 3-day hospitalization for an acute illness. As long as a patient needed treatment for the acute problem, custodial care in the nature of assistance in dressing, bathing, and other activities of daily living was covered by Medicare.

No geriatrician was at the decision-makers' table when Medicare was designed. The plan largely represented reliance on models from private insurance, which focused on medically necessary costs of acute care. Medicare was primarily an insurance program rather than a health program. Over the years, Medicare became more oriented toward preventive health care. When Medicare began, many beneficiaries expected the program to cover long-term care, but it was not in the law. Decades after Medicare began, insurance agents said they found many older persons harboring the belief that Medicare had a long-term care benefit. A reason for this omission was lack of insurance company experience on which to rely for estimating the costs of long-term care benefits. A common belief in Congress was that a long-term care benefit would stimulate demands for services that Medicare could not afford or control.

Medicare in Outline

The major elements of Medicare are Part A (hospital insurance), Part B (insurance for doctor, clinical laboratory, and outpatient clinical services), Part C (federal payments to capitated managed care systems), and Part D (outpatient prescribed drugs furnished through private insurers and managed-care systems). Parts A, B, and C are noted briefly here to give a context for discussing Part D. More detail on A, B, and C follows in another section.

Part A is supported by federal payroll taxes on employers and employees, Part B by beneficiary payments (25% of program) and federal general revenues (75%). Under Part A, the Medicare administration sets payment rates across the nation for hospital services sorted into diagnosis-related groups. Under Part B, Medicare pays chiefly for fee-for-service medicine according to resource-based relative value scales with geographical and other adjustments.

In Part C, the Medicare administration and managed-care systems negotiate an annual rate per beneficiary (capitation). The systems are at risk for costs beyond the capitation income. Funds for hospital and physician services are drawn from Part A and Part B.

Medicare Part D

Part D represents a private insurance market supported by beneficiary and federal payments, with minimum government oversight. As Part D began in 2006, 260 private insurers sponsored drug plans meeting minimum federal requirements for a novel drugs-only insurance approach. The plans were free to set premiums and deductibles, being mindful of competition by premium price and formulary, the list of drugs that the insurer chose to cover, provided the list had at least one drug in specified categories.

A controversial section of the 2003 Medicare Prescription Drug, Improvement, and Modernization Act prohibited Medicare from bargaining on price with drug makers. It authorized insurers to do the bargaining. (Meanwhile, the government bargained on prices for the Department of Veterans Affairs and secured large discounts.) The insurers were at risk for losses experienced by their programs.

About 29 million of the 41 million Medicare beneficiaries were expected to enroll in Part D in its first

year, 2006. Of 14.2 million persons eligible for low-income subsidies, 8.7 million were expected to apply and receive them. A study for the Kaiser Family Foundation estimated that 19 million enrollees would probably spend less on prescribed drugs, 7 million would spend more, and 3 million would spend about the same in out-of-pocket costs as they did before Part D. Because of premium subsidies, beneficiaries would pay on average about 25% of total Part D costs. An average drop of 83% in out-of-pocket costs was forecast for 8.7 million low-income beneficiaries. A decline of 37% (to $792 from $1257) was forecast for average Part D enrollees in 2006.

Part D was open to beneficiaries participating in traditional Medicare; participation was optional. Enrollment was not easy: applicants had the job of sizing up the market of plans available in their locales, sometimes well over a dozen. They had to identify those plans, review their premiums, and check their formularies to see if the generic or branded drugs they needed were listed at the needed dosage. Plans were at liberty to amend the formulary at any time, provided they gave 60-day notice during which the beneficiary could switch to another plan. In the initial year, one switch was allowed after the May sign up deadline. Ordinarily, the Part D participants had a once-a-year period to switch plans.

When satisfied with the details of a particular plan, the applicant had to sign up with the plan or sign up with Medicare. Dual eligibles were assigned to a plan by the state Medicaid agency. Participants in managed-care plans that already had drug benefits did not have to change; they might even see their benefits improve under Part D reimbursement.

Medigap plans could participate in Part D if they established a separate plan for drug coverage. Medicare beneficiaries in employer-sponsored retiree programs that included drug coverage deemed equal to Part D could stay in that program. If coverage was not equal to Part D, they could stay, but had to know that a late-enrollment penalty, a premium surcharge, would be applied in the future if they opted for Part D. The act offered subsidies to employers to maintain drug coverage in their retiree plans rather than discontinue the coverage and see retirees enroll themselves into Part D.

Part D provided subsidies to employers for maintaining their retiree drug coverage if found equal to the Medicare coverage. The subsidies were justified as necessary to prevent employers from closing down their programs and leaving drug payments entirely to Medicare. A survey of 300 of the largest US private employers found that 80% would accept government subsidies for continuing to offer retiree drug coverage in 2006. While most of these companies said they were likely to accept the subsidies in 2007, only half said they would do so in 2010, and 22% said they probably would not do so. The remaining 28% did not know.

The survey also found that many subsidy-taking firms had policies concerning retirees who enrolled in a Part D drug plan. Some 29% of these firms said that retirees taking such a plan would lose employer-sponsored medical and drug coverage, 31% said such retirees would lose only the drug coverage and retain other benefits, and 41% said retirees taking the Part D coverage would not be able to retain other benefits in the future. Firms that would continue to offer benefits and accept the subsidy in 2006 would save, on average, $626 per retiree. Firms that would supplement Part D and retain other benefits would save $826 per retiree.

Part D as a whole was criticized for give away to insurers and drug makers. When the Bush administration brought the legislation to Congress, the estimated 10-year cost was about $500 billion. A higher estimate was withheld from Congress before enactment. Some Republican members of Congress were upset by costs of the proposal endorsed by President Bush, while Democrats were upset by a precedent for privatizing more of Medicare and by the complexity of the program. The House of Representatives approved Part D by a narrow majority after the Republican leadership extended the time for voting to 3 hours (versus the customary 15 minutes). The extra time was used to round up and pressure members to back the President.

The model laid out in the legislation called for a maximum $250 annual deductible. After it was met, the plan covered 75% of total drug expenses, up to $2250. The enrollee paid 25%, or $500 ($2250 minus $250 = $2000 × 25% = $500; the remaining $1500 was paid by Medicare). After $2250, the program paid nothing until the total spent by the enrollee and Medicare reached $5100. Beyond this 'catastrophic' level, Medicare paid 95% of drug expenses and the enrollee 5%.

Medicare Parts A, B, and C

Most of Medicare spending is through Part A, or hospital insurance. Part A is funded primarily by a dedicated payroll tax of 1.45% paid by employers and 1.45% paid by employees on earnings up to a specified ceiling ($90 000 in 2005). Over the long run, some critics contend, this rate will not be high enough to cover the Baby Boom retirees and the expected rise in health costs at a pace faster than the growth of the economy.

Part A eligibility typically is established automatically at age 65 for persons with a specified record of payroll contributions made in parallel with Social Security (pension) contributions. Older persons lacking full Social Security status (because they had insufficient payroll credits) may buy into Part A.

In addition to hospitalization, Part A pays for posthospital care in a skilled nursing home or home-care program (for rehabilitation and convalescence), and for hospice care (for patients near death who require treatment for comfort and pain relief). Admission to a Medicare-participating hospital triggers a Part A deductible set by national formula ($912 in 2005). Only one deductible is charged for 60 days, even if there is a readmission for the same diagnosis after a brief interval at home or in the community. After 60 days of hospitalization, the patient incurred in 2005 a per diem charge of $228 until day 90, and thereafter until day 150 a per diem of $465.

The designers of Medicare were advised by private insurers to adopt this approach as a deterrent to long and unnecessary hospitalizations. Almost all Medicare hospitalizations nowadays are for less than 30 days. More in keeping with the finances of older people would have been a 30-day benefit, budget neutral, with no deductible. Part A provides for a limited amount of care (20 days) in a skilled nursing home at no cost to the beneficiary after a hospital stay of 3 days. From day 20 to day 100, the per diem charge in 2005 was $114. Home care was at no cost to the patient as long as medically needed and provided by a Medicare-approved agency.

Parts A and B constitute traditional Medicare. Hospitals are paid on the basis of costs generated in diagnosis-related groups of services (DRGs). Physicians are paid mainly by fee-for-service using resource-based relative value scales (RBRVSs), derived mainly from studies of time with patients for interviews and for conducting procedures.

In addition to physician services, Medicare Part B provides for clinical laboratory services, outpatient clinical services, and medically necessary equipment, such as wheelchairs. Part B is technically a voluntary program, but virtually all Part A beneficiaries choose it, pay a monthly premium, and meet an annual deductible before being reimbursed. In 2006, the Part B premium was $88.50 per month and the deductible was $124 per year. The law fixes Part B financing as 75% from federal general revenues and 25% from patient payments, such as premiums and coinsurance.

The model for physician payment, in brief: a Medicare-participating physician agrees to accept a Medicare approved charge as the full charge for a service. The approved charge represents a Medicare fee schedule using the RBRVS. Based on empirical research into what physicians actually do, this methodology established a Medicare fee schedule considered to be more fair than payment under the loose concept of 'reasonable and customary fees.' The method was said to improve payment for primary care services and usefulness in controlling costs.

If the patient's Part B deductible has been met ($124), Medicare sends 80% of the approved charge directly to the physician. The patient, or the patient's private Medigap insurance (see below), pays the remaining 20%. If the physician does not accept this method (called assignment), the physician sends the patient a bill. A physician may not legally collect more than the approved charge plus 15% from the patient. Medicare sends the patient a check for 80% of the approved charge. The patient pays the 20% plus the 15%. Most physicians take assignment because payment is quicker and more reliable. For patients, there is less paperwork and postage.

Medicare Part C covers managed-care systems, which are private insurance plans that provide hospital, physician, and other services under central management for an annual sum. Beneficiaries who join a system give up the option they have under traditional Medicare to obtain service from any participating hospital, physician, or other unit. The beneficiaries are limited to the system's providers, unless the plan has an option allowing provider choice outside the plan; the beneficiary pays extra for it.

An annual contract is negotiated between Medicare and a managed-care system, which can be an HMO (health maintenance organization) or a PPO (preferred provider organization). This contract limits the government's spending. The managed-care system takes the financial risk for costs beyond the payment negotiated with the CMS. The beneficiary continues to pay the monthly Part B premium. A system may charge an additional premium for benefits beyond those of Part A and Part B.

Medicare Part C aims to attract beneficiaries from traditional fee-for-service Medicare by offering them improved controls on costs and quality of service. Private insurance companies sponsor managed-care benefits, called Medicare Advantage. Previously, the benefits were called Medicare + Choice. Medicare + Choice began with an assumption that the plans, because of their cost controls, would readily average 5% less than per-beneficiary costs under traditional Medicare. Savings above 5% could be applied to additional benefits (such as dental care, eyeglasses, or prescribed drugs) or reduction in the managed-care premium. In 2004, significant numbers of beneficiaries returned to traditional

Medicare because of dissatisfaction with administrative restraints on service use. Meanwhile, some plans proved more costly than traditional Medicare and dropped out of Part C. In Congress, higher Medicare payments were authorized to keep plans going in Medicare. Calculations by the Commonwealth Fund indicated that the plans cost $2.72 billion more than traditional Medicare.

Medigap

Some 22% of Medicare beneficiaries bought supplemental coverage from private insurers (Medigap policies) to pay for expenses not paid by Medicare. One-third of Medicare beneficiaries had gap coverage from their former employers, and 14% had gap coverage from Medicaid because they were dual eligibles. Coordinated with Medicare, Medigap paid what was left of the approved charge after Medicare paid its 80% and the Medicare deductible had been met. Medigap policies paid the residual amount of an approved charge, provided that the separate Medigap deductible also had been met. To help beneficiaries evaluate Medigap policies, the federal government established 10 categories of benefit packages with price and other characteristics.

Private Long-Term Care Insurance

Of the $180 billion the nation spent on long-term care in 2002, 10% was paid by private insurance, 17% by Medicare (coincident to treatment for an acute condition), 21% out of pocket by recipients or families, and 47% by Medicaid. An estimate for the cost of long-term care in 2005 was $200 billion. The cost of unpaid or informal care by family members and friends was estimated at another $100 billion.

Private long-term care insurance, available from 100 insurance companies, generally offered a choice of premiums for a mix of care at home, in assisted living facilities, and in nursing homes, depending on selection of (1) waiting periods of 60 or 90 days before benefit payments start; (2) per diem amounts or overall spending caps; (3) inflation protections, such as periodic 5% rises in per diem amounts or caps; and (4) length of coverage, such as 3, 5, or more years. Age of the would-be insured person and sickness risk also were factored into premiums. A number of policies did not exclude coverage for Alzheimer patients.

Many middle-class individuals at or nearing retirement age were deterred from buying long-term care insurance because of the expense, which was relatively high for their retirement incomes. Insurers generally encouraged purchase of long-term care policies when people were in their 40s or early 50s, when premiums are relatively low, and when there is time to build reserves. There appeared to be a persistent public reluctance to buy the policies.

To encourage purchase of long-term-care insurance, the cost of policies meeting federal standards may be deducted in part from income taxes. In a few states, after a private policy meeting special requirements has paid for at least a year of long-term care in a nursing home, a policyholder may be eligible for Medicaid coverage with no risk to assets. However, income limits would apply and an examination of income receipts would be necessary for Medicaid.

Insurers may raise premiums for a class of policyholders but not for specific policyholders. If the insurer by design or happenstance accumulated more heavy-expense policyholders than justified by premium income, the insurer could go out of business, merge with another company, or raise premiums for a policyholder class. The regulation of insurers was largely in the hands of state insurance departments, some considered more friendly to insurers than to consumers.

Medicaid

All 50 states, the District of Columbia, and other jurisdictions had Medicaid plans meeting federal requirements on scope of benefits and administration. Fifty to eighty percent of the costs of these programs for the poor – children, expectant mothers, and others in addition to older persons, on whom this article focuses – were financed by the federal government. Poorer states received higher grants than richer states. All Medicaid programs had to cover hospital, physician, clinical laboratory, nursing home, dental, mental health, and outpatient clinic services. Home-care service was a benefit the state could adopt with federal approval.

The qualification of individuals to receive benefits was contingent on proof of poverty (a means test by the state, taking account of income and assets). While states had considerable latitude in designing programs, they had to cover aged, blind, or permanently disabled persons who received Supplemental Security Insurance (SSI), a federal program with an income test. For example, elderly and disabled beneficiaries with income below 74% of the federal poverty level ($6768 a year in 2005) had to be covered.

Nursing home residents with incomes above SSI levels but below $1692 a month may be covered. States can expand their programs with federal consent. If granted a waiver, a state program might cover individuals at risk of needing nursing facility care although still living at home.

A state may choose to cover medically needy persons for mandatory benefits, such as hospital,

nursing home, and physician services. A medically needy individual is a person who has an income that exceeds state limits but, net of health-care expenses, falls below the limits. A state may also choose to cover the medically needy for home and community-based services.

Memory

A D Smith, Georgia Institute of Technology, Atlanta, GA, USA

Glossary

Episodic Memory – Storage and retrieval from long-term memory based on contextual information about original learning experience (internal diary).

Implicit Memory – Indirect effects of memory without conscious awareness.

Prospective Memory – Remembering to do something in the future (intention to remember).

Semantic Memory – Storage and retrieval from long-term memory based on the conceptual nature of to-be-remembered information (internal encyclopedia).

Short-Term Memory – Memory for recent events that have been maintained in conscious awareness prior to recall.

Working Memory – Type of short-term memory that involves maintenance of information at the same time one is engaged in an information-processing task.

Introduction

It is clear that memory changes with age. Serious memory decline is associated with many of the diseases of old age (e.g., Alzheimer's disease), but memory change is also characteristic of normal, healthy aging. There are hundreds of research studies showing reliable age differences on a variety of different memory tasks. The age differences are seen with both cross-sectional and longitudinal research designs. It is also true that not all memory changes with age in the same way. Whereas some memory tasks show large adult age differences (e.g., working memory, episodic memory), other tasks show little or no effects of age (e.g., semantic memory, implicit memory). The explanation for these differential effects of age on different memory tasks depends on how one conceptualizes memory. Some theories suggest that age differences will be large when the task involves deliberate cognitive processing or the use of cognitive resources. The more cognitive resources needed to adequately remember, the larger the age differences. Other theories suggest that age effects are limited to specific memory processes or memory systems. It also has been suggested that memory differences between age groups are not memory effects at all, but rather reflect other confounding variables, such as health, motivation, or differential experience effects.

Theoretical Perspectives to Aging and Memory

Memory Stage Theory

Memory stage theory separates memory into the sequential components of remembering. As diagrammed in **Figure 1A**, information first has to be experienced at time 1 (i.e., encoding), then it has to be maintained over a retention interval from time 2 to time *n* (i.e., storage), and finally it has to be reproduced when memory is tested at time *n* (i.e., retrieval). Early researchers believed that adult age differences in memory were located primarily at retrieval, the final of the three stages of memory. For example, in the laboratory it was demonstrated that age differences in free recall of a word list (with instructions such as, 'Write down all the words you can remember having seen on the list earlier') were eliminated when recognition memory was used (with instructions such as, 'Pick out the words from this list that you saw earlier'). Because the use of a recognition memory task is assumed to reduce the retrieval requirement of the memory task, it was then inferred that the locus of the age effect must be retrieval. When retrieval requirements are large, such as in free recall, age differences are large; when retrieval requirements are minimal, such as with recognition memory, age differences are small or even non-existent. Such findings were prevalent in the 1960s and early 1970s. More recent research, however, has clearly demonstrated reliable age differences in recognition memory, and stage theory lost its appeal because of the methodological difficulties in isolating one memory stage from another in different age groups. In order to isolate retrieval, for example, everything must be held constant up until the time retrieval is tested. This is difficult to accomplish in aging research, however, because adults of different ages may process information differently at one of the earlier stages, thus violating the requirement that all be held constant until retrieval.

One interesting phenomenon that is associated with the retrieval stage of memory is the 'tip-of-the-tongue' state. There are many instances in everyday life when we cannot remember something even though we know that we know it. One way that this tip-of-the-tongue state has been simulated in the laboratory is by having subjects read definitions of words and then attempt to remember the word that goes with each definition. A tip-of-the-tongue state occurs when retrieval is blocked and the subject cannot think of the word that goes with the definition, even though he or she is absolutely confident that the word is known. In fact, subjects can often remember specific partial information about the words (e.g., number of syllables, the beginning letter of the word) even though they cannot access the word itself. Research shows that older adults experience more tip-of-the-tongue states than younger adults, are slower at resolving the retrieval blocks, and often have less access to partial information. However, when given sufficient time to resolve the tip-of-the-tongue block, older adults eventually may come up with the words, just like younger adults. The same result occurs with name-finding and picture-naming tasks.

For reasons not directly related to memory stage theory, memory research in the 1970s and early 1980s focused heavily on the encoding stage of memory. This focus on encoding was due to the development of a conceptual view of memory, the 'levels of processing' framework, that proposed that the ability to remember was determined by the extent of semantic processing engaged in during the encoding of the to-be-remembered information. For this reason, most cognitive aging researchers during this period focused on encoding processes and aging. That emphasis may have been well placed for several reasons. First, the memory performance of older adults, relative to

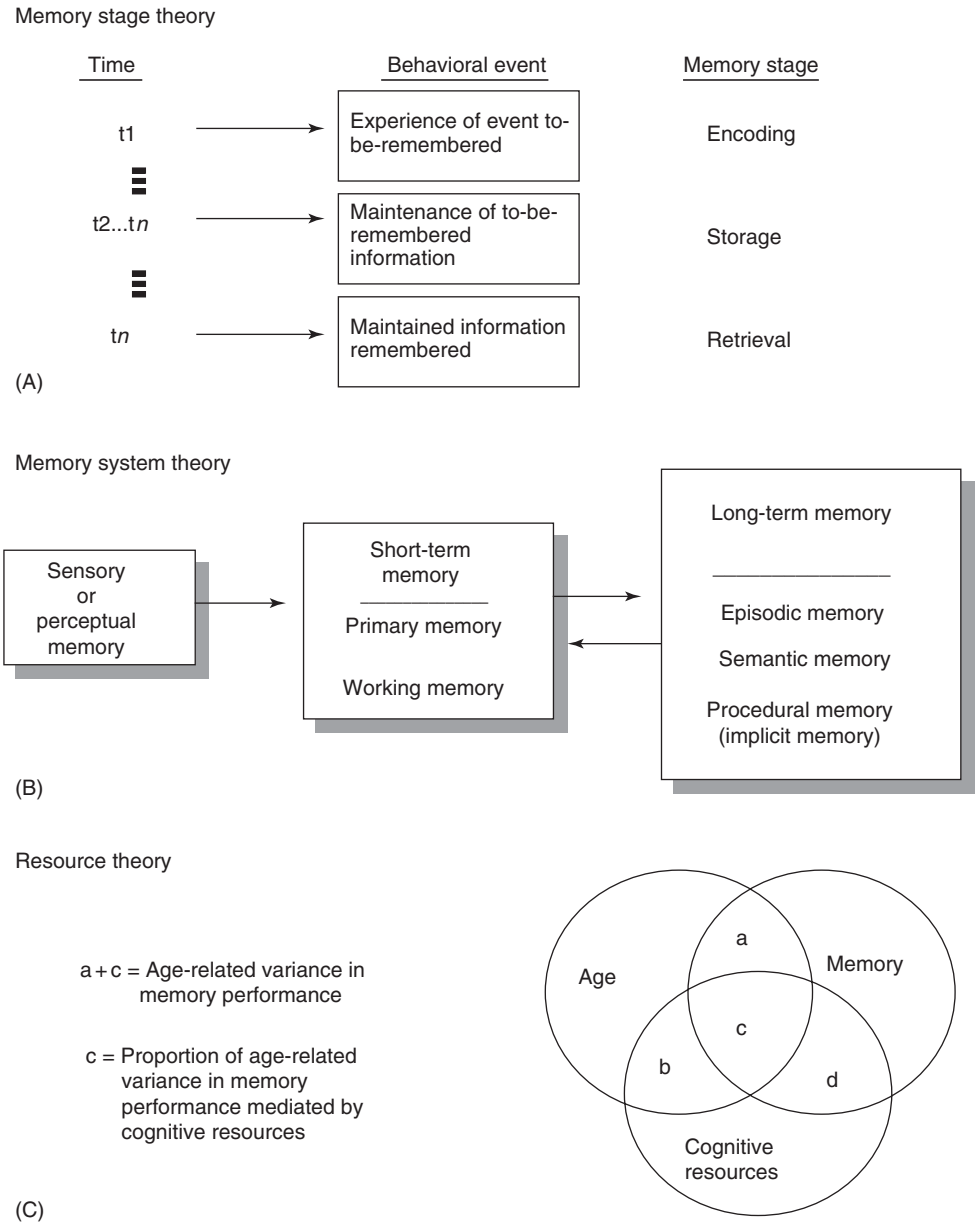

Figure 1 Three conceptualizations of memory useful in describing age differences in memory: (A) memory stage theory; (B) memory system theory; and (C) resource theory.

younger adults, is detrimentally affected by performing a divided attention task during the encoding stage of a memory task, but not if the divided attention task occurs at retrieval. Furthermore, data from neuroimaging studies with older adults suggested that age-related memory effects may be greater at encoding than at retrieval. By using functional neuroimaging, researchers are able to determine which areas of the brain are active while subjects perform different cognitive tasks. In several laboratories, it has shown more activation in the left hemisphere during the encoding stage of a memory task and greater activation in the right hemisphere during the retrieval stage, a lateralization of encoding and retrieval in different regions of the brain. When neuroimaging studies are done with subjects of different ages, the activation in the left prefrontal lobe seen in young adults during encoding is greatly attenuated in older adults. However, few age differences are detected in the level of activation in the right hemisphere when subjects are engaged in retrieving information from memory. This neurological evidence suggests that memory problems with aging may be more involved with encoding than with retrieval.

Memory System Theory

Another conceptualization of memory that has both behavioral and neurological support considers memory not to be a unitary construct, but rather a collection of different component systems. As can be seen in **Figure 1B**, memory is broken down into sensory memory, short-term memory, and long-term memory. Short-term memory is further divided into primary memory and working memory, and long-term memory is divided into episodic, semantic, and procedural memory. These systems differ in the nature of memory representations and how these representations are maintained and retrieved. They also differ considerably in the effects of aging.

Sensory-Perceptual Memory After an event is experienced, it is first represented briefly in the sensory-perceptual system. Here the information is represented as it is processed and analyzed by the perceptual systems. There has been very little work on this type of memory and aging, but some research does suggest that older adults are less efficient in this early type of processing, especially in the visual system. It should be pointed out, however, that differences in sensory-perceptual processing would be an unlikely candidate for an explanatory construct for memory differences found in later systems because later memory differences are not consistent, but vary according to what system is examined. Adequate perceptual processing of the to-be-remembered stimulus would seem to be a requirement for all types of long-term memory, and the fact that some long-term memory systems are minimally affected by aging while others show large effects would not support an explanation that relied solely on faulty perceptual processing at the very early stage of processing the information.

Short-Term Memory Short-term memory is conscious awareness. It consists of information that is currently in mind, a combination of incoming information being attended to from the sensory-perceptual system and information being retrieved from long-term memory to interpret and process the incoming information. For this reason, short-term memory is thought of as a complex information-processing system that involves a combination of storage (i.e., keeping things in mind) and processing.

The storage component, or how many things you can keep in mind at one time, is often called 'primary memory.' The digit span test found on most intelligence tests is a measure of primary memory. In this test, different strings of single digits are called out, and the subject has to repeat the digit strings. If the subject is correct, then an additional digit is added to the next string. Digit span is measured as the longest string of digits a person can repeat without making an error. When primary memory is tested by digit span tests with subjects of different ages, no reliable age differences are found.

Age differences are found, however, on measures of short-term memory that take into account both processing and storage. 'Working memory,' unlike primary memory, requires subjects to keep information in mind while engaging in another processing task at the same time. One commonly used working memory task is called reading span. Subjects read a series of short sentences (e.g., 'The boy ran with the dog') and answer questions about the sentence (e.g., 'Who ran?'). At the same time, subjects have to remember the last word in each of the sentences (e.g., 'dog') and report the words when told to do so. The number of sentences presented prior to recall of the words ranges from two to seven, and working memory capacity is the longest list of sentences for which subjects can correctly report the words. Because working memory tasks require simultaneous storage and processing, it is a better simulation of the everyday information processing required to understand language, solve problems, or make decisions. Other working memory tasks have been developed that involve different kinds of information processing such as arithmetical calculations (computational span) or spatial manipulations (spatial working memory). With all of these tasks, large, reliable age differences are found. Therefore, while the more passive primary memory tasks, such as simple digit span, do not show age differences, differences are found with working memory measures. As is discussed later, working memory capacity is considered by many researchers to be a fundamental mechanism for memory processing. Because age differences exist in working memory, and because working memory is assumed to be a fundamental requirement of processing efficiently at encoding and retrieval, this measure has been considered an important factor in determining the complex age differences seen in long-term memory.

Long-Term Memory Long-term memories are not kept in conscious awareness like short-term memories, but instead have to be retrieved when needed. Long-term memory is usually divided into episodic memory, semantic memory, and procedural memory.

Episodic memory Episodic memories are those recollections that are actively retrieved from personal experiences. In other words, the contextual information about when and how an event was originally

experienced is used to guide retrieval. 'Where did I leave my keys?' 'When did I last see Mary?' What was I supposed to get at the grocery store?' Each of these questions involves remembering by reconstructing the context of the original experience.

Episodic memory has been studied extensively by cognitive aging researchers. Typically, a list of words, or some other to-be-remembered information is presented to subjects, and then later, after a retention interval, memory is tested. Because the words were already known to the subjects, the memory task is to remember the words in the particular context of the presented list. While the magnitude of age differences varies considerably among different memory tasks using different materials, older adults tend to have greater problems with episodic remembering than do younger adults. The variable that seems important in determining the magnitude of age differences is the degree to which the memory task involves deliberate processing by the subject. At both encoding and retrieval, the more intentional processing required to perform the task, the larger the age differences that will be found with that task.

For example, if the to-be-remembered materials are complex pictorial scenes such as those that might be found on picture postcards, old adults remember them as well on a later memory test as younger adults. Because the pictorial images are rich in both semantic and visual context, little deliberate processing is necessary to encode the materials. This is called 'environmental support,' because the task and materials themselves provide the cues necessary for optimal performance. When the pictures are deleted of their rich content, however, either by taking out perceptual detail or by rearranging the components of the pictures to reduce meaningfulness, age differences are produced. Age differences can be increased by reducing environmental support and thereby increasing the requirement for deliberate processing on the part of the subject to adequately encode the information.

The same phenomenon is found for retrieval from episodic memory. The way in which the retrieval task is structured can influence the magnitude of age differences on the task. Earlier, it was mentioned that age differences in free recall are larger than age differences in recognition memory. In free recall, after seeing a list of common words, subjects are asked to recall as many of the words as possible. Other than the instruction to remember the words, no other cues are provided to the subjects, and age differences are typically very large on these free recall tasks. If recognition is used, however, age differences are considerably reduced. Instead of trying to free recall the items, subjects in a recognition task only have to pick out the words they saw earlier on a longer list of words presented at test. Compared to free recall, a recognition task provides the very best retrieval cues, the words themselves, and little deliberate retrieval is required to perform the task. Thus, age differences are greatly reduced because of the environmental support provided by the recognition procedure.

Because episodic memory is so dependent on contextual information, one of the reasons for older adults' poorer performance in these tasks is probably their inability to encode contextual information easily. Older adults, for example, do not do as well as younger adults in identifying the way in which information was presented to them. They do worse when asked to remember whether a word was presented in upper or lower case, presented auditorially or visually, spoken by a male or a female voice, in one color versus another, or in the upper part of a computer screen or the lower part. These tasks (often called source memory tasks) require subjects to remember contextual detail. Because older adults encode less contextual detail, they do not do as well on these tasks. In fact, because older adults encode less context, they are even less able to distinguish between events actually experienced from those just imagined, a process called 'reality monitoring.' In a typical reality monitoring experiment, subjects either read words at encoding or generate words in response to some cue. Older subjects have greater problems in determining whether remembered events were the ones read or the ones imagined in response to the cue. Older adults also have problems in being able to come up with new words when given a cue (e.g., 'Give me the name of a fruit not mentioned before'). Older adults are more likely to generate words generated earlier in the task (inadvertent plagiarism).

Because of the dependence of episodic remembering on context, an important principle in determining the level of performance is the 'encoding specificity' principle. The encoding specificity principle states that the optimal condition for episodic remembering is when the contextual situation at retrieval matches the contextual situation that was experienced during the original encoding. Because older adults encode less contextual detail, they should be less influenced by the encoding specificity principle. Some studies, however, find that young and old subjects are affected in the same way by changing the contextual situation at retrieval, such as using cues at retrieval different than those used at encoding. Other studies, however, find that the older subjects are less affected by contextual change from encoding to retrieval. The distinguishing feature of

these studies seems to be the extent to which the context at encoding was integrated with the to-be-remembered information. Studies showing equal encoding specificity effects often involve cues and memory targets that are already integrated and do not require deliberate processing to relate them together. The studies showing less encoding specificity in older adults, on the other hand, involve situations in which integration of the target with the context requires deliberate processing by the subjects. This supports the view stated earlier that episodic memory deficits in older adults are increased by increases in the processing requirements of the task.

Older adults also have more memory illusions. They are more likely than young adults to produce false memories, producing a word that was not presented on an earlier list because it is related to words presented earlier. For example, when words related to the word 'sleep' are presented (e.g., nap, bed, snore), they are more likely to falsely recall the word sleep when later asked to recall the words on the list.

One interesting type of episodic memory, 'prospective memory,' involves remembering to do something in the future rather than remembering something from the past. 'Don't forget to take your medicine at noon today.' 'When you see Bill, tell him I called.' 'Will you pick up the kids after work today?' All of these memory tasks produce an intention to remember in the future, or remembering to remember. Age differences are typically found with simulations of prospective memory tasks performed in the laboratory (e.g., press a key when the face has a beard, ask for a red pen when signing your name, or phone the laboratory at a certain date). With simple laboratory tasks, however, such as pressing a key when a certain word is presented, age differences in prospective memory are not found. Again, the determinant of whether age differences are found seems to be the degree of deliberate recollection required to perform the task.

In one study, age differences were found when subjects were asked to press a computer key every 10 min while performing another computer cognitive task (time-based prospective memory), but were not found when they were asked to press the key when a certain cue word appeared (event-based prospective memory). Because this particular event-based prospective memory task involved less deliberate processing given the external cue, age differences were not found. When no external cue was provided to trigger remembering as in the time-based task, age differences emerged.

Older adults themselves commonly describe their episodic memory problems as limited to remembering recent events. 'I can remember well what happened to me years ago; I just can't remember what I did yesterday.' This anecdotal self-description of memory problems implies stability for remote memories coupled with loss of recent episodic memories. There are problems, however, in studying very long-term memories. Older adults remember events from their remote past, but it is difficult to judge the accuracy of these recollections. Furthermore, they typically recollect salient events from the past that would be remembered regardless of when they occurred. And, finally, it is difficult to control for rehearsal (i.e., previous retrievals) during the long-term retention interval. When these variables have been controlled, research has shown that remembering is directly related to retention interval. Unlike the conclusion reached in the self-description, memory performance gets worse as the time between the original experience and the subsequent retrieval increases. This has been shown by collecting memory data at high school reunions, examining memory for foreign language skills learned in school over the life span, testing memory for the names of grade school teachers, and by examining autobiographical facts from diaries over an 18-year period. In these cases, there is some control of salience, good criteria of accuracy, and better control of rehearsal over the retention interval. The conclusion is clear: the older the memory, the more difficult it is to remember. It should be pointed out that while using retention intervals measured in years provides interesting data about remote memories, age is confounded with retention intervals in such studies. This constrains their interpretation in terms of understanding the effects of aging.

Semantic memory In order to remember something episodically, some aspect of the original encoding context has to be reinstated at retrieval. Often, however, we remember information without reference to how or when it was originally learned. We have access to a great deal of world knowledge that has lost all connection to the context of its original learning. 'Who was the first president of the United States?' 'What fruit is yellow and good with cereal?' 'What is your grandmother's maiden name?' Semantic memory is retrieved conceptually rather than contextually and represents accumulated organized knowledge.

Measures of semantic memory are often considered 'crystallized intelligence' on most intelligence tests. The general information test (answering questions such as 'What was Mark Twain's real name?') and vocabulary test (providing definitions of words) on the Wechsler Adult Intelligence Scale, for

example, measure access to conceptual knowledge. Few reliable age differences are seen on these tests, assuming educational level between age groups and other demographic variables are held as constant as possible. In fact, older adults often do better than younger adults on vocabulary tests until very late in life.

If young and old subjects were to differ in semantic memory, it most likely would reflect the way in which semantic memory was organized by the different age groups. There is little evidence, however, that the structure of organized knowledge differs in younger compared to older adults. One measure of semantic memory organization is the free association test. For example, words are given one at a time, and subjects are asked to come up with the first other word that comes to mind. If the associative structure of semantic memory differed between age groups, then this would be indicated by differences in responses given on free association tests. No age differences are found, however, in free associations to words, free associations to pictures, or in generation of category instances to category names such as 'fruit.' As mentioned earlier, older adults are less efficient and often take longer to retrieve semantic information, but the information in most cases can be ultimately retrieved.

Procedural memory Often memory has its effect automatically, without conscious awareness. 'Procedural memories,' once acquired, are automatic and do not require deliberate recollection at all. Once learned, we ride bicycles, type on our computers, and understand language without devoting a great deal of attention to the task. Procedural memories involve motor and cognitive skills.

Ingenious laboratory procedures have been developed to examine 'implicit memory,' procedural memory tasks that show memory effects even when subjects are not aware that remembering is occurring. For example, subjects first examine a list of words while performing some cover task such as rating the words for pleasantness. They then perform a series of other tasks unrelated to the word list seen earlier. Finally, they are given the task of completing presented word stems with any words that come to mind (e.g., 'por_____'). Compared to control subjects who did not read the words on the initial list, subjects that read those words will produce a word seen on the initial list more often, even though they are completely unaware that the word was presented earlier. If they are explicitly asked to use the word fragments to remember the words read earlier, large age differences are found. However, when asked instead to complete the fragments with any word that comes to mind and not implying a memory task, young and old show equal implicit memory. Age differences are typically not found on implicit memory tests, and when they are, they are very small compared to explicit memory differences. Longitudinal studies have also shown age change in explicit memory but no age change in implicit memory.

In summary, the memory systems approach has been very useful in describing when significant age differences in memory are found. It is also clear that even within one type of memory, age differences can vary considerably depending on the nature of the task and the nature of the processing required to perform the task. For this reason, memory researchers have been searching for better explanatory power in accounting for age differences seen in memory.

Resource Theory

A third view of memory assumes that there is a limited amount of cognitive resources that can be devoted to any cognitive task. If aging is associated with a reduction in cognitive resources, then memory performance should be detrimentally affected. To date there have been some successful attempts to measure deliberate processing using the process dissociation approach. The process dissociation approach uses separate indices of a memory task, one index that measures the amount of controlled processing (recollection) and the other that measures familiarity. Using this approach, age differences are found in the controlled recollection component of recall and recognition, while no age differences are found with the familiarity component.

Other investigators testing resource theory have adopted the correlational methods commonly used by individual difference researchers. The typical approach of resource theory is to identify resource mechanisms that can be independently measured, and then to determine their role in accounting for age-related variance in memory performance. The circles in **Figure 1C** represent the variance in measures of the three variables of interest: age, memory performance, and some measure of the cognitive resources. The overlap in the variance of age and memory performance is represented by the overlap in the two circles (i.e., $a + c$). The proportion of the age-related variance in memory accounted for by the cognitive resource variable is represented by the letter c.

Several different theoretical cognitive resource constructs have been proposed. Methodologically, in order to show that a cognitive resource mechanism can account for a significant proportion of age-related variance, the mechanism must be adequately measured at

the same time memory is tested. Then regression statistical techniques can be used to relate the mechanism to age and memory performance, as in the figure.

A proposed cognitive resource mechanism that has been proven fruitful in accounting for age-related memory performance is the working memory construct mentioned earlier. Assuming that working memory is a basic processing resource for engaging in remembering, then individual differences in working memory should account for individual differences in age-related, long-term memory performance. Regression analyses have shown that measures of working memory can account for more than 50% of the age-related variance in a variety of different memory tasks (e.g., free recall, paired-associate learning, text memory).

An even more basic cognitive mechanism, perceptual speed, has proven to be even more effective in accounting for age-related variance in memory. Perceptual speed is the ability to perform simple perceptual motor tasks, such as deciding whether two digit or letter strings are the same or different (i.e., number or letter comparison) or placing digits next to the appropriate symbol on a sheet by using an answer key showing the correct pairings of digits and symbols (digit symbol substitution task). Many studies have shown that very little age-related variance in memory performance remains after controlling for perceptual speed. One typically used memory task is the paired associate task, in which a subject recalls a response word that goes with a particular stimulus word after seeing the stimulus–response pair earlier during encoding. In one study, only 1% of the age-related variance in paired associate recall remained after controlling for perceptual speed.

It should be noted that speed and working memory are not mutually exclusive, or even opponent mechanisms in the search for understanding age and memory. In fact, studies have shown that variance in working memory itself is largely accounted for by the perceptual speed construct. In one study, statistical techniques of structural equation modeling were used to test the relationship among perceptual speed, working memory, and episodic recall. Using this technique, paths among the variables and their directional strength can be determined. It was shown that age had no direct effect on episodic recall performance when speed and working memory were included in the model. Age influenced recall in two ways, but only indirectly. First, age had an effect on perceptual speed that had a direct effect on recall. And second, age had an effect on speed that had a further indirect effect on recall through working memory. In other words, the best model in accounting for age-related differences in episodic memory performance in this case included the constructs of both perceptual speed and working memory.

Another candidate for a contributing mechanism to age-related memory performance is 'inhibition,' the ability to focus on target information by actively reducing attention to distracting, extraneous information. It has been suggested that as people grow older, they lose their ability to inhibit task-irrelevant information. The uninhibited information then reduces the available working memory capacity available for processing of the memory task. Decreases in inhibition have been demonstrated in a variety of different tasks. For example, when asked to read a text passage that has irrelevant information in a different type font interweaved throughout the passage, older subjects have greater problems in reading and processing the text.

In general, speed and working memory are considered to be basic mechanisms that measure resources available to perform cognitive tasks. In a sense, they measure neural efficiency. Research has shown that even sensory function that declines with age (vision and audition) can account for age-related variance in memory tasks.

Moderating Effects of Other Variables

Even more active than the search for cognitive variables that can mediate the relationship between aging and memory performance has been the attempt to find variables that can serve as surrogates for the relationship. Because most cognitive aging studies are cross-sectional (comparison of different age groups at a point in time), variables confounded with different age groups are candidates for these surrogates. For example, because subjects in different age groups were born at different times and therefore had very different life experiences, birth cohort is one such variable. To investigate this, memory performance must be studied as change within the same subjects rather than as differences across subjects. When cognitive abilities measured by psychometric intelligence tests were studied in this way, it was found that the cross-sectional age differences are typically overestimates of actual age change. Rarely, however, are cognitive age differences in cross-sectional studies eliminated when cohort designs are used. In fact, when longitudinal designs are used to study age change in laboratory memory tasks using longitudinal analysis, results similar to those found in cross-sectional studies are found. Age differences found with longitudinal designs look like differences found in cross-sectional studies when cohort and practice with the tasks are controlled.

More specific within-subject factors have also been examined as moderators of the age-memory relationship. Health, educational level, socio-economic status, and occupation have all been measured in conjunction with age. To the extent to which these factors influence memory performance, they can influence the size of age differences on memory tasks. Controlling these factors, however, does not eliminate the age effects. Health status, for example, can influence how one performs on memory tasks. However, even though health can influence memory performance, studies have shown that age differences in memory are not reduced much by controlling for self-reported health status. And even when more objective measures of health are used, such as the number of prescription medicines, only about 20% of the age-related variance in memory performance is reduced by controlling these factors. Controlling for health, therefore, can attenuate the relationship between age and memory but not eliminate it.

One criticism of research on aging and memory has been its reliance on controlled laboratory tests of memory. It has been suggested that these tasks are contrived and do not overlap with everyday memory tasks performed by older adults. Laboratory tasks are not relevant to older adults and therefore do not adequately reflect their memory abilities. In other words, memory research has been accused of not being 'ecologically valid,' because of the artificial, controlled nature of laboratory procedures. Laboratory memory tasks are seen as similar to the 'formal remembering' required in school settings and very unlike the everyday remembering engaged in by older adults. For this reason, younger adults may do better in these tasks because of their familiarity with situations used in the laboratory to test memory rather than because of their age per se.

Because of this criticism, there have been a large number of ecologically valid, everyday memory tasks used with different age subjects. Again, although using more familiar tasks can reduce age differences in memory performance, in most cases significant age differences are still found with everyday tasks. Such memory tasks as remembering faces, remembering facts from written stories, remembering a route taken through a town, remembering performed activities, remembering and understanding prescription medication information, and remembering grocery items all show memory differences favoring younger adults.

Furthermore, other lines of research suggest that differential familiarity or differential experience is not the critical factor in determining age differences in memory. Even when using older students and comparing them to younger students to control student status, age differences remain on a number of memory and cognitive tasks. There are also a number of memory studies using non-human animal subjects that show reliable age differences in memory performance, even though animal subjects of different ages shared identical everyday experiences since birth.

The conclusion emerging from these studies is that successful aging is not the absence of change, but rather the adaptation to change across the life span. Memory change appears to be a normal consequence of the aging process, and while non-cognitive factors such as motivation, health, or differential experiences can modify the magnitude of age differences in memory, rarely can these factors substitute for age itself in accounting for memory differences.

Interface of Cognitive Psychology of Aging with Other Areas

Individual Differences

As evidenced by the discussion of resource theory earlier, memory researchers are combining the methodologies of experimental cognitive psychology with the correlational techniques of individual difference research. Correlational techniques of regression, path analysis, and causal modeling are being used to determine what mechanisms are responsible for age-related variance in memory performance. The research so far has been consistent in pointing out the importance of perceptual speed and working memory as important factors in producing differences in memory performance.

These statistical techniques are not new; they have been used by individual difference researchers for a long time. What is new, however, is the use of the techniques to test hypotheses that have been developed in the experimental cognitive psychology laboratory. This combination of research traditions brings new promise to the study of aging and memory.

Cognitive Neuroscience

The same conclusion can be reached about the growing field of cognitive neuroscience, the interaction between experimental cognitive psychology (laboratory studies of memory) and neuroscience (studies of brain structure and function). With the development of functional neuroimaging techniques such as PET and functional magnetic resonance imaging (fMRI), brain activation can be measured while subjects are actually performing memory tasks.

Cognitive neuroscience research suggests that the prefrontal cortical areas of the brain are the locus for working memory. These parts of the cortex show unique activation when subjects are performing working memory tasks. Older adults show differential patterns of activity in the prefrontal areas of the brain while performing a working memory task.

Another area of the brain, the temporal-parietal area (hippocampal area), was hypothesized to be responsible for deliberate processing in long-term episodic memory. This conclusion, however, came primarily from the study of neurological studies of brain-damaged patients. These studies require autopsies before definitive evidence can be provided about the damaged brain areas that are responsible for the behavioral deficits. More recent neuroimaging studies have validated this conclusion, showing changes in the activation of this cortical area in older adults.

One of the major age differences found in neuroimaging studies of memory is a loss of asymmetry in the activation. Older adults show more bilateral activation with tasks that produce primarily unilateral activation in young adults. One suggestion as to why activation occurs in both hemispheres in older adults is possible recruitment of brain areas to compensate for brain losses.

In summary, both individual difference techniques and neuroscience techniques are expanding the methodological tools available for hypothesis testing by the research scientists studying aging and memory.

Conclusions

Memory changes as people grow older. The changes are selective, however, and primarily occur in working memory and in episodic memory. In general, the more self-initiated deliberate processing that is required to either encode or retrieve the information, the greater the age differences. Much of the age-related memory differences can be accounted for by simple cognitive mechanisms such as perceptual speed. Non-cognitive variables, on the other hand, do not seem to account for age-related memory differences.

Memory, Strategies

J A Sugar, University of Nevada, Reno, NV, USA

Glossary

External Strategies – Methods for remembering that make use of tangible, physical objects, places, or people, for example, writing out a list of items to buy at the grocery store.

Internal Strategies – Methods for remembering that rely on internal mental processes, for example, creating mental images of items to buy at the grocery store.

Metamemory – Perceptions, beliefs, and knowledge about memory functioning in general, and one's own memory in particular.

Method of Loci – A formal memory technique in which a visual association is created between an item to be remembered and a location along a path through a familiar site (e.g., one's home).

Pegword System – A formal memory technique in which a visual association is created between an item to be remembered and a keyword (peg) that has already been learned in a familiar sequence, one such sequence being 'one is a bun, two is a shoe,' and so on.

Prospective Memory – Remembering to carry out intended actions.

Retrospective Memory – Remembering events that occurred in the past.

Rote Rehearsal – A method for remembering whereby items to be learned are repeated, silently or out loud, over and over again. Also called maintenance rehearsal.

Introduction

Memory strategies are techniques or methods for increasing the probability of remembering events in the past (retrospective memory) as well as events that are to take place in the future (prospective memory). A critical issue for gerontology is to understand the extent to which older adults can, and do, use effective strategies to remember. Knowing what strategies older adults actually use, and why they use them, can help in understanding the potential effects of age, cohort, and historical events on human information processing across the life span. The extent to which older adults can use effective memory strategies is important for improving older adults' quality of life by decreasing perceived need for dependent living, increasing self-efficacy, and reducing health risks. Furthermore, experiences of forgetting are among the most frequent complaints of adults as they age. Good strategies for remembering are numerous, and older adults do use some and have the potential to learn others that are effective. Research has shown that even people with Alzheimer's disease can benefit from instruction to improve their memory (*see* Memory).

Why Use Memory Strategies?

Development of Memory Strategies

Human memory is fallible and people are generally bothered when they forget, especially as they age. Indeed, a common myth about memory is that the best memory is one in which nothing is ever forgotten. However, there are significant pitfalls of having a so-called perfect memory, and the renowned case described by Luria of a person (called *S*) with an astounding memory demonstrated many of them. For example, *S*'s exact memory for people prevented him from recognizing them if they changed their clothing or had a different haircut. Of course, forgetting important things is not desirable, and high levels of forgetting are symptoms of a variety of problems, ranging from stress to dementia. Thus, memory strategies are valuable because, if they are effectively applied, they enable remembering things that one considers important and wants to remember but might otherwise forget. When a person adopts strategies to remember events, it indicates a high level of cognitive functioning. Proficient use of memory strategies is a sign of good cognitive management skills.

Throughout history, humans have devised innumerable methods for improving memory. These methods generally depend on the kinds of materials available as well as prevailing conceptualizations and models of mental activity. Consequently, the variety and use of memory strategies have changed over time. The oldest known memory strategy, the method of loci, dates back to about 500 B.C. and was attributed by Cicero to Simonides of Ceos, a poet. The method is a formal memory technique (also called a mnemonic) in which visual associations are created between items to be remembered and locations along a path through a familiar site (e.g., one's home). Then, to recall the items, one takes an imaginary walk along the path, and the locations cue memory for the items. It is a strategy that was devised to aid memory long before materials such as paper and pencils were available for writing lists and notes.

Today, a burgeoning commercial enterprise is designing, manufacturing, and selling devices to assist memory. Among these devices are reminder notebooks that include daily planners, calendars, expense records, and so on; electronic appointment books with programmable auditory and visual reminders; and pocket-sized electronic notebooks that can record spoken messages as well as respond to vocal requests to display stored information visually. In addition, some relatively new telecommunication devices are being used in novel ways as memory aids, for example, leaving messages for oneself on a telephone answering machine.

Relationship between Memory Strategy Usage and Memory Performance

The relationship between how good a person's memory is and the quantity and quality of strategies used has yet to be worked out. On the other hand, there is no dispute that effective strategies can significantly

improve memory performance. This improvement in memory has been demonstrated across a wide variety of memory strategies and materials to be remembered. Formal mnemonics, for example, have been shown to result in recall that can be two to seven times better than rote rehearsal. Combinations of memory strategies can produce impressive feats of memory. For example, young and older adults have been shown to be capable of increasing their digit spans (the number of digits in a sequence that can be remembered) from a typical average of between seven and 11 digits to 72 or more by creating associations between their existing world knowledge and groups of digits; by 'chunking,' or grouping, sets of digits; and by practicing these two strategies together in multiple sessions over an extended period of time.

Theories of how memory works offer some explanations for the relationships between the use of memory strategies and memory performance, although they generally only do so at a fairly global level. In the 'three-box' model of memory, for example, use of memory strategies affects whether information will be passed from sensory memory to short-term memory and, ultimately, to long-term memory. Information not passed from one stage of information processing to the next is thought to be lost, or forgotten. Furthermore, better use of strategies increases the likelihood of information being retrieved later. Thus, paying attention to information after it enters sensory memory leads to the information moving into short-term memory. Rehearsal is necessary to maintain an item in short-term memory, and more elaborate processing strategies increase the chances that the item will be stored in long-term memory for later retrieval.

According to the levels-of-processing model, items that are processed at a 'deeper' level (e.g., the semantic or meaning level) are much more likely to be retained than items processed at a 'shallower,' or more surface, level (e.g., the phonemic level). This theoretical approach has helped to convince memory researchers that rhyming, which depends on surface characteristics of words, is not a terribly effective memory strategy (*see* Memory).

Types of Memory Strategies

Strategies for remembering are typically employed when an event is deemed important enough to remember. Thus, more often than not, strategies are intentionally implemented, though with practice they may become quite automatic.

Memory strategies can be grouped in a number of different ways. The most commonly used categories include formal mnemonics, image-based strategies, general internal strategies, and external strategies. **Table 1** lists examples of each of these types of strategies.

Table 1 Types and examples of memory strategies

Internal memory strategies
Formal mnemonics
Acronyms (e.g., HOME for Great Lakes)
Method of loci
Linking items with a story
Pegword method
Imagery-based strategies
Bizarre images
Interacting images
General internal strategies
Alphabetical searching
Categorizing
Creating associations
Elaborating
Grouping
Rhyming
Rote rehearsal
External memory strategies
Address books
Appointment books
Asking others for reminders
Bookmarks
Calendars
Diaries
Lists (e.g., grocery)
Medication organizers
Object placement
Personal digital assistants (PDAs)
Photographs
Recipe cards
Reminder notes
Tape recorders
Timers
Video recorders

Formal Mnemonics

Formal mnemonics are systems for remembering that must be learned through instruction, generally because they are complex systems built upon an acquired core of knowledge. Formal mnemonic systems are analogous to the scaffolding of a building upon which the remainder of the house depends; they provide a framework on which to 'hang,' or incorporate, information to be remembered. Prototypical examples include the method of loci (previously described) and the pegword system. For the pegword system, visual associations are created between individual items to be remembered and keywords ('pegs') that have already been learned in a sequence, one such sequence being 'one is a bun, two is a shoe,' and so on. To recall the items, one uses the familiar sequence to cue the visual associations, which then call forth the items.

Active memory researchers, who are presumably familiar enough with the theoretical and empirical underpinnings of memory research to be considered experts on memory, eschew formal mnemonics for themselves and do not recommend them to others. Formal memory techniques require much effort to learn and constant practice to maintain. They are most readily applied to simple situations, such as learning a list of words, in which, unfortunately, their use is often outmoded by present-day materials and technology. For example, using the pegword system to learn a list of items to buy at the grocery story is unduly cumbersome when a written list would serve the same purpose and be much more efficient. Thus, although formal memory strategies can significantly increase the amount of information a person can recall, they are impractical for meeting people's needs for remembering in many situations of everyday life.

Image-Based Memory Strategies

Image-based memory strategies are methods for remembering that rely on internal mental processes of visualization. Examples include the creation of bizarre images and visualizing interacting images.

Memory psychologists report that they seldom use image-based techniques for remembering and that these techniques are among the ones they are least likely to recommend to others. Image-based techniques are also not spontaneously used by older adults. In general, older adults do not like to use memory strategies that they perceive as silly, and many of them consider creating bizarre images of relationships between objects as silly.

General Internal Memory Strategies

General internal memory strategies are methods or techniques for remembering that depend solely on internal mental processes. Examples include making an association between something familiar and an item to be learned, and organizing items into categories of objects that are similar to one another.

Three general internal strategies – rehearsal, categorization, and elaboration – are among those most frequently used and recommended by memory researchers. Rote rehearsal is the only general internal memory strategy that older adults tend to use spontaneously; in fact, it is their most preferred internal memory strategy.

External Memory Strategies

External memory strategies are methods or techniques for remembering that depend on tangible, physical objects, places, or people. Examples of external memory strategies that have wide applicability include lists, reminder notes, asking others for reminders, and object placement (placing objects where they will not be forgotten). And, instead of paper as the medium for notes, personal digital assistants (PDAs) are among the many modern technological devices that can be the vehicle for enhancing memory in a broad range of arenas. Other external strategies can be highly specific in their applications, for example, bookmarks, recipe cards, and organizers for sorting medications according to the schedule on which they need to be taken. Although external memory strategies are often called 'aids' rather than strategies, both internal and external memory strategies rely on higher cognitive functions for effectively reducing instances of forgetting.

Memory researchers report extensive use of external memory strategies. In fact, their favorite memory technique is to write things down, which has been referred to as 'the greatest memory strategy ever devised.' Although older adults claim to use external strategies frequently, they commonly view these types of strategies disapprovingly, as 'crutches.' They think that using techniques such as making a list or writing themselves a reminder note is 'cheating.'

Age Differences in Use of Memory Strategies

Empirical Findings

Research comparing the use of memory strategies by young and older adults demonstrates age-related differences in both the number and types of strategies people use. Compared to younger adults, older adults rely on a smaller repertoire of memory strategies. In addition to these quantitative differences, many studies report that the elderly tend to use fewer internal strategies and more external strategies than younger adults. What is interesting about this latter age-related difference is that external strategies are especially helpful for prospective memory, that is, for remembering to do something in the future, and this is one area of memory in which older adults often perform better than younger adults.

Learning how to remember new information is a primary, if not the primary, foundation of schooling. Students learn memory strategies while they are in school, and being in school furnishes an ongoing opportunity to learn and practice strategies for remembering. Not surprisingly, then, adults who are not in school rely on fewer, and less effective, memory strategies than adults who are in school. Older adults who are not in school even reject as valuable those strategies, such as categorization and grouping,

that are particularly effective for learning and remembering many kinds of information.

In the absence of being in school, other activities may provide an intellectually challenging environment that demands significant memory performance. Engaging in activities, such as the card game of bridge, may provide opportunities during later adulthood to continue to exercise the mental capacities required to learn and practice memory strategies. And research evidence suggests that older adults who do engage in activities that have high memory demands perform better on memory tests than older adults who do not participate in challenging activities.

Theoretical Considerations

When it comes to accounting for older adults' patterns of usage of memory strategies, theory is lacking. Studies have been primarily descriptive, reporting the results of surveys and questionnaires on older adults' ratings or rankings of lists of memory strategies in terms of how often they use them. While acknowledging that the elderly seldom spontaneously use some of the more effective strategies, such as categorization, researchers have turned their attention to determining possible benefits to older adults of instruction in how to use particular memory strategies. These studies demonstrate that elderly people can learn to use strategies that they do not typically use for a task, and that their memory performance can be significantly enhanced by applying such strategies. However, a remaining problem is that the resulting enhanced performance is often transient.

One highly plausible reason for older adults' infrequent use of those effective memory strategies that are very often used by today's young adults is that older adults may never have learned them before memory researchers came along to teach them. Sophisticated information-processing strategies are generally learned through formal educational experiences. The primary technique for remembering that today's older adults learned when they were children and young adults was rote rehearsal, and, as research has shown, it remains their favored strategy for remembering.

Beginning in 1879, with the work of Ebbinghaus, and continuing through the first half of the twentieth century, memory research was dominated by a preoccupation with rote rehearsal and the serial learning of lists of verbal materials, often specifically constructed to be as devoid as possible of meaning. Thus, it is not at all surprising that most of today's older adults, who were in school during the 1940s or earlier, learned that to memorize meant to practice rote rehearsal. In fact, it was not until the 1960s that a significant body of experimental evidence began to accumulate that confirmed the positive effects of categorization and grouping strategies on recall of verbal materials. These important historical facts relating to the development of thinking about, and use of, memory strategies must be recognized as critical factors in affecting the way today's older adults think about memory and the kinds of strategies they will tend to use when faced with a task requiring memory.

Instruction in Memory Strategies

Features of Instructional Programs

Contemporary instructional programs for improving memory come in different forms. Self-help books and tapes are becoming more and more numerous, and they are very popular. It is important to note that these instructional materials are commonly directed not at older adults, but at younger and middle-aged people in the business world, suggesting that the perceived need to improve one's memory through better use of effective strategies is recognized well before late adulthood.

Memory improvement programs typically contain an overview of how memory works, followed by separate lessons on half a dozen or more memory strategies. Each lesson includes a thorough description of a specific strategy with examples, followed by an exercise or assignment for practicing the technique. The techniques that are taught in instruction programs are almost always internal memory strategies, and all of the programs seem to include at least one formal mnemonic system. Although many of the self-help products have been on the market for decades, they have yet to be subjected to careful scientific scrutiny to examine the extent to which they work, assuming their lessons are actually followed.

Scientific studies of instructional programs for memory improvement have generally focused on teaching a single memory strategy in small group sessions conducted in an atmosphere similar to a classroom over a period of no longer than 4 or 5 weeks. These studies have demonstrated that older adults can learn new strategies and that their memory performance improves with the use of these strategies. On the other hand, the effects of these instructional programs often seem to be relatively short lived; older adults do not seem to continue to use these newly acquired strategies once outside the classroom.

Difficulties in demonstrating robust and lasting effectiveness of memory instruction may be primarily

due to three factors: an emphasis on internal strategies and formal mnemonics, the relative brevity of instruction, and the role of undispelled myths about memory and aging. Among the strategies most commonly taught to older adults is the method of loci. Despite its effectiveness with sufficient learning and practice, the method of loci, like other formal mnemonics, is not well suited to people's everyday needs for remembering because it requires much effort to learn and is not easily generalized to novel situations. Furthermore, the instructional period in scientific studies is usually brief relative to older adults' lifelong history of relying on only a select few memory techniques. To develop proficiency with new strategies, it is necessary to practice in sessions that are distributed over time and to get extensive practice in generalizing the use of a specific strategy to situations other than the one(s) for which it was learned.

Myths about memory and aging abound in our society, and belief in these myths has been shown to affect memory performance in older adults. Motivation and the effort to learn new, and more effective, memory strategies are certainly negatively affected by beliefs that significant memory losses are an inevitable consequence of aging. Without dispelling these myths, it seems doubtful that older adults could glean or maintain much benefit from instructional programs that focus on techniques alone.

Rather than teaching one or two formal techniques and hoping they will be applied to many different situations, instructional programs, research suggests, may be better off teaching a large repertoire of strategies from which older adults can choose those that work best for them. Because many of the most effective strategies have quite specific applications (for example, medication organizers), teaching a large repertoire also enables older adults to have many different strategies to call upon in different situations. Refresher courses also may be valuable in helping older adults to modify techniques that are not working well for them and to continue to augment their repertoire of strategies. Computer-aided instruction may have promise in this regard, although the problem of accessibility will have to be resolved first.

Unfortunately, few instructional programs teach about the wide variety of highly effective external memory techniques available and how to use them. What little research has been done in this arena indicates that the value of these techniques in the daily lives of older adults can be demonstrated immediately. In fact, it seems likely that instruction on external memory strategies would be even more effective if introduced with a discussion intended to dispel older adults' notions that external strategies are inferior methods for improving memory.

Finally, a good repertoire of strategies may require not only learning new, effective strategies, but also getting rid of old, counterproductive strategies. One such strategy, frequently used by older adults, involves storing valuable or important objects in 'special' places. This strategy results in significantly more forgetting than remembering. One reason is that the special place is specifically selected because it is a highly unlikely place for the object, which means that the person who put it there will, over time, be increasingly unlikely to remember to look for it in that location. Unfortunately, the fact that the special place is so unusual may also lead the person to be unduly confident that they will certainly remember where they put the object. This overconfidence then leads to the person ignoring effective memory strategies that could help him or her remember.

Value of Instructional Programs

There are obvious advantages to older adults, as well as to society, of offering instruction in memory strategies. They are all related to improving the quality of life of older adults. Advantages include maintaining older adults' independent living, improving their self-efficacy, and reducing their health risks, for example, through increased medication compliance. Evidence emerging from the research literature even suggests that instructing depressed and anxious people on how to improve their memory may help to alleviate their depression and anxiety (*see* Anxiety Disorders; Depression).

Too often, fears of family members and friends about an older loved one's perceived forgetfulness lead to premature, or unnecessary, institutionalization. Concerns about forgetting to turn off the stove, leaving the front door unlocked, or being stranded at night after headlights have drained their car battery can worry older adults as well as their families and friends. Appropriate instruction in the use of memory strategies and modern technology, however, can do much to alleviate these fears. Furthermore, instruction provides a more reasonable, appropriate, and economical alternative to institutionalization. For example, one can teach older adults how to effectively use lists and reminder notes to remember to carry out important actions in their everyday lives and to prevent memory failures that could jeopardize their safety. New products on the market furnish other means for reducing concerns about older adults' personal vulnerability, such as steam irons that shut themselves off after a short period of not being used, cars equipped with headlights that automatically shut

off within a few minutes of the ignition key being removed, and good medication organizers that can make it much simpler to monitor medication regimes.

Research has shown that even people with Alzheimer's disease can benefit from instruction to improve their memory. Psychological research and theoretical perspectives have already led to remarkable results in increasing specific instances of both retrospective and prospective memory in Alzheimer's patients. Using spaced retrieval, an instructional technique for improving learning and memory by gradually lengthening retention intervals with successful recall at shorter durations, Alzheimer's patients are being taught to remember names of common objects, face-name associations, and prospective memory tasks. The application of these methods for helping Alzheimer's patients to improve their memories is all the more significant because progressive memory loss is such a devastating aspect of this disease for the patients and their loved ones (*see* Dementia: Alzheimer's).

Such innovative, and successful, instructional programs provide convincing evidence that research on the benefits of memory instruction for improving the quality of older adults' lives is only just beginning and there is much more to be done.

Menopause

R G Gosden, Weill Medical College of Cornell University, New York, NY, USA

Glossary

Estrogen – The female sex steroid hormone, which is produced mainly by the ovary and placenta.

Follicle-Stimulating Hormone (FSH) – A polypeptide hormone from the anterior pituitary gland that is required for follicle growth and estrogen synthesis.

Luteinizing Hormone (LH) – A polypeptide hormone from the anterior pituitary gland that is required for ovarian steroid production and to trigger ovulation.

Menarche – The first menstrual period (menses), which occurs in the late stages of puberty.

Menopausal Transition – The few years preceding menopause when menstrual cycles become irregular and perimenopausal symptoms commence.

Menopause – The final period or menses occurring after natural depletion of ovarian follicles or from damage to or removal of the ovaries.

Ovarian Follicle – The developmental unit of the ovary consisting of an oocyte (immature egg) surrounded by somatic cells (granulosa and theca cells). It is responsible for estrogen production and, after ovulation, is reorganized to form the corpus luteum, which secretes progesterone and estrogen.

Progesterone – A steroid hormone mainly produced by the ovary and placenta.

Introduction

Menopause generally occurs in midlife while most women are still healthy and vigorous. The word *ménespausie*, meaning the cessation of menstrual flow, was coined in eighteenth century France; later it was shortened to ménopause and became adopted by the English language. Menopause is defined retrospectively after 12 months of amenorrhea as the last day of menses, although there is still a 5% probability of more cycles. The associated terms perimenopause and climacteric apply to the variable phase before and shortly after the last flow when estrogen deficiency symptoms are showing. Although menopause normally marks the final and irreversible termination of the female reproductive life span, fertility is not coextensive with menstrual cyclicity: there is relative subfertility in both the early and late years of the menstrual life span.

Menopause is a transitory biological phenomenon, but it also marks a social passage, the significance of which varies in different cultures. It has often been regarded as a negative reinforcement of the aging process and loss of sexual attractiveness. Yet, in some societies, past and present, it is considered a welcome relief from the burden of continuously bearing children and of menstruation. While biologists attempt to find ways of slowing the process of reproductive aging, many women are glad to embrace the change and regard it as an exciting new phase of life. This positive attitude surely bodes well for health care and enjoyment of the remaining decades of life.

Epidemiology

Age

The average age of natural menopause is remarkably consistent between countries and races (**Table 1**). The age distribution in a given population is wide and negatively skewed with a 5–95 percentile range of approximately 45–54 years (**Figure 1**). Menopause can occur at any age after menarche, although virtually all women are postmenopausal by age 60 years. The median age is a better expression of central tendency for population comparisons, being generally 49–51 years of age, although several years earlier in malnourished and historical populations.

Menarche and Socioeconomic Factors

During the past century, the age of menarche has fallen by 4 years to approximately 13 years of age in most developed countries, a trend that has now reached a plateau. This so-called secular trend is believed to be due to better nutrition, faster child growth, and changes in body composition, especially fat/lean body mass ratios. But there appears to have been little or no corresponding change in menopausal age over the same period, nor is there a correlation between the age of menarche and menopause. It appears, therefore that menopause is more independent than menarche of environmental factors, the corollary being that age-specific numbers of follicles in the ovary have probably been historically constant, in contrast to some evidence of declining sperm counts in men.

Table 1 Estimated median age of menopause in selected countries and races[a]

Country	*Year(s) of study*	*Race*	*Median age (years)*
Australia	1978	Caucasian	50.4
Czechoslovakia	1967	Caucasian	49.0
England	1951–1961	Caucasian	49.8
	1965	Caucasian	50.8
India (Punjab)	1966	Asian	44.0
Netherlands	1977	Caucasian	51.7
New Zealand	1967	Caucasian	50.7
Papua New Guinea	1973	Melanesian	47.3
Scotland	1970	Caucasian	50.1
South Africa	1971	African	49.7
	1971	Caucasian	50.4
Sweden	1974–1975	Caucasian	50.4
United States	1966	Afro-American	49.31
	1966	Caucasian	50.0

[a] Adapted from Gosden (1985).

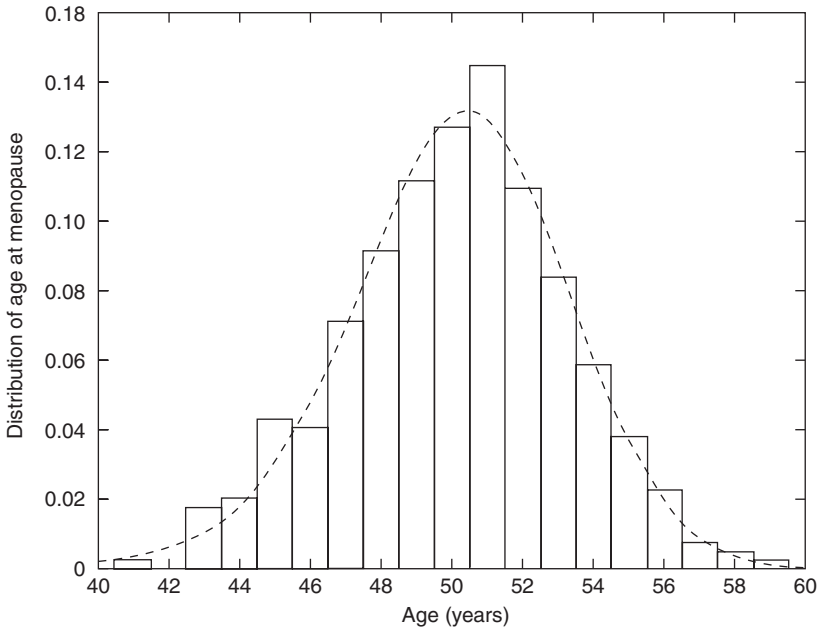

Figure 1 Distribution of ages at menopause in Caucasian American women. Adapted from Faddy MJ and Gosden RG (1996) A model conforming the decline in follicle numbers to the age of menopause in women. *Human Reproduction* 11: 1484–1486.

Genetics

A genetic foundation of menopause has been confirmed by the closer correspondence in timing in monozygotic twins than in dizygotic twins, and in blood relatives compared to unrelated persons. Moreover, a heritable tendency to undergo premature menopause can sometimes be attributable to genetic polymorphisms or mutations. Menopause is normally determined by many genes and, importantly, those that determine the formation of germ cells, the numbers of follicles, and the rate of follicle depletion by growth and degeneration (atresia).

Marital Status and Parity

There is little difference in menopausal age between women who have many children and those who have only one or none at all, although single women may have a slightly earlier menopause than married women. Since multiparity does not postpone reproductive aging and most follicles are lost by degeneration rather than ovulation, it is unlikely that steroidal contraception affects menopausal age, and most studies agree. On average, twin-prone women undergo menopause slightly earlier, but this cannot be caused by the higher ovulation rate since most follicles are lost by degeneration.

Tobacco Smoking

Menopause is advanced by 1–2 years in smokers compared to non-smokers and according to the number of cigarettes smoked. Tobacco smoke and tar constituents can damage the ovarian vasculature and damage follicle cells, polycyclic aromatic hydrocarbons being notable toxins that can interact with receptors in oocytes. The effects, if any, of recreational drugs on ovarian function and menopause have been less studied.

Disease, Drugs, and Radiation

Invasive diseases such as cancer and tuberculosis can spread to the ovaries and destroy follicles, hastening menopause. Less commonly, a viral infection may cause early loss of ovarian function. Ionizing radiation and some cytotoxic drugs, especially alkylating agents, destroy ovarian follicles in a dose-dependent manner and advance menopause in patients with cancer and autoimmune diseases. A radiation dose of only 2 Gray destroys half the follicle population and may temporarily cause amenorrhea; 20 Gray, or less in an older woman, causes irreversible sterilization.

Oophorectomy and Hysterectomy

Since the ovary is the principal source of estrogen in young, non-pregnant women, the surgical removal of both organs precipitates menopause. Removal of one organ or partial destruction has a small or only temporary impact on the menstrual rhythm, but it may shorten the reproductive life span. After uterine artery embolization or hysterectomy with intact ovaries, menopause may occur slightly earlier than normal if the ovarian blood supply is compromised.

Physiology

Ovarian–Pituitary–Hypothalamic Axis

Menstrual cycles depend on hormonal feedback between the ovaries and the hypothalamic–pituitary unit at the base of the brain. The pituitary hormones follicle-stimulating hormone (FSH) and luteinizing hormone (LH) are controlled by a decapeptide, gonadotrophin-releasing hormone (GNRH), which is secreted into portal vessels by neuronal terminals in the median eminence of the hypothalamus. Sequential and cooperative stimulation by FSH and LH is needed for the later stages of follicle growth and is obligatory for steroid production, ovulation, and luteal function. The length of the menstrual cycle varies between women and with age, having a median of about 28 days and with the luteal phase more constant in length than the follicular phase. It is determined by events in the ovaries, namely, the time to grow a follicle to maturity and the intrinsic life span of the corpus luteum.

Estradiol-17β is the most potent estrogen produced by the ovary, and the ovary is its principal source in non-pregnant, premenopausal women. Most of this hormone is produced by the dominant follicle destined to ovulate, and other follicles in the same cohort produce mainly androgens and undergo atresia before reaching maturity. Estradiol is produced by the cooperation between follicular granulosa and theca cells and requires stimulation by both FSH and LH (two-cell, two-gonadotrophin theory): LH promotes theca cells to secrete androgens, which diffuse to the granulosa cells where FSH promotes aromatization to estrogen. Growing follicles also produce the protein hormone inhibin B, which is a component of the negative feedback loop on pituitary function and is a clinical indicator of the size of the follicle reserve. When inhibin and estrogen levels rise in the follicular phase of the cycle, blood FSH declines, allowing only one follicle (or sometimes two) to survive to ovulation. In the absence of follicles after menopause, inhibin levels decline to near zero. Steeply rising estrogen from the dominant follicle triggers a positive feedback response from the pituitary by increasing both the pulsatility of GNRH secretion and sensitivity of pituitary cells. The surge of LH secretion triggers ovulation approximately 36 h later, and the collapsing follicle is remodeled to form a corpus luteum.

Actions of Ovarian Steroids

Steeply rising levels of estrogen during the follicular phase of the cycle stimulate the growth of endometrial glands and stromal cells in the uterus. They affect many organs and tissues, but especially those with high concentrations of estrogen receptors in the reproductive tract. The increased secretion of watery cervical mucins favors the survival and transport of sperm after coitus. At ovulation, estrogen levels temporarily fall and rise again from the corpus luteum, which produces much larger quantities of progesterone. This sequence of hormonal changes causes the endometrium to secrete a fluid that nourishes the embryo and becomes receptive for implantation. If conception fails to occur, the corpus luteum involutes, ovarian steroids decline precipitously, and the coiled vessels of the endometrium constrict, leading to menstruation. All of these changes are reversed after menopause – the uterine epithelium becomes thinner, the vaginal epithelium atrophies, and the rise in vaginal pH changes the bacterial flora. But they can be restored so effectively by treating with estrogen and progesterone that an embryo transferred from a donor can implant and establish a viable pregnancy in a postmenopausal woman.

The Follicle Population

Germline stem cells in the fetal ovary establish a fixed number of oocytes that combine with somatic cells to create more than a million primordial follicles at birth. According to conventional theory, these follicles cannot be renewed later in life. This store declines with age, faster during the last decade or more of the menstrual life span, until few remain at 50 years of age (**Figures 2** and **3**). Postmenopausal ovaries are normally completely sterile. Since there are normally only 13 ovulations per year in nonpregnant women and the average menstrual life span is 35 years, the great majority of follicles are wasted. Yet, many of the lost oocytes have fertile potential: they can be rescued by hormonal superovulation treatment, and, after *in vitro* fertilization (IVF), some produce embryos that are competent for pregnancy.

The Ovary and Estrogens After Menopause

Since the mature follicle is responsible for $>95\%$ of the circulating estradiol levels during the menstrual cycle, there is a profound fall in hormone levels after menopause. The postmenopausal ovary consists mainly of stromal tissue and fibrous remnants of corpora lutea (**Figure 3**). Surgical removal of postmenopausal ovaries has no significant impact on circulating estrogens, although the organs are a minor source of androgens.

A profound change takes place in the profile of circulating steroids after menopause (**Table 2**). The

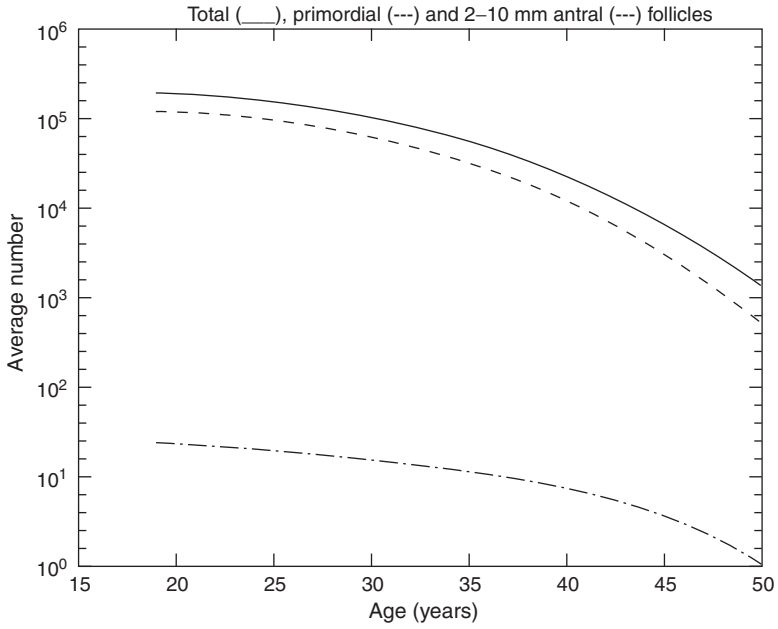

Figure 2 Numbers of follicles at different stages (total, primordial and antral) in human ovaries in relation to age (Faddy and Gosden, unpublished).

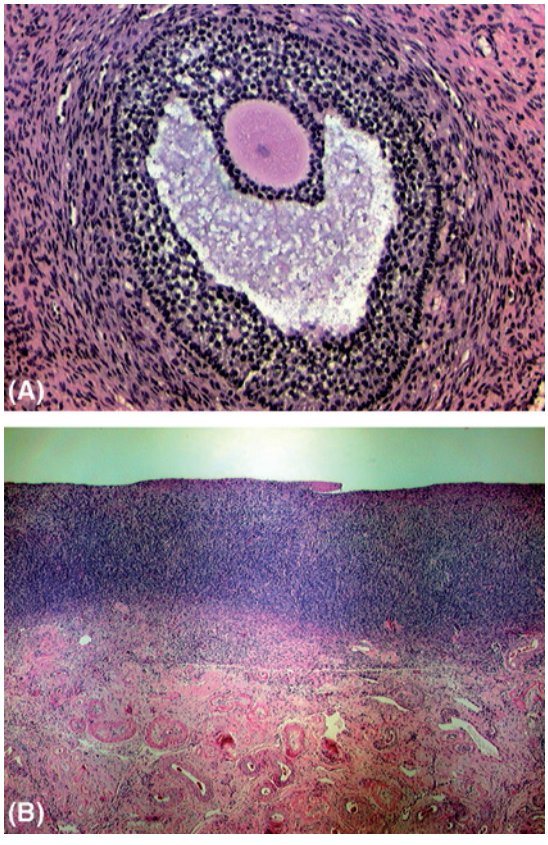

Figure 3 (A) High magnification of a growing follicle from the ovary of a woman of reproductive age showing a central oocyte surrounded by hormone-secreting granulosa and theca cells. (B) Low magnification of the ovary of a postmenopausal woman showing a complete absence of follicles.

principal estrogen changes from estradiol-17β to the less potent steroid, estrone, whose main source is extraglandular rather than the ovaries. Progesterone levels remain at a low plateau when ovulation ceases. The weak androgens, androstenedione and dehydroepiandrosterone and its sulfate, are mainly produced by the adrenal cortex and serve as precursors for conversion to estrone in adipose tissue, muscle, and other sites. In older women, there is a decline in the output of adrenal steroids. Body composition, especially adipose mass, affects the production of postmenopausal estrogens, which may account for obese women being slightly protected from hormone deficiency symptoms.

Perimenopausal Symptomatology

A wide range of symptoms is associated with the perimenopausal phase of life: hot flashes, nocturnal sweats, migraine, breast tenderness, palpitations, irritability, depression, and loss of sex drive. Symptoms of menopause are hard to dissociate from natural age changes, and none are absolutely specific to estrogen withdrawal. A majority of women experience some perimenopausal symptoms (80–85%), but the frequency is affected by cultural factors, domestic circumstances, and some medical conditions. The most common symptoms are vasomotor, which are centrally driven, physiologically inappropriate thermoregulatory reflex episodes. Since they are effectively treated by estrogen replacement

Table 2 Ovarian steroids during the menstrual cycle and following menopause[a]

Steroid	*Blood production rate (mg/24 h)*				*Peripheral plasma concentration (pg/ml)*			
	EF	*MC*	*ML*	*PMP*	*EF*	*MC*	*ML*	*PMP*
Estradiol	0.074	0.429	0.258	0.006	55	318	191	7

therapy, they have a stronger claim of being dependent on hormonal changes at menopause. Flushing and nocturnal sweating generally begin a year or two before menopause, peaking shortly afterward and usually tapering off. Symptoms can be more intense after surgical menopause of younger women, probably because estrogen levels fall more precipitously than during natural aging. By this time of life, degenerative diseases – such as non-insulin-dependent diabetes, osteoarthritis, cancer – have begun their inexorable rise with age, but only osteoporosis resulting from bone demineralization appears causally related to estrogen withdrawal. Bone loss accelerates rapidly in the first few postmenopausal years before settling down to a moderate rate for the rest of life. It often goes unnoticed until an accident or compression fracture occurs years later. Men suffer the consequences of brittle bones later in life because testosterone levels are maintained longer than estrogens in women.

Menopausal Transition and Reproductive Aging

A staging system for monitoring pubertal development was devised many years ago by J. M. Tanner; recently, an attempt has been made to create an equivalent system for reproductive aging and the menopausal transition (**Figure 4**). A major problem with any classification is that not every woman goes through an identical sequence of stages from optimal fertility (-5) to ovarian senescence and postmenopause ($+2$), and there is a lot of variation in the age at which they enter stages and the duration. Some women have a prolonged phase of irregular cycles called the menopausal transition (stages -2, -1) before becoming acyclical, whereas others skip stages and have an abrupt transition from regular cycles to postmenopause. Generally, the menopausal transition lasts about 4 years from onset until menopause.

To the extent that follicle numbers decline continuously, reproductive aging can be considered to begin at birth, but it is more useful to consider the commencement of infertility, which is most clearly revealed from historical and contemporary populations that never practiced contraception (**Table 3**). The time taken to conceive, the incidence of miscarriage, and the frequency of birth defects and obstetric complications all increase gradually from about 30 years of age, and more rapidly at the end of the decade. By 40 years old, half the population is effectively sterile, even though most women can expect 10 or more years of ovulatory cycles. Yet, while cycles continue, the possibility of conception remains and contraceptive precautions should be considered. While the frequency of sexual intercourse and the quality of sperm have both started to decline by these ages, the ovaries are believed to be primarily responsible for the onset of reproductive aging, which manifest before other organ systems. Since fertility treatment involving egg donation from young women to older recipients produces high pregnancy success rates, oocyte aging is evidently the factor primarily responsible for declining fertility.

Menopausal transition is marked by variable cycle lengths of <20 days and >35 days interspersed with more normal cycles. Episodes of amenorrhea >60 days in duration become more common, as do anovulatory cycles. Also, the character of apparently normal 28-day cycles subtly changes in advance of the menopausal transition. Follicles grow faster in the early stages of the cycle and estrogen levels may elevate earlier, leading to a slightly truncated follicular phase. Serum FSH levels rise: levels exceeding 10 mIU/ml early in the cycle indicate that the ovarian reserve is becoming depleted and fertility is already reduced. Other serum biomarkers, notably inhibin B and anti-Müllerian hormone, are useful for estimating ovarian reserve, as are the clomiphene citrate challenge test and the antral follicle count from ultrasound scanning. None of these tests, however, can provide a long-range and accurate prediction of the timing of menopause.

Premature Menopause

In addition to significant numbers of young women undergoing medically induced menopause, about 1 in 100 spontaneously undergo premature ovarian failure (POF) before 40 years of age. Most causes of POF are unknown, but genetic and iatrogenic factors have been identified (**Table 4**). Some genes that are critical for germ cell formation are encoded by the X chromosome, and, since only one of a pair is fully active in females, the loss of a whole chromosome or a deletion or translocation can cause POF or even gonadal dysgenesis. The so-called Turner genes are in the pseudoautosomal region at Xp11-22, where both homologues are normally active. Another critical region for oogenesis is on the long arm of the X chromosome (Xq13-26), where the identities of several candidate genes are known. In addition, some genes associated with POF are encoded on autosomes, including *Fu/cL2, FSHR,* and *GALT,* which is involved in galactose metabolism; its mutation is associated with destruction of follicles. The symptoms associated with POF are similar to those of women undergoing the change at the normal age, namely, anovulation and hypo-estrogenism, but the overall health impact is greater. There are additional years of bone demineralization, and a study of American Seventh Day Adventists showed that POF was associated with a higher total risk of mortality at all postmenopausal ages.

Autoimmune damage involving infiltration of ovarian tissue with immunocompetent cells and circulating ovarian autoantibodies may account for up to 30% of all cases of POF. Oophoritis is sometimes associated with Addison's disease and thyroid autoimmunity, perhaps because other endocrine organs share common antigens with the ovary.

The most common iatrogenic cause of amenorrhea is hysterectomy, but if the ovaries are preserved, the benefits of cyclical hormone production continue almost until the normal age of menopause. In recent decades, there has been a steady increase in iatrogenic POF corresponding to the improving survival rates among cancer patients. As mentioned previously, some drugs and radiation damage the ovaries according to dose and age.

Table 4 Premature ovarian failure (menopause)

Category	*Types*	*Examples*
Karyotype	X chromosome monosomy, deletion and translocation	Xp11-22, Xq13-26 (critical regions)
Genic	X-chromosome	*FMR1* premutation, *BMP15*,
	Autosomal	*FOXL2, FSHR, GALT*
Autoimmune	Cell-mediated, ovarian autoantibodies	Addison's disease, thyroid autoimmunity
Iatrogenic	Reproductive surgery	Partial oophorectomy
Idiopathic	Cytotoxic treatment for cancer, etc.	Chemotherapy, radiotherapy

Comparative Biology and Evolution

Menopause occurs universally in women by middle age. Hence, women can look forward to at least one-third of their lives in a postmenopausal physiological condition. As a fraction of the maximum life span, the number of postreproductive years in our species is exceptional compared to virtually all other animals for which reliable data are available. In captivity, and occasionally in the wild, a few chimpanzees and macaque monkeys reach a brief postreproductive phase of life with elevated serum FSH levels and low estrogens, indicating that primary ovarian failure has occurred. Non-primates do not have menstrual cycles and, strictly, cannot undergo menopause; yet all animals lose follicles with age and, if they live long enough, will eventually become sterile and estrogen deficient.

From an evolutionary standpoint, menopause is perverse because it prohibits reproduction and further transmission of genes to the next generation, as well as potentiating some degenerative changes. Whether the explanation for menopause is that it is an artifact of civilization (i.e., through prolonged survival) or a species adaptation (kin selection) continues to be debated. Adaptive theories, such as the grandmother hypothesis, propose that, because of the greater obstetric risks of reproduction later in life, it is advantageous to sacrifice one's own reproductive potential and instead devote energy to assisting daughters and other relatives in rearing children. Although this evolutionary interpretation is challenged by many comparative animal biologists, the positive outlook on menopause is sometimes welcomed as a counterbalance to the generally pathobiological view of the medical community.

Treatment and Prevention

Hormone replacement therapy (HRT) is controversial because menopause is a milestone in a natural process of reproductive aging. Yet, the symptoms of estrogen deficiency are sometimes so distressing that women seek medical intervention; this is more important for women who undergo premature menopause. Treatment delivery options for estrogen replacement include oral, subcutaneous, transdermal, and vaginal routes, in doses adjusted to age, needs, and circumstances. Coadministration of a progestin in women with an intact uterus minimizes the risk of endometrial cancer but carries the disadvantage of reinitiating menstrual flow. The Women's Health Initiative study of more than 16 600 older American women using a formulation of estrogen plus progestin found that the health benefits did not outweigh the risks of cardiovascular disease, breast cancer, pulmonary embolism, and stroke. Consequently, HRT is now recommended for the shortest time necessary and at the lowest effective dose, and many women have sought alternatives, including greater physical activity, dietary supplements, non-steroidal medications, and complementary and alternative medicine. Vaginal dryness is an indication for topical treatment with estrogens, but, since sex drive does not abruptly stop after menopause, HRT is not an indication for improving libido. The benefits and long-term side effects of prescribing androgens for these women are still controversial.

Establishing pregnancy after irreversible ovarian failure requires the donation of oocytes or embryos from a fertile woman. These IVF procedures have in exceptional cases established pregnancies in women past the natural age of menopause, up to 66 years of age. On rare occasions, menstrual cycles and fertility have also been established after ovarian tissue transplantation between genetically identical twins or from tissue or eggs and embryos stored by patients before undergoing sterilizing treatment for cancer. Some women with autoimmune POF have been given corticosteroids to restore ovulatory function, but long-term treatment is discouraged. In experimental animals treated with cytotoxic drugs to destroy follicles, administration of sphingosine-1-phosphate has an ovary-sparing effect. Perhaps other inhibitors of germ cell death and follicle growth will be found that can slow the normal process of ovarian aging. This development might address the desire of increasing numbers of women who seek to defer childbearing to their less fertile years and to postpone menopause.

Mental Health

B G Knight and L Lee, University of Southern California, Los Angeles, CA, USA

Glossary

Comorbid – Disorders occurring together at the same time, such as in a patient who is experiencing depression, hypertension, and heart disease.

Meta-analysis – A statistical method of summarizing primary studies in order to understand the average finding.

Psychotropic – Acting on the brain's neurochemistry to affect psychological or mental functioning; psychotropic medications are drugs given to alleviate psychological symptoms such as depression, anxiety, hallucinations, or delusions.

Introduction

Mental health can be defined as freedom from mental illness. It can also be considered well-being or life satisfaction. The focus of this article is on the system developed to provide services to alleviate psychological suffering in older adults. Mental health care of the older adult in its optimum form is interdisciplinary, involving psychology, social work, psychiatry, and other fields, intertwined in a mental health-care system that delivers a wide variety of services. To more fully describe the mental health system in the context of older adults, the article discusses the populations of older clients in need of mental health services, what services are offered, the various systems

set up to provide this care, and the financial incentives that shape mental health-care services for the elderly (*see* Life Satisfaction; Psychological Well-Being).

Populations of Elderly Needing Mental Health Services

There are various populations of older people who may need mental health services. Some client populations clearly have mental illnesses that would be diagnosable at a younger age, whereas others develop disorders in old age; some might not even be commonly labeled as 'mentally ill' but can benefit from mental health care. The groups often need different types of services and settings for care.

The Severely Mentally Ill Elderly

The severely mentally ill elderly include older adults with schizophrenic and paranoid disorders as well as bipolar disorder and some severe or chronic cases of major depressive disorder. In 2001–02, the Centers for Disease Control and Prevention estimated that about 2.4% of older adults aged 65 or older had a severe mental illness. Diagnosis and severity do not necessarily predict the setting of care. Historically, older persons have tended to be overrepresented in inpatient psychiatric units and still account for about 16% of all psychiatric inpatients. The older patient has tended to remain on the inpatient unit longer as well, thus taking up an even more disproportionate amount of services, stays average more than twice as long for geriatric inpatients in state and county psychiatric hospitals when compared to younger adult inpatients. This has typically been attributed to the rising prevalence of organic brain syndrome diagnoses in the later years of life; however, depressive disorders make up a larger part of geropsychiatric admissions. Mentally ill elderly are also present in long-term care settings; more than 50% of the 1.6 million older adult nursing home residents have a diagnosable form of mental illness.

The Acutely Distressed Older Adult

The psychological problems of the acutely distressed elderly are likely to include depression, anxiety disorders, phobias, and sleep disorders. These problems are also likely to co-occur with medical illness and may therefore complicate medical treatment and lead to unnecessary medical visits and costs. This population is generally assumed to be best served in outpatient mental health settings, although they most often present themselves to medical settings such as primary care physicians (*see* Depression).

The elderly underutilize outpatient mental health services relative to their representation in the population. In 2001, fewer than one out of four older adults with mental illness and substance abuse disorders obtained any type of mental health care.

The Elderly with Dementia and Their Caregivers

The dementias affect about 6 to 8% of persons over 65. The prevalence of dementia doubles about every 5 years, and the prevalence for persons over 85 was found to be around 24%. The elderly with dementia represent about 50% of nursing home residents and are present in large numbers in residential care facilities and in community-based long-term care for the elderly. Older adults with early-stage dementia as well as caregivers of persons with dementia at all stages may benefit from outpatient services as well. Although the most widely recognized source of dementia is Alzheimer's disease (AD), it is important to note that dementia may be the result of many other conditions. Accurate neuropsychological assessment is crucial to differentiate among these disorders (and reversible sources of cognitive impairment such as delirium or severe depression).

The increased number of cognitively impaired persons among older adults, many of whom suffer from irreversible brain impairment, poses the dilemma of whether they should be categorized as mental health or medical clients. This decision has varied from state to state, as has the decision to separate the mental health service system from the systems for developmentally disabled and for substance abusers. The decision will have an impact on the type and scope of programming for the elderly. Given their different needs, older adults with dementing illnesses require types of services distinct from those with acute psychological disorders or psychoses. On the other hand, some older adults with dementia develop behavioral problems in the middle stages of their decline for which the treatment consists of psychotropic medications and behavioral interventions. These treatments are typically provided in the mental health system to people whose brain impairment began earlier in life. In addition, with the brain-impaired older person, as with others who are severely disabled, the caregiver may be in need of mental health services to be able to continue to care for the patient at home. The most common first choice for a caregiver is the spouse, generally older adults themselves, who may experience a wide range of needs in response to the caregiving situation. Prevalence rates of depression, anxiety, and hostility are extremely high in this population. Comorbid depression in dementia patients is associated with increased

disability, more functional and behavioral problems, and greater stress to caregivers. The prevalence of major depressive disorder in dementia has been estimated to range from 11 to 25%. Numerous studies have revealed that depression in dementia is mild, and is more commonly caused by cerebrovascular diseases than by Alzheimer's disease.

Results of different treatments for dementia are varied. Reality orientation is an intervention administered in a classroom-style setting to institutionalized individuals. Its goals are to reduce confusion and improve quality of life through the use of orienting tactics and mentally stimulating activities. Although its long-term effects are unclear, it has been shown to improve cognition and decrease mood symptoms in randomized control trials. Researchers also found memory training programs to be useful in improving recall and recognition abilities in demented patients, but treatment gains disappeared within 1 year. When patients are no longer capable of participating directly in therapy, caregivers can be enlisted to assist with implementing behavioral strategies such as increasing pleasant events to improve the mood of the patients. Other helpful interventions for caregivers include respite care, stress reduction training, and therapy for depression (*see* Caregiving and Caring; Dementia; Dementia: Alzheimer's).

Medically Ill Elderly

Certainly not all medically ill people require mental health care. The probability of physical disability and disease increases with age, creating patient populations with a high percentage of older adults, and many of these medical problems can cause psychological distress that is a legitimate focus of clinical attention. According to the Centers of Disease Control and Prevention, in 1995, arthritis affected almost 46% of those over 65, hypertension about 40%, heart disease about 23%, and deafness about 29%. These figures are even higher for those over age 75. In 2000, approximately $6140 was spent on medical expenses for each American 65 or over, compared to $2120 for those under 65. Depression is considerably more common among medical inpatients than in the population as a whole, affecting about one-fifth of patients. Illness-related functional disability is a good predictor of subsequent depression in community samples of older adults (*see* Arthritis and Rheumatic Diseases; Cardiovascular System; Hearing).

The hospital is a setting for many geropsychologists involved in health psychology, who deal with issues such as pain management, behavior management in cardiac patients, the effect of depression and anxiety on medical symptoms as well as depression itself in medical settings, adapting to loss of physical or cognitive functioning (e.g., stroke patients), and sex therapy for patients whose sexual functioning is affected by surgery or illness. Coping with chronic conditions such as heart disease, cancer, and stroke, the three leading causes of death in individuals over 65, is a focus of therapy both inside and outside of the hospital setting. Mental health intervention in medical settings is of particular interest to cost-conscious medical care providers such as health-maintenance organizations (HMOs) because successful treatment of clients can reduce excessive and unnecessary medical visits. Attention to mental status also may affect recovery from medical ailments. Early results from interventions for psychological distress related to medical problems are encouraging. For instance, Rybarczyk, Lopez, Alsten, Benson, and Stepanski showed that cognitive behavior treatment (CBT) resulted in improvements in self-report measures of sleep at posttreatment and 4-month follow-up among older adults with chronic illness and comorbid insomnia. Rybarczyk, DeMarco, DeLaCruz, Lapidos, and Fortner assessed an intervention that included education on mind–body relationships, relaxation training, cognitive restructuring, problem solving, communication, and behavioral treatment for insomnia, nutrition, and exercise. The intervention resulted in reductions in sleep difficulties and an increase in health behavior, which were maintained at 1-year follow-up. Given the complex interplay between psychological and medical origins of adjustment to and recovery from medical disorders, more research is needed on treating psychological distress related to medical problems.

Anxiety Disorders

Although anxiety disorder rates are lower for older than for younger adults, they are more prevalent than mood disorders among older adults. Information about rates of mental disorders among older adults is scarce, and researchers often rely on the Epidemiological Catchment Area survey data collected in the 1980s. Among individuals over 65, the 1-month prevalence rate for anxiety disorders was 7.3%, compared to 5.1% for affective disorder. Phobic disorders were found to be the most common anxiety disorder, affecting about 6.2% of the population. On the other hand, figures from a community study of inner-city residents over 65 indicated a prevalence rate of 15% for all anxiety disorders. Despite the copious amount of research done on the subject of anxiety, late life anxiety remains a largely unstudied area (*see* Anxiety Disorders).

Although medication is often employed as a first-line treatment for anxiety disorders, empirical evidence for the psychological treatment of anxiety

disorders has begun to emerge. In numerous studies, CBTs were found to be generally effective in treating anxiety disorders among older adults, and the effects were often maintained at follow-up. Mohlman, Gorenstein, Keber, de Jesus, Gorman, and Papp demonstrated that adaptations of CBT for older adults, through inclusion of memory aids and frequent review of treatment techniques, resulted in a further increase in treatment effectiveness. Relaxation training is another common intervention for anxiety disorders; it has been found to improve self-reported psychiatric symptoms and decrease trait anxiety among older adults.

Sexual Disorders

The sexual response changes with normal aging. Many older adults do not expect these normal developmental changes and misinterpret them, leading to a decrease in sexual activity and enjoyment. Psychoeducation can aid the older adult understand and adapt to these normal age-related changes. Many older adults also must cope with illness-related changes in sexual functioning. Chronic disease-related pain (such as with diabetes or cancer) can interfere with normal sexual functioning. Sex therapy can aid the older client to adapt to the losses in sexual functioning and maintain a satisfying sex life. A barrier to this is often the therapists' discomfort with discussing sex with older clients or the misperception that the topic of sexuality is inappropriate to discuss with older adults. This is unfortunate because the majority of older adults welcome information and discussion and are not uncomfortable with the topic. Just as in younger adults, however, some older adults do exhibit sexual disorders of a deviant nature (exhibitionism, pedophilia, etc.), which are an appropriate target of intervention, either by the mental health-care system or by the legal system (*see* Sexuality, Sensuality, and Intimacy).

Substance Abuse

Substance abuse in later life can be considered an appropriate target for mental health system intervention. For example, alcohol abuse is a major problem among older men and is a legitimate mental health problem, as is the abuse of both illegal and prescription drugs. Older adults commonly are on multiple prescription medications and experience side effects or drug interactions. Older adults who abuse alcohol are at risk for physical health problems and psychiatric comorbidity such as anxiety, depression, and cognitive impairment. Long-term use of alcohol may lead to behavior problems, exacerbation of a previously existing personality disorder, or organic brain disorders, such as Korsakoff's syndrome, that can be distinguished from other dementing illnesses by comprehensive neuropsychological assessment. Misuse of over-the-counter (OTC) medications can cause problems in the elderly, who are more sensitive to medications. The most common substance abuse disorder is tobacco dependence; it accounts for more medical disability and mortality in the elderly than all other substances combined. Polysubstance use disorders may be a problem for many elderly who are using prescription medications, OTC medications, and/or alcohol. In reviewing available treatment options, Schonfeld and Dupree reported cognitive and behavioral interventions to be more effective than 12-step and social support models in treating alcohol abuse and dependence among older adults. Carstensen, Rychtarik, and Prue found that treatment gains from a behavioral treatment for older males were maintained at 2-year follow-up.

Services Offered in the Mental Health System

Psychological Testing

Assessments of cognitive functioning or personality are a specialty of clinical psychologists; those specifically trained to work with older adults are in a position to be able to accurately test and interpret results for this population with its higher frequency of sensory or other cognitive limitations and cohort differences. Assessments are done in response to a number of needs, such as diagnosis of any type of mental illness, differential diagnosis of depression or types of dementia, diagnosis of functional abilities after stroke, or forensic work, such as establishing competence or incompetence for a court of law. Neuropsychological testing is often done with older adults; this type of assessment uses special tasks to try to determine level of functioning of cognitive abilities such as verbal and visual memory, speech, spatial ability, or reasoning. Different disorders or locations of brain injury show different patterns of deficit on the various tasks, which aids in diagnosis.

Psychotherapy

The most commonly recognized form of mental health-care services is probably the provision of individual psychotherapy in either the inpatient (hospital) or outpatient (clinic or private practice) setting, but there are many other forms of mental health care provided to the elderly. In the outpatient clinic or the inpatient psychiatric facility, individual therapy is only one of a number of therapy modalities, such as

group therapy, support groups, family therapy, and couples therapy. Two types of therapies that are not unique to but are more often used with older adults are life review and grief work. These services are provided by psychiatrists, psychologists, social workers, and counselors.

Medication

A large segment of mental health care is provided in the form of psychotropic medications, which are prescribed by psychiatrists or primary care physicians. According to Lebowitz and Niederehe, most elderly present their symptoms to a primary care physician; about 70% of physician visits by those 75 and older resulted in at least one prescription, and 44% received multiple medications. Ten percent of physician visits by those 65 and older resulted in a psychotropic drug prescription. Ninety-five percent of visits resulting in prescriptions for psychotropic medications were made to non-psychiatrist physicians, mostly primary care physicians. Additionally, over half of nursing home patients are prescribed psychotropic medications, 20% of these without recording of an appropriate diagnosis. Psychotropic medications are therefore not only prescribed by psychiatrists, but also by non-specialist physicians, which highlights the importance of effective coordination of care. Some interdisciplinary teams use clinical pharmacologists to advise proper medication usage due to their knowledge of medication action and interaction in the elderly (*see* Pharmacology).

Case Management

Case management is another form of mental health-care service to the elderly. This service helps the frail or cognitively impaired older adult with referrals to professionals in any field, coordination of service providers, household help, help with legal or financial matters, and various other tasks. Case managers are often social workers, nurses, or gerontologists.

Social Services

Social activities and centers or services set up to provide seniors with social interaction are often organized and funded by aging-related agencies and sometimes are staffed by mental health-care professionals or paraprofessionals. Examples of these are congregate meal sites, friendly visitor programs, and senior recreation centers.

Problem-Specific Services

Problem-specific services are also an important part of mental health-care delivery, especially to the elderly, who most often experience specific challenges rather than general loss. Day care for dementia patients and respite programs for caregivers are two examples of programs tailored to the specific needs of older adults. Other types of specific services are bereavement and widowhood counseling and support, and specific interventions designed to decrease geropsychiatric inpatient stays.

Health Psychology and Other Hospital-Based Services

Hospital-based mental health-care services cover a wide range of psychological and psychiatric issues and modalities, such as consultations, assessments (both neuropsychiatric and psychological), psychotropic medication, pain management, individual counseling on a wide range of medical or psychological issues, work on treatment adherence (most notably in cardiac patients), rehabilitation training, self-help groups or therapy groups for patients with specific disorders such as breast cancer, social services, and discharge counseling.

Do Treatments Work?

Many of the services and treatments provided to older adults have been shown empirically to be effective. There is still a great need for studies validating treatments on special groups such as the elderly, but a number of meta-analyses (quantitative summaries of a number of studies on the same topic) have supported the use of psychological treatments such as CBT, brief psychodynamic therapy, and pharmacotherapy for depression, as well as other interventions to aid caregivers of dementia patients. Non-quantitative literature reviews suggest that effective interventions exist for insomnia, the dementing elderly, and the severely mentally ill. The need for this type of outcome research will continue to grow as reimbursement agencies like insurance companies want support for the efficacy of services provided.

Models of Service Provision and Systems of Care

Multiple Systems of Care for the Elderly

Appropriate placement of older adults, even when they have the same diagnoses as younger patients, introduces some complexities. In terms of long-term care for the elderly, there is an age-based system and a system for the mentally ill. Placement of the mentally ill elderly is a complex issue: are they best served in the mental health system or the aging care system? Older people often have complex chronic and acute medical needs. Nursing homes for older adults are

equipped to handle chronic medical issues and some psychiatric issues, such as mild dementia, but are often not able to handle more severe behavioral problems, psychotic residents, or suicidal residents. Psychiatric facilities, on the other hand, are often not equipped to handle the complex medical needs of the older patient. The staff of psychiatric facilities often do not have the medical expertise to care for the elderly, and the staff of age-based long-term care facilities do not know about psychological or psychiatric issues; they do not effectively coordinate with each other either. This issue is also salient in assessing and interpreting assessments of older adults, who often perform differently on tests and require different norms than younger adults, especially when accounting for overlapping comorbid medical conditions or sensory limitations.

The notion of ranges of care within separate care systems can organize our thinking about the institutional environments for the elderly. It has been argued that conceptually and legally separate systems of care for the elderly exist. The long-term care system for the elderly as defined by licensing regulations moves from independent living to residential care and locked residential care, intermediate care, skilled nursing care, and locked skilled nursing care. The psychiatric system could be viewed as including acute psychiatric hospitals, state hospitals, and locked skilled nursing facilities. Based on the preceding discussion of coexisting medical and mental health problems, the acute medical care system must also be considered as a third system of care through which older adults with psychological problems also move. The medical system provides an interesting example of care that is more integrated with the corresponding outpatient care and that serves as a gateway to long-term care.

There are several problems in considering the range of care within any of these systems as a progressive hierarchy. First, patients enter and leave the system and move from level to level in a wide variety of ways. The popularly accepted view may be that the elderly gradually deteriorate and progressively move up the scale, but reality fails to confirm this image. For example, dementia patients who also have behavior problems may move from independent living to high levels of locked care and then move to more 'independent' levels of care as their physical condition deteriorates and they are no longer capable of causing trouble. The rationale for movement within the three systems is also different. Movement within the aging long-term care system is based on physical frailty and functional ability in terms of the activities of daily living (ADLs). Movement within the psychiatric system is based on the degree of acuity of the psychiatric disorder, the overtness of behavioral problems, or both. Movement within the acute medical care system (and from acute to chronic or long-term care) is based on diagnosis, response to treatment, and intensity of need for nursing care. Thus, three interlocking but conceptually distinct systems with built-in tensions exist and are bound together by serving some of the same patients and many similar patients. Mental health patients, former mental health patients, and the cognitively impaired inhabit all levels of care in all three systems. The ideal goal for the person who serves elderly clients is to seek the level and type of service required by the patient's condition and to avoid unnecessarily restrictive placement. The concern with avoiding inappropriately restrictive and excessively costly treatment has led to a focus on community-based care. Although the distinction is more salient in some systems than others, for most services there is a dividing line between 24-hour care and community-based care systems.

Problems in Care Delivery That All Systems Must Address

What are some of the problems that prevent older adults from receiving care in the most appropriate location? Assessment of mental health problems in older adults can be complex due to the array of possible presenting problems and the high rates of comorbidity. Specialized training in assessment of older adults is desirable and can be obtained in graduate, postgraduate, or continuing education settings. Moreover, some elderly may simply not see their problems as psychological, or they may be unaware of the existence of outpatient therapy. A second pervasive source of complexity is that older adults with mental health problems are embedded in a variety of distinct care systems at both institutional and community-based levels: medical care, long-term care for the elderly, mental health services, aging network services, and possibly dementia care services. Professionals need to be aware of other agencies' waiting lists and available services so that referred clients do not 'fall through the cracks.' Unfortunately, due to limited resources and shrinking budgets, agencies' eligibility requirements for services are strict, and it may prove difficult to find agencies that can accept clients, leaving areas of need unfulfilled by any of the service providers. Difficulties in coordination of care may therefore be a function of economic pressures rather than planning failures (*see* Health Care and Services).

The complex needs of the older client will necessitate working with a range of professionals, such as aging network service providers, health-care providers, and the legal system. This need for interdisciplinary

and intersystem cooperation requires both conceptual understanding of how systems work together and practical training in manipulating complex systems for the good of the client. The interdisciplinary approach also requires respect for and understanding of other professionals in diverse fields. It should be common in the geriatric mental health team setting to find all members listening intently to valuable perspectives about clients offered by volunteers, nurses' aids, homemaker aides, and meal-site workers. In fact, the usual economies of health and social systems dictate that those with the least training and status will have the greatest actual exposure to the client and therefore the best opportunities for behavioral observation (e.g., the client's physician sees him or her 5 to 10 minutes a month, the home health nurse, half an hour per week, and the homemaker aide, 8 hours per week).

Program Principles in Mental Health and Aging

Fortunately there are guidelines available for providing more appropriate services to older adults. High-quality, community-based mental health services for the elderly share some common features:

1. All emphasize accurate diagnosis of older adults.
2. All are interdisciplinary and treatment focused.
3. All use active case-finding methods and community education approaches to bring clients in. They also collaborate actively with other agencies that serve older adults, and in some cases with postal carriers, meter readers, and other 'community gatekeepers.'
4. All of them deliver mental health services to older adults at home.

These are key elements of successful community-based programs in mental health and aging. The Veterans Affairs (VA) system provides a model for hospital-based care. Like the community-based programs, the VA emphasizes accurate assessment, active treatment, and interdisciplinary coordination of services. Many VA mental health services are provided in medical settings (acute wards, chronic care, nursing homes, etc.) as well as in distinct psychiatric units. Home-care services are also a part of the VA continuum of care. Furthermore, the VA has played a major role in developing training in geriatric mental health across the constituent disciplines.

Other model programs are those that focus on problem-specific outreach services for older adults. Specific problems are more salient than generic loss; programs that target specific needs and offer services to meet those needs are well utilized. This schema for relating programs to needs and populations grows from the discovery that utilization of outpatient services in community mental health programs was uncorrelated with utilization of inpatient services by the elderly. Four programs that have been successful are senior outreach teams, family-based services for dementia care, intensive case management, and day treatment services for the older adult. These programs are tailored to the needs of the different subpopulations of the elderly who need mental health services. Throughout this range of programs, the outreach principles of educating the clients, educating the providers, and improving the availability, accessibility, and affordability of services will help to assure that those in need understand and use effective mental health interventions.

The key issue in the continued development of services to older adults is their affordability. Most program development in mental health services for the elderly has taken place in contexts that do not rely entirely on fee for service or on Medicare funding. Other sources of funds have included state funding for mental health services, community mental health system funding, VA funding, training grants, research grants, and grants from various private, non-profit agencies. These sources can be motivated by perceived client need, interest in creative program development, and training goals.

Payment Systems and Their Impact on Service Delivery

Since about 1980, there has been a privatization movement in mental health care characterized by an increasing reliance on private practice providers and organized for-profit systems that are driven by market forces such as demand for services and the need to profit from service provision. This has led to the development of what has been described as a medical-industrial complex comparable to the military-industrial complex.

The main source of money for mental health services for the elderly is still government funding (75%, mainly from Medicare and Medicaid). The Medicare health insurance program provides coverage for inpatient psychiatric care, partial hospital care (i.e., day treatment), and outpatient psychiatric services delivered by qualified Medicare providers. The Omnibus Budget Reconciliation Acts (OBRA) of 1981, 1989, and 1990 resulted in the lifting of the annual cap on reimbursement of outpatient mental health-care services and provided for direct payment of clinical psychologists and clinical social workers; however, certain services are still restricted. The 1989 OBRA changes have led to increases in Medicare spending on inpatient psychiatric care, including an

expanding number of geropsychiatric inpatient units. In terms of the principles of care outlined previously, this program has the advantage of emphasizing assessment and encouraging the development of services at several levels of care throughout the nation. The ability of fee-for-service Medicare to produce rapid changes in service delivery to older adults by a wide spectrum of service entities with minimal administrative overhead is its greatest strength.

Despite such policy revisions, recent figures indicated that Medicare specialty mental health service policies continue to falter in promoting service use among older beneficiaries. For instance, Medicare spending on mental health accounted for less than 4% of total Medicare spending. Slightly more than half of these expenses covered the service use of disabled beneficiaries who were under 65 and constituted only 14% of the Medicare beneficiary population. Although the 1989 OBRA changes promised increased access and use of outpatient services, Medicare continues to require that beneficiaries assume a 50% co-payment for outpatient mental health care, compared to a 20% co-pay for medical care.

Another significant problem is that Medicare allocates a much higher amount for inpatient care than day treatment and outpatient services, hence it fails to provide sufficient services in the least restrictive setting possible. Medicare allocated approximately $3.2 billion for inpatient psychiatric services in 2001, and slightly more than $1.2 billion for day treatment care and outpatient mental health services in 1998. Medicare regulations have also tended to discourage, if not eliminate altogether, home visits for mental health services. Interdisciplinary cooperation is present to the extent that communication with the primary care physician is encouraged, but this falls short of working in an interdisciplinary team setting. The emphasis on inpatient care tends to exacerbate the existing imbalances of older adults in inpatient versus outpatient care and is bad mental health policy in any case because outpatient care is generally more effective and less expensive. The impact of Medicare through the fee-for-service reimbursement model seems to have been to expand mental health service delivery to older adults dramatically and to encourage the privatization of mental health care for older adults, with a built-in predilection for the encouragement of inpatient over outpatient options.

Summary

The mental health system for older adults is still evolving. Although some differences in mental health care for older adults are due to specific problems (especially dementia), the largest differences lie in the mental health-care system itself: in specialty services provided to older adults, in the dilemmas faced by elderly with comorbid conditions, and in the systems of payment for mental health services. The response to the needs of the elderly has included a number of specific services geared to this population and the extension of services originally developed for younger adults to the elderly via active outreach and case finding. The future of mental health services for older adults will be influenced by new knowledge and techniques from research and program development, by the growing number of specialists in mental health and aging, and by the continuing evolution of mental health policy, especially changes in Medicare.

Glossary

Adaptation – Acquisition of a new steady state in response to environmental change.

Allosterism – A regulatory mechanism that involves ligand binding. A cooperative interaction that occurs when a ligand binds at a site distal to the catalytic site and influences (inhibits or enhances) the activity of the catalytic or active site of an enzyme or receptor or transporter. In general, allosterism results from interactions among subunits of multiunit proteins, and these interactions determine the activity of the total protein.

Anabolism – Reactions or reaction sequences that result in synthesis of macromolecules such as glycogen, proteins, triacylglycerols, and so on.

Apoptosis – Programmed cell death.

ATP – Adenosine triphosphate; a high-energy compound that functions in energy transfer within the cell.

Catabolism – Reactions or reaction sequences that result in degradation of macromolecules to their smaller component molecules.

Citric Acid Cycle (Krebs Cycle) – Cyclic series of reactions that enables cells to oxidize metabolites and that results in the production of reducing equivalents for use by the respiratory chain and citrate, which can be transported to the cytosol for hydrolysis to oxalacetate and acetyl CoA. This cycle takes place in the mitochondria.

Gluconeogenesis – Synthesis of glucose from two and three carbon metabolic intermediates. Gluconeogenesis is stimulated when the intake of glucose is deficient or when glucose is not being metabolized by cells. This occurs in the disease *diabetes mellitus*. Gluconeogenesis takes place in the cytosol and shares many of its reactions with glycolysis.

Glycogenesis – When more glucose is provided to the body than can be immediately used, some of this glucose is stored in the form of glycogen through a series of reactions beginning with glucose-6-phosphate and ending with a branched glucose polymer. Glucoses are joined by linkages between carbon 1 and carbons 4 or 6.

Glycogenolysis – When the body is in need of glucose it raids its glycogen stores through glycogen hydrolysis.

Glycolysis – The main pathway for the use of glucose by the cell. This use begins with the phosphorylation of glucose and, through a series of enzymatic steps in the cytosol, results in the production of the three-carbon molecule, pyruvate. If oxygen is in short supply, pyruvate is converted to lactate, pyruvate enters the mitochondria for further use by the citric acid cycle.

Homeostasis – A condition of constancy within the living animal characterized by the steady state maintenance of metabolism where anabolic and catabolic pathways counteract each other as appropriate for the nutritional, environmental, and hormonal condition of that animal.

Lipogenesis – Synthesis of fatty acids from acetyl CoA and the esterification of these fatty acids to glycerol to make triglycerides. Lipogenesis occurs in the cytosol.

Lipolysis – Cleavages of fatty acids from glycerol usually followed by the oxidation of these fatty acids and the reuse of glycerol. Lipolysis occurs in the cytosol, whereas fatty acid oxidation occurs in the mitochondria.

Membrane – Lipid bilayer consisting of phospholipids and cholesterol. Proteins, which serve as receptors, carriers, or enzymes, are embedded in this bilayer, either wholly or partly.

Metabolic Control – Regulation of metabolic processes with the result of optimal efficiency of energy and metabolite conservation.

Mitochondria – Organelle responsible for energy transformation. The citric acid cycle, respiratory chain, oxidative phosphorylation, and fatty acid oxidation occur in this compartment.

Nucleus – Organelle of the cell that contains the genetic material, DNA. Gene codes for almost all the proteins synthesized by the cell are in this cell component.

Pentose Phosphate Shunt – When glucose is consumed in excess of need, some of the glucose is metabolized by way of this shunt. This series of

reactions yields two reducing equivalents per molecule of glucose used. These reducing equivalents are used in the *de novo* synthesis of fatty acids. The shunt also produces ribose-5-phosphate, an important constituent of RNA, and three carbon intermediates, which can enter the glycolytic sequence. The shunt takes place in the cytosol.

Respiration and Oxidative Phosphorylation – Series of reactions that results in the joining of oxygen to hydrogen to make water. Respiration produces energy, which is trapped (under closely regulated conditions) in the high energy bond of adenosine triphosphate (ATP); ATP, in turn, transfers this energy to the synthetic processes of the cell.

Steady State – A characteristic of a living system in which all fluxes are maintained to optimize that system's survival. It is an open system that has maximum thermodynamic efficiency.

Ureogenesis – Cyclic series of reactions for the synthesis of urea from ammonia.

Introduction

Aging is a continuum of metabolic change from conception to death. As cells multiply and as differentiation occurs, the needs for specific nutrients (substrates) and fuels change. Hormones, genetics, and nutrients interact and affect the orchestration and regulation of this process called growth. Upon the attainment of full maturity, subtle changes in this regulation occur such that the system is maintained with little or no growth of new tissue. There are exceptions to this; adipose tissue fat stores can increase given an energy surplus and in the adult female, pregnancy and lactation are processes that inherently are characterized by the growth of new tissue. Of concern to this article is the regulation of metabolism in the postmaturation phase of life; that is, the postreproductive period of the female and the equivalent time period in the male.

The regulation of carbohydrate, lipid, and protein metabolism is an integrated process that occurs at many different levels in the body. Metabolic regulation is, in fact, the summation of all those processes and reactions that ensure a continuous supply of fuel and substrates necessary to sustain life. It includes both anabolic and catabolic processes that use or release energy and use or produce needed substrates or end products. Living organisms survive and thrive when all of these processes are interdigitated and synchronized. Characteristic of aging is a gradual, subtle, and not so subtle loss in this synchrony. How this loss occurs is the subject of much discussion. The pattern of loss is not the same in all individuals, although some similarities do exist. Genetic differences, gender differences, and species differences influence the gradual loss in metabolic control and the gradual loss in the homeostatic mechanisms that assure continuance of life.

Nuclear DNA

Although it is generally assumed that healthy life span is genetically dictated as well as modified by dietary conditions, no one gene or group of genes has been identified that is directly responsible for life span determination. Researchers interested in the aging phenomenon as well as those interested in the genetic aspects of age-related degenerative disease have found age-related changes in both nuclear and mitochondrial DNA. DNA, although a very large molecule, is also a liable one. When in solution, it decomposes at the liable N-glycosyl bond. In living systems this permits base substitutions and deletions (mutations) to occur, and if sufficient numbers of these occur, aberrant gene products will result that can explain in part, the age-related losses in particular cell functions. Nuclear DNA, although subject to hydrolysis, oxidation, and non-enzymatic methylation, can repair itself. **Figure 1** illustrates where damage can occur. The base substitutions can be reversed by a series of reactions shown in **Figure 2**. In young animals this repair is quite efficient. However, one of the consequences of aging is a loss in DNA repair efficiency. It should be noted that mutations are spontaneous and occur randomly. Not all cells or cell types are affected, nor does the process occur all at once. Losses in cell function occur cell by cell, and cell types differ in their vulnerability and in their repair capacity. Nonetheless, with age there are changes in DNA that result in functional losses. With this loss is a rise in the presence of methylated cytosines, base deletions, base substitutions, and strand breaks. All of these deviations from normal are biomarkers of aging (*see* Markers of Aging). Of interest is the observation that food-restricted animals have fewer DNA aberrations than ad libitum fed animals of the same age. Food-restricted animals live longer than non-restricted animals when both sets of animals are housed under the same conditions and are fed the same diet and are of the same genetic background. Should the genetic background differ,

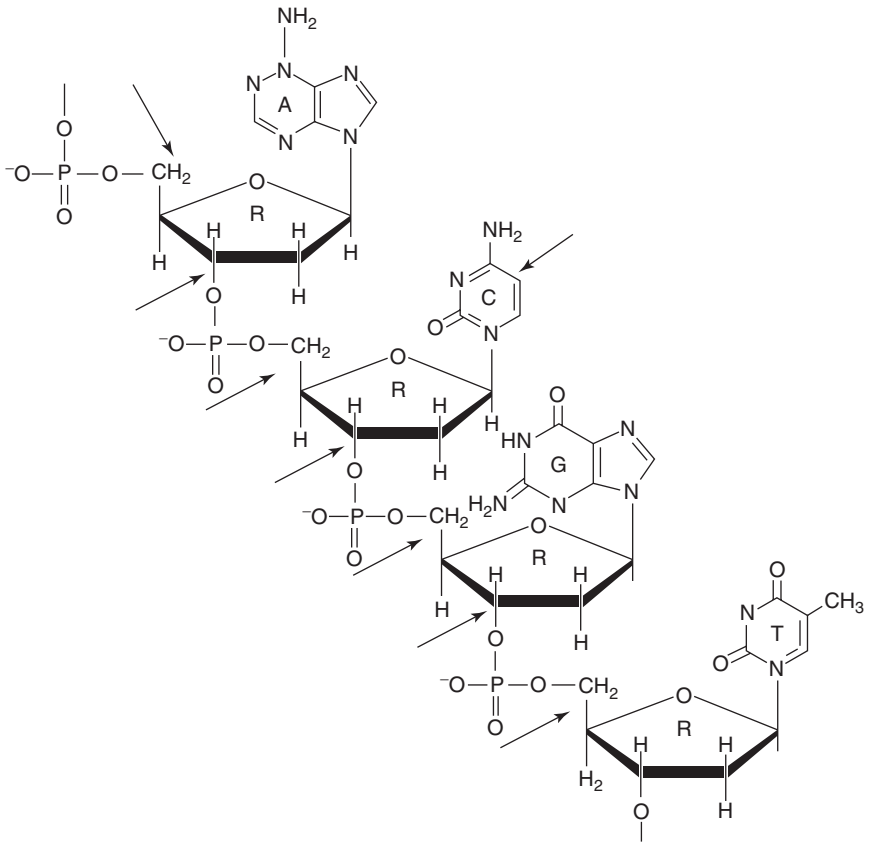

Figure 1 The bases that comprise the DNA polynucleotide chain are joined together by phosphodiester bonds using ribose as the common link between the bases. A, adenine; C, cytosine; G, guanine; T, thymine; R, ribose. Labile sites for DNA damage are indicated by arrows.

the difference in life span due to food restriction will also differ. In other words, although life span can be increased with food restriction, length of life will ultimately be controlled by the genetics of the consumer. Rats from short-lived strains will die sooner than rats of long-lived strains, and rats of both strains will live longer when food is restricted. Those of the long-lived strain when food is restricted will live longer than those food-restricted rats of the short-lived strain. This probably also occurs in other species; however, there is the caveat of environmental control. Larger animals, and humans in particular, cannot be maintained in controlled environments where infections are minimized and climatic conditions are ideal. Furthermore, the complexity of human life with its social and economic demands does not lend itself to a stress-free environment.

Mitochondrial DNA

Nuclear DNA damage is forestalled in many instances by its protective histone coat. Mitochondrial DNA lacks this protection. Furthermore, mitochondrial DNA has limited repair capability. Mitochondrial DNA carries only a few messages when compared to nuclear DNA, yet should wholesale damage to this DNA occur, the results could be devastating. That damage occurs is without doubt, but seldom is the effect of this damage devastating. This is because each cell contains many mitochondria; the liver cell, for example, contains about 800. In addition, although cell turnover might be slow to non-existent in some tissues, mitochondrial turnover is much more rapid. Thus, although mitochondrial DNA repair is limited, the larger number per cell and turnover rate compensate for damage that might occur to a single mitochondrion or indeed to a group of mitochondria within a cell.

Normal aging is characterized by an accumulation of deletions in mitochondrial DNA. Different tissues accumulate these deletions at different rates. Deletions have been found in human skeletal muscle, liver, skin, neural tissue, and cardiac muscle. Skeletal muscle from humans shows a 10 000-fold increase in deletion over the course of a normal life span. In the

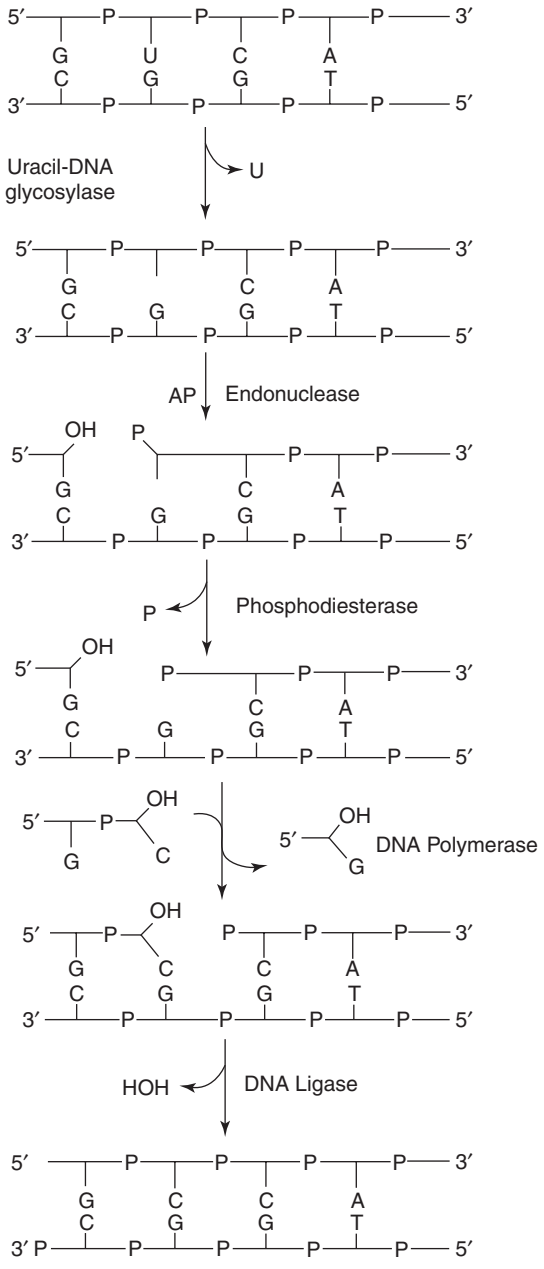

Figure 2 DNA repair. Shown here is the excision of uracil and the base-free deoxyribose phosphate, followed by replacement and correction of the missing residue by DNA repair synthesis. The glycosylases recognize the base substitution and remove it (step 1). These enzymes also recognize bases that are methylated and oxidative damage. Cell viability is dependent on the presence of these glycosylases.

rat, the increase in deletion is more rapid in hepatic and cardiac muscle cells than in skeletal muscle cells. The deletion mutation in the mitochondrial genome has been attributed to free radical attack on the labile N-glycosyl bond. Free radicals can readily form in the mitochondrion because of its structure and function. The mitochondrion is comprised of two dual membranes that are rich in phospholipids, which contain a high percentage of fatty acids as polyunsaturated fatty acids. Because the mitochondria consume about 90% of all the oxygen consumed by the cell, and because this oxygen is usually in its ionic or charged state, there exists ample opportunity for free radical formation. With age, lipid peroxide levels rise in a variety of tissues from humans, mice, and rats. These very reactive substances attack the DNA, resulting in deletions. In turn, as the number of deletions accumulate, cell function and then organ or tissue function is compromised as the mitochondria lose their ability to respire and synthesize ATP. This sequence of events has been suggested as an explanation for heart disease, accelerated aging due to diabetes mellitus, renal disease, Parkinson's disease, and Alzheimer's disease.

Membranes

The membranes serve as geographical boundaries of cells and cellular compartments. These structures are composed of phospholipids arranged in a dual layer with their hydrophilic aspects facing outward, and their hydrophobic aspects facing inward. Cholesterol is also part of the membrane and provides a measure of lipid structural stability. Four major phospholipids are found in these membranes: phosphatidyl choline, phophatidyl serine, phosphatidyl ethanolamine, and phosphatidyl inositol. Each of these phospholipids has fatty acids at carbons 1 and 2, and at carbon 3 of the glycerol backbone there is a phosphate group to which is attached either choline, ethanolamine, inositol, or serine. These structures comprise the charged portion or hydrophilic portion of the phospholipid. The fatty acids at carbons 1 and 2 comprise the hydrophobic portion of the molecules and provide the fluidity that is characteristic of a membrane. Fluidity is conferred by the ratio of saturated fatty acids to unsaturated fatty acids, and the ratio of these fatty acids to cholesterol. When the content of unsaturated fatty acids rises in a membrane, the membrane could become more fluid. This is compensated for by a rise in cholesterol. This compensation ensures a constancy in membrane fluidity. However, not all membranes are similarly regulated. The plasma membrane is carefully controlled in this way but the mitochondrial membrane is not. There is very little cholesterol in this membrane, thus this membrane

can vary substantially. Diets rich in polyunsaturated fatty acids will affect the mitochondrial membrane to a greater extent than the plasma membrane. With age there is a gradual reduction in the fluidity of membranes as subtle shifts in the ratio of saturated fatty acids to unsaturated fatty acids occurs. This in turn affects those cell functions that are dependent on fluidity (*see* Cholesterol and Cell Plasma Membranes).

The membrane phospholipids create the environment for protein function. Just as these lipids are amphipathic so too are the proteins. The proteins are distributed in a non-uniform fashion throughout the lipid bilayer. Some are anchored in the surface facing the plasma, others face the cytosol, and still others are inserted through the bilayer. Most of these peripheral and integral proteins do not interact directly with the phospholipids that surround them, yet these lipids can have effects on their function. In some instances these lipid effects are due to their fluidity. Proteins that function by changing shape would be less able to do so when surrounded by relatively rigid lipids. Changing membrane fluidity would thus result in changing the ease with which these proteins could change their conformation and hence activity. An example of this influence is the effect of plasma membrane fluidity on insulin receptor activity. Where the membrane is more fluid because of polyunsaturated fatty acids in the diet, the numbers of receptors available for binding and their binding affinity are increased. Another example relates to the mitochondrial membrane. In rats fed highly unsaturated (fish oil), moderately unsaturated (corn oil), moderately saturated (beef tallow), or very saturated (hydrogenated coconut oil) fat, mitochondrial respiration coupled to ATP synthesis is very efficient in the first group with gradual losses in efficiency observed in the subsequent groups. Both the enzymes of the respiratory chain and the many subunits of the ATP synthetase are embedded in the mitochondrial membranes and, in membranes that are very fluid, these proteins have optimal flexibility and function. Similarly, the transporters of the metabolites and adenine nucleotides that are required for optimized oxidative phosphorylation are likewise optimized in a more fluid environment.

Although the diet fat can have these influences, hormonal influences can be just as strong. Hypothyroidism is characterized by increased fatty acid saturation and decreased function of both plasma and mitochondrial membranes. Characteristic of hypothyroidism are derangements in carbohydrate use, notably a decrease in glucose oxidation, decreased protein synthesis, and accumulation of fat in the adipose tissue. Decreased thermogenic capacity characterized by an inability to maintain body temperature in a cold or chilly environment also characterizes hypothyroidism. Heat production results when ATP is synthesized. Thus, if ATP synthesis is reduced, so too is heat production. Providing a hormone replacement will reverse all these features. The membranes will become more fluid, and ATP synthesis will increase. Heat production will increase partly due to increased mitochondrial activity and partly due to an effect of ATP on protein synthesis that in turn has effects on skeletal muscle activity. Altogether, then, hormone replacement has a cascade of effects that appear related or integrated by the hormone's effect on membrane fluidity and function.

Other hormones likewise have effects on membrane phospholipid fatty acid saturation and fluidity. Growth hormone, the glucocorticoids, insulin, glucagon, the sex hormones, and some of the pituitary hormones (e.g., ACTH and thyroid-stimulating hormone have been found to influence membrane function through effects on membrane composition). In some instances, these effects are indirect. That is, the hormone in question stimulates the synthesis of fatty acids in the cytosol. Because these fatty acids rapidly exchange with those in the membrane phospholipids, there are effects on fluidity via this mechanism. Other hormones may stimulate the lipolysis. This results in a release of fatty acids from the stored triacylglycerides, which in turn can exchange with the phospholipid fatty acids in the membranes. Many of the catabolic hormones (i.e., glucagon, glucocorticoids, etc.) act in this way to influence membrane composition and function (*see* Endocrine Function and Dysfunction).

Age has a profound effect on membrane lipid saturation and fluidity. As animals age the membrane fatty acids become more saturated, fluidity falls, and those enzymes, carriers, and signaling systems that depend on a fluid environment become less active. In addition to changes in fatty acid saturation, the cholesterol content rises, and this lends a further degree of rigidity to the system. Thus, age-related declines in membrane-associated reactions or pathways may be attributable in part to these age changes in composition without regard to diet or hormonal perturbations. The latter can modify the age changes either suppressing or magnifying them as described above.

In addition, there are age changes in free radical production and suppression. With age, there is a decline in oxidative phosphorylation efficiency. Mitochondrial respiratory activity declines with the result that there is greater opportunity for superoxides and

fatty acid radicals to form. These very reactive substances can react with the mitochondrial DNA as well as with the various proteins in this organelle, causing damage and loss of function. Hepatic mitochondrial respiratory function has been shown to decline with age, as has the biosynthesis of mitochondrial inner membrane proteins. Mitochondrial DNA mutation has been shown to rise with age and increase in peroxidized lipids. These changes have cumulative effects on carbohydrate, lipid, and protein metabolism.

Intracellular and Intercellular Communication

Hormones and their secondary messenger systems are the central integrators of the communications that exist between the brain and the rest of the body and between the different organs and tissues. With age there is a decline in the efficiency with which these communications are transmitted. This is due to a myriad of age-related structural and functional changes. Aging is associated with anatomical changes of the endocrine glands. Some glands, the ovary for instance, have a defined life span and the cells are programmed to cease functioning at midlife. Programmed cell death, apoptosis, is both genetically determined and nutritionally influenced. With age there is a general decline in gene expression (translation and transcription) with a related decline in the accuracy and efficiency of protein synthesis. In part this is due to the age-related accumulation in DNA mutations due to free radical damage. Protein turnover also declines with increasing age, and this is manifested by an age-related increase in protein half-life (*see* Cell Death).

Many hormones are proteins, and as such one might expect that age will have effects on their synthesis, release, activity, and degradation. Best studied is the protein hormone, insulin. With age the pancreas becomes less responsive to signals for insulin release, and the target tissues become less responsive to its action. In part this may be due to age-related increased plasma membrane phospholipid saturation, but it is also due to age-related increase in fat cell size. As fat cells accumulate stored fat they become less sensitive to the action of insulin in promoting glucose uptake and use. Muscle cells likewise may have age-related changes in membrane fluidity that impair their response to insulin. As well, there is an age-related decrease in muscle use. Working muscles have little need for insulin bound to its receptor to facilitate glucose use. Altogether then, this decrease in muscle activity plus the increase in fat cell size has a negative effect on the insulin–glucose relationship. Glucose levels rise and the β cells of the pancreatic islets of Langerhans increase their output of insulin to meet the glucose challenge. However, this excess output does little good in reducing the blood glucose in the aging, overly fat, inactive individual, and it is not uncommon to have noninsulin-dependent diabetes mellitus develop as a consequence. Age-related impaired glucose tolerance can be mitigated by food restriction and increased activity that reverses the above physiological state. Because insulin is one of the main regulators of intermediary metabolism and because its action is counterbalanced by the glucocorticoids, the catecholamines, the thyroid hormones, glucagons, and several other hormones, it should be no surprise that age changes in these hormones occur as well. Again, some of these changes can be attributed to age changes in membrane lipids, but some can be attributed to changes in hormone production and in the synthesis and activity of the receptors that mediate their action. **Table 1** lists some hormones affected by age. The blood levels of most of these hormones decrease in the aging human and laboratory animal. A few pass through a phase where they are elevated above normal then fall below normal as aging continues. All of these hormones serve to regulate the metabolism of carbohydrate, lipid, and protein.

Table 1 Hormone changes with age

Hormone	*Age effects*
Serum thyroxine (T_4)	↓
Serum triiodothyronine (T_3)	↓
Thyroid-binding globulin	No change or ↑
Thyroid-stimulating hormone	↓

Fuel Fluxes

Although all nucleated cells carry the same genetic messages for enzymes and constituents, many of these messages are not transcribed and translated. Thus, certain cells have special functions or processes that are their unique properties, whereas other

cells appear to be more versatile. Adipose cells for example, synthesize and store triacylglycerols; kidney and liver cells synthesize glucose via gluconeogenesis; liver and muscle cells synthesize, store, and use glycogen as a fuel. Renal glomerular cells or tufts filter the blood, the central nervous system does none of the above and is unique as a central integrator of communication. Age has unique effects on each of these tissues and their respective metabolic processes. The pathways of intermediary metabolism are outlined in **Table 2**. Each of these pathways has specific control points that in turn are affected by age. Although various studies have shown age-related declines in enzyme activities, it should be remembered that these are *in vitro* measurements in conditions where substrates and coenzymes are in optimal amounts to assure saturation. This rarely occurs *in vivo*. Hence, a decline in activity may not mean a decline in *in vivo* function. In a number of instances the age-related decline in activity of a pathway or reaction can be inhibited by chronic food restriction. This inhibition of aging effects on metabolism probably has to do with the decreased fat stores that are the result of food restriction. A decrease in fat store reduces the supply of fatty acid precursors to free radicals, and this may lead to a reduction in error rates in the genetic material as well as a reduction in protein damage with resultant loss of function. In addition, a reduced fat store has effects on peripheral cell responsivity to insulin vis-á-vis glucose use and of course, in the absence of hyperinsulinemia, there is a decreased release of the anti-insulin hormones. As described earlier, age-related alterations in hormone balance do occur, and these alterations have an impact on carbohydrate oxidation, glycogen storage and mobilization, hexose monophosphate shunt, and gluconeogenesis.

Table 2 Effects of age on intermediary metabolism and its control

Pathway	*Control points*	*Effects of age*[a]
Glycolysis	Transport of glucose into the cell (mobile glucose transporter)	↓
	Glucokinase	↓
	Phosphofructokinase	↓
	α-glycerophosphate shuttle	
	Redox state, phosphorylation state	
Pentose phosphate shunt	Glucose-6-phosphate dehydrogenase	↓
	6-phosphogluconate dehydrogenase	↓
Glycogenesis	Stimulated by insulin and glucose	ND
	High-phosphorylation state (ratio of ATP to ADP)	ND
Glycogenolysis		ND
	Stimulated by catecholamines	ND
Lipogenesis	Stimulated by insulin	
	Acetyl-CoA carboxylase	
	High-phosphorylation state	
	Malate citrate shuttle	↓
Gluconeogenesis	Stimulated by epinephrine	
	Malate aspartate shuttle	↓
	Redox state	↑
	Phosphoenopyruvate carboxykinase	↓
	Pyruvate kinase	
Cholesterogenesis	HMG CoA reductase	
Ureogenesis	Carbamyl phosphate synthesis	↑, ↓
	ATP	ND
Citric acid cycle	All three shuttles	
	Phosphorylation state	↓
Lipolysis	Lipoprotein lipase	↓
Respiration	ADP influx into the mitochondria	↓
	Ca^{2+} flux	
	Shuttle activities	↓
	Substrate transporters	↓
Oxidative phosphorylation	ADP-ATP exchange	↓
	Ca^{2+} ion	
Protein synthesis	Accuracy of gene transcription	↓
	Availability of amino acids	↓
	ATP	↓

[a] ↑, increased as the animal ages; ↓, decreased as the animal ages; ND, no data.

As aging proceeds there is a rise in blood lipids coupled with a decrease in adipose tissue lipoprotein lipase. Adipocytes have a less competent lipid uptake system due to this decline in lipase activity. In normal aging animals the rates of cholesterol synthesis do not change; however, the uptake of this cholesterol as well as its oxidation and excretion declines. This has the result of an age-related increase in serum cholesterol levels. Genetics plays an important role in these age-related changes in serum lipids. Some genotypes are characterized by a sharper decline with age in lipid uptake processes than other genotypes. For example, those whose lipoprotein receptors are genetically aberrant will show a far earlier rise in serum lipids than those whose receptors are fully functional. Some may only have a decline in cholesterol uptake or triacylglyceride uptake, whereas others will have a decline in the uptake of both. Age-related declines in thyroid hormone production, thyroxine conversion to triiodothyronine, glucocorticoid release, and the insulin:glucagon ratio will have effects on fatty acid mobilization and oxidation. The results of this decline in hormone-stimulated lipolysis are observed as an age-related expansion of the fat stores. Although age has effects on fatty acid synthesis in rats and mice, these effects are minimal in humans consuming the typical Western diet. This is because this diet is relatively rich in fat, so the need for its synthesis is almost non-existent. Humans tend to use the dietary carbohydrate as their primary fuel and the surplus dietary fat is transported to the adipose tissue for storage. Hence, *de novo* fatty acid synthesis is negligible. In rats and mice this is not the usual situation. The typical rodent diet is low in fat. Most of the energy comes from carbohydrate and deaminated amino acids (those in excess of need for protein synthesis). In the young animal there is considerable protein synthesis, and with age there is a decline in this synthetic activity. With an age-related decline in protein synthesis there is an increased need to rid the body of amino groups, as the surplus amino acids are deaminated for use in gluconeogenesis and lipogenesis. This means that if the protein intake is not reduced to accommodate the decreased need for protein, there will be an increase in the activity of the urea cycle. Studies in aging rats have shown that dietary intake excess of energy and protein are associated with an age-related increase in urinary protein and renal disease that is preceded by first an increase then a fall in ureogenesis. Food restriction or protein restriction ameliorates these age-related changes in renal functions and urea synthesis.

All of these age-related changes in intermediary metabolism are linked together by age changes in mitochondrial oxidative phosphorylation. As discussed previously; age carries with it a progressive change (increase) in mitochondrial membrane saturation, a progressive loss in ATP synthetic efficiency, and an increase in free radical damage to mitochondrial DNA and its translation products. These progressive changes mean a progressive loss in the tight control of intermediary metabolism exerted by the concentration and flux of the adenine nucleotides. In turn then, one might expect to find progressive changes as described above in carbohydrate, lipid, and protein metabolism in addition to and in response to the progressive changes with age in the endocrine system and the central nervous system.

Mid-Life and Later-Life Crises

D Carr, Rutgers University, New Brunswick, NJ, USA
T Pudrovska, University of Wisconsin, Madison, WI, USA

Glossary

Chronic Strain – Persistent or recurrent demand that requires behavioral, cognitive, or psychological readjustments over a prolonged time period.

Coping Resources – Personal and social characteristics upon which people may draw when managing crises or stressors.

Coping Strategy – Cognitive and/or behavioral effort to manage crises or chronic stressors that are perceived as distressing or exceeding one's ability to adapt.

Life Events – Objective changes in one's social roles, contexts, and relationships that require major behavioral readjustments within a relatively short time period.

Well-Being – A state that encompasses any or all of positive mood, good physical health, and general life satisfaction.

Introduction

Social gerontologists do not share a single conceptualization of midlife and later-life crises. Rather, different subdisciplines offer distinctive yet complementary perspectives. Developmental and life span psychologists conceptualize a crisis as a normal stage in the life course when an individual must resolve a developmental or psychosocial challenge. Sociologists and social epidemiologists, in contrast, broadly conceptualize crisis as a transition that deprives an individual of a meaningful role, status, or relationship and thus requires a restructuring of and adaptation to one's new environment. Such crises may be acute events or chronic stressors. Important mid- and later-life crises include divorce, widowhood, retirement and job loss, health problems, parental bereavement, grandparent–grandchild coresidence, and caregiving. These acute and chronic crises compromise the well-being of middle-aged and older adults because they may threaten one's self-concept, create secondary stressors and role conflicts, and indicate a failure to achieve one's earlier goals. The extent to which a crisis taxes one's well-being is contingent upon its timing, meaning, and social context. Both psychological and sociological perspectives share the assumption that crises often have unanticipated positive consequences; they may foster personal growth, an enhanced sense of self-efficacy, and the pursuit of meaningful new challenges and relationships. Empirical research on the causes and consequences of mid- and later-life crises is most persuasive when it is based on large-scale representative community samples, on longitudinal data that obtain pre-crisis measures of one's personal characteristics, and when a diverse array of physical, psychological, and social consequences of crises are considered.

Conceptual Issues: Defining Crises

Psychological Perspectives

Developmental psychologists and life span psychologists conceptualize a crisis as a stage in the life course when an individual must resolve a developmental or psychosocial challenge. Only when this crisis is resolved can the individual adapt successfully to the aging process. Robert Havighurst proposed that individuals must accomplish a set of age-defined developmental tasks in order to achieve successful adult development. For midlife persons, these challenges include asserting oneself, while persons in their 50s through early 60s are charged with creating a new lifestyle. At age 60 and beyond, developmental tasks include deciding whether and how to disengage from social roles such as paid employment. The failure to accomplish such tasks is indicative of a crisis or poor psychological adjustment.

Similarly, Erik Erikson proposed that as an individual ages, he or she passes through eight psychosocial crisis stages. Successful adult development is contingent upon the sequential resolution of each crisis. The distinctive challenge of midlife is to resolve the conflict between generativity versus stagnation. A midlife adult is expected to avoid the lure of self-absorption and to instead become generative – working to preserve values and opportunities that will benefit succeeding generations. Older adults, in contrast, face the challenge of ego integrity versus despair; this entails resolving conflicted feelings about the past, adapting to the changes associated with the aging process, and accepting the inevitability of death.

More recently, social scientists have debated whether a psychological midlife crisis exists, and if so, what such a crisis comprises and what the consequences are for emotional well-being. Theoretical writings propose that at midlife, adults may reach a psychological turning point where they evaluate their past accomplishments and shortcomings, give up an unfulfilled life dream, or carve out a new life plan for themselves as they recognize their own personal finitude. Empirical research finds little evidence that adults undergo a midlife crisis. Estimates vary, but no more than 10 to 25% of older adults report that they have experienced a midlife crisis. Rather, most adults describe their 20s and 30s as the years when they grappled with crises including economic strain, difficult choices about work, marriage, and childbearing, and skepticism about the rewards promised by the Protestant work ethic.

One of the most important contributions of midlife crisis research is the recognition that a crisis need not be defined in terms of objective life conditions, nor must it necessarily refer to negative experiences. Qualitative research reveals that adults typically describe their own midlife crises as psychological turning points, such as learning something new about oneself or a loved one. Older adults who recall having experienced a crisis earlier in life consistently describe the event as having had unanticipated positive consequences. Although an experience might have been distressing at the time of its occurrence, in retrospect people believe that they enjoyed personal growth or enhanced self-efficacy as a result.

Sociological Perspectives on Crises

Early Influences While psychological perspectives on mid- and later-life crises typically conceptualize a crisis as a normal and anticipated challenge of the aging process, sociological perspectives on crises conceptualize such events or conditions as nonnormative, unexpected, and necessitating adjustment and adaptation. Sociological research and theory on life crises developed out of early animal and biological research on stress. Research by W. B. Cannon concluded that emotionally distressing experiences could be adaptive because they help animals to cope. For instance, fear triggers heightened adrenal gland activity, which in turn gives animals the energy necessary to fight or flee from a threat or aggressor. Adolph Meyer proposed that normative (and even positive) life transitions, such as marrying or having a child, are potentially distressing – both psychologically and physically – and require subsequent adjustment. Perhaps the most influential early research on stress was conducted by Hans Selye; his experiments with animals revealed that a diverse range of physical stressors could trigger a similar set of physiological responses, including alarm, resistance, and exhaustion.

Reflecting the early biological emphasis on stress, sociological research seldom uses the term 'crisis', and instead uses the terms 'life stress' or 'stressor' to capture an event or transition that requires readjustment. The main objective of early empirical sociological research on crises included identifying and measuring the potentially harmful consequences of a broad array of stressors. The first comprehensive measure of life stress, the Social Readjustment Rating Scale (SRSS), devised by social scientists Thomas H. Holmes and Richard H. Rahe, included a list of 43 events that were believed to be distressing and thus to require readjustment. Even experiences or transitions that are generally regarded positively, such as vacations, were considered potentially stressful, although the intensity of this distress was far less than for events such as the death of a loved one. The SRSS has

been criticized on the grounds that it presumes that a given event is equally stressful for all individuals, regardless of one's role history, coping resources, or subjective appraisal of the event. However, the idea that crises could be measured and that their psychological consequences could be evaluated empirically set the groundwork for empirical research on mid- and later-life crises. Taken together, early research on stress generated several important conclusions that underlie contemporary research and theory: crises affect physical and emotional well-being by overwhelming one's coping abilities and resources; individuals are variable in both how and the extent to which they respond to diverse stressors; and even expected, normative life transitions can have harmful consequences.

Contemporary Perspectives Over the past three decades, sociological research on crises has grown from a focus on discrete life events only to a broader view that conceptualizes crises as also encompassing chronic stressors and daily hassles. Some researchers also would include in this list 'non-events', or the nonoccurrence of events that were desired or anticipated. Life events are objective life changes or transitions that typically require readjustment. Events may disrupt one's regular activities, roles, and relationships and also may threaten one's emotional, physical, or economic well-being. Events can vary widely in their severity. Traumas are a particularly distressing class of life events. A trauma is a crisis that is outside the range of usual human experience and would be markedly distressing to almost anyone. Traumas are relatively rare, however, and are not the primary focus of most empirical research. Rather, most research on life events – particularly among older adults – focuses on role losses, including retirement, widowhood, divorce, or even the loss of one's physical capacity to live independently. Role loss is considered a crisis because it excludes older adults from significant social participation and thus devalues them.

Crises can transcend an individual's own personal experiences and may encompass the experiences of one's significant others. Network events refer to crises that are experienced by members of one's social network and that also have direct personal consequences. For instance, a sibling's widowhood experience may be distressing to an older adult and may require readjustment. Likewise, mid- and later-life crises need not be acute events; they may be ongoing chronic experiences. Chronic stressors are enduring, persistent difficulties, such as physical disabilities, poverty, or marital difficulties that tax one's personal resources. A less severe variant of chronic stressors, hassles, are minor events that require small behavioral adjustments in the course of a day, such as transportation difficulties or inclement weather. For older adults, particularly those with cognitive or physical impairments, even daily hassles may be perceived as crises that require adjustment.

Methodological Issues in Studying Crises

Social gerontologists are interested primarily in how, why, and to what end crises affect the well-being of midlife and older adults. Identifying the personal consequences of both acute and chronic crises poses several methodological challenges for researchers. The most persuasive and rigorous research is based on large, nationally representative surveys, rather than clinical samples, or non-representative samples limited to persons who have experienced a specific crisis. Longitudinal data that include personal information both prior to and following the purported crisis are necessary. Moreover, scholars ideally will focus on multiple outcomes in their research; a focus on a single outcome, such as depression, may conceal a much broader range of consequences. Finally, studies should have sufficient numbers of subjects from diverse age groups in order to evaluate whether and how crises affect adults at different life course stages.

Population-Based Studies

Studies of life crises that focus on patient, clinical, or self-help samples only cannot be generalized to broader populations. By definition, these older adults are already seeking help, and findings from such studies may overstate the negative consequences of a crisis. For instance, widows who are seeking psychiatric treatment presumably are more symptomatic than their bereaved peers not seeking help. Population-based samples, in contrast, allow researchers to compare those persons who have undergone a crisis with their peers who have not; in doing so, researchers can identify the causes and personal consequences of a crisis. Large community samples enable researchers to examine subgroup variation even among those who have experienced an identical crisis. Researchers can examine whether the consequences of a crisis vary based on the meaning, timing, or expectedness of such an experience.

Longitudinal Data

Longitudinal data are superior to cross-sectional data for studying the consequences of life crises, because they enable researchers to identify the factors that gave rise both to the crisis and to one's subsequent

adjustment. Although some late-life crises may occur randomly and are unrelated to the personal characteristics of their target (e.g., losing one's home in a natural disaster), most mid- and later-life crises are selective and reflect one's prior experiences and personal characteristics. Most discrete events or crises take time to come to fruition and often occur after a long period of chronic stress. For example, forced retirement may occur after months of workplace strife and uncertainty. Longitudinal data also allow researchers to examine changes in well-being that occur during the time period prior to and after the crisis of interest. Longitudinal data allow researchers to track one's role history prior to the crisis. In some cases, a role loss may not be particularly distressing if the role was stressful or problematic. For instance, widowhood may come as a relief rather than a crisis to a frail older person who has been providing intensive care to a dying spouse with severe dementia.

Multiple Outcomes

Most research on mid- and later-life crises focuses on psychological well-being; however, social gerontologists may develop a richer understanding of how older adults adjust to crises by considering a fuller range of psychological, physical, social, and behavioral outcomes, including social engagement and participation, social support from family and friends, physical health, strategies for managing daily activities, and personal growth in the face of crisis. Moreover, commonly used global measures of adjustment – such as depression – may mask more specific adjustments to crisis. For example, depression scales are composed of subscales including depressed affect, motivational loss, cognitive evaluations, and somatic complaints. Older bereaved spouses with clinical depression may not exhibit a dysphoric or sad mood, but instead may show elevated somatic concerns and irritability. Research focusing only on one overarching depression scale may mask these important distinctions.

A focus on multiple outcomes also enables researchers to identify important subgroup differences in how individuals respond to crises. To the extent that different groups have distinctive reactions following a crisis, studying a single outcome may conceal meaningful group comparisons. For instance, age-related emotional and cognitive changes affect the ways that midlife and older adults adjust psychologically to a crisis. Compared to younger adults, older adults have a greater capacity to manage or regulate their emotional states; they report less extreme levels of both positive and negative affect and less variability in their emotional responses to crisis. However, they may show elevated somatic or physical reactions. Studies that focus on a single psychological outcome would not reveal the physical consequences of the crisis.

Why and How Do Crises Matter?

Crises, particularly role losses, have long been recognized as an important influence on the well-being of older adults. In the classic work *Personal Adjustment in Old Age*, Ruth Shonle Cavan and colleagues set forth the idea that activity is an important source of well-being among older adults, thus the loss of roles is potentially distressing. While early theories of aging (e.g., activity theory and disengagement theory) equated role loss with reduced activity and, consequently, social withdrawal, more recent perspectives suggest that crises (particularly role losses) are distressing because they threaten one's identity, create secondary stressors, indicate a failure to comply with personally held goals and pervasive social expectations, or violate a socially and institutionally sanctioned timeline to which one should adhere.

Identity Threat

Crises can threaten individuals' self-concepts and thus make them more susceptible to psychological distress. Because an individual's identity and sense of self are based largely on social attachments and are derived from social interactions, both chronic and acute stressors that disrupt or damage relationships with significant others – such as divorce, widowhood, job loss, or the onset of disability or cognitive decline – can have harmful consequences.

The consequences of such crises are most acute when they threaten identities that individuals value highly and from which they derive a sense of meaning, purpose, and direction. Identity-threatening crises in highly salient domains have a greater impact on psychological well-being than those in less salient or personally important domains. For instance, job loss is most disruptive for men who highly valued the role of breadwinner, whereas widowhood is most distressing for those persons who were in very close, dependent marriages and who based their personal identity on their role of spouse.

Secondary Stressors and Role Conflict

Crises may threaten older adults' well-being because they often give rise to secondary stressors that, in turn, compromise one's ability to cope. Secondary stressors are both chronic and acute stressors that are triggered

by the primary stressor. For example, a severe chronic illness (or providing care to a spouse with a severe chronic illness) could precipitate a job loss, which, in turn, might entail economic hardship. For older women, in particular, the loss of a spouse often leads to social isolation, economic difficulties, or relocation to a less desirable home. Marital disruption also may strain one's relationship with adult children, who may not fully accept the termination of their parents' marriage or who may perceive their newly single parent as incapable of maintaining his or her independence.

Crises and the secondary stressors that result from them may also give rise to role conflict or overload. Although the loss of key roles is a threat to one's identity, the acquisition (particularly the unwanted acquisition) of multiple social roles may threaten one's emotional well-being. Older adults may not have the time, energy, or social and economic resources necessary for managing the responsibilities associated with each of their social roles. When the demands of one role, such as spousal caregiver, become especially taxing, an older adult may be less well equipped to perform other important social roles (such as worker or parent) and may experience psychological distress or physical exhaustion.

Failure to Achieve Goals and Expectations

At midlife and later-life, individuals reflect on their past and evaluate their successes and disappointments. This retrospective process of life evaluation often engenders regrets over missed opportunities and unattained goals. Empirical research reveals marked gender differences in the sources of regret, and these differences reflect distinctive opportunities and constraints facing men and women in their young adult years. Older women tend to express regrets over their educational and career pursuits; most wish that they had received more education and had pursued careers that meshed with their interests and intellectual capacities. Men, in contrast, are more likely to report regrets over their decision to give priority to work over family. Regrets over missed opportunities often are triggered or exacerbated by a life crisis. After divorce, women who have devoted their energies to nurturing their husbands and children may regret not having channeled more of their efforts to personal pursuits and accomplishments. Upon unwanted job loss or a disability leave from work, older men may recognize that they sacrificed family relationships for a career that was ultimately unsatisfying.

Off-time or Premature Crises

Although early research on crises presumed that an event is uniformly distressing, regardless of when and whom it strikes, more recent scholarship recognizes that the impact of a crisis is contingent upon its timing. Because most individuals try to adhere to culturally and institutionally endorsed time tables, events that occur 'off-time' are more difficult to cope with than those that occur 'on-time.' On-time events happen at the normative age for a given transition, whereas off-time transitions occur either earlier or later than expected or desired. Off-time transitions are considered particularly distressing because individuals who experience them are less prepared and are less likely to have peers who share their experience. Consequently, they may not have the social, instrumental, or institutional support necessary to weather such a transition. For example, older women have been found to cope with widowhood better than midlife women because spousal loss is a much more common event for older women, who may turn to their widowed peers for guidance and support.

Specific Mid- and Later-Life Crises

Marital Disruption: Divorce and Widowhood

Marital disruption is one of the most common crises experienced by older adults, particularly older women. Because men die younger than women, women are much more likely than men to be widowed at mid- and later-life. Although men and women are equally likely to divorce, midlife and older women are more apt than their male peers to remain divorced (or widowed) because they have limited prospects for remarrying, due to the imbalanced gender ratio and men's preference for younger wives. Among Americans age 55 and older, just 50% of women but 74% of men are currently married, as shown in **Figures 1** and **2**.

Widowhood and divorce are considered among the most disruptive life crises, yet recent empirical research indicates that mid- and late-life marital dissolution is not uniformly distressing. The personal consequences vary widely and are contingent upon the time lapsed since marital disruption, the nature and quality of the lost relationship and the dissolution process, and the number, type, and intensity of secondary stressors that follow the marital dissolution.

The negative consequences of marital dissolution decrease over time. Although many older bereaved persons experience elevated anxiety and depressive symptoms in the first 12 to 18 months following the loss, these symptoms eventually return to predissolution levels. In the longer term following dissolution, widowed and divorced persons – particularly women – experience personal growth and discover inner strengths and abilities.

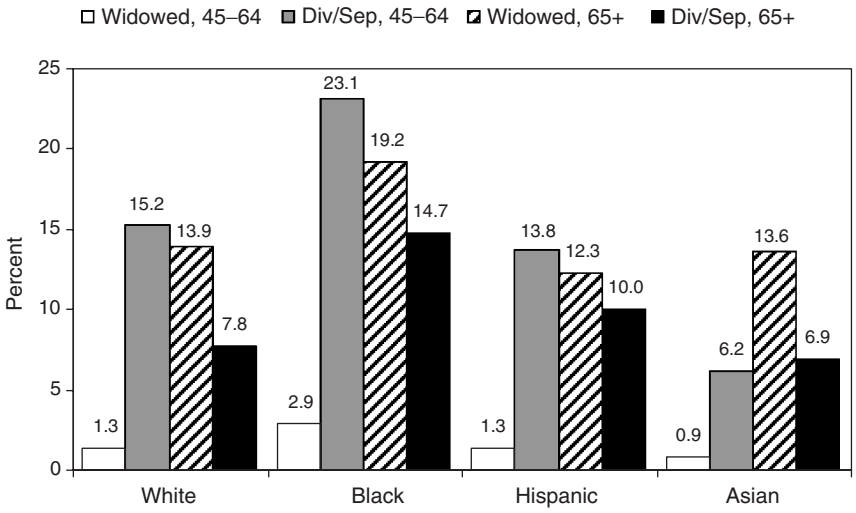

Figure 1 Percent of men age 45 years and older who were currently widowed or divorced/separated by age and race: 2003. From the US Census Bureau, Current Population Survey Reports, March 2003.

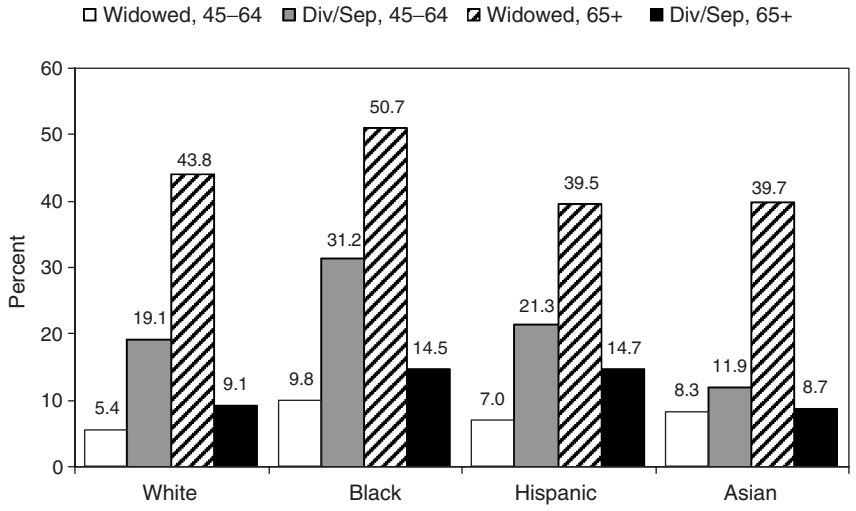

Figure 2 Percent of women age 45 years and older who were currently widowed or divorced/separated by age and race: 2003. From the US Census Bureau, Current Population Survey Reports, March 2003.

The short-term emotional consequences of marital dissolution are closely tied to the nature of the former marital relationship and the context in which the dissolution occurred. Divorces that dissolve a marriage to an unfaithful spouse are associated with subsequent increases in psychological health. The extent to which older bereaved persons adjust successfully to the loss of a spouse is contingent upon the quality of the late marital relationship, their level of dependence on their late spouse, and the extent to which the spouse's dying process was marked by physical pain, poor-quality medical care, and interpersonal difficulties. A purported crisis such as marital dissolution may have beneficial implications for the survivor when it brings an end to severe chronic strains.

Marital dissolution may trigger secondary stressors that cause psychological, physical, and financial distress. Women typically suffer economic hardship when a relationship ends, whereas men face challenges in maintaining a household and establishing supportive emotional relationships. The personal implications of these secondary stressors are most acute during the first year or two following the marital transition. The extent to which secondary stressors create distress for older adults also varies by sociohistorical context. Current cohorts of older women were highly dependent on their spouses for economic

security, whereas current cohorts of older men were dependent on their wives for emotional support. As the boundaries between traditional male and female gender roles erode, future cohorts of widowed and divorced older adults may be better equipped to manage the secondary strains associated with marital dissolution.

Employment Transitions: Unemployment and Retirement

The retirement experience has changed dramatically over the past half-century. Whereas retirement was largely a man's experience in earlier decades, retirement is now an experience of both men and women. Current cohorts of older women are more likely than prior generations to have worked for pay and thus are more likely to retire, as shown in **Figure 3**. Consequently, married couples must adjust to both spouses' retirements, rather than just the husband's; this raises the challenge of synchronizing spouses' career exits.

Retirement today is a process rather than a discrete event. Rather than making the clear-cut transition from worker to retiree, midlife and older adults are following diverse pathways to retirement. Some workers may make the gradual transition from full-time worker to part-time worker to retiree, while others will leave their career jobs for a bridge job before exiting the labor force. Others may retire completely, only to re-enter the labor market due to economic need. Although anticipated retirement is generally perceived as a desirable life transition, other late-life work transitions – such as forced retirement, lay-offs, or unwanted moves to less challenging or prestigious jobs – are perceived as crises.

The personal consequences of workplace transitions are contingent upon the quality and nature of one's former job and postretirement activities. In general, unwanted job loss is a risk factor for major depression, alcohol abuse, and physical health declines. However, the involuntary loss of a job that was highly stressful is not associated with adverse mental health outcomes. Similarly, retirees typically show lower levels of anxiety and higher levels of positive affect than their employed peers, yet some also experience a lower level of perceived control, reflecting the unstructured nature of their postretirement daily activities. At least some of the purported negative consequences of job loss are due to selection characteristics; job loss often is a consequence of prior physical and emotional health problems.

Health Crises and Disability

Chronic illnesses affecting older adults and, to a lesser degree, middle-aged persons are the main source of disability and physical impairment. The leading causes of death to older adults today – heart disease and cancer – are chronic illness that may persist for long time periods and that impair daily well-being and functioning (see **Figures 4** and **5**). Functional impairment, in turn, creates chronic strain and heightens one's dependence on others. Chronic illnesses reduce both actual life span and healthy life span, or the number of years that one enjoys good health and high levels of physical functioning.

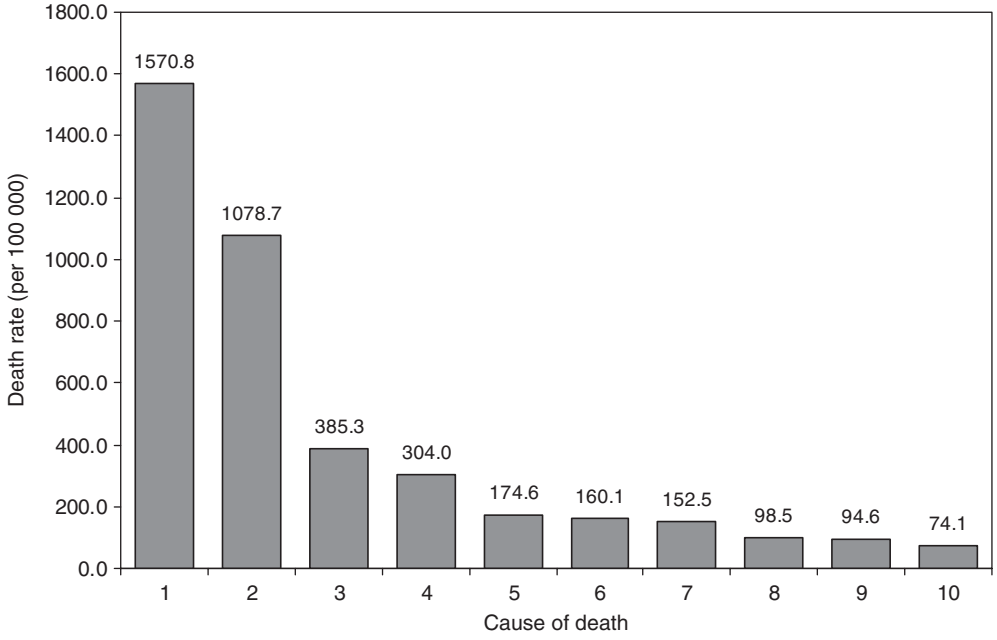

Figure 5 Death rates (per 100 000) for the 10 leading causes of death in late life (65 years and older): United States, 2003. Note: 1, diseases of heart; 2, malignant neoplasms; 3, cerebrovascular diseases; 4, chronic lower respiratory diseases; 5, Alzheimer's disease; 6, influenza and pneumonia; 7, diabetes mellitus; 8, nephritis, nephrotic syndrome, and nephrosis; 9, accidents; 10, septicemia. From National Center for Health Statistics, National Vital Statistics Reports, Vol. 53, No. 15.

Disability is both the cause and consequence of other acute and chronic stressors. Disability and health problems are among the most powerful predictors of changes in one's labor force participation. Health problems also trigger economic hardships. Direct expenditures on health care typically increase with the severity and duration of one's illness. Health problems also have indirect costs, in that they force older adults to either exit the labor force or cut back on their paid employment. Similarly, caregivers to ill family members may cut back on work or exit the labor force in order to care for their ailing loved one.

Disability may force adults to limit their social interactions and activities; persons with impaired mobility, chronic pain, and intrusive symptoms and who must participate in intensive treatment regimens are

susceptible to social isolation. Disabling and life-threatening physical health conditions often trigger mental health problems, including depression, anxiety, and anger, although social support may buffer the adverse impacts of disability.

Other Bereavements

Much is known about spousal bereavement in mid- and later-life, yet relatively little scholarly attention is paid to other deaths to significant others. Given steady increases in life expectancy over the past half-century, particularly among the oldest-old (i.e., persons age 85 and older), midlife and older adults are more likely than past generations to experience the loss of a very aged parent. Parents who die very late in life are likely to have experienced a chronic and debilitating illness and an accompanying period of physical or cognitive impairment. Adult children often are the primary source of instrumental and financial assistance to oldest-old persons; consequently, the death of an aged parent may indicate a termination of difficult caregiving activities and a relief from chronic strain and overload.

Yet parental death can be a highly distressing crisis, even for middle-aged and older adult children. Parental death may trigger identity changes, a heightened realization of one's own mortality, and a re-evaluation of one's priorities and personal relationships. Parental death may also create strain for one's marital relationship; some bereaved children report heightened levels of marital conflicts and dissatisfaction with the amount of emotional support they receive from their spouse.

Network Events: Child Problems and Grandchild Coresidence

The problems experienced by one's adult children may have a profound impact on the quality of life among midlife and older adults. Adult children with relatively minor problems, such as unstable employment or a troubled marriage, may coreside (temporarily) with a parent. Parent–child coresidence is not necessarily distressing; most parents express high levels of satisfaction when they coreside with adult children, particularly when the parent–child relationship is warm and close. However, when children's problems are protracted or severe and the children are financially dependent or unable to maintain an independent residence, both parental satisfaction and intergenerational relationship quality suffer.

When adult children's problems are severe or protracted, middle-aged and older adults often must coreside with their grandchildren and assume either custodial or coparenting responsibilities. In 2002, nearly 6 million children under age 18 lived with their grandparents. Reasons for grandparent–grandchild coresidence include a child's divorce, incarceration, financial problems, drug use, severe illness, psychological problems, teenage pregnancy, and inability to care for their child (i.e., the older adult's grandchild).

Coresidence with grandchildren – and custodial grandparenthood, in particular – is often an unanticipated and involuntary transition that places older adults at risk of increased economic burden and elevated levels of psychological distress, insomnia, and hypertension. The extent to which grandparent–grandchild coresidence creates distress varies widely across racial and ethnic groups, however. Black women report greater satisfaction than their White peers, reflecting cultural differences in expectations for family relationships and roles.

Caregiving Responsibilities

Midlife adults have been dubbed the 'sandwich generation', as they face the competing demands of providing emotional, instrumental, and financial support to both adult children and their aging parents. Older adults, particularly older women, often are charged with providing care to chronically ill spouses and, on occasion, siblings, friends, and other relatives. Although intensive caregiving responsibilities often tax the coping resources of midlife and older adults, recent research shows that the caregiving experience is not uniformly distressing and in some cases may provide an important source of purpose and identity.

Most research shows that caring for an ill or disabled person is associated with declines in physical and mental health. Yet the health impact is contingent upon role context and coping resources. Personal characteristics including high psychological well-being, good physical health, religiosity, multiple role involvements, and social integration buffer the psychological strains of caregiving. Moreover, recent research documents the beneficial psychological implications of caregiving. Caregiving is positively related to mastery, self-esteem, and the belief that one matters to loved ones.

Coping with Mid- and Later-Life Crises

Coping Resources

Over the past two decades, a vast amount of research has explored the processes by which midlife and older adults cope with crises. Coping typically refers to both one's coping resources and coping strategies. Coping resources are personal and social resources that people draw upon when dealing with crises. Personal coping resources include individual-level attributes that

enhance (or limit) one's ability to manage stress, such as education, self-esteem, and a sense of control or mastery over one's life. One's social resources typically refer to social support, or the emotional, instrumental, or informational assistance received from significant others, including family members, friends, neighbors, or co-workers. The perception that support is available is a much more powerful influence on psychological adjustment to crisis than is the actual receipt or availability of such support. More generally, coping resources are believed to shape both the coping strategy that one undertakes and the potential effectiveness of that strategy.

Coping Strategies

Coping strategies are behavioral and cognitive tactics used to manage crises, conditions, and demands that are appraised as distressing. An important development in coping research was the creation of Robert Folkman and Susan Lazarus' Ways of Coping scale. This scale was devised to assess the extent to which one uses one of two general types of coping. Problem-focused coping is directed at problem solving or taking action to change the source of the stress. Emotion-focused coping, in contrast, focuses on reducing or managing the emotional distress that results from the crisis. Some emotion-focused coping strategies include wishful thinking, distancing, avoidance, and positive reappraisal. The effectiveness of any particular coping strategy varies according to the situation, and there is not one generally accepted way for older adults to cope with stress. Moreover, most crises warrant both types of coping.

Problem-focused strategies are typically invoked when constructive action can be taken, whereas emotion-focused coping is used when people feel that the situation cannot change and must be endured. In general, problem-focused coping strategies are considered more effective for managing crises than emotion-focused tactics. Persons who use active coping strategies typically view themselves as in control, hold positive self-views, and adopt a proactive, optimistic and self-reliant approach to managing life stressors. In contrast, those who rely on emotion-focused coping strategies, including self-blame, avoidance, or even the use of drugs or alcohol, cope less well than those who adopt active strategies, such as seeking social support. However, for older adults, problem-focused coping is not always effective when a loss is irrevocable. Rather, emotion-focused strategies such as the positive reappraisal of a permanent condition or situation are associated with enhanced mental health.

Resilience in the Face of Crisis

One of the most consistent findings to emerge from empirical work on crisis is that the negative psychological and interpersonal consequences of most stressful transitions, such as widowhood, parental bereavement, or caregiving, are short-lived, and most older adults eventually reach levels of psychological and social well-being that are on a par with their precrisis levels. Moreover, most healthy older adults find substitutes for lost roles, activities, and relationships; for example, healthy retired persons are more likely than others to perform volunteer work, and bereaved spouses often develop new skills and forge new (or renew old) interpersonal relationships. These empirical findings mesh with a core assumption of both psychological and sociological perspectives on crises: personal growth and satisfaction may result from the resolution of a crisis. In Erik Erikson's stage theory, when an adult resolves each of the eight psychosocial crises, he or she may emerge with a new skill or sense of confidence that can be incorporated into his or her coping skills. Likewise, sociological perspectives on crises hold that events or circumstances involving adverse change can have positive effects on coping skills and world views, as individuals increasingly view themselves as efficacious and capable of managing crisis.

Challenges and Future Directions

The Distinctive Experience of Aging Baby Boomers

Most research and theory on mid- and later-life crises has focused on current cohorts of older adults who came of age in the early and mid-twentieth century; it is not clear whether similar patterns will be found among the large cohort of aging Baby Boomers, born between 1946 and 1964. The Baby Boomer cohort is more ethnically and racially diverse than past cohorts of older adults; however, surprisingly little research explores racial or ethnic differences in older adults' exposure and response to crisis. This reflects the fact that most large-scale sample surveys include inadequate numbers of non-White elders. Consequently, researchers have little understanding of how a crisis can vary in its causes, consequences, and cultural meaning across ethnic groups and how sociopolitical and historical contexts of ethnic groups shape their late-life experiences. Baby Boomers also are more highly educated than past cohorts of older adults and are far less likely to adhere to gender-typed social roles in the family and the economy. They are more likely to divorce and have fewer children than prior generations, thus they may turn to a more diverse set of significant others to cope with crises, including

siblings, friends, unmarried romantic partners, or gay and lesbian partners. Future research should investigate the types, frequencies, and responses to mid- and later-life crises evidenced among the large and diverse Boomer cohort.

The Blurring of Crisis Boundaries

In future cohorts of midlife and older adults, crises will increasingly be experienced as protracted processes rather than events. Late-life deaths today occur largely due to chronic illness, and life-sustaining technologies mean that terminally ill adults, often with cognitive impairment and limited functioning, will stay alive in a compromised state long before they die. Consequently, spousal and parental loss may be a slow process rather than an acute transition. Similarly, retirement is now a gradual process rather than a discrete event, as older adults transition into part-time or self-employed work prior to a complete exit from the labor market. Although older adults have more time to prepare for and adjust to important crisis-like transitions, the protracted experience may overwhelm their personal, social, and financial resources.

Moving beyond the Individual

Research and theory on mid- and later-life crises focuses overwhelmingly on the individual. Significant others are conceptualized as a source of support for managing a crisis, yet very few studies explicitly recognize that crises often strike a dyad or social group, and individuals must work together to adjust to such a crisis. For example, bereaved older spouses must adapt along with their adult children, who have lost a parent. Older workers' retirement decisions typically are made in coordination with their spouse, just as an individual's decision to provide care for an ailing parent often is made in tandem with his or her siblings. Crises do not occur in social isolation; future studies should acknowledge the inherently social and interpersonal nature of both the onset of mid- and later-life crises and adults' subsequent adaptation.

Migration

C F Longino Jr., Wake Forest University, Winston-Salem, NC, USA

Glossary

Interstate Migration – Per the US census, residence in another state 5 years before the census is taken.

Retirement Migration – Interstate migration of persons aged 60 and over, some of whom may have become employed since moving.

Introduction

Retirement migration is one aspect of a broader cultural happening that is very old. Winter palaces, the social season in the capital city, mineral springs, spas, and Italian villas have for centuries been part of the lifestyle of the European elite. Vacationing, seasonal migration, and retirement resettlement to a more healthful climate offering leisurely lifestyles are becoming widespread phenomena in the United States, but only after the development of a substantial middle class and transportation technology that makes travel to distant places possible and affordable. Thus, these activities have become common only in this century. Although the individual community histories of retirement settlement may extend back to the 1920s and 1930s in some places, retirement migration became more than a novelty only after World War II.

In each decade between 1960 and 2000, both the number of Americans and the number of older Americans have increased; the latter increased faster. Not surprisingly, the number of interstate migrants also grew in each decade. The proportion who moved in each 5-year period preceding the census, however, remained nearly constant, both for the population over age 5 (at about 9%) and the population over age 60 (at about 4.5%). A trend that reaches back for five censuses is very stable. Local mobility declined during this period for both categories.

Retirement migration is an alternative lifestyle. Most Americans over age 60 have not moved in any census migration period. Roughly three-quarters are living at the same address as earlier; only one in ten has moved across country or state lines. Most tend to stay put when they retire (*see* Retirement).

Conceptual Issues

Lifestyles and Place Ties

Asking why most people do not move is one way of ascertaining why some people do move. People are tied to their environments by investments in their property, by the many community contexts in which they find meaning, by friends and family, by their past experiences, and by lifestyles that weave these strands together into patterns of satisfying activity. Any lifestyle requires a unique combination of environmental resources, and a retirement lifestyle is no exception to this rule. It is the combination of place ties, person ties, and resources that is the key to understanding what is behind a retirement move. The retirees who are most likely to relocate are those who have the fewest moorings and those whose desired retirement lifestyles are not compatible with their present community, neighborhood, and housing environments.

Person Ties

Lifestyle-motivated moves tend to be place centered. When migration researchers focus on particular popular retirement destinations, they often find amenity-seeking migrants there. Person-centered motivations for moving are equally important.

Resources

If place and person ties often go undifferentiated when motives are assessed or inferred, it is equally true that place ties and resources are often confused. Retirees vary considerably in their possession of the resources needed to relocate – particularly their economic, health, and psychic resources. Psychic resources refer to the inner strength and freedom needed to take the risks involved in moving. Strong community moorings can reduce these psychic resources by lessening the ability to mount the effort to move even if income and health resources are abundant.

Search Space

When the members of a retired household are considering a move and begin looking for housing, geographers define the territory in which the couple will search for a new residence as a search space. The search space of the couple is defined by their previously acquired knowledge. This knowledge, of course, is informed by earlier visits, discussions with migrants and travelers, and reading. Rarely does someone move to a place completely unknown to that person, unless the move was forced. The primary

reason that people choose new locations where they have vacationed and visited is because they have gained the necessary knowledge base to make that choice.

Because the search space is conditioned by knowledge requirements and motivational factors, the size of the target area will vary from retiree to retiree. Migration flows, therefore, are not narrowly targeted because of varying amounts of search space.

Migration Motivation

Older migrants, like people in general, come in many types. The research literature tends to classify them into two major categories: dependency migrants and amenity migrants. Dependency migrants are typically forced to move due to deterioration of health or financial resources or the death of a spouse. Amenity migrants are looking for settings that will afford a new and better lifestyle. Communities located on or near lakes, beaches, and mountains and those in temperate, tropical, or desert climates have an advantage in attracting this type of migrant, who tends to be recently retired and therefore younger, usually married, and economically better off than many other retirees. Interstate migration streams to the Sunbelt are laden with amenity migrants.

Life Course Models

One popular way of combining an analysis of place and person ties and resources is to examine the way that migration motivation tends to change during the retirement years. Litwak and Longino argued that long-distance movers during the retirement life course tend to fall into three categories. The first are recently retired amenity-seeking migrants. The pressure for the second type of move, however, occurs when people develop a disability that makes it difficult to carry out everyday household tasks, a situation often compounded by widowhood. Limited kin resources is the motive for the third basic type of move, from more or less exclusive care by kin to institutional care. Most movers that fit the third type are local, not long-distance, movers (*see* Life Course).

Migration Decision Models

The origins and destinations of the migrant have attractions and repulsions ('pushes' and 'pulls'). In migration research there is a strong tendency to attempt to infer the motivation of the migrant by studying the characteristics of the places they leave and the places to which they move. For example, in aggregate, origins have lower average winter temperatures and higher costs of living than destinations; both factors are pushes. Rural areas in the southeast United States that have consistently attracted older migrants tend to have mild climates, to be growing economically, and to have lower taxes. They tend to be coastal or mountainous and many are adjacent to metropolitan areas.

Migration decisions may be triggered by push and pull factors such as climate, traffic and street crime, or cost of living and facilitated by endogenous filters such as personal resources or the housing market. There are also feedback loops. People who do not decide to move, or who cannot successfully choose a destination, may adjust to their present location through various mechanisms in order to avoid feeling trapped there. Furthermore, over time, migration outcomes that initially are improvements can generate new pushes and pulls that may eventually trigger another move. Daydreams about moving that precede the actual process and information about push-pull factors are obviously also important.

Place Identity Models

Some migrants who never put down roots remain emotionally tied to their former communities. Others have problems with the transition from being a vacationer to being a permanent resident after they arrive in their destination communities. Considering these issues with a social psychological approach has brought a new dimension to the understanding of migration and migrants.

Migration

Patterns of Migration in the United States

State Flows and Streams One of the defining characteristics of interstate retirement migration is that the migrants coming from many states are concentrated in only a few destinations, a result of highly focused flows into certain states. In 2000, over half of older migrants, 54% (compared to 56% in 1990), arrived in just 10 states. Florida dominates the scene, having attracted from one-fifth to one-quarter of all interstate migrants over 60 in all five censuses from 1960 to 2000.

A new phenomenon occurred in 1990. There was a small, gradual decrease in the proportion of migrants received by the major destination states, with a gentle spreading out of the flows (as compared with earlier migration periods). As **Table 1** shows, the proportion of total migration going to Florida and California has declined each decade since 1980, with California losing its second-place ranking in 2000 to a much less populous state, Arizona. Although the losses for Florida and California were relatively small, the trend is clear and persistent. These declines are particularly noticeable because the numbers of

interstate migrants leveled off between 1990 and 2000, causing the number as well as the proportion of migrants into Florida and California to drop in the past two censuses. It would be wrong, however, to predict the demise of Florida as the leading destination for retired migrants on the basis of these trends. It still attracts more later-life migrants than Arizona, California, and Texas combined.

Counties of Origin Out-migration in 2000, at least when it comes to large substate migration streams, was a metropolitan phenomenon with few exceptions. The majority (58) of the largest 100 streams across state lines between large counties or clusters of smaller counties (which the US Census Bureau calls PUMAs, for public use microdata areas) originated in metropolitan areas outside the Sunbelt, led by New York City, Los Angeles, and Chicago and their surrounding suburban counties. In 2000, the five boroughs that make up New York City sent 16 of the nation's largest streams to Florida and New Jersey, primarily the former.

The Los Angeles pattern is very different from that of New York City. In 2000, Los Angeles County sent seven large streams of retirees to locations in its three adjacent states: Arizona, Nevada, and Oregon. Adjacency, therefore, is at the heart of the Los Angeles out-migration pattern.

From the vantage point of Chicago, the popular Sunbelt destination states all seem about the same distance away. New York loves Florida, but Chicago plays the field. Retired Cook County residents are nearly ubiquitous. They are as apt to show up in southern California, Arizona, or Nevada as Florida. Of its nine major streams, seven go to these states.

Why should it be surprising that most retirement out-migration to interstate destinations is from metropolitan counties? These are the places of economic opportunity. More city retirees can afford to move and more have been geographically mobile during their working years.

The surprise in 2000 was that 42 of the largest 100 migration streams originated in the states that attract the most interstate migrants, all Sunbelt states. Thirteen are in Florida. There were far more interstate migrants who arrived in these Florida counties than who left them for counties outside of Florida. However, migrants of retirement age do leave Florida and other Sunbelt states. Indeed, Florida ranks third, below only New York and California, on the list of major sending states.

Receiving Counties Using the 2000 census microdata files, counties or county groups were ranked in terms of net interstate migration. Thirty-one of the top 100 destinations for interstate migrants, or nearly a third, were in Florida, in keeping with its longstanding status as the leading migration destination for older migrants.

Nationally, the leading substate destinations are located in coastal, mountain, and desert counties across the United States – from seaside Maine and Cape Cod in Massachusetts to the Puget Sound in Washington and coastal Oregon. Maricopa County, Arizona (Phoenix) and Clark County, Nevada (Las Vegas) rank first and third, respectively, and are the leading substate destinations in the west. Riverside County, California (Palm Springs) ranks 28th and is California's only entry on the list of major substate destinations.

Although the Sunbelt is generally the dominant regional destination, there is greater variety in destinations than is commonly assumed. Ocean County, New Jersey, for example, has consistently received enough retirees from New York and Pennsylvania to keep it among the top 100 interstate destinations for several decades.

Regional destinations disproportionately attract migrants from adjacent states. Examples are Cape Cod, Massachusetts, the New Jersey shore, and the Pocono Mountains of northeastern Pennsylvania, all located outside the Sunbelt. Other locations in the Appalachian Mountains and the Ozark region of Missouri and Arkansas are in the non-coastal Sunbelt. Southern and western Nevada and areas in the Pacific Northwest are all retirement areas of strong regional attraction and are frequently cited in retirement guides as good places to retire.

Migration Selectivity

Local movers over age 60 are generally not as economically and socially well off as non-movers, and migrants are the most positively selected. These differences have been relatively stable over time. Men and women are about equal in terms of making long-distance moves. Married couples predominate in this type of move. Perhaps unsurprisingly, the very old tend to move shorter distances. Migrants with the most education tend to move the farthest.

Studies comparing in-migrants with non-migrant age peers at their destination find that the migrants are financially better off. This is attributed to the tendency of migrants to move to locations with a somewhat lower cost of living than their origin. Cost of living and income is higher in larger cities. Also, moving is costly, so it tends to screen out those who cannot afford to move. Further, amenity migrants tend to move soon after retirement, before there is

any decay in their retirement income relative to more recent retirees.

Seasonal Migration

The US Census Bureau does not directly attempt to measure seasonal migration. There have been several surveys of seasonal migrants, however, conducted in Texas, Arizona, and Florida, that have provided snapshots of older visitors at their destinations. Data from these surveys are accumulating and are beginning to be compared, thereby providing a broader national picture. In this picture, the migrants are overwhelmingly White and retired. They are healthy, married couples in their mid- to late 60s with higher levels of income and education than the older population in general. One study compared samples of Canadians who wintered in Florida with US citizens who wintered in the Rio Grande Valley of Texas. The similarities between the two were impressive.

Climate is apparently a very strong factor in motivating seasonal migration. The propensity to seasonally migrate to Phoenix, Arizona, was highest in the northern plains and mountain states that border Canadian provinces. The trails that bring snowbirds south to Arizona or Florida are not strange or innovative; they follow the Sunbelt regional pattern noted previously. Perhaps the primary difference between seasonal and permanent migrants is that seasonal migrants sometimes travel farther, implying that the climactic change may be more important to them than it is to permanent migrants. The northward seasonal patterns from Florida and the desert states to cooler mountainous locations in North Carolina and New England in the east and to Colorado in the west have not yet been systematically studied.

The dialogue among researchers concerning whether seasonal migration is part of a process leading to permanent migration has concluded that seasonal migration generates its own lifestyle and culture, different from that of permanent migrants, but equally valuable. Once the lifestyle has been adopted, seasonal migration is likely to last for several years, finally interrupted or terminated by a fluctuation or decrease in necessary resources. Some do settle down and stay, but those are often people who have strong person ties in and place ties to the host community. They have family members and others living permanently nearby who tend to anchor them.

Counterstream Migration

Paired exchanges of migrants between some states are referred to as streams and counterstreams. The stream is the larger of the two. These paired exchanges are an expected part of the migration landscape. Furthermore, the migrants in the counterstreams are somewhat older on average, and more often are widowed and living dependently with relatives, than those who move in the larger streams.

Using 1990 census data to compare the 50 largest pairs of streams and counterstreams, researchers found three geographical patterns. The first involved exchanges between Florida and some of its major partners. The streams flowed into Florida, of course, with counterstreams moving in the opposite direction. The second geographical pattern was exchanges between California and adjacent or regional states. The smaller counterstreams flowed back to California. The third pattern, also regional, was the Mid-Atlantic exchange system, which involved streams out of New York to three adjacent states, Pennsylvania, New Jersey, and Connecticut, with counterstreams back to New York. These three exchange patterns continued to hold in the 2000 census.

These findings led to the speculation that counterstreams contain large proportions of returning migrants who had moved at an earlier time to a popular destination and are later returning to the state from which they had come. This speculation is bolstered by data showing the large proportions of migrants in counterstreams who are returning to their states of birth.

Return Migration

It was once thought that a majority of migrating retirees were likely to be returning to their home state. This popular myth was squashed by a study that showed that the return migration rate of older migrants, in 1970, was identical to that of all migrants, about 20%. More recent research shows that return migration is waning slowly among retirees. The rate of return migration was 18.6% in 1980, declined to 17.5% in 1990, and leveled off at 17.5% in 2000.

All of the reports on older return migrants have found that some states and regions are more popular with return migrants than others. For the year 2000, after subtracting out all persons leaving their state of birth (because they cannot be return migrants), 29% of the remaining older migrants were returning to their home states. North Carolina and Florida attracted half of their potential return migrants, whereas Wyoming and North Dakota attracted less than 15%. The pattern is unstable from one decade to another.

A popular ethnic explanation for return migration to the south and southwest concerns the return migration of African Americans and Hispanics. Regional return migration involves a historical work cycle. Industrial states recruit workers from rural

parts of the country. Streams of workers continue to tie these sending and receiving states together. However, over time, return migration streams develop that carry some of the retired workers back to their states of birth. These return streams build in a delayed but roughly proportional response to the earlier stream development for work. Although the principle applies to all, it is easier to discern when combined with ethnic identification.

In this context, it is not surprising to find that a majority of African American migrants age 60 and older are moving into the southern states. Nor is it surprising to find that return migration rates are high among these migrants. It is too early in the process of industrial recruitment of Hispanics to see high rates of return migration among Hispanics from Illinois and Michigan to the southwest. However, projecting from the African American work and retirement migration patterns, it would not be surprising to find such a development in the future.

There are two additional types of return migration discussed in the literature. The first is 'provincial return migration,' a subset of amenity migration. It consists of lifestyle-motivated movers who choose to move to their states of birth. They are younger, slightly better educated, more affluent, and far more often married than return migrants in general. The second type, 'counterstream return migration,' is a subset of 'dependency migration,' a move undertaken to gain assistance in activities of daily living. Interregional migration, returning to states of birth in the northeast and midwest, fits the aggregate description of counterstream return migration, and interregional migrants to the south and southwest fit the aggregate description of provincial return migration.

Metropolitan and Non-metropolitan Migration

One of the macro-level processes that affect geographical mobility in our time is metropolitan deconcentration. The long-term trend of population movement to cities slowed and reversed in the 1970s. Older people were in the vanguard of migration to non-metropolitan counties; the turnaround for them happened in the 1960s.

About three-fourths of later-life migrants move from metropolitan areas. Nearly that proportion of metropolitan out-migrants move to other metropolitan areas, but they tend to move to a smaller city, thereby increasing their quality of life by lowering the hassle factor. Although amenity migrants express a desire for a change of surroundings, they do not want to give up completely the comforts afforded by an urban lifestyle. Locations that are reasonably proximate to cities are especially attractive if the cultural and service amenities these migrants expect (e.g., museums, restaurants, theater, shopping, and an international airport) can be found in a city just an hour or two away. Sun City was built near Phoenix for a reason. And it is unthinkable that Cape Cod would have developed as it has without its proximity to Boston. One migrant described living on Cape Cod as 'the best of both worlds,' a place somewhere between the remoteness of rural living and the fast-paced life of the region's metropolitan centers.

Migration Impact

Economic Impact The 1990s began with a spate of articles considering the economic impact of retirees at their destinations. A sizable amount of annual income is transferred to and from states as a result of interstate migration. This money tends to concentrate, of course, in the major destination states. Unfortunately, a comprehensive measure of consumer spending is not included in the census. Income in these studies is a proxy for consumer spending.

During the same period, 515 rural counties, in which the older population was growing through migration, outperformed non-metropolitan area averages for job growth, ostensibly a result of retiree consumer spending. Other studies seemed to support these findings. By the end of that decade there was nearly complete consensus among researchers that the economic impact of retirement migration is positive.

Local Political Activism and Support for Public Services The positive economic impact must be balanced against a negative effect for public school financing. Local voting studies have examined the results of local school budget referenda. A study using the results of school district bond elections in Florida found that a higher percentage of elderly residents and voters in a school district predicted a lower level of support for schools. Citizens, and older citizens in particular, were much less supportive of public services, such as schools, that they did not expect to use. This does not imply that only older citizens, or the migrants among them, vote against school bonds. Younger persons without children and those who send their children to private and parochial schools tend to do the same.

Impact on Community Social Structure and Values Retirement enclaves in rural counties often tend to be worlds unto themselves, relatively unattached to local social structure. They are essentially 'common interest developments.' This social isolationist view is no longer normative. Migrants are sometimes seen as proactive agents of change in their

communities. For example, middle-class amenity migrants are likely to band together to protect the environmental ambiance of the community. Chambers of commerce trying to recruit both retirees and industry to their communities could find the retirees actively opposing industrial development on environmental grounds.

Mitochondria and Aging

D McKenzie and J Aiken, University of Wisconsin, Madison, WI, USA

Glossary

Apoptosis – Cell death.

Introduction

The mitochondrion has long been viewed as the Achilles heel of a cell. It is essential for energy production, yet the oxygen radicals generated during oxidative phosphorylation (OXPHOS) as well as the susceptibility of the mitochondrial genome to damage suggest a role for mitochondria in the etiology of aging processes as well as in age-related diseases. Oxidative phosphorylation occurs within the mitochondria, generating both ATP and, as a by-product, reactive oxygen species (ROS). The requirement for functional mitochondria (i.e., production of ATP) as well as the production of ROS make mitochondria pivotal players in the aging process and has led to the mitochondrial theory of aging. This theory, first developed by Denham Harman in 1956 and further refined by Jaime Miquel in 1980, states that aging results from an accumulation of oxidative damage to mitochondrial DNA (mtDNA), resulting in an accrual of damage to proteins critical to OXPHOS and energy production.

Evidence for the role of mitochondria in the aging process is provided by cell culture studies in which the mitochondria from old cells are isolated and then microinjected into mitochondria-less young cells. The young cells undergo a cellular degeneration not observed in young cells repopulated with young mitochondria. Age-related dysfunction of mitochondria has the potential to trigger cellular damage through a number of routes and can be manifested by a number of effects: oxidative damage to macromolecules (proteins, lipids, and nucleic acid), accumulation of mutations in the mitochondrial genome, and changes in the ability of the mitochondria to respond to apoptotic signals. Although there is a plethora of data to support each of these events, neither the cause and effect nor the synergistic effects of these events have been completely elucidated. Since damage to the mitochondria is hypothesized to result in cell death, ascribing the fate of these cells is complicated. This problem was described by the late George Glenner as the Mafia syndrome, i.e., the fatally affected cells cannot be found because the bodies have been assassinated and removed.

Approximately 90% of cellular oxygen is metabolized in mitochondria, with 1–5% of this being

converted to ROS as a normal by-product of electron transport system (ETS) activity. Mitochondria may, therefore, be the primary cellular source and target of endogenous ROS. Oxidative damage, secondary to endogenous or exogenous free radicals, is hypothesized to accumulate throughout the lifetime of an organism, eventually giving rise to physiological and structural changes that are recognized as aging. This is reflected in skeletal muscle by the age-associated increases in oxidative damage to proteins, lipids, and nucleic acids. ROS can directly modify proteins, forming protein carbonyls. In addition, carbohydrate and lipid derivatives can react with proteins to form adducts that can be analyzed. Protein carbonyl content (PCC) is the most widely used marker of oxidative modification of proteins. There are several methodologies for the quantitation of PCC; in all of them 2,4-dinitrophenyl hydrazine is allowed to react with the protein carbonyls to form the corresponding hydrazone, which can be analyzed optically by radioactive counting or immunohistochemically. Using PCC as a marker, it has been shown that oxidative damage to proteins correlates well with aging processes.

Lipid peroxidation is another type of oxidative damage that has been extensively studied with respect to age. The allylic hydrogens in the polyunsaturated fatty acid components of phospholipids in cellular membranes make the membranes sensitive to oxidation by free radicals. Lipid peroxidation is relevant to the aging process because increases in peroxidation result in decreased membrane fluidity and increase the leakiness of membrane bilayers. The measurement of lipid peroxidation has, however, been complicated by the lack of specificity of a number of the biomarkers originally measured. More recent means of determining lipid peroxidation have demonstrated that peroxidation increases dramatically with age.

The mitochondrial genome may be particularly susceptible to oxidative damage during aging. Mitochondria contain their own circular, double-stranded genomes (2–10 per mitochondria) that replicate independently of the nuclear genome. The mitochondrial genome is located in close proximity to the source of ROS and lacks cognates of the nuclear histone proteins that confer protection from ROS. Of the three principal DNA repair activities detected in the nucleus (i.e., base excision, nucleotide excision, and recombinational repair), nucleotide excision repair activity has not been detected in mammalian mitochondria. Oxidative damage to mtDNA increases with age in human brain, diaphragm, heart, and lung and in mouse liver and may directly disrupt mitochondrial gene expression or cause mtDNA mutations. For example, a specific oxidative DNA lesion, 8-hydroxydeoxyguanosine (8-OHdG), causes point mutations *in vitro*.

The generation of transgenic mice expressing a proofreading-deficient mitochondrial polymerase γ provided an animal model for determining the effect of mtDNA mutations on aging processes. These mice displayed a premature onset of many aging-related phenotypes, including weight loss, reduced fat, osteoporosis, and cardiomyopathy. Molecular characterization of the mtDNA in these animals demonstrated an increase in the number of point mutations and deletion mutations in the mtDNA, providing a causative link between mtDNA point mutations and tissue damage.

Damage to mtDNA directly impacts the ability of the mitochondria to function normally. The mitochondrial genome, in mammals, is approximately 16 kb in length and encodes 22 tRNA, 13 subunits of the ETS, and its own 16S and 26S ribosomal RNAs. It is a very compact genome lacking noncoding regions with the exception of the D loop (control region), responsible for controlling initiation of replication and transcription. The mitochondrial transcripts are synthesized as long polycistronic messages and are transcribed from both strands. The mitochondrial genome encodes 13 subunits of four protein complexes critically important for the functioning of the ETS and OXPHOS pathways. All other proteins required for maintenance of mitochondrial function are encoded in the nucleus, synthesized in the cytosol, and imported into the mitochondria by specific targeting sequences at the N-terminus of the proteins. Oxidative damage to, or mutation of, the mitochondrial genome may affect the activity of those ETS complexes to which this genome makes its largest polypeptide contributions, namely, complexes I and IV (i.e., NADH dehydrogenase and cytochrome *c* oxidase [COX], respectively). Biochemical analyses of tissue homogenates identified decreased complex I and IV activities with age in postmitotic tissues that rely heavily on the ETS and OXPHOS such as brain, heart, and skeletal muscle. *In situ* histochemical studies demonstrate increased abundance of ETS abnormal cells with age in a variety of tissues including heart, extraocular muscles, limb muscles, parathyroid, and diaphragm. An absence of cytochrome *c* oxidase activity (COX^-; three subunits encoded by the mtDNA) is the most commonly reported abnormal ETS phenotype and is often observed with a concomitant increase in the entirely nuclear-encoded ETS complex, succinate dehydrogenase activity (SDH^{++}). The SDH hyper-reactivity is likely due to compensatory nuclear upregulation of mitochondrial biogenesis. The SDH^{++} phenotype (typically in combination with the loss of COX activity) within a

skeletal muscle fiber represents the ragged red fiber (RRF) phenotype observed in Gomori trichrome staining of skeletal muscle from aged individuals or those with mitochondrial myopathies.

mtDNA mutations have been shown, in humans, to result in a number of diseases, including myopathies and encephalopathies, a broad class of conditions characterized by muscle weakness and central nervous system dysfunction. Myopathies can be divided into two major groups: those caused by a single mtDNA base substitution, such as Leber's hereditary optic nerve atrophy and myoclonic epilepsy and ragged red fiber (MERRF), and diseases caused by large mtDNA deletion mutations, including chronic progressive external ophthalmoplegia (CPEO) and Kearns-Sayre syndrome (KSS). In myopathy patients, the levels of the mutated mtDNA genomes are very high, 73–98% mutated mtDNA in symptomatic MERRF patients. Deletion mutations are generally present as 20–80% of all mtDNA genomes in KSS patients. Cybrid cell studies of myopathic mitochondrial deletions demonstrate decreases in cell growth, ETS/OXPHOS activity, mitochondrial membrane potential, and rate of ATP synthesis, suggesting that similar *in vivo* deficits may occur in ETS abnormal cells or segmental portions of muscle fibers.

Age-related mitochondrial dysfunction also plays a critical role in both the initiation and progression of a number of age-related diseases. Somatic mutations in the mitochondrial genome have been linked to Parkinsonism, late-onset sporadic Alzheimer's disease (AD), and Wilson disease, to name a few. A substantial body of evidence suggests that mitochondrial dysfunction, the resultant increase in ROS production, and decrease in energy production are responsible for the loss of neurons in AD.

Direct evidence for the age-dependent accumulation of mtDNA abnormalities required the development of the polymerase chain reaction (PCR), a technology that provided the sensitivity necessary to identify these abnormalities in tissue homogenates. Initial studies focused on human tissues and identified an age-associated increase in a specific 4977 bp mtDNA deletion mutation, often termed the common deletion. Subsequent studies identified other mtDNA deletion mutations to accumulate with age in a variety of species, including humans, rhesus monkeys, mice, and rats. These studies, largely based upon the analysis of tissue homogenates, demonstrated that mtDNA deletion mutations increase in frequency with age. Accurate estimates of the abundance of these abnormalities required the design of experiments that considered the focal (and not homogeneous) distribution of these abnormalities.

Initial quantitation experiments of aged human tissue utilizing radioactive PCR methods determined the abundance of the specific deletion mutation, $mtDNA^{4977}$, to be $<0.1\%$ of the total mtDNA present in the tissue homogenate. The low abundance of this deletion led to the speculation that mtDNA deletion mutations are of minor physiological significance and impact. All of the initial quantitative analyses, however, were performed using cellular homogenates, in which thousands of cells were present. Estimating the abundance of mtDNA deletion mutations from homogenates assumed an equal cellular distribution of the deletion-containing genomes, an assumption subsequently determined to be incorrect. *In situ* hybridization analyses of aged muscle tissue provided the first evidence of a focal accumulation of mtDNA deletion mutations. The initial *in situ* hybridization studies of age-associated mtDNA deletion mutations were performed on human skeletal muscle and were focused on the detection of common mtDNA deletion mutations. Using mtDNA probes located either within or outside the deleted regions, high levels of mtDNA deletion mutations were localized to individual cells, suggesting that deletion mutations accumulate focally and that neither their abundance nor distribution can be accurately assessed in cellular homogenates.

Histological examination of tissues, particularly skeletal muscle, using stains for the activity of mitochondrial ETS enzymes has facilitated an analysis of the physiological effects of mtDNA deletions. Dramatic changes in the activities of two ETS enzymes, COX and SDH, were observed in myopathy patients and were later demonstrated to occur in a number of different mammalian species with age. These two enzymes were monitored because several of the COX subunits are encoded by the mitochondrial genome and, thus, would be indicative of changes in the mtDNA. Although SDH is entirely encoded by the nuclear genome, decreases in mitochondrial energy output results in a compensatory upregulation of nuclear encoded genes.

One example of the impact of mtDNA deletion mutations occurs with sarcopenia, the age-related loss of muscle function, fiber mass, and fiber number. In the skeletal muscle of rodents, humans, and rhesus monkeys, intrafiber increases in mtDNA deletion mutation abundance are closely linked with declines in ETS enzyme activities and with physical changes in muscle fibers. For these studies, muscle tissue was examined histologically by staining consecutive slide sections for COX and SDH activity. Using these two enzymatic stains, the age-dependent increase of ETS abnormalities has been demonstrated in several different muscles and animal models. When these

abnormal fibers are followed histologically along their length (longitudinal analysis), many of the ETS abnormal fibers displayed an overt decline in cross-sectional area (intrafiber atrophy) within the ETS abnormal region of the fiber. The cross-sectional area of the ragged red region is smaller than that observed in normal fibers, and the longer ETS abnormal regions are more likely to atrophy than shorter ETS abnormal regions. Longitudinal analysis of atrophied fibers also showed some decrease in cross-sectional area until they are no longer observable by light microscopy, suggesting that they are broken. The fiber can often be found again several sections later. These data clearly demonstrate that ETS abnormalities have a localized physiological impact on the cell and can result in fiber atrophy and fiber breakage.

By focusing on cells displaying an ETS abnormal phenotype, it is possible to specifically define the mtDNA genotype (mutation) associated with that phenotype in a single cell. A single section of a cell can be captured by microdissection, the DNA isolated from the cell and the mtDNA amplified using PCR. In all cases, the mtDNA deletion mutations were concomitant with the COX^{-}/SDH^{++} regions of affected muscle fibers. When ETS normal regions of the same muscle fiber (i.e., from sections further along the fiber) are analyzed, only full-length wild-type mtDNA genomes are identified. When the same ETS abnormal region was sampled in two different places from the same fiber (i.e., 70 μm apart), the same deletion product was obtained, demonstrating that mtDNA deletion mutations are clonal events. These studies suggest a process in skeletal muscle initiated by the mtDNA deletion mutation that accumulates, triggering the COX^{-}/SDH^{++} phenotype and, ultimately, fiber atrophy and fiber breakage.

Point mutations in the mtDNA have also been demonstrated to accumulate with age. Initial efforts emphasized single nucleotide changes associated with mitochondrial myopathies, and the point mutations characteristic of MERRF and MELAS (mitochondrial myopathy, encephalopathy, lactic acidosis, and strokelike episodes) were identified in normally aging humans. Many other myopathy-related point mutations have been examined in aging humans using tissue homogenates. Although these studies produced variable results, point mutations in homogenates from various tissues of aging individuals are present at very low levels (0.04–2.2%) compared to levels in myopathy patients.

Point mutations can be detected when they have clonally expanded within a mitochondrial population, i.e., when they occur in the germline and are present throughout all tissues. If, however, point mutations accrue at low levels randomly throughout the mtDNA genome, detection becomes much more difficult. The aggregate burden of mtDNA point mutations can, however, be determined by cloning and sequencing a specific region of the mtDNA genome. For example, a PCR-cloning-sequencing strategy has demonstrated that mtDNA from brains of elderly humans has a higher aggregate burden of mutations than mtDNA from younger patients. These mutations were, in general, individually rare point mutations. Interestingly, although the aggregate burden of point mutations is high, the majority of the mutations are rare. When single cells were analyzed, point mutations were observed to accumulate to high levels in an age-dependent and tissue-specific manner. Several specific point mutations occur at high levels (up to 50%) in skin fibroblasts from individuals older than 65 years, but the same mutations are not observed in muscle from the same individuals. The absence of a readily detectable phenotype (like the COX^{-}/SDH^{++} observed with deletion mutations) makes the physiological relevance of these mutations difficult to determine.

The lack of overt phenotypes has hampered attempts to relate point mutations in mtDNA to the aging phenomenon, although the mutations appear to increase with age. Cellular impacts of age-associated point mutations in mtDNA have not been reported. The point mutations in the control region of mtDNA may have little impact on cellular physiology, so cells could accommodate and accumulate them to high levels. If single cells can accumulate high levels of point mutations and still function within normal parameters without expressing abnormal phenotypes, point mutations may be an age-associated phenomenon, but not causally linked to aging.

It has been difficult to determine the cause of mtDNA mutations (both deletion and point). It was initially suggested that oxidative damage was the causal factor in initiation of deletion and point mutations events. Although the amount of oxidative damaged mtDNA has been shown to increase in tissue homogenates with age, the demonstration of causation has been much more difficult. Oxidative damage can be detected in atrophic, ETS abnormal cells but not in the adjacent ETS abnormal regions that are not atrophic, suggesting that the oxidative damage detected was a result and not a cause of mtDNA mutations.

Dietary restriction (DR), the restriction of calories without malnutrition, is the most successful anti-aging intervention tested to date in mammals, greatly extending maximum life span and keeping animals younger longer. Reduction in oxidative stress is a feature of DR in skeletal muscle in mice. DR

attenuates the age-associated increase in rates of mitochondrial ROS and H_2O_2 generation and reduces the accrual of oxidative damage. Mitochondrial function is also preserved with age in skeletal muscle from DR animals as indicated by decreased alkane production, delayed loss of membrane fluidity, and increased metabolic potential compared to control animals. In the studies of sarcopenia described previously, adult-onset DR has a protective effect on skeletal muscles, reducing muscle mass loss and maintaining fiber number.

Mitochondria also play a critical role in cell death pathways, particularly apoptosis. Proteins localized within the mitochondria are involved in the activation of the caspase proteases, initiating a series of events that result in cell death. In apoptosis, a transient opening of the mitochondrial permeability transition pore of the mitochondrial inner membrane results in the movement of cytochrome *c* from the intermembrane space of the mitochondria into the cytosol. In the presence of dATP, cytochrome *c* forms an apoptosome with Apaf-1. This apoptosome activates a protease cascade resulting in apoptosis. Changes in mitochondrial function with age appear to have confounding effects on apoptosis, dependent on the cell type involved. Mitochondrial dysfunction in certain cell types, such as neurons and cardiomyocytes, results in the initiation of apoptosis and subsequent loss of these cell types. These apoptotic events may be critical in diseases such as age-related dementia and cardiac dysfunction.

Mitochondrial dysfunction can also, however, affect the cell death pathways. In cell culture, the lack of mtDNA in hepatoma cells makes these cells resistant to apoptosis. It has also been demonstrated that a lack of ATP production is sufficient to switch the cell death pathway from apoptotic to necrotic. The inability of the tissue to rein in aberrantly dividing cells is a key step in the development of cancer cells.

In summary, the mitochondrion, although essential to the functioning of eukaryotic cells, can lead to the degeneration of a cell. Chronic exposure to ROS, a by-product of oxidative phosphorylation, damages many macromolecules, including DNA, lipids, and proteins. Age-dependent increases in the somatic mutations of mtDNA, particularly deletion mutations, affect both OXPHOS and ETS activities in a cell. The resultant declines in energy production and increases in ROS production lead to cellular dysfunction and, ultimately, tissue/organ dysfunction.

Mobility and Flexibility

H Mollenkopf, German Centre for Research on Ageing at the University of Heidelberg, Heidelberg, Germany

Glossary

Mobility – The physical ability to move and the possibility to realize trips and activities outside the home.

Introduction

This article deals with an essential precondition of older adults' independent living and societal participation: the ability and possibility to move about. In principle, mobility constitutes a basic need and behavior of people of all ages. This statement applies to both the fundamental physical capacity to move and the farther-reaching ability to travel for bridging spatial distances between spheres of life that are

central for enabling every individual to conduct an autonomous lifestyle and maintain connectedness with his or her community and culture. These conditions of mobility are usually taken for granted. With advancing age, however, mobility is increasingly jeopardized. Aging is accompanied by the growing risk of physical disabilities and declining sensory abilities, and hence restriction of mobility. Outside the home, unfavorable circumstances such as inaccessible buildings and modes of transportation, the replacement of previously personal services by machines, and the speed and complexity of traffic can further complicate older adults' ability to move about. At the same time, the importance of mobility increases, because social changes such as grown children leaving home, retirement, and the loss of close confidants demand a growing measure of mobility and flexibility if the elderly individual is to continue being part of society.

Moreover, mobility and flexibility are crucial to modern industrialized societies. This holds for mobility in the sense of social mobility, including the dissolution from social classes and hereditary positions, and the loosening of binding social roles and norms that have led to the pluralization of lifestyles and variety of life course regimes. It goes also for mobility in the sense of geographic mobility, including the migration of individuals or groups, moving from one place to another and traveling to attractive destinations in an increasingly global world (although that may not apply to the whole of the population), and not least in the sense of the actual journeys performed by each member of society, whether by foot or employing any means of transportation.

In connection with this historical development emerged the association of mobility with modern values such as autonomy and freedom of choice, flexibility, and variability of behaving and thinking. As a result, mobility implies highly appreciated societal goals and symbolic meanings in addition to its significance as human need for physical movement and functional necessity to overcome distances between different locations.

As various as the components of mobility are, as manifold are the theoretical and empirical approaches addressing them. As for the micro-level of person-related physical, sensory, and cognitive competencies and impairments, of individual motivations and behavior, and of sociodemographic and structural aspects, behavioral and social as well as medical sciences are in demand. Sociological theories are also needed concerning the macro-level of societal and technological conditions and related developments. Traffic and transport policy and research are just as relevant as geography and urban planning, architecture, and vehicle engineering. Further disciplines may be necessary depending on the focus of interest.

In an article like this it is not possible to do justice to all of these aspects in detail. Therefore, it concentrates on those aspects that can be considered most relevant for older adults' out-of-home mobility from a social science perspective. It proceeds as follows: first it traces back why mobility and flexibility have become so significant in modern society and shows the many facets accumulating in this phenomenon. Second, the main components of older adults' mobility and the respective theoretical views and empirical findings concerning these components are presented. Whether the increasing number of old and very old people can move about and get to places to which they wish or need to get depends on various personal resources and environmental circumstances. These conditions are dealt with in the next section. The article continues by pointing to a range of future challenges to mobility and possible improvements for meeting older adults' mobility needs and flexibility desires. And finally, it tries to link the different strands in a more holistic concept of older adults' mobility.

The Significance of Mobility and Flexibility in Modern Societies

Historic Developments

In order to understand the tremendous importance mobility has gained in current society it may be useful to locate it in a larger historical context.

In the sense of the physical ability to move and to flexibly take up the demands of the social and physical environment, mobility has constituted a key to survival of the human species. For centuries, mobility has meant locomotion on foot or on horseback and travel by cart or boat. Over the course of the nineteenth century, industrial development opened up new opportunities for individual mobility and traffic. After its first run between Liverpool and Manchester in 1830, the railroad quickly gained ground. As steam and rail technology improved and electric power became practical, railways became the dominant means of land transport in many parts of the world for nearly a century.

After a delay of a few decades, progress in aviation occurred. The turn of the century saw the first motor planes, and 1911 the first transcontinental flight. Commercial aviation took hold in the 1950s and 1960s, and from 1969 on the Boeing 747, the largest passenger-carrying aircraft ever built, started to revolutionize commercial air travel. Meanwhile, mass tourism is an important industry worldwide.

The automobile developed much faster. Just 14 years after the first practical gasoline-powered automobile, which drove on German roads in 1886, there existed about 12 000 automobiles worldwide. From 1908 on, the assembly-line mass production of cars has developed, and meanwhile, the automobile has become the preferred means of transportation. Simultaneously, the length of the motorway network grew while the length of the rail networks contracted.

Altogether, these technological developments, accompanied by corresponding organizational transformations, led to mobility and travel increasing continually. Whereas estimated global traffic volume amounted to approximately 5.5 trillion person-kilometers (motorized mobility per capita in 11 world regions) in 1960, this figure had risen to 23.3 trillion in 1990. The distances traveled have increased in particular, because while transport technologies have improved, the shape of urban and rural settlements and the constitution and nature of neighborhoods have changed as well. Underground and street railways built in large cities and the provision of extended road infrastructure accelerated extensive suburban development and the establishment of industrial and commercial enterprises beyond residential areas. The growing dispersal of travel origins and destinations, in turn, increased the importance of mobility for bridging the widening gap between functional areas.

Looking for causal directions in this close relationship between transportation and land use will probably be in vain. The question of whether transportation infrastructure influences urban form or whether land use patterns impact travel behavior has been discussed in theory and empirical studies for many years. One can assume that both directions are partial equilibrium and interdependent interactions. In any case, the interrelated trends of advances in transport options and urban sprawl complementing one another have contributed to the fact that for every member of society, mobility has become a major condition of ensuring the ability to lead an autonomous life and participate actively in society.

The Subjective Meaning of Mobility

There is increasing empirical evidence that older adults' diminishing actual mobility as it was observed in many studies (usually measured as frequency of trips made – see next section) does not correspond to their needs and wishes. As early as the 1980s, Carp (1980: 140) stressed the importance of mobility in old age: "In modern society old people, like those of other ages, must go outside their homes to provide for maintenance needs as well as for sociability and recreation." If life is to have an acceptable quality, she argued, needs such as those expressed in, for example, trips for relaxation and enjoyment are as essential as shopping trips or commutes to work, and they are requisite to independent living.

A series of European studies demonstrated that the possibility to move about and to pursue outdoor leisure activities contributes significantly to older adults' subjective quality of life. Lower trip rates did not correspond with lower levels of desire to do certain trips, especially leisure-related trips. Instead, older people who were limited in their mobility either by health impairments or by the lack of a car were less satisfied not only with their possibilities for reaching the destinations they wished but also with their possibilities for participating in leisure activities. In addition, individuals themselves place a high value on the ability to move about. Statements like "It's everything, it's life," clearly show that mobility means much more than merely a derived demand. In the United States, similar answers were received with respect to the meaning of transportation, albeit mostly related to being able to drive a car. Elderly people described the strong linkage between transportation, independence, and overall life satisfaction. Thus, individual needs and societal necessities, economic interests, and modern values mutually reinforcing each other have resulted in mobility as an increasingly important precondition of maintaining quality of life and well-being in aging individuals.

Theoretical Views and Empirical Findings

The out-of-home mobility of aging and aged persons is a complex phenomenon that cannot easily be captured. It is complex, because so many different aspects come together with this interaction between persons and their environments. As shown previously, mobility means both the physical ability to move and the realization of all types of trips and activities outside the home. It can be motivated by diverse, often inseparably intertwined motives and manifested in a goal-directed mode or for its own sake. Actual travel can be performed by foot or by employing any mechanized or motorized means of transportation. Furthermore, spatial and traffic conditions and context for mobility can differ widely. The persons themselves who move, walk, drive, travel, etc. are different with respect to their individual health and mental states, economic and social resources, and their mobility may depend on individual capacities, attitudes, and interests. These different aspects have been addressed from diverse perspectives. In the following sections, the most important approaches are discussed.

The Health Perspective

Whether elderly men and women can fulfill their mobility-related needs and desires and how they manage as they go about their daily affairs and out-of-home activities depend first of all on their state of health. All kinds of movements demand a minimal amount of physical and cognitive capacity, for walking, cycling, driving, or using any other means of transportation. In this respect, the process of aging is accompanied by multiple changes. For decades, a broad range of research has been conducted to understand, among other areas, the increasing decline in mobility performance, including decrements in motor control and force production and regulation; loss of voluntary strength; reduced sensory abilities and sensorimotor integration; slowing motor action and speed of processing; shrinking range of motion and flexibility; and decreasing ability to stabilize posture, resulting in an increased risk for falls. All of these age-related changes may restrict older persons' ability to ambulate and move about.

As there exist excellent comprehensive reviews and contributions on specific aspects of these issues, they are not further addressed here. However, it is worth mentioning that although the deficiencies in walking, visual acuity, hearing, memory, etc. can be substantial, they do not automatically confine all older individuals to their homes. Moreover, there is evidence that physical activity and regular training can minimize the decline in motor function.

Furthermore, functional decline is significantly related to demographic characteristics, lifestyle, social relations, and neighborhood conditions. Difficulties in getting about outdoors were found most frequently among women of older age and among elders with low education, lower income levels, and previous chronic conditions; people with few social contacts; and those living in problematic neighborhood environments. Obviously, conditions of physical and cognitive impairments interact in a complex fashion with sociophysical environments.

The Environment Perspective

The outdoor environment with its various physical-spatial and social components constitutes both the target and context of older adults' mobility. Shops and service facilities, recreational spots and favorite restaurants, a close friend's home or a medical care facility: all of these and many more close or distant places can be a target, and every action undertaken to get such a target always takes place in a concrete spatial context. From the perspective of environmental gerontology as formulated by Lawton and colleagues in the early 1980s, mobility can be regarded as a prototypical person–environment interaction. On the one side, the aging individual with his or her competencies and impairments, needs and desires, is involved. On the other, the specific sociospatial characteristics of the environment are concerned. Both the social and physical environments are inseparably interwoven and can constitute at the same time major resources and constraints for an aging individual's potentials and scope of action, because they can differ widely. This holds for general features like a region's geographical, topographical, and climate characteristics, welfare systems, and the various kinds of urban or rural settlements, and for the immediate natural and built surroundings, including, for instance, social networks and other traffic participants, neighborhood and community conditions, and the modes of transportation one can use to achieve out-of-home goals. Environmental conditions can be safe or dangerous, provide a variety of shops, medical services, and leisure facilities, and offer a dense and accessible network of public transportation systems – or can hinder people because of lacking opportunities, unfavorable distances, or traffic density, noise, and inconsiderate road users.

Service and Security Aspects Since Carp's early studies on environmental effects upon the mobility of older people, several studies have shown that characteristics of the area in which older adults live strongly affect their mobility and related activities. Generally, facilities for daily necessities and cultural opportunities are less accessible and adequate health and community-based services are less abundantly available in rural than in urban areas. Moreover, rural areas are often characterized by a lack of public transit services. Thus, and not surprisingly, older adults in rural areas can reach basic facilities less often on foot or by public transportation than their urban counterparts. Instead, they have to use the car more often, both as driver and as passenger.

Rural elders, in general, go out less than older urbanites. They are also less satisfied with their possibilities to be mobile and active, and they would like to take more trips than they actually do. The factors impeding their access to important facilities are mainly related to health and great distances. Hence, the less competent an individual is, the greater the impact of environmental factors, and the greater the importance of neighborhoods that provide easily accessible amenities nearby for maintaining independent living.

Findings on urban–rural differences in health status are, however, inconsistent. US studies showed that rural and urban older persons did not differ significantly regarding chronic health problems, although there is some evidence that some dementing

illnesses are more prevalent in rural regions. Similarly, no, or only slight, differences between urban and rural areas were found regarding functional health in a recent European study.

Apart from the accessibility of services, facilities, or public transportation, the fear of crime can influence mobility-related decisions and inhibit outdoor behavior in a specific residential area. Security does not seem to be a concern for most older adults living in the countryside, whereas in urban areas there are substantial percentages of people who perceive their local environment as unsafe.

Social Aspects Regional conditions – especially those relating to distances between places of residence – also affect the frequency and nature (personal, technically mediated) of social contacts and activities that are crucial prerequisites for satisfactory aging. The transportation times needed in, for instance, large metropolitan areas or sparsely settled rural regions increase the difficulties of maintaining social relationships. At the same time, the social context affects older adults' out-of-home mobility: those with a diversified social network make more trips than older individuals without persons outside their household who are important to them for emotional or personal reasons.

In an analysis of visually impaired elders' out-of-home activities in Germany, the motivation to go out was significantly associated with social resources in urban but not in rural areas. This might be related to the greater geographical distances to important persons in cities. That is, in urban areas one might have to be more motivated to go out to maintain social relationships. Older urbanites live generally farther away from their most important confidants than older adults in rural areas, and the closer an individual lives to important persons, the more frequently they meet. However, it might also be that in urban regions social resources enhance outdoor motivation because social contacts with others living farther away might be an important reason to go out.

Spatial Aspects Clear differences in older adults' spatial mobility patterns reveal when differentiating by residential location. 1995 Nationwide Personal Transportation Survey (NPTS) data show that elders living in suburban or rural areas made more trips, traveled longer, and used the car more often than those living in high-density urban areas. However, living in high-density urban areas is usually related to age, family size, and income, all of which are also associated with less travel.

Regarding the impact of different kinds of neighborhoods on trip frequency, findings suggest that compared with conventional neighborhoods, single-family households in neo-traditional neighborhoods make a similar number of trips, but substitute walking trips for driving trips. Characteristics of the residential environment seem to affect the modal choice of older people who do not have a car of their own. If they own a car, they often use it, independent of where they live. Evidence from a review considering differing neighborhoods suggests that beyond sociodemographic predictors, environmental characteristics such as higher density, greater connectivity, and more land use mix contribute to higher rates of walking and cycling.

The spatial range of older Europeans' out-of-home mobility – and thus their activity space – is quite restricted. Forty-four percent of the trips have a destination within a circle of 1 km, and an additional 24% between 1 and 3 km. Only 14% of the trips go further than 10 km from home. But as in the United States, the range of mobility is larger in rural than in urban areas. While in most European urban areas the elderly can reach essential facilities mainly on foot or by public transit, they often depend on a car or on other (family, formal) transportation support in rural areas. It is no wonder that rural elders are usually better equipped with private cars than elders living in urban areas. Exceptions are, on the one hand, countries such as Italy, where car ownership among older adults is generally high (about 83%), and on the other, countries with a low level of individual motorization, such as Hungary (36.5% car ownership in the city and 17.4% in the rural area).

The Transport Perspective

In transport research and planning, mobility usually has been defined as locomotion, as a movement in time and space. It is measured in terms of trips or journeys made and reported in standardized diary forms. Information is generally collected and provided on travel origins and destinations, distances, travel modes used, periods of time, and the activity pursued at the destination reached. Based on this kind of statistical data, many national and international studies and reports have provided abundant information not only on traffic flow of vehicles and travel patterns of the entire mobile population, but also on older adults' actual travel behavior and its sociodemographic background conditions.

To summarize the findings, in general – albeit to a diverging extent depending on national levels of motorization – travel of older adults has clearly increased for about two decades. Among the older population, older men make more trips per day and travel more miles than older women; individuals with a driver's

license and access to a private automobile travel more than those who do not have a car at their disposal; and the older they are, the more people tend to decrease traveling, mainly due to increasing health and sensory impairments. Older women of the present generation have less education and a lower income, and less frequently possess a driving license, than men of the same age. These conditions can to a great extent explain why they stay closer to home and use public transportation more than men. This may change, however, when new cohorts of women reach retirement age for whom driving a car for getting around has become a matter of course, as it is the case today for most older men.

For some years now, this functional approach to mobility has become more and more questioned. To better understand actual travel-related choices, the focus has shifted to more activity-based and process-oriented models of travel and driving behavior. These approaches usually focus on the population as a whole, which consists predominantly of commuting working-age people. Therefore, even such advanced approaches do not seem adequate to capture the key concerns and various aspects of older adults' mobility. Trip chains composed of several modes are mostly judged by the main mode only, resulting in an underestimation of small trips and non-motorized means of locomotion, that is, older adults' most common travel modes, at least in Europe. Activities that might be subjectively significant, but that are pursued only once or twice a year, risk being neglected in studies limited to 1- or 2-day diaries.

Most of all, however, mobility comprises more than the functional aspects of getting from place A to destination B under certain conditions. Mobility can be performed for its own sake and not just as a derived demand. Moreover, in modern society, mobility – the ability to travel – is associated with highly valuated societal goals such as freedom, autonomy, and flexibility. The assessment of mobility should therefore include as much as possible of these aspects. The automobile, in particular, symbolizes such modern values, and among the whole range of currently available transportation modes, it opens up the most independent and flexible options for moving about.

Travel Patterns As has been reported repeatedly, the vast majority of older adults in the United States, but increasingly also in Europe, are largely dependent upon access to private automobiles. There is no cohort of older Americans that takes fewer than eight out of ten trips in a car.

In Europe, elderly people – at least currently – are far less 'auto-mobile' than in the United States. They make significantly fewer trips per day and travel fewer miles than comparable American elders. Currently, walking is clearly the most common travel mode of older Europeans. Almost half of all trips made by the people who participated in a study comparing the mobility needs and patterns of older adults in five European countries (Finland, Germany, Hungary, Italy, and the Netherlands) were on foot (45%). The car, used as driver (28%) or as a passenger (11%), was the second most important mode, with altogether usage by 39%; public transport including all modes (bus, tram, train, taxi, and special transport) was used in 8% and the bicycle in 10% of the trips. However, an area's provision with public transportation systems, the topographical conditions, and the availability of a car in one's household clearly affect older adults' choices of transport modes: In the German cities with relatively good public transport options, for instance, 54% of all trips are made on foot, and cars are used for only about 32% of all trips, whereas in the Finnish and Italian rural areas, the percentage of trips taken on foot barely amounts to one-third. In Italy, using the car (as a driver or passenger) is even more common than walking. The bicycle is used most often (up to 20%) in regions with favorable topographical conditions such as the flat Finnish, Hungarian, Dutch, and eastern German rural areas included in the study.

Older adults who are able to drive and actually use a private automobile are by far more satisfied with their general mobility than those without access to a car or who use cars as passengers only. When the impact of individual predictor variables on mobility satisfaction was examined, a clear and consistent pattern was observed: fair or good physical mobility, the ability to drive (and not just to have a car available), and being satisfied with the local public transportation system were found to be the most important variables in almost all regions studied. Only in Hungary did the availability and use of an automobile have no impact on satisfaction with mobility at all.

These results demonstrate that, in addition to good health and the capability to drive, good and accessible public transit can be crucial for satisfactory mobility. But often, the alternatives currently offered by conventional public transportation systems – if they exist at all – do not meet older people's need for mobility. In the United States, just 2.3% of older people use public transit for making trips. While in urban areas this figure amounts to 8.2%, it reaches only 0.3% in rural areas where transportation alternatives to the car are even less available.

Driving and Safety Issues The share of pensioner households that own a car still varies greatly. In the United States, it depends largely on income, gender,

family size, and ethnicity. In Europe, car ownership depends on the size of household, age, gender, income, and the country somebody is living in. This relation will change in both the United States and Europe in the coming years when the growing number of license holders who are used to relying on a car for conducting an active and mobile life style – in no small part consisting of women making up mobilization – reaches retirement age. Thus, travel trends in Europe are moving in the same direction as in the United States.

For about two decades now, the driving behavior and safety of the increasing number of old and very old traffic participants have been given great attention. The focus has been on assessing and improving the safety of older drivers and on driving problems, in particular those that are caused by chronic illnesses, sensory and mobility decrements, or dementia.

It is true that older drivers do not have a disproportionately greater frequency of involvement in accidents than younger drivers. As a person ages, though, the risk of his or her having an accident grows in relation to driving performance (and hence in relation to the exposure to danger), and when an older individual experiences an accident, the consequences are more severe than among younger adults. Walking or biking are not good alternatives either: elderly people are also very vulnerable as unprotected road users. Hence, helping older adults continue to drive safer has become a dominant goal in policy and practice. Activities include finding ways to screen and identify unsafe drivers, develop adequate education programs, and weigh different relicensing standards. Further efforts concern vehicle redesign and adaptation to older drivers' capacities as well as respective roadway improvements as compiled in, e.g., the Federal Highway Administration's *Highway Design Handbook for Older Drivers and Pedestrians*.

The Psychology Perspective

Psychological aspects have only recently received some attention in assessing and understanding older persons' mobility and flexibility. Motivational, cognitive, or personality aspects can, however, play an important role in their decisions about going out. For example, outdoor orientation, wayfinding, the use of automatic ticket dispensers, and the interpretation of mobility-related information depend strongly on cognitive abilities. At the same time, the experience of being in control over one's life circumstances and a high motivation for being on the go may motivate an aging individual to invest time and effort in maintaining a maximum level of out-of-home mobility even when confronted with functional or mental health decrements and/or adverse environmental conditions.

A sense of optimism and positive expectations of life were found to constitute main building blocks for the transport dimension of older adults' perceptions of quality of life. Psychological variables also played a role for characterizing groups of older adults who differed in their out-of-home mobility patterns. Perceptual motor processing, working memory, or visuomotoric coordination, which has repeatedly been found to be a major indicator of basic cognitive functioning, clearly and consistently decreased from the highly mobile and satisfied to the almost immobile and dissatisfied group. In addition, external control beliefs (measured with the control beliefs questionnaire used in the Berlin Aging Study) increased, while individual importance attributed to being out (assessed using an 11-point rating scale [0–10], higher scores indicating higher importance) decreased substantially from the first to the last group. Even in severely vision-impaired elders, this outdoor motivation turned out to contribute to mobility in terms of out-of-home leisure activities, particularly in urban areas.

A further psychological aspect may be the cognitive and emotional benefits conveyed by different options of performing mobility. In a comparison of private car users with users of public transportation, access to a car and, in particular, being a car driver appeared to confer more psychological benefits such as autonomy, self-esteem, and mastery than using public transport. This proved true independent of age, gender, or social class. Among men, in particular, driving and the type of car were associated with self esteem and prestige, while women appeared to gain more mastery and protection from car access, reflecting differing significance of cars in men's and women's lives. Similarly, besides instrumental functions, car use fulfills important symbolic and affective functions.

Altogether, these findings suggest that although physical, social, and technical resources, as well as the structural resources provided by a region or locality, constitute basic preconditions for moving about, they appear to be mediated by individual needs and emotions and by the subjective assessment of situations and one's own abilities.

Future Challenges and Perspectives

In the face of the acute demographic change, accompanied by a perpetually increasing proportion of older drivers in almost all industrial countries of the Western world, the related growth in driving and subsequent growth in traffic volume and congestion

have become an issue of general concern. At the same time, attention has been turning to the challenges that more and more older men and women face when they are no longer able to drive. Several studies showed that social isolation and depressive symptoms may increase when people are unable to get to shops and recreational facilities and stay connected with friends and community.

Both of these issues are particularly salient, as older adults in the United States, but increasingly also in Europe, are highly dependent on the car to obtain the mobility necessary for maintaining an independent lifestyle and active participation in society. Therefore, manifold efforts are undertaken to meet the diverse transportation needs of the growing older population and, on the one hand, to secure safe mobility for a maturing society, and on the other, to promote safe and sustainable environments. Among the strategies are driver programs; improving routes and highways; promoting attractive, accessible, and flexible public transit; developing alternative transportation options; creating pedestrian-friendly zones, walkways, and altogether livable communities; and suggesting policy agendas.

Of particular relevance are technological advances at various levels that can further support older adults' mobility needs. Improvements in road transport informatics and in-vehicle technologies promise to facilitate travel and improve safety for everyone and for older drivers, in particular. Automobiles can be redesigned to better fit older drivers' capabilities by a variety of cutting-edge technologies that include, for instance, vision systems, emergency systems, cruise control, stop and go assistance, parking assistance, collision avoidance systems, and curve lighting with global positioning systems (GPS). There are clear benefits for older drivers from road transport informatics and advance information on routes and travel times as well. However, all these devices and appliances still need further improvement. Due to limited information-processing capacity, assistive devices and telematic systems might overload older drivers by requiring continuous monitoring. The application of acoustic warning methods is limited because the ability to understand speech information at a low signal-to-noise ratio declines with advancing age.

Not least because of these developments that are suited to amplify driving options, the current generation and the generations of people to come will increasingly rely on the automobile. As a private and flexible means of transport, the car will not decline in importance, specifically for older people with an impaired ability to walk, especially those living in rural areas and suburbs with reduced local public transport service – at least not until mass transit systems begin to approach the flexibility and convenience of motoring about in an automobile. Aside from this, car use has been shown to be associated with symbolic functions, emotional benefits, and important societal values.

The greater availability of private cars and technological advances may expand older adults' scope of movement and action. At the same time, the growing volume and density of traffic that result also increase the potential hazards of such travel. Traffic congestion, particularly in urban centers, has reached an extent that may unsettle elderly people and keep them from venturing out. In several European studies, the perceived speed and volume of traffic has emerged as the key issue in the local area and in moving around in general. Therefore, the question of whether and how external conditions and demands of the environment can be harmonized with individual needs and resources will be a societal and political topic in the years to come.

Toward a More Holistic Concept of Older Adults' Mobility

The various perspectives on older adults' mobility presented here have shown the great variety of biological, social, environmental, psychological, and technological aspects that come together with this complex phenomenon. Some of them – for instance, the health perspective and the transportation and technology perspectives – have already contributed rich theoretical and empirical material for understanding older adults' physical, sensory, and cognitive preconditions for moving, and for describing – and, to some extent, explaining – their actual travel behavior.

However, our knowledge about some further aspects, both on the micro- and macro-levels and the interaction between the two, is still limited. Older adults' physical, social, and technical resources, as well as the structural resources provided in a region or locality, constitute only the basic preconditions for moving about. Equally important are, on the micro-level, their motives for traveling, the importance they assign to going out, their emotions and beliefs, and the experiences made when venturing out, all of which may influence their mobility in a variety of ways.

Examining characteristic connections between health, sociodemographic, psychological, and structural variables, on the one hand, and mobility measured in terms of actual trips made, modes of transportation used, and activities performed, on the other, points to clearly distinguishable subgroups of older adults who differ in their mobility options and behavior. The scope comprises the whole range between those who are well able to realize their

mobility needs and those who are at risk to become or already are completely immobile due to health decrements and/or who are lacking support and quality of the local community.

On the macro-level, there are not only population density and land use, types of settlements and institutional arrangements, welfare regimes, driver license regulations, and transport management that affect older adults' options for moving about, getting places, and staying connected with their social communities and physical environment, but also a society's level of modernization and mechanization, cultural traditions, habits, and values. These aspects and their interaction with micro-level aspects have largely been neglected in previous research.

Hence, compiling sociological, behavioral, physiological, and transportation research and urban planning can provide deeper insights for understanding older adults' concerns about mobility and developing strategies that are suited to meet their respective needs.

Models of Aging: Invertebrates, Filamentous Fungi, and Yeasts

S M Jazwinski, Louisiana State University Health Sciences Center, New Orleans, LA, USA

Glossary

Allele – An alternate form of a gene.

Epistasis – An interaction between genes in which the action of one gene masks that of another.

Eukaryote – An organism whose cellular DNA is in a nucleus.

Gene – A unit of genetic information.

Genome – All of the genetic material of an organism.

Longevity-Assurance Gene – A gene that sets the limit (upper and/or lower) for longevity of an organism.

Mitochondrial DNA – The DNA containing the genome of the ATP-generating organelle of the cell, the mitochondrion.

Mutant – A member of a species carrying an alteration (mutation) in one or more genes.

Phenotype – The entire set of physical characteristics of an organism.

Introduction

The major invertebrate models in aging research are the nematode worm *Caenorhabditis elegans* and the fruit fly *Drosophila melanogaster*. Early studies in which fruit flies were selected for late reproduction over several generations, resulting in strains that displayed extended longevity, cemented the role of genes in determining life span. The isolation of the *age-1* mutant in the worm, which enhanced longevity, further bolstered this role. Since then, some 60 worm genes that affect life span, belonging primarily to two groups, have been identified. The list is considerably smaller in the fruit fly, overlapping one of these two groups.

Invertebrates

Age Changes

Life span in worms and flies is measured chronologically as the time from emergence of the adult form to death. Reproduction occupies only a fraction of the adult life span in the worm, while in the fly it continues until close to the end. In both animals, aging is accompanied by a variety of changes. The loss of mobility is seen readily, as is the accumulation of age pigments. There is also an accumulation of oxidative stress and induction of antioxidant enzymes. Some evidence for genome instability has been gathered in the worm in the form of transposon Tc1 mobilization with age. Declining mitochondrial function has also been seen during aging. In the worm, extended longevity is associated with metabolic changes that can readily balance declining mitochondrial function, because they include activation of the glyoxylate cycle (about which more will be said in the discussion of yeast aging later). This suggests that extended longevity is fundamentally a metabolic mechanism. Further support for this notion comes from the fact that extended longevity is associated with fat and glycogen storage.

A systematic study of the tissue pathology of aging has been carried out in the nematode. This analysis showed a wide array of changes that proceed to a different extent in different individuals. These changes are profound, and they essentially portray a gradual dissolution of tissue structure and hence of function.

Metabolic rate has been studied in both worms and fruit flies as a function of age. An analysis of the rate of living theory of aging has been carried out based on such studies using strains that have different life spans. It is difficult to generalize from this effort and determine whether the theory is correct, as there is evidence both for and against it. A major difficulty in interpretation is the fact that metabolic rate is measured by oxygen consumption and carbon dioxide production. The determination of metabolic rate from these measures rests on certain assumptions regarding the nature of the metabolism, which may be quite different in the various conditions. For example, utilization of the glyoxylate cycle would significantly lower the carbon dioxide produced given the same oxygen consumption, as glyoxylate cycle utilization is more economical.

Environmental Effects on Life Span

Calorie Restriction Calorie restriction increases life span in both worms and flies. The difficulty in equating this phenomenon with that described in rodents is that it has not actually been demonstrated that the animals eat less, especially on an individual basis. That is, the food concentration is lowered or the calorie source changed in the medium, but the

actual food consumption is not measured. At least two studies demonstrated that the food composition plays an important role in fruit flies, not simply total calories. This also distinguishes the so-called calorie restriction in vertebrate and invertebrate species.

There is another difference between calorie restriction in fruit flies and in mice. In fruit flies, the calorie restriction appears to operate by the insulin/IGF-1 pathway, while in mice, calorie restriction and the IGF-1 pathway appear to be distinct. The latter may also be the case in the worm. This discrepancy may be due to the fact that calorie restriction in mice and in invertebrates is not the same phenomenon. In the invertebrates, it may be purely a nutrient signaling phenomenon, while in mice it may entail more than that. This issue is discussed further in the section on yeast.

In the worm, there is a form of calorie restriction that is imposed genetically. The worm *eat* mutants have a defective pharynx and have difficulty consuming bacteria; they are actually starved rather than calorie restricted. Nevertheless, this treatment can extend their life span. Knockdown of the target of rapamycin (TOR) pathway in the worm extends life span, reflecting the role of nutrient sensing in determining longevity.

Heat Stress Sublethal heat shock extends the life span of both worms and fruit flies. In the worm, heat shock induces hsp16, and it is this heat shock protein that is required for life extension. In fact, overexpression of hsp16 can extend worm longevity without heat shock. In the fruit fly, it is the hsp70 homologue that is essential for life extension. Additional copies of the gene generate a greater life extension on administration of the heat stress.

Long-lived strains of the nematode show resistance to heat shock, oxidative stress, and ultraviolet radiation. This multiple stress resistance requires the activity of the DAF-16 forkhead transcription factor that is required for life extension by at least one of the mechanisms of extended longevity. This suggests that extended longevity is a stress resistance phenomenon. Overexpression of copper, zinc-superoxide dismutase in the fruit fly extends its life span, supporting this view.

Mechanisms of Aging

Caenorhabditis elegans Several different mechanisms by which life span can be extended in the worm have been differentiated, although they may not all be completely distinct. The first and most prominent mechanism into which most of the others seem to feed is the dauer or *daf* signaling pathway (**Figure 1**). This pathway is of significant interest because it is conserved in many of its features from the worm to the fruit fly to the mouse.

The nematode has numerous potential ligands for a single insulin/IGF-1-like receptor encoded by *daf-2*. Binding of at least one of these, which can be replaced by human insulin, activates the DAF-2 signaling pathway. An activated DAF-2 transmits the signal to phosphatidylinositol 3-hydroxyl kinase (PI3 K), one of whose subunits is encoded by the *age-1* gene. The signal is relayed to protein kinase B (Akt) through a phosphatidylinositol-dependent protein kinase (PDK). Phosphorylation of the forkhead transcription factor DAF-16 by protein kinase B prevents its translocation into the nucleus and activation of the target genes. Thus, abrogation of DAF-2 signaling extends life span, and this is prevented by deletion of *daf-16*. The *old-1* gene encodes a tyrosine kinase receptor, whose expression is under the control of DAF-16 and which impinges upon the DAF-16 pathway.

There is some controversy as to the critical site or tissue in which DAF-16 signaling is important for life extension. Clearly, signaling in the nervous tissue is important. In particular, the neuroendocrine system with the chemosensory amphid neurons that signal the presence of food is involved, as their ablation extends longevity. However, there is evidence that the endoderm or gut also plays a role. Since the latter tissue is the site of lipid storage, it would be a likely target of signaling, and the activation of the glyoxylate cycle in *daf-2* mutant worms makes sense because this metabolic pathway allows the worm to use fat as a source of energy and for the synthesis of protein and carbohydrate.

There is a complex interaction between the DAF-16 pathway and the somatic and germline gonads that involves signaling through the DAF-12 transcription factor. DAF-12 belongs to the thyroid hormone/steroid hormone/retinoic acid receptor superfamily. Ablation of the germline gonad extends life span on its own.

Mitochondria have been demonstrated to play an essential role in determining life span in *C. elegans*. The first indication came from implication of the *clk-1* gene in life span determination. This gene impacts timing in the life cycle of the worm and affects its bioenergetics. It is a homologue of the yeast *COQ7* gene, which is involved in ubiquinone synthesis. Ubiquinone is a lipid-soluble electron carrier in the mitochondrial respiratory chain. Indeed, provision of ubiquinone in the medium allows the *clk-1* mutant worm to grow. Interestingly, limitation of ubiquinone in the diet can extend life span independent of

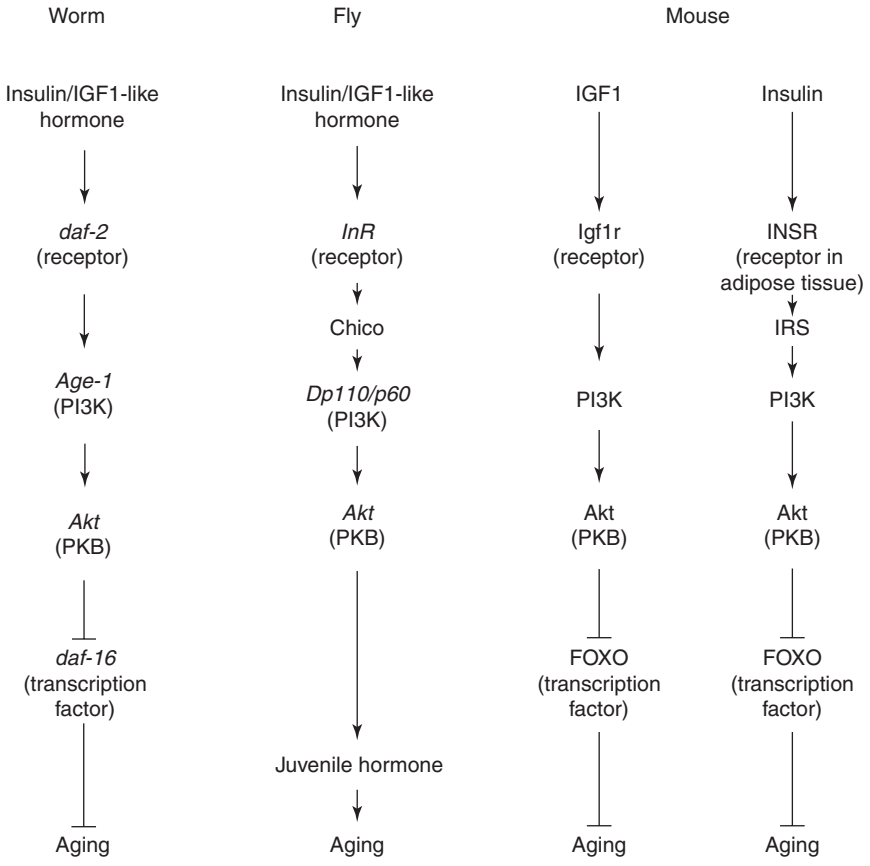

Figure 1 The insulin/IGF-1 signaling pathway is conserved in metazoans. In invertebrates such as *C. elegans* (worm) and *D. melanogaster* (fly), hormones related to insulin and IGF-1 bind to their cognate receptors initiating a signal transduction pathway, which includes a phosphatidylinositol 3-OH kinase (PI3K), and a protein kinase B (PKB) known as Akt. Among the downstream targets are transcription factors belonging to the forkhead family (DAF-16 and FOXO). The result of the activation of this pathway is a curtailed life span. In mammals, there is an IGF-1 pathway that is separate from the insulin pathway. Activation of these pathways in mice, in the case of adipose tissue for insulin, favors aging. In both the fly and the mouse insulin pathway, an insulin receptor substrate (Chico or IRS) is interposed between the receptor and PI3K. Pointed arrows, stimulation; blunt arrows, inhibition.

the *daf-2* pathway. This may lead to the activation of fumarate reductase, an alternative oxidase, which functions in the electron transport chain of these worms. Fumarate reductase is known to be induced in dauer worms, a long-lived larval form that can be induced by mutation of *daf-2*. These effects on worm longevity are reminiscent of the retrograde response (discussed later), which extends life span in filamentous fungi and yeasts.

A genome-wide as well as directed RNA interference (RNAi) screen has shown that knockdown of genes encoding mitochondrial proteins extends life span. The resulting mitochondrial dysfunction is likely to activate compensatory changes in gene expression. The results provide strong support for a life-extending retrograde response in the worm. It has been shown that RNAi knockdown of the worm frataxin gene, which encodes a protein that transports iron into mitochondria, extends life span.

Drosophila melanogaster Studies in *D. melanogaster* confirm the importance of insulin/IGF-1-like signaling for longevity. Mutants in the fruit fly insulin receptor yield dwarf animals that display extended longevity. Mutants in the fly homologue of the insulin receptor substrate, *chico*, exert similar effects. These studies also point to the importance of the neuroendocrine system in aging, because a downstream target of the insulin/IGF-1-like receptor pathway is the juvenile hormone.

Fruit fly mutants have been screened for extended longevity. This yielded the *methuselah* mutant, which displays increased resistance to thermal and oxidative stress and to starvation. This gene encodes a transmembrane receptor kinase. One of the first longevity mutants in the fruit fly was *indy*. This gene encodes a dicarboxylic acid transporter, and the effect of this mutation has been interpreted as being similar to calorie restriction – an intriguing possibility that is highly cogent to the entire problem of

nutritional effects on longevity. Finally, it has been convincingly shown that the deletion of the fly *rpd3* histone deacetylase homologue extends life span. As in yeast, this effect is due to an overlap with calorie restriction. In the fruit fly, this effect is due to the derepression of the *sir2* gene. This is different from the corresponding effect in yeast. Nevertheless, the results indicate that the Rpd3 histone deacetylase is a master regulator of life span in diverse models of aging.

Filamentous Fungi

Several filamentous fungi have been studied as models of aging. Among these, *Podospora anserina* and various species of *Neurospora* have been examined extensively, and an understanding of the causes of aging in these organisms has developed. Life span in these fungi is measured by total reproductive output. It is measured by the length of the mycelium before it senesces and dies; it can also be measured as the time between inception of mycelial growth and its cessation. The reproductive effort involved is the extension of the mycelium by the directional production of new cells, one after another. Senescence is marked by slowed growth, difficulty in aerial hyphae production, and increased pigmentation.

The etiology of aging is clearly mitochondrial in filamentous fungi. Aging is associated with instability of the mitochondrial genome, whose causes differ in *P. anserina* and in *Neurospora*. In *P. anserina*, various portions of the mitochondrial genome can excise as the organism becomes older. These DNAs are circular and amplify. They are recombinogenic, causing further rearrangements in the mitochondrial genome with the loss of sequences essential for respiratory function. In *Neurospora*, some strains possess indigenous, linear plasmids in their mitochondria. These plasmids can integrate into the mitochondrial DNA, inactivating target genes and causing DNA instability. The inactivation of mitochondrial energy production is lethal in filamentous fungi, which are obligate aerobes.

Senescence has been subjected to genetic dissection in filamentous fungi. Due to the more advanced state of the field, the work on *P. anserina* senescence is discussed here. The genes identified are encoded by the nuclear as well as the mitochondrial genomes. The work has been followed up with a molecular dissection of the aging mechanisms involved, resulting in a rather sophisticated understanding of the role of two of the genes in aging in this fungus. Not surprisingly, these studies revolve around mitochondrial function.

Mechanisms of Aging

Alternative Oxidase and Reactive Oxygen Species *Grisea* is a nuclear gene that encodes a transcription factor that is active at low copper levels. Under these conditions, it induces the expression of a high-affinity copper transporter and manganese superoxide dismutase and additional genes as well. The import of copper into the cell is essential for the assembly of complex IV (cytochrome oxidase) of the mitochondrial electron transport chain. Thus, the loss of *Grisea* should result in lethality, because *P. anserina* is an obligate aerobe. It does slow down growth, likely due to lower ATP production, but the fungus lives about 60% longer. The resolution of this dilemma comes from the induction of an iron-dependent alternative oxidase, which accepts electrons from ubiquinone, leaving only complex I (NADH:ubiquinone oxidoreductase) to generate an electron motive force.

The generation of reactive oxygen species is much lower when the fungus respires using the alternative oxidase as compared to cytochrome oxidase. This strongly suggests that an important reason for the longer life span of the *grisea* mutant is a decrease in oxidative stress generated by mitochondria. However, there is also a complete absence of the mitochondrial DNA rearrangements and deletions, and production of circular DNAs, in this mutant. Excess copper in the growth medium reverts this phenotype, indicating that the recombination involved in these rearrangements is copper dependent. The fact that the *grisea* mutant ages, albeit with a delay, in the absence of accumulation of circular DNAs derived from the mitochondrial genome indicates that these are not the cause of senescence. This point is also supported by cytoplasmic ribosome mutations that prevent the appearance of these circular DNAs yet do not prevent senescence.

There is still some cytochrome oxidase activity in the *grisea* mutant due to a low amount of copper uptake by a low-affinity transport system. This may lead to some reactive oxygen species production through a diminished activity of the standard electron transport chain. This may be the cause of the limited, if longer, life span of the mutant. Because GRISEA also transcribes the mitochondrial manganese superoxide dismutase, the damaging effect of this residual production of reactive oxygen species would be amplified, as superoxide dismutase removes certain of these damaging molecules. This effect would be further exacerbated by the reduced activity of cytoplasmic copper, zinc-superoxide dismutase, which requires copper for activity.

In the ex1 mutant, the alternative oxidase is also induced. This mutant has a deletion of large parts of

the *CoxI* gene, which encodes the largest subunit of cytochrome oxidase in the mitochondrial genome; consequently, it is completely devoid of standard electron transport chain activity. This makes ex1 entirely dependent on the alternative oxidase for survival, and it dramatically reduces production of reactive oxygen species. The ex1 mutant is immortal in keeping with the interpretation that it is oxidative damage to mitochondria that is the cause of senescence in *P. anserina*.

A Retrograde Response in Podospora? In *Saccharomyces cerevisiae,* mitochondrial dysfunction signals a program of nuclear gene expression changes that compensate, resulting in life extension. The *grisea* and ex1 mutants conjure up something akin to this retrograde response. The question is whether this represents a normal physiological process during aging of the fungus. The senescent phenotype makes its presence known at the tips of the growing hyphae in the mycelium, where growth requires substantial energy production. This is where oxidative damage and mitochondrial DNA instability evolve during aging. Replacement of damaged mitochondrial material by functional components requires the concerted action of both mitochondrial and nuclear DNA. Once the capacity for replacement is overwhelmed, the only recourse prior to senescence would be the activation of alternative oxidase in a retrograde response. It will be of interest to determine whether alternative oxidase is indeed induced prior to senescence.

There are several observations consistent with the interpretation that mitochondrial deficits result in activation of a retrograde response with attendant life extension. A long-lived nuclear mutant that encodes the PaTOM70 protein of the mitochondrial protein import apparatus has been isolated. In this case, a deficiency in the assembly of active mitochondria would activate the retrograde response and extend life span. It has also been argued that certain nuclear gene mutations, such as in the protein translation factor eEF-1α, that alter translation accuracy extend life span by altering the mitochondrial protein profile. Such changes could well induce a retrograde response.

It is interesting to recall early studies that demonstrated the life-extending effect of various inhibitors of mitochondrial metabolism provided at doses below a growth-inhibitory threshold. These inhibitors included inhibitors of mitochondrial ribosomes, compounds that intercalate into mitochondrial DNA, and respiratory poisons. The effects closely resemble those that activate the well-characterized retrograde response in yeast.

Yeast

Phenomenology of Aging

Longevity and aging have been studied in the budding yeast *S. cerevisiae* and in the fission yeast *Schizosaccharomyces pombe*. However, the investigations in the latter species include only one publication describing the phenomenon of limited replicative capacity. Thus, this discussion is confined to budding yeast, simply called yeast from this point on. The first and most extensively studied form of aging in this organism is the replicative life span, defined as the limited capacity of an individual cell to continue dividing or producing daughter cells. In the 2000s, several reports pertaining to the chronological life span of yeast have appeared. Chronological life span is defined as the time spent in a non-dividing or stationary phase before the ability to produce progeny is lost. Replicative life span is an individually measured trait, while chronological life span is determined for a yeast culture or population. Not all yeast cells stop metabolizing immediately after their last division, so the notion of a postreplicative life span should be entertained. There is clearly a negative impact of chronological aging on the replicative life span of cells emerging from stationary cultures.

The mortality rate of dividing yeast cells can be expressed as a function of replicative age. This mortality rate increases exponentially with a plateau at later ages, such that the last 10% of the surviving population shows no further increase in mortality rate. For chronological aging, mortality rate fluctuates dramatically, but this may not be due simply to regrowth of the culture from the surviving cells. A multitude of changes has been described in yeasts progressing through their replicative life span. These changes have been seen at the cellular, subcellular, physiologic, and molecular levels; many of these changes describe a loss of function. Thus, it is possible to speak of aging of replicating yeasts. The changes that have been identified in yeasts aging chronologically are much less numerous. The mode of death of replicating and chronologically aging yeasts, as described by a few studies, appears to be apoptotic by several of the standard criteria applied to animal cells. There is some evidence that this apoptosis represents 'altruistic' behavior on the part of the dying cells, which in the process provide nutrients for the survivors.

A mathematical model of an aging system has been formulated that predicts a stratification of an aging population due to change in the individual aging organism. This model is applicable not only to the organism but also to lower levels of biological organization, down to the molecular. Several predictions of

this model have been met by yeast cells. By extension, random age changes must have predictive value with regard to the longevity of the individual. Indeed, this was shown to be the case when the random changes in budding patterns of individual yeast cells were examined during the replicative life span. Thus, the role of chance in aging has been subjected to experimental analysis in yeast.

Most of the work on replicative life span has dealt with the question of what determines the aging of the mother cell. However, a full understanding of the yeast replicative life span requires an assessment of the factors that determine why a daughter is born young and has before it the potential for a full replicative life span. Evidence for a senescence factor that accumulates in mother cells and only 'leaks' into daughter cells produced by very old mothers was obtained early on. Furthermore, it has been demonstrated that the daughters of older mothers have a shorter life span than those produced by young mothers, providing additional support for the existence of the senescence factor. The fact that daughters are born young during most of the life span of the mother cell is a manifestation of age asymmetry between mother and daughter.

Genetic Determinants of Longevity

Numerous genes impact the replicative life span of yeast, while fewer have been demonstrated to have this effect on chronological life span (**Table 1**). There is some overlap between these two gene sets. It is evident that the more numerous genes that determine replicative life span encode a wide range of biochemical functions. However, these functions fall into four obvious categories: metabolism, stress resistance, chromatin-dependent gene regulation, and genome stability. Of course, there is always the omnibus category of other. This breakdown coincides with those categories important in other genetic model systems of aging, both invertebrate and vertebrate.

Most of the genes alluded to previously were discovered by testing specific hypotheses about the mechanisms underlying yeast aging, using a reverse genetic approach. A few were identified by either examining a presumed surrogate phenotype associated with longevity or screening for genes that were differentially expressed during the yeast replicative life span. No one thus far has attempted a direct screen for mutants in genes that affect life span in yeast. However, a screen for genes that affect longevity has been carried out on a genome-wide collection of gene deletion mutants. At present, only two yeast longevity genes possess orthologues that have been shown to affect the life span of higher organisms, *C. elegans* and *D. melanogaster*: the genes encoding the silent information repressor complex component Sir2 protein and the yeast protein kinase B (Akt) Sch9 protein. Overexpression of Sir2 protein extends replicative life span, although not in some studies. Sch9 protein has the distinction of affecting both replicative and chronological life span.

Environmental Effects on Life Span

Calorie Restriction Three environmental manipulations have been used to alter yeast life span. The most heavily analyzed is nutrient limitation, which has been given the misleading name of calorie restriction. In this paradigm, the concentration of a nutrient, usually glucose, is changed in the growth medium and the effect on life span is determined. Although the concentration of the nutrient is lowered, it is provided without any curbs. Sir2 protein in yeast appears by some accounts to function in life extension induced by nutrient limitation, although at least two studies dispute this interpretation. Polyphenols, such as resveratrol, extend yeast life span by activating the NAD-dependent protein deacetylase activity of Sir2 protein, which in yeasts appears to be directed at acetyl groups in histones. However, resveratrol did not affect a true protein deacetylation reaction in another study; it did not extend life span in that study either. The significance of the positive effects of resveratrol resides in its reputed role as a calorie restriction mimetic in yeast. The ambiguities raise the possibility that resveratrol may be acting primarily as an antioxidant in yeast.

Deletion of the glucose sensor gene, *GPR1*, extends replicative life span. The signaling pathway in which Gpr1 protein functions has been described. The results indicate that glucose curtails yeast longevity through a signaling pathway whose downstream target is protein kinase A (cyclic AMP-dependent protein kinase), whose negative effects on yeast longevity have been known for quite some time. Thus, so-called calorie restriction in yeast may actually be more of a signaling phenomenon. This conclusion, however, requires a demonstration that glucose limitation and Gpr1 protein function are coextant in determining yeast replicative life span.

Oxidative Stress Pro-oxidants such as paraquat curtail yeast replicative life span; this effect also pertains to hydrogen peroxide. The negative effect of hydrogen peroxide on life span can be reversed by the antioxidant glutathione. Oxidative stress increases with age. All of these findings suggest that oxidative stress is a life span-limiting factor in yeast.

Table 1 Yeast longevity genes

Gene	*Function*	*Category*
Replicative aging		
LAG1	Ceramide synthesis	Stress resistance
LAC1	Homologue of *LAG1*; ceramide synthesis	Stress resistance
RAS1	GTP-binding (G-) protein, signal transduction	Stress resistance
RAS2	G-protein, signal transduction	Metabolism, stress resistance
CDC35	Adenylate cyclase (also called *CYR1*)	Metabolism, stress resistance
BCY1	Regulatory subunit of protein kinase A	Metabolism, stress resistance
PHB1	Membrane-bound, mitochondrial protein chaperone	Metabolism, stress resistance
PHB2	Homologue of *PHB1*; chaperone	Metabolism, stress resistance
CDC7	Protein kinase; cell cycle control	Other
BUD1	G-protein; cell polarity	Other
RTG2	Unknown; retrograde response	Metabolism, genome stability
RTG3	Transcription factor	Metabolism, stress resistance
RPD3	Histone deacetylase; transcription	Chromatin-dependent control
HDA1	Histone deacetylase; transcription	Chromatin-dependent control
SIR2	Histone deacetylase; transcriptional silencing	Genome stability
SIR4	Transcriptional silencing	Chromatin-dependent control
UTH1	Mitochondrial biogenesis	Metabolism
UTH4	Unknown	Other
YGL023	Homologue of *UTH4*	Other
SGS1	DNA helicase; DNA recombination	Genome stability
RAD52	DNA repair	Genome stability
FOB1	Replication fork block protein	Genome stability
CDC25	GDP–GTP exchange factor for Ras proteins	Stress resistance
TPK2	Protein kinase A catalytic subunit	Metabolism, stress resistance
GPR1	Plasma membrane glucose sensor	Metabolism
GPA2	G-protein	Metabolism
ZDS1	Transcriptional silencing	Chromatin-dependent control
ZDS2	Transcriptional silencing	Chromatin-dependent control
NMT1	N-myristoyltransferase	Other
SIP2	Unknown; N-myristoylprotein	Metabolism
SNF1	AMP-activated protein kinase homologue	Metabolism
SNF4	Regulatory subunit of Snf1 complex	Metabolism
SOD1	Copper, zinc-superoxide dismutase	Stress resistance
SOD2	Manganese-superoxide dismustase	Stress resistance
CTA1	Peroxisomal catalase	Stress resistance
CTT1	Cytoplasmic catalase	Stress resistance
NPT1	Nicotinamide phosphoribosyltransferase	Metabolism
PNC1	Nicotinamidase	Metabolism
SCH9	Protein kinase B (Akt) homologue	Metabolism, stress resistance
Chronological aging		
SCH9	Protein kinase B (Akt) homologue	Metabolism, stress resistance
CDC35	Adenylate cyclase (also called *CYR1*)	Metabolism, stress resistance
RIM15	Protein kinase	Stress resistance
MSN2	Transcription factor	Metabolism, stress resistance
MSN4	Transcription factor	Metabolism, stress resistance
RAS2	G-protein	Metabolism, stress resistance
SOD2	Copper, zinc-superoxide disumutase	Stress resistance

This view is bolstered by the negative effects on longevity of deletion of the catalase and superoxide dismutase genes.

Heat Stress The third environmental factor that has been shown to affect yeast replicative life span is heat stress. The effects of heat stress on longevity are complicated. Sublethal heat stress extends replicative life span. This effect is seen even when this stress is applied in several independent bouts. The life extension under these circumstances is due to a persistent, but not permanent, decline in mortality rate. However, there is a limit to the number of bouts of stress that can be applied to achieve an attendant increase in life span. Beyond that point, life span declines. The *RAS2* gene is essential for the cell to withstand chronic bouts of sublethal heat stress. Upon application of the stressor, a program of gene

expression changes is activated to protect the cell. In the absence of *RAS2*, these genes remain turned on for a long time even when the stress has long been absent. The protective effect of *RAS2* requires its capacity to activate adenylate cyclase and hence to induce the synthesis of cyclic AMP.

The life extension obtained on administration of a limited number of bouts of sublethal heat stress requires both *RAS1* and *RAS2*. The former has a peculiar role in supporting glucose-stimulated inositolphospholipid turnover. The *LAG1* gene, the first longevity gene identified in yeast, operates ceramide synthesis, which impacts resistance to heat stress. Interestingly, the dependence of life span on *LAG1* expression is bimodal, with an initial rise in life span on increased expression followed by a decline at higher levels of expression.

The deletion of *RAS2* increases chronological life span, which is undoubtedly the result of massive derepression of stress resistance genes. Cells in stationary culture must 'stay and fight' for the population to survive. This differs markedly from the situation in a replicating yeast culture, in which even rare survivors can restore the population. In the absence of overt stress, overexpression of *RAS2* extends replicative life span. This effect is due to the stimulation of a cyclic AMP-independent pathway. These effects of *RAS2* point to a recurring theme in aging. The effect of a manipulation on life span depends very much on the particular set of circumstances. The organism has evolved to adapt to a certain range of environmental conditions, leaving a narrow window in which life span can be optimized without compromising this adaptability. This is an example of a trade-off.

Mechanisms of Aging

Extrachromosomal Ribosomal DNA Circles Ribosomal DNA is present as a tandem array of between 100 and 200 repeats in yeast. This arrangement facilitates intramolecular recombination events to produce circular, episomal DNA species. It has long been known that these circles are at equilibrium with the chromosomal copies, expanding in number or contracting under various conditions. In some studies but not in others, the cellular content of these circles was suppressed by the Sir2 and Sgs1 proteins. The circle content increases with the replicative age of the cells. These studies formed the foundation for the claim that the major, if not sole, cause of aging in yeast is the ribosomal DNA circles and that the role of Sir2 protein in yeast longevity is based exclusively on its effect on circle formation. This interpretation of the role of Sir2 protein neglects its well-known action in silencing gene expression.

There is little doubt, however, that extrachromosomal ribosomal DNA circles contribute to yeast cell demise during the replicative life span. Deletion of the replication fork block gene *FOB1* completely eliminates the production of the circles and at the same time increases life span substantially. It has become clear in at least two studies that the formation of circles masks other mechanisms of replicative aging in yeast. Nevertheless, these circles underscore the role of nuclear genome instability in aging.

Interorganelle Signaling: The Retrograde Response Mitochondrial dysfunction in yeast signals a wide array of gene expression changes in the nucleus. These gene expression changes are confined to metabolic and stress response genes. The retrograde signaling pathway contains several signal transduction proteins that were discovered through its study, as well as many others known originally from other investigations. Ras2 protein and the target of rapamycin (TOR) complex modulate the retrograde response. Ras2 protein and TOR are both involved in sensing the intracellular status of yeasts, broadly defined as metabolic and stress state. Activation of the retrograde response extends yeast replicative life span (**Figure 2**). It is therefore not surprising that Ras2 protein affects yeast longevity; we expect that TOR does as well.

The activation of the retrograde response compensates for the loss of full mitochondrial function. The genes that are induced encode proteins destined for the cytoplasm, mitochondria, and peroxisomes. The metabolic changes that occur bolster the activity of part of the tricarboxylic acid cycle and provide other sources of biosynthetic intermediates with which this truncated cycle can cooperate, most notably the glyoxylate cycle. The glyoxylate cycle allows the yeast cell to use acetate to make carbohydrate and protein, because the two carbons of acetate are not lost as carbon dioxide as they are in the tricarboxylic acid cycle. This effect is reminiscent of the activation of the glyoxylate cycle in *C. elegans* strains that display extended longevity. As mentioned earlier, induced mitochondrial dysfunction in this worm extends its life span.

It is evident that the retrograde signaling pathway and the pathway that signals nutrient limitation in yeast are distinct. However, it is also clear that there is overlap between the two pathways in terms of their downstream effectors. The retrograde response compensates for mitochondrial dysfunction. On the other hand, calorie restriction augments the activity of this organelle in what appears to be a preventive mechanism. It is this effect of calorie restriction that is likely to result in life extension. Sir2 protein may

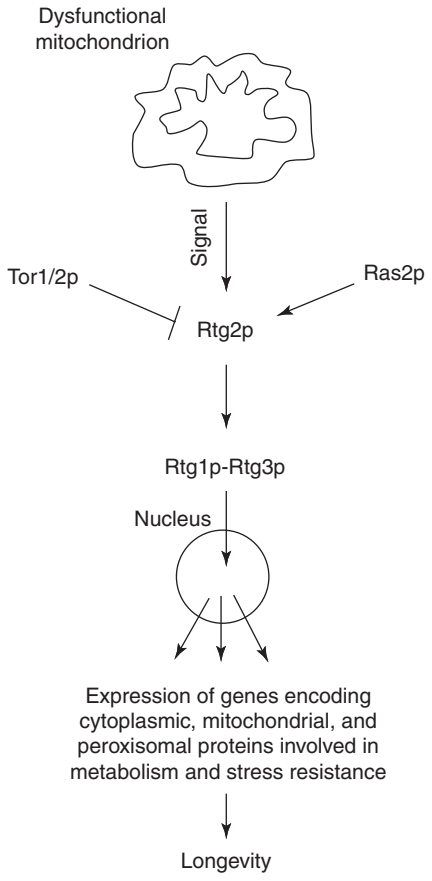

Figure 2 The retrograde response in yeast. Mitochondrial dysfunction elicits a signal that is relayed by the Rtg2p to the Rtg1p–Rtg3p transcription factor, which enters the nucleus and induces the expression of many genes encoding proteins destined for the cytoplasm, the mitochondria, and the peroxisomes. These proteins are involved in metabolism and stress resistance. This increases longevity. Ras2p and the TOR complex potentiates or represses the retrograde pathway, respectively.

respond to the metabolic state of the cell, because it requires the oxidized coenzyme NAD rather than reduced NADH for activity. However, some studies indicate that the NAD concentration changes that could regulate Sir2 protein function do not occur in cells. In addition, other studies argue that Sir2 protein is actually regulated by the levels of nicotinamide, an inhibitor of the enzyme, rather than by NAD. Given the available evidence, the most reasonable hypothesis is that Sir2 protein activity is a permissive factor in the effect of nutrients on yeast longevity in some cases but is not directly involved in signaling nutrient availability.

Activation of the retrograde response not only extends life span, but also postpones the manifestations of senescence. Studies demonstrating the role of the retrograde response in life extension involved experimental manipulation of yeasts to abrogate the activity of the electron transport chain. However, it has been shown that there is a decline in mitochondrial function with replicative age, which coincides with an increase in oxidative stress, and that this is associated with the induction of the retrograde response. It has also been found that the retrograde response titrates accumulating mitochondrial dysfunction, such that the greater the dysfunction, the greater its activation. Thus, this mechanism operates in normal yeast aging. In fact, it is the only such mechanism, because it fulfills four criteria: its activation extends life span, it postpones senescence, it impacts a normal aging process, and it is induced during the course of normal aging. Perhaps its activation is why yeasts live as long as they do.

There is a connection between the retrograde response and extrachromosomal ribosomal DNA circles. Activation of the response increases circle production. However, approximately one-half of the life extension effect of the retrograde response occurs through the amelioration of the deleterious effects of the circles. This explains why the retrograde response extends life span even in the face of circle accumulation. The retrograde signal transducer Rtg2 protein plays a pivotal role in circle formation. This protein suppresses genome instability, including the instability manifested by circle production. But it can only do so when it is not transmitting the retrograde signal from the mitochondrion. Thus, the mitochondrial dysfunction that activates the retrograde response harnesses Rtg2 protein, making it unavailable for maintenance of genome stability.

When the Rtg2 protein travels from the cytoplasm to the nucleus on sensing mitochondrial dysfunction, it becomes a component of the transcriptional coactivator complex called SLIK, for SAGA-like. In this complex, which contains the histone acetyltransferase Gcn5, Rtg2 protein participates in chromatin-dependent gene activation. The activity of SLIK is counteracted by the histone deacetylases Rpd3 and Hda1, whose deletion is known to increase longevity. Rtg2 protein in the SLIK complex links mitochondrial activity to chromatin-dependent gene activation, metabolism, and stress responses, and to genome stability. This dependence points to the primary role of metabolism, especially mitochondrial metabolism, in determining yeast life span.

Age Asymmetry A mutant that disrupts the age asymmetry between mother and daughter cells such that the daughters are born old was isolated. It is in the *ATP2* gene, which encodes the β-subunit of mitochondrial F_1-ATPase. The cell pathology that occurs in this mutant involves a gradual loss of mitochondrial membrane potential, abnormal

morphology and distribution of mitochondria, and gradual loss of segregation of active mitochondria to daughter cells. This is accompanied by clonal senescence, which is a population manifestation of the birth of daughter cells possessing the same replicative age as their mothers at the time of birth. Interestingly, the defects observed in this mutant also occur in normal mother cells as they get older, causing the 'leakage' of dysfunctional mitochondria to daughter cells. Thus, defective mitochondria appear to be the senescence factor described earlier. These results have led to the suggestion that, more generally, age asymmetry depends on the sequestration of damaged components within mother cells. It has been shown that oxidized proteins contained in mitochondria among others are indeed retained in mother cells, at least when they are young, and that this depends on the Sir2 protein. The mechanism by which Sir2 protein accomplishes this is not clear, but it is not likely to involve extrachromosomal ribosomal DNA circles.

The studies of age asymmetry point to another feature of mitochondrial function that is important in aging, namely, mitochondrial membrane potential. During aerobic metabolism, the electron transport chain is largely responsible for providing the force driving its generation. However, the F_1-ATPase, together with the ATP-ADP translocator, assumes this function in fermenting cells. Mitochondrial membrane potential plays an essential role in powering the transport of biosynthetic intermediates between the mitochondrial matrix and the cytoplasm and in mitochondrial biogenesis.

Summary

Lower organisms make excellent model systems in aging research if they have facile genetics. The premier models of this sort are *C. elegans*, *D. melanogaster*, *P. anserina*, and *S. cerevisiae*. Each of these models has contributed to our understanding of aging in mammalian systems. As true metazoans, the worm and the fruit fly have revealed the operation of a conserved signaling pathway in aging, the insulin/IGF-1 pathway, which operates in mice as well. Yeasts have one component of this pathway in common, and there may be others as well. Yeasts and filamentous fungi have pointed to the retrograde response as a mechanism that compensates for accumulating mitochondrial dysfunction during aging. The nature of experimental models is to simplify studies. By this token, model systems constitute only an approximation of the phenomenon as it occurs in other organisms. Thus, it is essential to examine carefully the results obtained using model systems when attempting an extrapolation. It is certain that some features of the model systems will not have counterparts elsewhere. However, the generalization that there are four fundamental processes that determine life span (metabolism, stress resistance, chromatin-dependent gene regulation, and genome stability), which was developed in studies of yeast, has withstood the test of time. This provides optimism in the utility of model systems in aging research.

Models of Aging: Vertebrates

E J Masoro, University of Texas Health Science Center, San Antonio, TX, USA

Glossary

Animal Models – Animals used in experimental settings as surrogates for human subjects.

F_1 Hybrid Strain – Progeny resulting from the mating of animals from two different inbred strains of the same species.

Genotype – The genetic constitution of an individual.

Inbred Strain – A population of individuals within a species with an identical or nearly identical genotype as the result of inbreeding.

Inbreeding Depression – The decrease in vigor including a decreased longevity that normally accompanies a program of extensive inbreeding.

Life Table – A concise, standardized summary of population survival characteristics in relation to age.

Mammals – The class of vertebrate animals that are warm-blooded, possess hair, and suckle their young.

Species – A taxonomic category of living organisms within which effective gene flow occurs or could occur.

Vertebrates – A major subgroup of the phylum Chordata composed of animals possessing an internal bony skeleton, particularly a backbone.

Introduction

Animal models are used in gerontological research for the exploration of aging processes, with the ultimate goal of uncovering the basic nature of human aging. In choosing a particular species or strain of a species as a model, certain criteria should be considered; the extent to which these criteria are met is a significant factor in the success of the study. In executing these studies, it is critical to pay careful attention to animal husbandry issues. Although a variety of vertebrate species have served as animal models for aging research, most studies have used mice and rats. However, the future use of a wide diversity of species is essential since only such diversity can lead to the accumulation of knowledge needed to meet the growing gerontological challenges of this century; the increasing public opposition to the use of animals for biomedical research poses a problem for attaining this knowledge.

Role of Animal Models in Aging Research

Animal models serve as surrogates for humans in biomedical science since they enable studies that cannot be done on humans because of legal, ethical, economic, or technical considerations. The basic premise underlying their use is that much of what is learned will apply to the human condition. The validity of this premise for a particular model is often questioned, and new species continue to be assessed in the quest for a model that most closely mimics humans.

These considerations also apply to the use of animal models for aging research, because human aging is the ultimate interest of most gerontological investigators. However, because of logistics peculiar to aging research, the aim of similarity to humans is often compromised. For example, rodents, rather than non-human primates that are phylogenetically much closer to humans, are the mammalian models most often used; the cost of maintaining rodents and their relatively short life span make aging studies more feasible and much easier to conduct. The likelihood that basic aging processes are similar in all mammalian species is the scientific justification for this choice. Nevertheless, there is growing recognition that valuable information about aging can be most readily gained by studying a spectrum of species, those phylogenetically closer to humans as well as those further removed. A case in point is research on invertebrate animal species, such as the nematode (*Caenorhabditis elegans*) and the fruit fly (*Drosophila melanogaster*). Of course, the interest in exploring aging processes in diverse species relates, in part, to our curiosity about the varied mechanisms of aging that have evolved in living systems. In addition, mechanisms that are well developed and easily studied in a given species may yield insights on aging processes that are expressed in a subtle and less easily studied fashion in humans. Therefore, although this article focuses on vertebrate (primarily mammalian) models, it should be noted that invertebrate animal species, as well as other species such as yeast, can provide, and have provided, important information on aging; this should be kept in mind when choosing a model for the exploration of a particular question.

Criteria for Selection of Animal Models

In addition to relevance to the human condition, there are several other criteria that should always be considered when choosing a model because of their impact on the successful execution and interpretation of any aging study. Of course, no one model is likely to be optimal in regards to all of the criteria. However, the extent to which a species or strain of species meets these criteria should be carefully weighed, along with factors relevant to the specific research question.

Availability of Life Table Data

Life tables contain the mortality characteristics of an animal population. Such information as the median length of life, the age of tenth percentile survivors, etc., is readily obtained from the table. These facts are needed when designing an aging study; without such data, gerontological interpretation of the findings is not possible. For example, an investigator using a specific strain of rat was unaware of the life table data available for that model as he made gerontological interpretations of data from rats ranging in age from 1 month to 6 months. Because the rat strain he chose has a median length of life of about 24 months and the age of the tenth percentile survivors is about 32 months, the interpretations were meaningless. Since life tables are available, the ignorance of the investigator was the problem. However, life tables are not available for many species and strains of species; in such cases, investigators must undertake the time-consuming task of generating a life table for the particular species or strain of species before designing the aging study. For example, some researchers studying atherosclerosis used rabbits as the model, and they interpreted their findings in gerontological terms, despite the fact that there are no reliable life tables for this species. Clearly, the first order of business should have been the generation of a life table for the gender and strain of rabbit to be used.

Longevity Characteristics

The resources required to execute an aging study are, to a great extent, determined by the longevity characteristics of the animal model. Provided that other factors are not compromised, the shorter the model's life, the better; both the cost of animal maintenance and the time commitments of investigators and their technical staff are thus minimized. One reason why laboratory rodents are the most widely used vertebrate model for aging research is their short life spans as compared to most other mammalian species.

Availability of Data on Age-Associated Pathology

The prevalence of many diseases increases with advancing age, and much of this age-associated pathology is characteristic of a particular species or strain of the species. Whether this age-associated pathology is part of the aging process or a different process is the subject of much debate. Regardless of how this debate plays out, it is critical to know the age-associated pathology of the model when designing a study; lack of such information hinders the ability to appropriately design a study. It is also necessary that a pathological assessment be made of the animals used in the research. In cross-sectional studies involving sacrifice of the animals, such analyses can usually be readily accomplished. In longitudinal studies, pathological analyses are possible at the time of spontaneous death or at the end of the study.

Defined Genetic Characteristics

The genetic characteristics of an animal model population should be known and stable. These criteria aim to permit studies by another investigator or at a later time to be executed with an animal model whose genetic characteristics are ideally unchanged, thereby facilitating comparisons with earlier work. While these criteria can be largely met with rats and mice, it is difficult, if not impossible, to do so with many other vertebrate species. Even with rats and mice, the investigator must take special care to meet these criteria. For example, outbred Sprague-Dawley stocks of rats are maintained by randomly mating the members of the stock. However, the mating is often not sufficiently random and, as a result, Sprague-Dawley rats from different suppliers, or from the same supplier at different times, may differ genetically.

Inbred strains of mice or rats are often used in an attempt to achieve uniformity and stability of genetic makeup. Every animal in an inbred strain has the same or nearly the same genotype as every other animal in that inbred population. Thus, insofar as genotype influences phenotype, inbreeding should maximize the phenotypic uniformity of a population. However, the putative advantage of reduced variability comes with a cost because of the phenomenon known as inbreeding depression. On the other hand, populations of F_1 hybrids (crosses between two inbred strains) are as genetically homogeneous as inbred strains, and they do not suffer from inbreeding depression. Moreover, for many phenotypic characteristics, populations of F_1

hybrids exhibit less variability than populations of inbred strains.

It must be noted that there is a significant drawback in the use of either inbred strains or F_1 hybrid strains. That is, what is being studied may be unique to the specific genotype rather than representative of the species as a whole.

Availability and Cost of Animals

It is a challenge to obtain a wide range of ages of any vertebrate animal species that has been carefully maintained, including a complete record of husbandry. The alternative is for investigators to maintain the animals from birth. However, even for short-lived vertebrate species, such maintenance not only requires sizable funding for food, supplies, and caretakers, but also demands the long-term commitment of animal holding facilities. For long-lived species, most investigators simply cannot marshal the necessary resources; such is often the case even for short-lived vertebrate species. In the United States, the National Institute on Aging (NIA) has partially addressed this problem by subsidizing a commercial supplier's maintenance of several commonly used mouse and rat strains. The NIA not only makes available to investigators *ad libitum*-fed animals of a spectrum of ages, but also provides rodents that have been maintained on a life-extending caloric restriction regimen. In addition, the NIA functions as a supplier of banked tissues obtained from a variety of species. The investigator can contact the NIA to find what is currently available, the eligibility criteria for receiving the animals or tissues, and the application procedure. For the investigator who is unable to maintain the animal model of his or her choice from birth or from a young age and either the model is not available from the NIA or the investigator is not eligible for NIA-maintained animals, there are various other possibilities. These include contracting with a commercial supplier or collaborating with another laboratory that is maintaining the model. In such cases, it is vitally important for the investigator to make certain that the husbandry procedures used by the supplier or the collaborator are appropriate and that the lifetime characteristics, such as body weight and dietary history, are available.

Animal Husbandry Issues

It must be recognized that long-term studies, such as those carried out in aging research, are markedly influenced by the conditions under which the animals are maintained. A telling example is a study with female C3H/HeJ mice that are prone to develop mammary tumors. In a conventional holding facility, 65% of these mice developed such tumors by 400 days of age, compared to only 10% of those mice protected from the noise and odors of a conventional facility. Clearly, for most aging studies, it is imperative to maintain the animals in a defined and optimal environment. With effort, this can be achieved when the investigator maintains the animals from birth. However, it is a challenge to be certain that such is the case when animals of various ages are obtained from a commercial supplier or another external source. The following are factors that must be carefully addressed.

Housing

The size and number of animals per cage have long been important considerations. In fact, there are regulations about the cage size relative to the size of the animal and the number per cage. Surprisingly, these regulations do not appear to be based on hard data. For instance, in the case of number of animals per cage, the published data have ranged from greatest longevity for singly housed rodents to just the opposite. Perhaps both a high-density population and isolation entail stress. However, different species and strains of species probably vary in this regard. Thus, the optimal size of cage and number of animals per cage must be determined specifically for each animal model. Moreover, the question addressed by a study may determine the specific housing needed. For example, if the study includes collection of data on the food intake of each animal, then single housing is required. Although there are still many questions concerning optimal cage size and/or number of animals per cage, it is essential that investigators standardize this aspect of the study and that they clearly present this information when publishing the work. Failure to do so makes it impossible for others to repeat the study.

Bacterial, Viral, and Other Infections

Infectious disease can distort an aging study. With mice and rats, this problem can be dealt with relatively easily by utilizing specific pathogen-free animals. Specific pathogen-free means that a predetermined consortium of pathogenic organisms is absent; specific pathogen-free status is evaluated by serologic, culture, and histopathologic analyses. The rodents should be housed in a barrier or related facility that maintains the specific pathogen-free status. Such facilities vary in structure and complexity, but the aim of all is to exclude the entry of pathogens. So-called sentinal animals are maintained in the barrier facility for the sole purpose of monitoring the specific

pathogen-free status; periodically during the course of the research, one or more of these sentinel animals is removed and assessed for specific pathogen-status. The results of this monitoring should be reported when publishing the research findings. Unfortunately, in the case of many mammalian species, maintenance of the animals in a specific pathogen-free state has not been well developed, and this presents a problem for investigators using such animal models.

Diet

Studies with rodents have shown that diet can profoundly influence aging processes. Indeed, it is well established that decreasing dietary energy intake by mice and rats markedly extends the life of these species. Less information has been reported in regard to aging and diet for other vertebrate species, but based on the limited data available, it appears that diet influences the aging of most, if not all, vertebrate species. Thus, diet is a factor that must be defined and controlled; the composition of the diet and the amount consumed should be reported in any publication of such research.

Exercise

The level of physical activity is another factor that is believed to influence aging. However, this factor is difficult to address in animal studies. The investigators can provide animals with the opportunity to exercise (e.g., by providing rodents with running wheels), but the animal and not the investigator determines the extent of physical activity. When publishing an aging study, all information on exercise (including the lack of exercise) should be reported.

Other Environmental Factors

Many other environmental factors have the potential to affect aging studies. Therefore, as far as possible, the environment of the holding facility should be defined, controlled, and reported in publications of the research. The effects of noise and odors have already been mentioned. The intensity of light and the dark–light cycle need to be controlled. Ambient temperature should be maintained in an optimal range for maximal longevity. Adventitious chemicals from bedding materials or disinfectants or insecticides should be avoided; even at low levels, such substances over a long period of time may markedly affect aging studies.

Vertebrate Species That Have Been Used

Fish

Although fish have been used as models in a few aging studies, remarkably little work has been done with this vertebrate class. This is both surprising and unfortunate because the rate of aging varies greatly among fish species, ranging from imperceptible to very rapid. Clearly, fish are a relatively untapped but potentially valuable source of animal models for aging research.

Birds

Birds are another class of vertebrates used only to a limited extent as models for aging research. Because most species of birds are much longer lived than mammalian species of similar size, birds may be uniquely useful models in that they may have specialized protective mechanisms against damaging agents related to the aging processes. Thus, studies with birds may well provide important insights on aging processes and on possible interventions of human aging. Several commercially available bird species seem well suited to serve as models for such research.

Mice

The mammalian species *Mus musculus* (the laboratory mouse) has been widely used as a model for aging research. Indeed, it is the preferred mammalian model for the study of the genetics of aging because of the availability of many genetically defined strains (more than 500 inbred plus many F_1 hybrids) and because of the detailed knowledge of its genome. Moreover, the molecular technology for the generation of a spectrum of genetically altered mice is well developed, ranging from abolishing the expression of a gene to its marked overexpression. The longevity characteristics of many mouse strains have been determined and found to vary significantly among strains. The small size of the mouse has both positive and negative impacts on its use as an animal model for aging research. Its small size reduces the resources needed for maintenance, with the relatively small space requirement a major plus. However, the amount of biological material that can be obtained from a single mouse is quite limited, and physiological measurements on such a small animal are a challenge. Husbandry is well worked out for mice, and there is a wealth of information on age-associated pathology for some strains. The development of manipulations that slow aging in animal models has proven to be a powerful tool for the study of aging. Mice are extremely useful in this regard since the environmental manipulation of caloric restriction slows aging in this species, and genetic alterations (both those occurring spontaneously and those resulting from the use of the tools of molecular genetics) have been found that extend the life of mice.

Rats

The rat is another mammalian species that has been widely used as a model for aging research. There is much information on husbandry and age-associated pathology for several stocks and strains of rats. In addition, life table data are available for several rat stocks and strains. Moreover, the size of the rat is a plus in that it enables physiological and pathophysiological analyses to be readily accomplished. Also, a single rat provides sufficient material for most biochemical and related analyses. Indeed, longitudinal life span studies, involving periodic blood sampling or other physiological measurements, can be accomplished without compromising longevity. As with mice, caloric restriction extends the life of rats.

Hamsters

Hamsters are mammals that have been used only to a limited extent for aging research. The species most used is the Syrian hamster, *Mesocricetus auratus,* but the Chinese hamster, *Cricetulus griseus,* and the Turkish hamster, *Mesocricetus brandti,* have also been used, and life table data are available for all three. Syrian hamsters, including several inbred strains, are available from commercial sources. Although husbandry has not been as thoroughly studied as for rats and mice, the information on hamsters is adequate for the execution of aging research. About the same size as the mouse, the Chinese hamster has the same size-related advantages and disadvantages. Syrian hamsters and Turkish hamsters are much larger than mice, but are less than half the size of rats. Thus, these two species are easier to use for physiological measurements than mice. There is a sizable literature on the age-associated pathology of Syrian hamsters and Chinese hamsters, but not for Turkish hamsters.

Cats

The cat is a mammalian species that has been widely used for research in neuroscience. Since nervous system dysfunction is a major problem encountered in human aging, cats are potentially valuable as an animal model for aging research. However, very little use has been made of them in this regard. One reason is the lack of a readily available source of well-characterized cats. Indeed, the only cat colony with the characteristics needed for aging studies was one maintained by the British Medical Research Council at Mill Hill. However, that cat colony was not used for aging research. The little aging research done with cats has been accomplished by investigators who pieced together a range of ages by obtaining cats from a variety of sources: university-maintained animals, commercial sources, and pets made available by veterinarians with consent of the owners. Clearly, this has not provided investigators with a reliable, well-standardized source of genetically defined animals. On the positive side, life tables and data on age-associated pathology collected on pet cats are available. Of course, cats are large and long-lived compared to rats and mice, which makes aging studies expensive.

Dogs

It has recently been shown that caloric restriction extends the life of dogs, the first non-rodent mammalian species for which this has been demonstrated. While widely used as a mammalian model for physiological studies, the dog has not been a major animal model for gerontological studies for many reasons. A major reason is that well-characterized dogs in a range of ages are not commercially available. In fact, much of the aging research on dogs has involved control groups of dogs in studies on the effects of ionizing radiation. For such research, a breeding program was established to develop a beagle colony with a stable gene pool; clearly, such colonies are needed to provide dogs for aging research. On the positive side, life table data are available for beagles and Labrador retrievers maintained under laboratory conditions. Also, much is known about the husbandry and age-associated pathology of dogs. Of course, dog breeds vary greatly in size, but even the small breeds are large compared to laboratory rodents, making them costly to maintain, particularly in regard to the space required. For example, the beagle weighs about 10 kg (most rats weigh less than 1 kg and mice less than 0.1 kg). Moreover, appropriate care of dogs requires attention to their social environment, including an exercise program, which can be quite costly in terms of time.

Non-human Primates

Because of the long life span of most non-human primate species and the high cost of maintaining these mammals, it is difficult to use them as models in aging research. Nevertheless, there are at least two reasons such models must be used for aging studies. The first is to make certain that gerontological findings in other vertebrates (primarily mice and rats) are also seen in non-human primates; because of their phylogenetic closeness to humans, it is assumed that aging processes in non-human primates are likely to occur in humans. The second is to study those age changes that occur only in humans and non-human primates. In the United States, government-sponsored primate centers generally employ good husbandry and maintain careful records on each animal. Commercial suppliers are also a source of these animals, but in many instances,

the quality of care may be questionable and information about the animals is lacking. In the past, genetic characterization of the primate model has been nonexistent. However, this problem has been rectified by breeding programs in United States government-supported primate centers and in other institutions funded from a variety of sources. Also, genetic characterization of primates has been greatly facilitated by advances in molecular genetics. Although life table data are available for several non-human primate species, the quality of these data is often less than desirable; this has led to the conclusion that currently available information on longevity characteristics must be viewed as tentative. Non-human primate species vary greatly in size; squirrel monkeys, for example, are in the size range of rats, while other species span a range of sizes similar to those seen in various breeds of dogs. Although husbandry is rather well developed for some species of non-human primates, such as the rhesus monkey, much remains to be determined for other non-human primate species, for example, marmosets. It must be emphasized that social environment is a major issue that needs to be addressed when using non-human primate species. Substantial literature is available on the age-associated pathology of several non-human primate species.

Current Issues and Status of Animal Model Use

Since 1970, there has been great progress in the development of rat and mouse models for aging research. In fact, husbandry for these two species is such that their life span maintenance can now be carried out relatively easily.

This has led to the dominance of rats and mice as models in vertebrate aging studies. This dominance is unfortunate because the use of diverse vertebrate models would almost certainly provide new insights of great value in our quest to understand the biology of aging and, in particular, human aging.

Of course, it is important to make certain that the quality of husbandry developed for rats and mice is adhered to when other models are used. Alas, the information needed to meet this standard is not available for most other species. Also, in each case, these data will be costly and time consuming to obtain. For example, reliable life table data for rabbits will require studies of many years' duration. Similarly, determining husbandry requirements for maintenance of a previously unstudied species will require careful study of dietary needs, environmental temperature, and caging requirements, and a host of other factors. In addition, information on age-associated pathology must be developed for each species. The bottom line is that while diversity of vertebrate animals is clearly needed in aging studies, it will require substantial investment. To obtain realistic fiscal support, administrators of funding agencies and members of scientific review panels must be made aware of the whole picture. And the whole picture includes the realization that state-of-the-art molecular biology is of little value in the absence of appropriate animal models.

It is recognized that understanding the basic biological nature of aging will be essential to successfully meet the gerontological challenges of the twenty-first century. It should also be recognized that achieving this understanding requires the use of diverse animal models. Regrettably, in recent years, many laypeople, including a few leaders in the arts and politics, have condemned the use of animal models for biomedical research, and these critics have had a significant negative impact on animal model use.

Probably most of those opposed to the use of animal models are concerned about animal cruelty. Indeed, everyone should have this concern – especially those using animal models for aging research. Nothing is more damaging to the validity of an aging study than the maintenance of the animals in a less-than-optimal environment. As is evident from this article, husbandry procedures must be employed that provide an optimal diet, maintain optimal environmental conditions, and protect the animals from infection by pathogenic organisms. To do otherwise is counterproductive from an experimental standpoint, let alone humanitarian considerations. Of course, physiological measurements need to be made, and they may perturb the animal. However, the extent of the perturbation should be no greater than what humans experience when undergoing tests by physicians. To markedly perturb would be experimentally counterproductive. When sacrifice of an animal is required, it can and must be accomplished without pain.

Many ask why use animal models for aging research when there are alternatives. One suggested alternative is the use of cells in culture obtained from consenting humans. This is not an option since there is no evidence to support the view that cell culture systems serve as models of organismic aging; even scientists who champion their use recognize that cell culture systems serve as adjuncts rather than replacements for animal models. The other suggested alternative is the use of computer models. Given the current state of the gerontological knowledge base, there is no way in which computer models can replace animal models. On the plus side, computer modeling can be a powerful tool for optimizing the use of animal models.

Modernization and Aging

J Leavitt, University of California at Los Angeles School of Public Affairs, Los Angeles, CA, USA

Glossary

Extended Households – Related or unrelated people sharing the same living quarters.

Independent Living – Non-family and family households who share living quarters in a unit that has a full bathroom and kitchen within the unit.

Neighborhood Families – Formal and informal support structures to households, with easy access to aging households, and replacing some functions that individual families provide.

Introduction

Modernization theory was used to promote a western model of development in the 1950s. By the 1970s, scholars rejected the idea that this theory was a blueprint for industrialization and democracy in developing countries. The idea that progression was linear was discredited. In the 1970s, the research agenda for aging expanded to include issues about the older population in developing nations. Researchers on aging agreed that a demographic revolution was occurring based on the worldwide growth of the older population in the twentieth and twenty-first century. The demographic revolution affects and is affected by modernization. Revised modernization theory offers insight into the implications of an increasingly aging population in developed and developing countries undergoing globalization. This article begins with an overview of the demographics of aging and then reviews alternative views about modernization in relation to globalization. A description of the demographic revolution's influence on household and family structures, living arrangements, and the intersection with modernization follows. Aging issues in community, housing, labor, and employment policies are explored. The last section turns to a description of global institutional policies and proposed transnational policies. Under globalization and given governments' weak commitment

and/or budgetary problems, the role of civil society as being significant in enfranchising older populations is discussed.

The Demographics of Aging

The United Nations Department of Economic and Social Affairs (UN DESA) has stated that population aging is unprecedented, pervasive, and enduring and has profound implications. The reasons for increased aging are due to numerous interrelated factors.

- Mortality and fertility rates are declining, increasing the proportion of the older population. Grandparents will outnumber children.
- Longevity is increasing. In 2002, it was 66 years. In the least developed countries, men who reach 60 can expect to live another 15 years and women 16. In developed regions, life expectancy at age 60 is 18 years for men and 23 for women.
- The fastest growing population in the world is 80 and over. About 180,000 persons worldwide are centenarians and their numbers will reach 3.2 million by 2050.
- The majority of older persons are women. The percentage rises among the oldest. In developing countries, among people over 60, the ratio of men to women is 88 to 100; in comparison the ratio is 71 men for every 100 women in developed countries.

Absolute numbers are dramatic. The numbers of those 60 years and over will reach about 1.2 billion by 2025 and 2 billion by 2050. The overall rate of growth for older persons is increasing faster than the population as a whole. In 1950, the proportion of older persons was 8%; in 2000 it was 10%; by 2050, it is projected to reach 21%. The most startling revelation to many is that population aging is occurring faster in developing countries than industrialized. According to the World Health Organization (2002), "In 2002, almost 400 million people aged 60 and over lived in the developing world. By 2025, this will have increased to approximately 840 million representing 70 percent of all older people worldwide." The growth of the older population is changing the profile in communities and preferences for living arrangements. Migrating working adults are leaving more elderly behind in rural areas in developing nations, and the elderly in urbanized areas in developed nations are facing a lack of affordable housing.

- About one-third of the world's older population lives in rural areas, but 51% live in urban areas. The percentage of older people in urban areas in developed nations is 74% compared to less developed regions, where only 37% live in urban areas.
- Three-quarters of population growth will occur in second-tier cities and smaller urban areas with populations between 100 000 and 500 000.
- The growth of the older population bears directly on labor, employment, and immigration policies.
- From 1950 to 2000, the ratio of working-age adults (15 to 64 years of age) per person 65 years and over – the old age dependency ratio – dropped from 12 to 9 and is expected to fall further to 4.

Too often overlooked in the attempt to fully appreciate the relationship between modernization and aging are distinctions among the older population. In addition to differences among and within nations, regions, development status, and rural or urban location, the older population varies by class, race, ethnicity, education, gender, sexual preference, marital status, religion, culture, etc.

Statistics tell one side of the story. Considering the implications of modernization makes aging seem far more complex. Analysis cannot simply target a specific age as old or elderly. For example, in France, most men retire between 55 and 64 years of age, but pressing demands to offset the decrease in the labor force of younger working-age adults may reverse the trend of early retirement. Age targets overlook the variations among the old as a result of longevity and medical advances in treating infectious diseases in many regions of the world. The 'new old aged' or active aged engage in sports, education, sexual activity, and work at ages once thought to be devoted to extremes of idle leisure or isolation. Demographic shifts can shape the ways in which neighborhoods are experienced, that is, as senior ghettos or as age integrated. This also depends on how policy makers distribute resources to satisfy the needs of an area in which the elderly are a majority.

The life course concept is a way of integrating modernization and globalization trends. The life course identifies interacting policies or nests of policies that have effects throughout one's life. Old age is no longer a fixed status but is subject to circumstances that can shift back and forth in response to numerous environmental factors, including education, urbanization, medical advances, residential segregation, and migration. The life course takes into account the fact that policies that influence people in their earlier years will also have repercussions in later life. For example, a mandatory education policy for young girls will affect later choices about pregnancy, the number of children conceived, and whether women have greater options in the labor

force. As mortality rates and fertility rates decline, a result of advanced technology and health and education policies, community and family institutions are altered. Tied to these policies is the need to rethink the belief that modernization leads to less respect for the elderly.

First, what is meant by modernization and the relationship to globalization?

Modernization and Globalization

The term modernization can be explained in multiple ways. The framework includes the shift from agriculture to industrialization, institutionalizing democratic government, creating bureaucracies, the spread of urbanization, and the increasing use of technology. Modernization is sometimes used interchangeably with globalization. Other times, globalization is referred to as a near cousin to modernization, that is, the economic and social underpinnings that lead to development. Globalization is also used as an umbrella term for modern, postmodern, or late modern periods when national priorities rapidly change, the social order becomes more diverse, and the elderly are less likely to be placed in institutions.

One question is whether or not modernization aptly describes societies in which industrialization is subordinate to the informational economy. The expansion of financial integration into a global market and the growth of the health-care, education, and transportation sectors depend on a stable, reliable, and fast informational economy. Douglas Kellner, in the essay "Globalization and the Postmodern Turn," identified a current period of transition where "globalization signifies both continuities with the past, with modernity and modernization, as well as novelties of the present and the already here future."

Modernization theory varies over time. The first wave of modernization theory appeared in the social sciences in the 1950s and 1960s, although the concept reaches back to seventeenth-century European thought. The second wave of critical theory in the 1970s and 1980s was an attack on the imposition of western ideas on developing countries. In the 1990s, a postmodern interpretation was linked to a third wave of globalization.

Modernization theory emerged after World War II, a time when the United States was considered a superpower, European nations withdrew from or were forced to leave their colonies, and a power center coalesced around the Soviet Union and communist ideology. The Cold War divided the globe into friends and enemies of the United States. Tension existed between communism and democracy. Scholars such as Walter Rostow postulated that the United States was the model to be emulated and that foreign aid should be used to kick-start progress in developing nations as they passed through the evolutionary stages from craft to mass production. The promised result would be economic growth leading to higher per capita income. Social benefits would include raising the standard of living. The combination of economic and social improvements would result in favorable conditions for institutionalizing democracy.

In the second wave of modernization theory, critical theorists reacted strongly against the model's western bias, failed policies, persistence of poverty, and the rise of dictatorships. The Cold War mentality blinded policy makers to differences among countries and nation-state identity that wars did not eliminate. In the late 1970s, privatization policies escalated. In some countries, nationalization of utilities, transportation, and state-run housing bureaucracies was criticized as being inefficient and unprofitable. New Zealand and Great Britain led the way in selling their nation's assets to the highest bidders. Except for China, Cuba, and Vietnam, primarily in Asia, Africa, and Latin America, nationalization within a country wrested economic control from a market-dominated minority.

The current wave of postmodernization theory acknowledges an increasingly complex and uncertain world where financial integration is accompanied by social fragmentation at the individual and societal level. Modernization may occur in some parts of a country or region and not in another. According to Michael Hardt and Antonio Negri, economic miracles in one sphere, as in Italy's knowledge industry, can co-exist with less complete transformation in another sphere, such as small peasant farms. Cheap telecommunications create a global marketplace in which the opportunity to become a producer is just a computer keyboard away, available to individuals, businesses, and the nation-state.

In this hyper-marketplace, generous social welfare programs in many industrialized countries are dumped. Dwayne Swank refers to diminished democracy, in which democratic institutions are unable to sustain policies when market measures are used to determine success. Former state socialist countries are adopting legal tenure systems based on western models of private property rights, escalating the trend toward privatism.

In countries where little social security exists for the elderly, *de facto* policies rely on the family, but the results are mixed as to whether modernization/globalization undermines this traditional support and diminishes the worth of the older population. In Kenya, the once special status of elders has given

way to viewing elderly slum dwellers as unsuccessful because they do not have money to return to their home villages and grow old. In India, the authority and prestige of old people is being replaced by the idea that they are a burden. Distinctions between younger and older elderly can change the dynamic. For example, according to one study, younger elderly married people who live in rural areas in the Republic of South Korea, who have more modern attitudes, and whose children are educated have more power than older elderly. A similar finding was observed in the Philippines.

Modernization/globalization is multifaceted and can lead to positive outcomes, but the outcomes can generate unintended consequences or insufficient change. Physical longevity may occur as a result of wiping out infectious diseases, yielding higher crops, and improving nutrition and sanitation. However, income may still be too low for the elderly to afford housing and other necessities. Literacy may increase, but limited access to advanced technology during younger years may not lead to higher-skilled well-paying jobs that provide economic security in old age. Globally, individuals with disabilities are expected to decline in number, but survivors may be unable to afford 'assistive technology' that helps increase their functionality. Wars, skirmishes, and ethnic clashes restructure land holdings, but they do not eliminate unequal distribution of power among men and women and can result in older people losing their claims to property and relative security.

Some scholars suggest that modernization theories and by extension globalization theories are helpful on a macro- but not a micro-level scale. Kellner says that globalization is most apparent in the 'realm of culture' in terms of consumer products, images, and ideas, and questions whether the homogenization of global culture is so overpowering as to sever ties to local places, break religious and ethnic identities, and replace the role of nation-states. While some scholars support globalization, deregulation, the openness of trade borders, and international financial integration, Chua lists negative consequences to these events such as ethnic conflict, militant Islam, taking property, killings, displacement, and genocides. In short, globalization, like modernization, should not be misunderstood as progress. Such events are devastating to the cultural and collective memories of the older population.

In developing nations, even among the 'Asian tiger' nations who sustained financial success and 'won' transnational corporations and foreign investment to their shores, poverty is pervasive. The United Nations HABITAT reports that in 2001, 924 million people were slum dwellers – 31.6% of the world's urban population, 43% in developing regions, and 6% in developed regions. The number of slum dwellers might increase to as high as 3 billion by 2050, absent any interventions. The litany of slum conditions – lack of basic services, unsafe buildings, overcrowding, and lack of tenure – is a declaration of non-modernization in a globalizing world. The aging population suffers along with other slum dwellers, compounded by lifelong difficulties with nutrition, health, and multiple pregnancies among women.

The lack of public accountability under modernization/globalization is writ large in Africa, where the 'modern' disease HIV/AIDS has systematically broken up families. The African continent has a young population, but the number of elderly aged 77 to 84 is expected to grow, and it is questionable whether the government and community can offer support. Currently, elderly women are the primary caregivers for children and ill relatives, but this care infrastructure is fragile given that older women are also susceptible to HIV/AIDS.

Gender reform is closely linked to modernization. The role of women in developed and developing nations is tied to their class and society's cultural and religious values, norms, and laws, which shape family and household structure.

Family, Household Structure, and Gender

Family and household structure and the diversity of social arrangements are a function of demographics, but demographic changes interact with urbanization, industrialization, and the influence of religion.

In industrialized countries, the dominant model of the nuclear family is a working husband and stay-at-home wife. Lifestyle choices, rising divorce rates, formation of single parent households, same-sex couples living together and/or marrying, and the elderly choosing to live independently have all contributed to various types of household structures. The diversity in industrialized countries is linked to women experiencing greater rights, having access to birth control, and benefiting from labor-saving devices in the home, all of which enable them to participate more fully in the labor force. This is constrained by the scarcity of child-care programs, particularly for single parents and women of color who rely on older caregivers among their family, friends, and kin. Conversely, Hardt and Negri suggest that in countries where Islamic fundamentalism is practiced, the belief in a traditional family can be interpreted as postmodern. A rejection of western models of diverse family institutions and liberatory policies for women is consistent with thinking that western life is generally corrupt.

Women in developing nations have fewer rights than women in industrialized countries. Although women produce between 60 and 80% of the food and are the foundation of small-scale agriculture, their status declines as they get older, and their conditions worsen with less access to resources. Because women live longer than men, their widowhood is fraught with financial problems once husbands and sons die. Women are not allowed to own land or apply for credit. Women in sub-Saharan Africa and the Near East are primarily responsible for animal husbandry, processing, and marketing. Traditions prevent them from starting their own businesses. A lifetime of earning low incomes and the absence of savings increase older women's dependency as they age. Wage discrimination for women in industrialized nations leads to similar consequences, although their rights are greater.

Bongaarts and Zimmer's research on living arrangements in 43 developing countries showed that elderly women were nearly twice as likely to live alone as men. Asian elderly are more likely to be living with children compared to Africans or Latin Americans. A preference for living with adult male children is evident in Asia, but gender preferences are not homogeneous even there. Education levels, rather than wealth and urbanization, are more likely to influence the elderly's living arrangements. The higher the level of education, the greater the likelihood that the household is smaller, and the greater the chances for living alone.

Ultimately, the choice of living arrangements may be constrained by housing options. The interaction of changing compositions of living arrangements and increased urbanization in market economies has led to housing crises all over the world.

Community and Housing

Issues about community and housing are directly related to not only increased urbanization, but also migration of working-age adults and government policies. Housing policies have community-wide impacts; the housing package includes the community setting. Older people are best served when public transportation, commercial facilities such as markets and pharmacies, and recreation and community health centers are within walking distance. Public social venues where the elderly can meet can offset feelings of isolation and contribute to preventive health practices. Canada is exploring ideas of combining recreation centers and schools with wellness centers where the elderly can conveniently find health services. Safety in communities is an important issue that has been taken up by women's groups in collaboration with municipalities. Increasing the number of bus stops and instructing drivers to stop closer to destination points help enable the elderly to have access to greater mobility.

In industrialized countries, the degree to which a country supports the older population depends on factors such as tax incentives, community-based programs, and financing for innovations such as 'smart houses' that incorporate technological advances. In the United States, homeowners receive government tax relief, the deepest subsidy program in the form of tax write-offs that totaled about 73 billion dollars in 2005. Public housing, which encompasses only 1.4 million units and which is routinely underfunded, houses one-third of the elderly, with the largest subsidy program for poor seniors of color. Whether single-family owner-occupied homes or public rental housing, these units may not be modernized and may lack supports for aging. Conditions become worse for the elderly under inflationary periods, when expenses for food and utilities can rise. In other cases, the government's withdrawal of subsidies, as with Russia in 2004, deprives the elderly of essential benefits.

At the same time that modernization/globalization promotes independence, the private housing market, particularly in large metropolitan areas, is too expensive for older people on fixed incomes. The International Alliance of Inhabitants documents worldwide forced evictions in developing and developed nations in cities such as Nairobi, Kenya and Rome, Italy. Displacement can be government driven. In countries that once had deeper social housing programs, for example, England, government selling of council housing accelerated gentrification in areas ripe for market development, with the effect of displacing poorer people who could not afford the rising rents.

In Singapore, where the government plays a substantial positive role, 81% of the people live in public housing. In Hong Kong, 47% of the population lives in public housing. In countries where Confucian values promote reverence of the elderly, cultural values may concede to pragmatic decisions given urbanization. Co-residency in China, Taiwan, Singapore, and Hong Kong is sensible considering their conditions of a shortage of affordable housing. The possibility of co-residency must be weighed against the option of living in urban areas in smaller apartments and cramped quarters. Policies to counter adverse modernization trends can help keep families intact. Housing-related policies promote co-residency, such as in Hong Kong, where families with elderly persons are given priority for obtaining housing. Singapore favors young people who live in multigenerational households.

Housing policies reinforce and reflect racial and ethnic as well as economic segregation. Spatial patterns become 'fixed' for life, especially because the generally agreed-upon consensus in industrialized nations is that older people should age in place. The availability of housing options impacts the lives of older as well as younger populations regarding whether communities are mixed by age. In developed countries, age-specialized housing such as retirement homes or continuing care facilities, seniors-only complexes, and group homes is increasing. Shared living services match people in assisted housing, where collective spaces can include kitchens and living rooms. Direct services such as meals may be provided. Accessory units, sometimes called mother-in-law or granny houses, can be attached to or detached from single family houses; the arrangement can be with kin or not. Japan offers something similar in the form of garden suites built adjacent to main houses to accommodate modified extended families.

The elderly who age in place are both renters and owners. In countries such as the United States where health care and nursing homes are costly, owning offers one form of security in old age, although poor elderly homeowners, primarily women, can have trouble paying for other necessities. A primary concern is whether health and other services are accessible and available. In Sweden, for example, a house care and repair program helps the poor and disabled. In Denmark, assistance with shopping and laundry is provided, and elderly residents receive night and evening home-care visits. Increasing numbers of states in the United States are using a combination of federal, state, and local subsidies to provide funding for home-care providers – also referred to as home aides – including paying family members who perform this service. This enables the elderly who meet financial requirements to continue to live independently from families and eliminates the need to place them in nursing homes. As often as not, older women earning low wages are caring for other low-income elderly women.

The most vulnerable elderly include the frail, disabled, and poor as well as those who live in rural areas and urban slums. The United Nations' call for poverty reduction programs is based on increasing ways to earn a living and providing greater access to credit, especially for women. Other approaches are through labor employment policies. John Myles reports that Canada and Sweden have less than a 5% poverty rate in the older age group; the former offers a guaranteed annual income to the elderly, and Sweden offers a guaranteed minimum pension.

Labor and Employment

Labor and employment policies under modernization/globalization influence and are influenced by the role that governments play in achieving economic stability for the individual and the society. In industrialized countries, income for the elderly includes pension plans, savings, private investments including stocks and real estate, and long-term care insurance. The elderly may continue to work, reduce their hours, or find new part-time jobs. These options are insufficient for those whose earnings were limited at younger ages or who held jobs that paid moderate wages and either had no pensions or had pensions with limited benefits. Women in particular face an uncertain future given past discrimination.

The role that governments play in providing social security for the elderly in industrialized nations is in transition and is linked to changes in the market, the decreasing ratio of working-age adults to elderly, and lower fertility rates. This affects policies regarding education and immigration. Education and job training can be promoted as a way to retrain older people. Another alternative for replacing the growing older work force is recruiting additional women into the labor force, although individuals have been entering for reasons of survival as well as raising their standard of living. Flexible policies about immigration are a contentious issue in many industrialized countries where questions are being raised about citizenship and rights to housing, among other benefits. Immigration, particularly when not legal, is a factor in debates about who is responsible for retirement benefits.

Retirement programs are an aspect of employment policy. Choices about extending the retirement age, reducing social security payments, and increasing the hours in the work week are designed to combat disruptions that the private and public sector encounter in the face of rapid globalization. Encouraging the elderly to work longer may be necessary on an individual level, for example, when corporations mismanage pension plans, declare bankruptcy, or lower their contributions. In the United States, there is vehement debate about privatizing social security and switching from defined benefits to defined contribution pension plans in order to reduce government payouts. Unions in industrialized nations have a stake in the debates; they are concerned about protecting the rights of workers as well as hard-won gains such as hours in the work week, vacation time, and health benefits.

In contrast to the elderly in developed nations, it is assumed that the elderly in developing nations will remain economically active throughout their lives.

This is largely due to minimal social insurance programs. There are other difficulties that relate to the degree of modernization. In 2005, Global Action on Aging reported that Nigerian pensioners were dying because they had not received their monthly pensions. The contradictions of modernization/globalization are visible in Ciudad Juarez, Mexico, where medical and nutritional improvements leading to longevity will see the older population doubling between 2000 and 2005, a trend that will continue every 5 years. Meanwhile, the government, civic organizations, and religious organizations are not responding to deaths from illnesses such as diabetes, hypertension, and heart attacks. In East Asia, one scholar warns, countries could go bankrupt trying to take care of the elderly, and the elderly have to find ways to give back to society.

World Organizations and Civil Society

In the face of modernization/globalization, global institutions are proposing policies that are transnational, promoting programs that will optimize the lives of the older population. The United Nations has played a role since 1948, when their activities concerning aging began. In 1982, the World Assembly on Aging adopted the International Plan of Action on Aging, making recommendations about health and nutrition, protection of elderly consumers, housing and environment, family, social welfare, income security and employment, and education. In 1991, the UN adopted principles in five categories – independence, participation, care, self-fulfillment, and dignity. In 1999, the International Year of Older People was observed; in 2002, in Madrid, at the second World Assembly on Aging, the adopted recommendations were comprehensive, including the topics of financial security, health care, housing, and protection against exploitation. The needs of elderly women were included as a priority. The World Health Organization's program for active aging has also attracted global support. Transnational institutions recognize that programs are dependent on resources and urge governments to accept responsibility for developing programs.

In industrialized countries, civil society is playing a major role in advocating for the older population. Volunteer groups have grown from a scattering in the 1950s to become institutionalized organizations after the 1970s. Many types of organizations exist that differ in purpose, numbers, activity, and militancy. Organizations in industrialized countries foster intergenerational relationships, gay and gray lesbians fighting against isolation and loneliness, retirees organized around companies and occupations, professional and business people, and state employees. Among more militant groups in the United States are the Raging Grannies and the Gray Panthers, both of whom have local chapters, some of which are more active than others. Among the most influential groups in the United States is the AARP, a strong lobbying group with a large membership base.

The World Health Organization observes that richer nations were able to get richer before they got older. The developing world will be getting older long before they achieve an infrastructure of support for the elderly. The Organization for Economic Co-operation and Development reports that it took 140 years for the aged population in France to double; in comparison, in China it will take about 34 years and in Venezuela, about 22. Under these circumstances, coalitions of non-governmental organizations (NGOs) are essential as lobbyists, program operators, and capacity builders of organizations. The NGOs may be able to act as a countervailing force in the face of rapid changes. Collectively, the message from NGOs is to demand and promote the integration of the elderly into the development process. The elderly can transmit traditional skills but also can be useful in production industries or in public welfare and safety tasks. In Ciudad Juarez, Mexico, for example, people 60 and over are being hired as members of an unarmed elder police force at elementary schools and parks. In India, more than 500 NGOs are providing services such as old age homes and senior day care centers and are advocating for benefits such as priorities for transportation and hospital appointments.

Civil society and organizations of the older population are essential under modernization/globalization, especially when public responsibility flags and the private sector retrenches. The longevity of the population, the very fact that more people at older ages will remain active, combined with networking power through the technology of the Internet, is significant. The aging population itself can use the tools of modernization/globalization to make visible their needs and rights. The dramatic reversal of the demographic revolution, the rapidity of changes in the market, and a misrepresented faith about the all-encompassing benefits of modernization and globalization mean that the aging population cannot advocate on its own behalf alone. With globalization, it is important to recognize the diversity and differences among young-old and old-old, but at the same time to join with broad-based social movements including the pre-old to challenge the negative aspects of modernization.

Motor Control

R D Seidler, A S Bangert, J A Anguera, and C M Quinn-Walsh, University of Michigan, Ann Arbor, MI, USA

Glossary

Closed-Loop Control – When sensory feedback is used in the planning, execution, and modification of actions.

Coordination – The simultaneous, smooth motion of multiple body segments.

Kinematics – Descriptors of motion, without taking into account the forces that produce the action (for example, limb displacement, velocity, and acceleration).

Motor Control – The integrative action of the nervous system in the control of posture and movement.

Motor Unit – A group of muscle fibers and the motor neuron that innervates them.

Neural Noise – Random neural background activity arising in the sense organs, neural pathways, and the brain.

Open-Loop Control – When an action plan is generated prior to movement onset; movements are then executed without regard to sensory feedback.

Signal-to-Noise Ratio (SNR) – The ratio between the amount of modulation due to the invariant program component (signal) and the amount of unpredictable modulation (noise). A high SNR suggests a more reproducible movement.

Speed–Accuracy Trade-off – The well-known phenomenon that when a performer attempts to move more quickly, he or she becomes less accurate.

Introduction

Older adults often exhibit impairments in motor performance that can affect their everyday activities. Motor skills are influenced by deficits in processes that occur before a movement, such as slowing in central processing speed, and by changes taking place during performance of a movement, such as an inability to properly regulate force. The speed, variability, and kinematic profiles of older adults' motor responses usually are not comparable to those of younger adults. Some of these declines can be partially mitigated with practice. The causes of these motor performance declines are not well understood. Regardless of the etiology of these declines, they can have a substantial effect on the independence of older adults.

Typically, as individuals get older they experience substantial declines in sensorimotor processing. Motor performance often becomes slower and more variable. Research has also revealed that the elderly show (1) an increase in movement duration, (2) more variable actions, and (3) difficulties with motor coordination. Age-related changes in sensorimotor processing may lead to impairments in motor activities of daily living (ADLs); however, some deficits may be reduced with practice and/or familiarization. The purpose of this article is to describe how aging alters the ability to control and execute movement, and to document the manner in which such movements differ from those of younger subjects. As the topics are reviewed, we present several of the current theories of why such impairments occur.

General Slowing of Movements with Age

One of the more pervasive changes in motor performance with age is an increase in movement duration as seen on a variety of tasks. Older adults are slower to initiate movements in response to stimuli; they also execute movements more slowly than younger adults.

Motor Slowing

The measure of movement time provides information regarding declines in sensorimotor processing. Compared to younger subjects, the elderly execute movements approximately 15–30% more slowly. In addition, they are disproportionately affected by increasing movement difficulty. An example of the effect of increasing difficulty is shown in **Figure 1**. In 1954, Fitts' law was formulated to establish the relationship between movement time and index of difficulty (ID) for aiming movements of varying amplitudes and target widths. This law can be

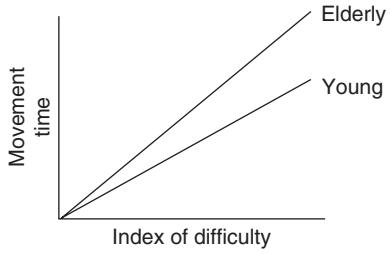

Figure 1 Fitts's law: Movement duration increases as a function of the index of difficulty for the young and the elderly. The elderly show prolonged movement durations with increments in task difficulty.

mathematically represented as

$$\mathrm{ID} = \log_2 2A/W \text{ bits/response},$$

where W is target width and A is movement amplitude (distance from the starting position to the target center). Fitts demonstrated a linear relationship between the time taken to execute a movement and the logarithm of the required relative accuracy. Relative accuracy is measured as twice the movement amplitude, $2A$, divided by the target width, W. Movements of greater amplitudes to smaller targets take longer. To further investigate this phenomenon, performance speed for the young and elderly was compared on tapping tasks requiring movements of three amplitudes to three target widths. The slope of the line relating movement time to index of difficulty increases with age, but not the y intercept. As seen in **Figure 1**, the slowing is not in constant increments, but in increasing increments with age, implying that the elderly take considerably longer to execute movements that require greater precision but have little difficulty with low ID movements. It is important to distinguish whether this effect represents a difference in movement strategies that might be eliminated by appropriate payoffs and/or training, or whether the prolonged movement represents a fundamental limitation of the motor control system present in older adults.

Contributions to Motor Slowing

Explanations of slowing in older adults can be divided into at least three main categories: (1) older adults produce slower movements in an attempt to minimize error, (2) with advancing age, there is an increase in perceptual noise in the system, and (3) with advanced age, there is an increase in motor noise in the system. These explanations are not mutually exclusive and probably overlap to some degree, explaining why older adults make slower movements than younger adults.

Minimizing Error In all movement tasks, an individual must deal with the issue of speed versus accuracy. As the resulting speed of a movement increases, so does the probability of making an error, as these faster movements do not always end at intended target locations. For each task situation, a decision must be made on how to optimize performance with respect to speed and accuracy. Speed–accuracy relationships hold for all age groups, but older adults tend to choose to emphasize higher accuracy levels at the cost of movement speed.

Increased Perceptual Noise Older adults are known to have relatively more noise in their visual processing system than young adults. Such increases in noise are thought to hinder visually guided feedback capabilities of movement-related information. In motor task situations in which some visual guidance is expected, as in the deceleration (or homing in) phase of movement, there would be increased errors from imprecise monitoring and ensuing corrective movements. This explanation postulates that older adults produce slow movements because of prolonged deceleration phases, a well-documented phenomenon associated with movements in the elderly (*see* Vision).

Increased Motor Noise Movement slowing has also been explained by decreases in signal-to-noise ratios. This explanation of slowing is based on the assumption that motor noise increases with the amplitude of force generated. When older adults produce a certain force level, the noise associated with it is thought to be greater than that observed in younger subjects. Thus, this argument suggests that older adults produce slower movements than younger subjects because moving more slowly offsets the changes in signal-to-noise ratio and allows older adults to achieve the same level of accuracy as young adults.

The problem with these explanations is that they are not mutually exclusive. As is apparent, these hypotheses are interrelated and make very similar predictions about motor performance. This explains why it has been so difficult to localize the exact cause of movement slowing in older adults.

Kinematic Changes with Age

Kinematics refers to the branch of mechanics that studies motion without taking into account the forces that produce an action. Movement descriptors such as limb displacement, velocity, and acceleration can be calculated from data captured with high-speed cameras or other motion-monitoring devices. Kinematic investigations have contributed greatly to our understanding of age-related changes in motor control.

Movement Substructure

The kinematics of aiming movements can be divided into two components: an acceleration phase, from movement initiation to peak velocity, and a deceleration phase, from peak velocity to the end of the movement (**Figure 2**). The deceleration phase is seen as a 'homing in' on the target. Kinematic investigations have typically required subjects to perform aiming movements such as pointing at a target or using elbow flexion and extension movements to control a manipulandum that positions a cursor at different target locations. The most readily observable difference between young and older adults is seen in the velocity curve (**Figure 2**). Although young subjects perform movements with symmetrical, bell-shaped profiles, older adults spend a greater proportion of the movement in the deceleration phase (period following the first vertical line in **Figure 2**). This effect is intensified as the accuracy requirements of a movement increase, consistent with a speed–accuracy trade-off strategy for the elderly. This lengthening of the deceleration phase contributes to increases in total movement duration. Although the acceleration phase of movements is assumed to be under open-loop control, with no need for feedback information, the deceleration phase is assumed to be at least partly under closed-loop control, in which error detection and correction information from motor and sensory systems are used. Because the deceleration phase of movement is lengthened with little changes appearing in the acceleration phase, this deficit may depend on the ability of the elderly to efficiently coordinate sensory and motor information.

In aiming tasks, young subjects perform the major portion of the movement as an initial, ballistic primary subcomponent and then employ a shorter, corrective secondary subcomponent (the period after the second vertical line in **Figure 2**) to reach the target. These successive episodes of acceleration and deceleration of the limb are referred to as submovements. Researchers have shown that older adults do not project the limb as far during the primary ballistic submovement and are therefore required to use a longer secondary submovement to reach the target accurately. It is not known why young and elderly subjects exhibit different time profiles for these components. The lengthening of the secondary component may reflect an inability to produce adequate force to rapidly move the limb during the primary component. It may also be caused by the greater amount of time required for older adults to process sensory information regarding position of the arm with respect to the target.

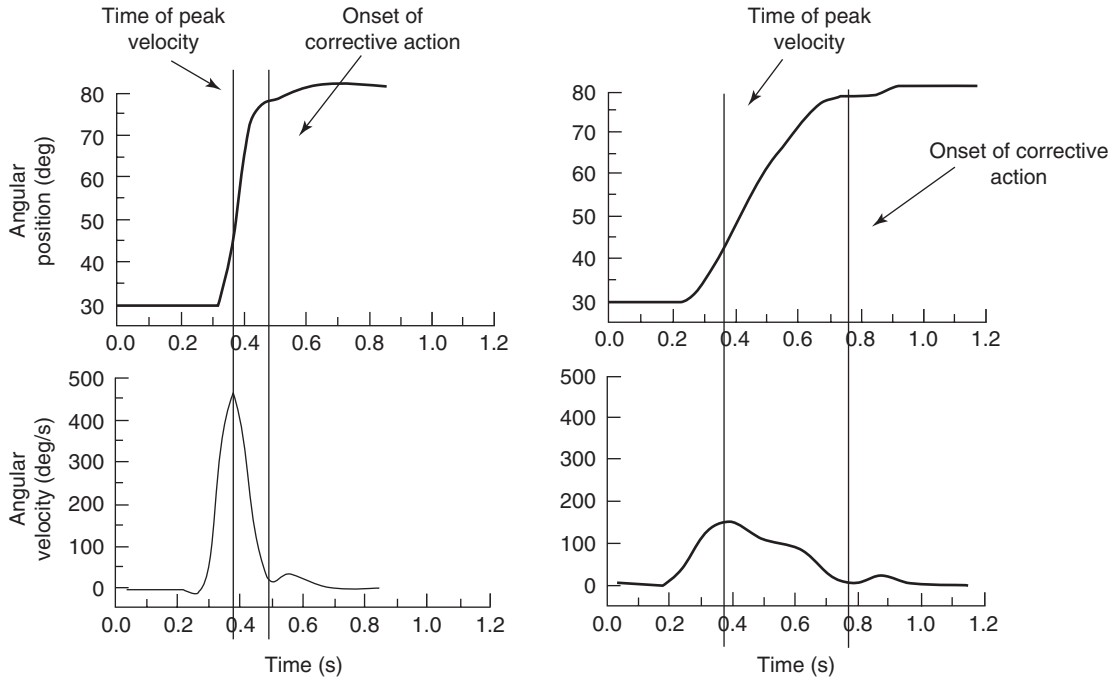

Figure 2 Kinematics of a rapid, aimed movement. Typical results for younger subjects are shown on the left, while those for the elderly are on the right. The acceleration and deceleration phases of the movements are divided by the first vertical line (time of peak velocity). The primary and secondary submovements are divided by the second vertical line (onset of corrective action). The elderly exhibit both a prolonged deceleration phase and an extended secondary submovement in comparison to young adults.

Movement Scaling

When younger adults perform movements of differing amplitudes, the temporal features of the movement often remain invariant; thus, relative timing is preserved. It is normal for the motor system to increase acceleration for movements that have longer amplitudes. As a result, the ratio of peak velocity to mean velocity remains fairly constant when movement amplitude increases. This suggests that the movement pattern remains invariant and is simply rescaled as the amplitude of movement changes. However, this does not appear to occur with the elderly. In a study requiring young and older subjects to perform elbow flexion and extension of varying amplitudes, older adults exhibited greater variation in the ratio of peak velocity to mean velocity, with the highest ratio values displayed for smaller amplitudes. This ratio is more variable for the elderly subjects, suggesting that the amplitude of their movements cannot be modified by a simple rescaling of the initial impulses in order to produce movements of differing sizes.

Movement Variability

Compared to younger subjects, the elderly exhibit greater variability in their movements, with performance fluctuations occurring both between and within trials. For simple elbow movements, the elderly exhibit greater variability for short movement amplitudes in which the deceleration phase of the movement contains several submovements. High variability in this phase suggests that older adults need to make extensive modifications during this final movement.

Movement variability may also arise from peripheral changes in the neuromuscular system. Aging is associated with the progressive death of alpha motor neurons. Some of the muscle fibers that were once innervated by these motor neurons are re-innervated into remaining motor units. These reorganized motor units produce greater force due to their larger number of muscle fibers, potentially leaving older adults with a reduced degree of control over force production, particularly at lower force levels.

Aging is also associated with greater fluctuations in motor unit discharge rates. Computer simulations linking motor unit structure with discharge rates and force output suggest that discharge rates may have more of an impact on muscle force variability than the motor unit reorganization described previously. It appears that older adults can compensate for heightened muscle force variability by co-activating the antagonistic muscles surrounding a joint. However, this compensatory strategy is only employed for simple, single joint actions (*see* Neuromuscular System).

Another factor that can influence trial-to-trial movement variability is the motor control strategy that subjects employ. Older adults make larger errors when vision is unexpectedly occluded during a movement, suggesting that they rely more on visual feedback control for motor performance than young adults. This greater reliance on feedback control is associated with numerous corrections to ongoing movements, producing trajectory fluctuations. When movements are performed in a feedforward fashion, in contrast, a consistent movement plan can be executed repeatedly with little variability from trial to trial. Motor variability decreases with practice for young adults, as movement control shifts from feedback to feedforward. Older adults have shown similar practice benefits in an arm aiming task, with movements becoming more consistent over repeated trials. However, the underlying strategies producing this reduced variability differ between young and older adults. Following practice, younger adults perform a greater portion of aiming movements under feedforward, programmed control. That is, their primary submovement covers most of the distance between the start and the target location. In contrast, elderly adults increase the efficiency with which they use feedback information as a function of practice. After practice, their primary ballistic submovement does not increase in amplitude; rather, their corrective actions become more accurate and make up less of the overall movement. This increased reliance on feedback mechanisms for older adults is associated with slower and more variable movements.

Motor Coordination

Coordination refers to the simultaneous, harmonious action of multiple body segments, resulting in a smooth movement. The execution of coordinated movements requires the precise temporal integration of sensory and motor information. This process begins to break down with advancing age.

Multi-joint Coordination

Multi-joint movements are not as smooth and coordinated for older adults compared to younger adults. For example, older adults make jerkier movements, which are irregular in their time course, when they draw with the wrist and fingers simultaneously, as opposed to moving just the wrist or just the fingers alone. Similar results are obtained when older adults make reaching movements that require motion of both the elbow and the shoulder joint simultaneously, as opposed to elbow or shoulder single-joint actions. The same pattern of deficits, although to a greater extreme, is seen in deafferented patients who lack proprioception. Patients with cerebellar damage show comparable behaviors, decomposing multi-joint movements into a series of single-joint actions. These findings indicate that coordination difficulties observed in older adults may be due to age-related degeneration of the proprioceptive system and the cerebellum (*see* Touch and Proprioception).

Bimanual Coordination

When individuals are asked to make discrete movements to targets that are short or long distances away, both older and younger adults are more accurate and less variable when they make symmetrical movements (e.g., the two hands move to both short or both long targets) than when they have to make more complex asymmetrical movements (e.g., one hand goes to a short target while the other moves to a long target). However, older adults tend to make more movement errors, are slower to initiate and execute movements, and show greater differences in initiation and termination time between the two hands than younger adults, especially as coordination complexity increases. Older adults also have more difficulty adapting the movement time of each hand to make up for any differences in initiation time.

A typical task used to assess bimanual coordination is the performance of arm extensions and flexions in the horizontal plane, with the two arms either moving 'in-phase' or 'anti-phase'. In-phase movements require subjects to move the arms away and toward the body midline in a mirror-symmetric fashion. The more complex anti-phase pattern requires subjects to move the arms in the same direction (both arms simultaneously toward the right, then the left), asymmetrically about the body midline (see schematic in **Figure 3**). Older adults are slower than young adults for both types of bimanual actions, regardless of whether they are moving at their preferred or maximum speed. Moreover, except when moving at very slow speeds, older adults show greater coordination breakdowns for the

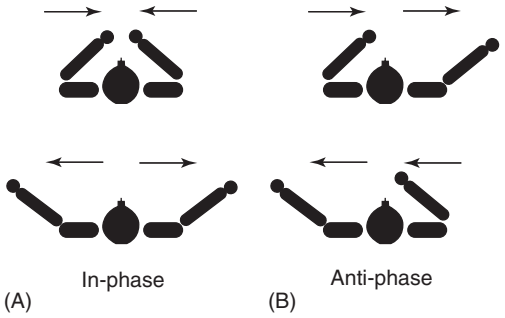

Figure 3 Panel A depicts the 'in-phase' pattern of bimanual movements, while panel B depicts the 'anti-phase' pattern.

anti-phase condition than young adults. These breakdowns are typically associated with a shift from the anti-phase pattern to the easier-to-maintain in-phase pattern.

Learning a novel bimanual coordination pattern is especially difficult for older adults. Even after extensive practice, they show fewer gains than younger adults and, after having learned the task, less long-term retention of the new pattern. These problems are thought to result from older adults' greater difficulty at inhibiting preferred patterns of coordination. At the start of learning a novel coordination task, both young and old subjects will show frequent transitions into preferred modes of coordination. However, older adults take longer to overcome this tendency than younger adults.

Coordination of Transport and Grasp in Prehensile Actions

In recent years, aging research has increasingly emphasized tasks involved in daily living. The appeal of these functional tasks, such as reaching to grasp an object, is that they stress goal-oriented behavior and are highly practiced. Thus, the data obtained provide a better approximation of how aging affects sensorimotor performance. Prehension research paradigms require subjects to reach and grasp objects using either a whole-hand grip (thumb opposite all fingers) for large objects or a precision grip (thumb opposite the index finger) for smaller objects.

Coordination of hand transport and grasp components in prehensile tasks can be examined by determining the correlation between the amplitude and temporal characteristics of wrist and grip. There is conflicting evidence regarding whether there is a breakdown of coordination in prehension in the elderly. One study has reported such correlations as higher for younger adults than for older adults, suggesting that the coupling between the two components becomes less stable with advanced age. However, another investigation has reported only minor changes with age in the coordination of the two components. Nevertheless, both studies showed that, when expressed as a percentage of movement duration, maximum grip aperture occurred earlier for the elderly adults. The slowing of movement and the longer deceleration times imply that the elderly may rely to a greater extent on on-line feedback, suggesting perhaps a greater emphasis on accuracy. This is further supported by the observation that some older subjects slightly close and then reopen the grip aperture during wrist transport. This suggests that the elderly may place greater reliance on visual feedback during the reach, consistent with the finding that removal of visual feedback has a more detrimental effect on the elderly than on the young.

Changes in Timing Abilities with Age

Coordinated action requires the precise temporal synchronization of multiple body segments. One contribution to age-related declines in coordination across a variety of tasks may be deterioration in timing abilities with advancing age due to slowing down or increased variability of an internal pacemaker mechanism. Tasks that require absolute duration judgments, such as verbally estimating the length of a presented duration or trying to produce a duration that matches a verbal label, do not involve having to synchronize to an external pacemaker; therefore, one would expect them to be highly sensitive to internal pacemaker changes with aging. Studies using this type of task to assess the effects of age on timing ability have led to mixed results. Those in which the interval duration to be timed was filled with some other task reveal age-related slowing, while those using empty intervals show an increase in pacemaker speed with age. One possible reason for these differing results is that older adults may be more sensitive to the attentional demands of timing tasks than younger adults. In particular, attention may modulate how representations of temporal durations are formed from the workings of the internal pacemaker. If an appropriate amount of attention cannot be focused on the timing of a specific duration, the number of pacemaker pulses that are stored as a representation of that duration will be affected. Support for this view comes from studies that reveal that older adults have more trouble than younger adults on tasks with high attentional demands (e.g., having to time multiple durations concurrently or having to process compound stimuli). However, when concurrent tasks involve non-temporal processing, increases in attentional demands do not always lead to worse performance in older as compared to younger adults.

Neural Correlates of Age-Related Changes in Motor Performance

The use of brain imaging techniques to study changes in cognitive processes with age has contributed greatly to our understanding of the aging brain. Some studies have demonstrated that performance deficits are correlated with reduced activation for older adults in the brain regions that support task performance in young adults. Studies have also reported additional brain activation in older adults in regions that are not associated with task performance in young adults ('dedifferentiation'). In some cases,

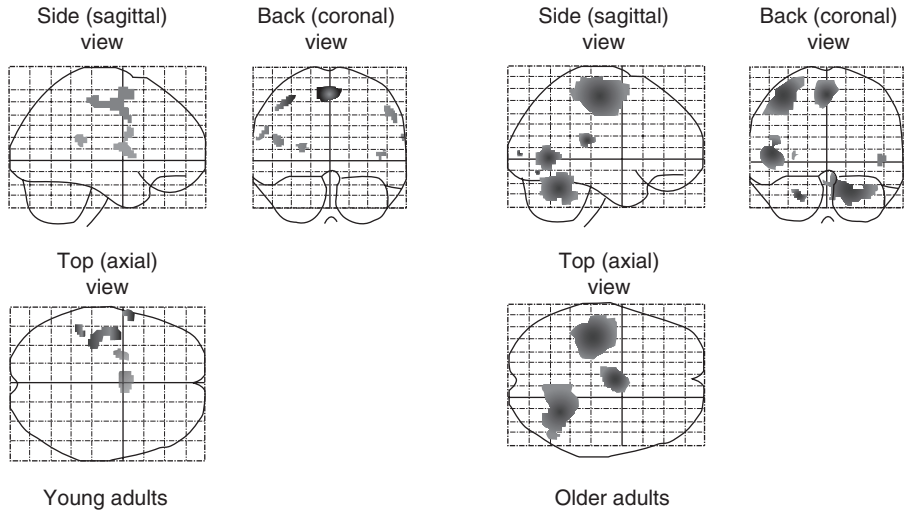

Figure 4 Brain activation during right hand tapping for young (left display) and older (right display) adults. Tapping consistency was equal between the two subject groups. Older adults exhibit more activation in the sensory and motor cortical and subcortical regions of the brain than younger adults.

this activation occurs in the absence of activity in regions that were identified as task-relevant in young adults. This pattern of brain activity has been termed substitution. In some studies, the additional activation has been observed in the contralateral homologous region to that typically observed in young adults. This contralateral activation often appears to be compensatory, as it is correlated with better task performance in older adults. This activation has been termed HAROLD, or hemispheric asymmetry reduction in older adults. In contrast to this view of dedifferentiation as compensatory, it is also possible that nonselective recruitment of additional brain regions in older adults reflects dysfunctional processes.

There are only a few examples in the literature in which brain imaging techniques have been utilized to study motor control processes in the aging brain. While the results of these studies hint that bilateral compensatory brain activation may be seen in motor as well as cognitive tasks, only one of these examples correlated performance with brain activation. In this study, subjects performed a manual choice reaction time task while in a functional magnetic resonance imaging (fMRI) brain scanner. Older subjects had a greater area of activation in brain regions associated with task performance in the young adults (motor and sensory cortical and subcortical brain regions). Older adults also recruited additional areas that serve sensory, motor, and attention functions. For older subjects, greater activation in several of the motor cortical areas was correlated with faster reaction times, supporting the idea that recruitment of additional brain regions may serve a compensatory function, aiding motor performance. Data demonstrating that older adults recruit more brain regions than young adults to perform a given task are presented in **Figure 4**. Engagement of additional brain regions may be a general compensatory strategy that occurs in older adults. However, it remains unclear how this additional recruitment affects the available neural resources for performance of more complex tasks in older adults (*see* Neuroimaging (MRI, PET)).

Are the Observed Deficits Transitory in Nature?

Elderly subjects often perform more poorly on unfamiliar than on familiar tasks. Such a finding raises the possibility that the observed age differences are not fundamental limitations of the motor system. These limitations should be thought of as transitory effects rather than primary deficits if practice can reduce or eliminate the observed age differences (*see* Skill Acquisition and Physical Therapy and Rehabilitation).

Motor Learning in Older Adults

Multiple studies have demonstrated that older adults do not acquire new motor skills as quickly as young adults. Even following additional practice, performance for the older adults typically does not reach the same levels as for young adults. One theory suggests that this may be due to older adults requiring more time to consolidate new information into a long-term motor memory. An alternative theory suggests that older adults may have difficulty integrating cognitive strategies into the motor learning process. One exception to the oft-reported finding of skill acquisition

deficits in elderly adults is the learning of very simple motor tasks, such as repetitive finger tapping. Older adults show substantial gains with practice on these tasks, effectively eliminating age-related performance deficits. In addition, age-related motor declines seem to be absent for skills that have been practiced extensively throughout the lifetime. For example, highly skilled typists and skilled musicians seem to be relatively immune to age-related performance changes in their tasks of expertise.

Variability of Movement

In some tasks, older adults have been shown to reduce their variability of performance with practice. For example, some research has shown that both elderly and young subjects become more accurate at a triangle-tracing task that utilizes opposition forces between the thumb and index finger over 3 days of practice. The elderly subjects did improve more than the young from day 1 to day 2, but then their performance stabilized by day 3. The young subjects, however, improved in a linear fashion across all 3 days. Moreover, the elderly have shown reduced movement-to-movement variability in an arm aiming task after practice. Following practice on an arm aiming task, young adults show the capacity to increase their initial ballistic submovement to reach a given target in a single effort. Older adults failed to show this adaptation. Instead, elderly adults demonstrate greater efficiency using feedback information in making their corrections. The increased reliance on these feedback mechanisms does, however, lead the elderly to be slower and more variable than the young on these maximal speed aiming tasks. From these two examples it appears that the elderly can reduce the variability in their movements, but typically do not reduce it to the level exhibited by young subjects following practice.

Movement Trajectories

There appear to be marginal effects of practice on many of the kinematic features of simple arm movements for the elderly. Young subjects exhibit a decline in the percentage of the movement spent in the deceleration phase and in the variability of arm position at the end of the acceleration phase with practice. Older adults, however, do not demonstrate changes in the acceleration to deceleration phase ratio, even after extended practice.

It appears that practice can be beneficial for improving the motor performance of older adults on some tasks. In some cases, older subjects improve at a faster rate than the young. However, performance levels often fail to reach those of younger adults, even after extended practice. This implies that the deficits observed in motor performance are a result of limitations in the capacity of the aging motor system.

Conclusions

It is evident that older adults exhibit decreased motor performance abilities with advanced aging that may affect their capacity to perform everyday activities. Age-related deficits include a slowing of movement time and in alterations in control that suggest a greater reliance on feedback. An inability to precisely control and modulate force appears to be a limiting factor in a variety of activities. Coordination deficits may arise due to age-related declines in proprioception and/or timing. These reduced capabilities can be somewhat mitigated with practice, but in general performance levels seldom reach those of younger adults.

Narrative and Aging

G Kenyon and W Randall, St. Thomas University, Fredericton, New Brunswick, Canada

Glossary

Lifestory – An amalgam of memory and imagination, fact and fiction, inseparable from identity Narrative Practices Forms of self-telling, life genres, ways of life, or storying styles that underlie how we talk about and therefore how we experience our lives.

Narratives – Biographical materials including life-stories, self-reports, autobiographies, memoirs, thematic interviews, diaries and letters.

Introduction

A stereotype of older adults is that, given the right conditions, they welcome the opportunity to talk about their lives, or tell their stories. The fact that people's stories are important to them can be taken as a starting point for discussing the intricate relationship between narratives and aging. The various matters that this discussion raises can be grouped in terms of the commonsense structure of any story: having a beginning, middle, and end. Accordingly, this article (1) outlines influences that have given rise to interest in narrative in the past, particularly in relation to aging; (2) considers issues of ongoing relevance in relation to the definition, dynamics, and dilemmas of narrative; and finally (3) identifies areas within gerontological theory and practice to which a narrative perspective can continue to be applied in the future.

Past Influences

The impetus for the growth of interest in the topic of narrative and aging is the realization that the emphasis in gerontology has been placed on what could be called the outside of aging. By this is meant aspects of aging that are more or less visible or measurable, such as age-related changes in our bodies and our cognitive abilities, or the impact of an aging population on societal structures, health-care policy, pensions, and the like. An almost exclusive employment of experimental and statistical methods in research on aging has led, however, to dissatisfaction on the part of many gerontologists and a sense that vital dimensions of aging are being overlooked. The increasing utilization of narrative approaches in gerontological circles thus bears out the insight that it is necessary to inquire into aging from the inside. Further, narratives or a narrative perspective is particularly suited to the investigation of biographical aging. Narratives, in this context, thus comprise a range of biographical materials, including life stories, self-reports, subjective or guided autobiographies, memoirs, thematic interviews, personal documents such as diaries and letters, and archival data. In the case of literary gerontology, narratives include stories or images of aging in films, novels, and other works of art. The idea of using narrative methods to study the individual originated with John Stuart Mill in the 1850s and Wilhelm Wundt in Europe. Sigmund Freud also employed narratively constructed case histories in his work. The distinction between nomothetic and idiographic methods, a standard distinction in psychology, was first used by William Stern, and later by Gordon Allport. In the 1920s, George Stanley Hall used autobiographies in studying adolescence, and Henry Murray is considered a classic source of narrative approaches in the field of personality psychology.

The precursors to narrative approaches in aging from a sociological perspective are the symbolic interactionist perspective of the Chicago School and the work of Wilhelm Dilthey. John Dollard is a final figure worthy of mention in this context, as he introduced the life history method into sociology in the 1930s. Moving from this first historical period, authors who are considered to be part of the gerontology context itself include Erik Erikson, Charlotte Buhler, and Bernice Neugarten. Another significant figure is Hans Thomae, for his contribution to the Bonn Longitudinal Study. This study

employed both narrative and experimental methods, an integrative approach that is becoming more common in contemporary gerontology. In terms of methods, an important approach that is widely used in aging research is that of grounded theory, developed by Glaser and Strauss. This approach has found its way into most gerontology textbooks with its contribution to the understanding of the nurse–patient biographical encounter, care of the dying, geriatric units, and other aging studies.

In the 1970s narrative studies of aging included Lowenthal, Thurner, and Chiriboga's *Four Stages of Life*; Levinson, Darrow, Klein, Levinson, and McKee's *Seasons of a Man's Life*; Gail Sheehy's *Passages*; and Roger Gould's *Transformations: Growth and Change in Adult Life*. In sociology, the main figures at this time were Bertaux and Bertaux-Wiame, with their studies of the professional life of the French baker, which appeared in *Biography and Society*.

During the 1980s a number of key texts appeared that highlighted the methodological aspects of narrative research. These works have had a strong influence on research, specifically in the field of aging. Included in this group are William Runyan's *Life History and Psychobiography* and, very significantly, Donald Polkinghorne's *Narrative Knowing and the Human Sciences*, Theodore Sarbin's *Narrative Psychology*, and Jerome Bruner's *Actual Minds, Possible Worlds* and *Acts of Meaning*.

To complete this selected history of narrative in the study of aging, reaching to the present, pertinent works include Sharon Kaufman's *The Ageless Self*, Peter Coleman's *Ageing and Reminiscence Processes*, Erik and Joan Erikson's *Vital Involvement in Old Age,* and Barbara Myerhoff's *Remembered Lives*. The contemporary scene has witnessed an intense growth of interest in narratives and adult development. Important works in this context are Dan McAdams' *The Stories We Live By*, Jaber Gubrium's *Speaking of Life*, Ken Gergen's *The Saturated Self*, William Randall's *The Stories We Are*, Ruth Ray's *Beyond Nostalgia*, and Robert Atkinson's *The Gift of Stories*. Special issues of a number of journals, as well as several edited volumes, have also appeared.

The use of narratives in the field of aging is part of the larger postmodern turn in the human sciences, with its critique of traditional notions of truth, meaning, power, and authority. From this point of view, all phenomena may be seen as based on language, narrative, and interpretation. It is also a central assumption of this view that such phenomena as human behavior, identity, and relationships are, at least to some degree, socially constructed.

The use of narratives in gerontology is, moreover, a multidisciplinary enterprise. It is also characterized by a wide range of methodological approaches that share the common conviction that human nature is storied and by a wide range of topics of interest. A partial list of these topics includes widowhood, frailty, chronic pain, dementia, holocaust trauma, longitudinal studies, age identity, wisdom, spirituality, end-of-life issues, and caregiving.

Present Issues

Insofar as the inside of aging, or inner aging, can be explored via narratives, or by adopting a narrative approach, three broad issues emerge as requiring ongoing consideration: the definition of narrative, the dynamics of narrative, and the dilemmas that are involved in understanding narratives of, or about, aging selves.

Definitions of Narrative

The term narrative has a number of references, which can easily be confused. First, it refers to a certain type of data, that is, stories as opposed to statistics, or anecdotal comments on particular themes as opposed to scores on tests or yes–no answers on survey questionnaires. Second, it refers to a variety of methods that are employed both for collecting such data and for analyzing them afterward. These methods are central to qualitative research in general and to research on topics like reminiscence in particular, as well as to such areas as qualitative gerontology, narrative gerontology, feminist gerontology, and literary gerontology. Third, narrative can refer to a theoretical construct, namely, personal narrative or self-narrative or simply 'the story of my life.' However, the relationship between life and the story – or, more accurately, stories – that one tells or internalizes is an intricate one. Indeed, some theorists collapse the two terms into one and speak of lifestory, seeing it as an amalgam of memory and imagination, fact and fiction, that is inseparable from identity. Fourth, narrative can refer to an entire intellectual paradigm, or root metaphor, whereby humans are viewed as fundamentally story-telling creatures and narrative as our primary mode of knowing, of making sense of our world. As such, it represents an essential heuristic to employ when exploring the experience of aging. It is on narrative as construct and as paradigm that the rest of this article is focused.

Dynamics of Narrative

Narrative is widely used as a more technical term for story. Indeed, wherever the narrative turn has had an

impact, the two are typically (though not always accurately) equated. Yet story itself, while a common enough construct, is scarcely easy to unpack, as literary theorists can certainly attest. It can be argued, however, that a story in its most basic sense is someone telling somebody about someone doing something. This basic formulation goes to the heart of the structural dynamics of narrative, whatever type is considered: fictional, historical, or lived. At the same time, it points to several intertwining issues – or dilemmas – of an epistemological, ethical, ontological nature to which those dynamics give rise, and with which an examination of the narrative dimensions of aging obliges us to wrestle.

Someone Telling Someone A story is told by someone to someone. As such, it involves both a narrator (or narrators) and author (or authors), though in some stories the two seem as one. Obviously, it involves the act of narration as well, which can be carried out from various points of view, ranging from third person to first and omniscient to unreliable; from various vantage points in time, ranging from recent to remote; and with various narrative tones, ranging from optimism to pessimism and tragedy to irony. In short, stories are recounted according to genres. Also, they are told within particular settings and thus, explicitly or implicitly, to particular audiences, although with some stories, such as those one tells oneself, narrator and audience, author and reader, seem to be fused.

About Somebody Doing Something A story is always about something. In the most basic sense, it is about actions or events that affect, or are affected by, its characters. Typically, it entails an element of tension or conflict, plus its resolution, with the movement from one to the other comprising the plot. In essence, no conflict, no plot; and no plot, no story. In turn, plots often have subplots and, obviously or not, are divided into chapters, episodes, or scenes. They also reflect the unfolding of various themes. Great stories are about a number of themes at once, from love to war, faith to philosophy, history to ethics. As already noted, this makes the analysis of narratives an interdisciplinary endeavor. It also means that stories are never innocent but are told to accomplish a range of agendas, often several at once. In general, authors attempt to persuade readers, and tellers attempt to influence listeners. At the same time, listeners influence tellers, and can determine to a powerful degree what tellers tell and how they tell it.

Given these basic dynamics of narrative, it is apparent that when people tell the story of their life, they are, paradoxically, author, character, narrator, and reader all at once. Moreover, they are all of these within the story. Yet each of these roles is an identifiable rhetorical function of a self that, from a narrative perspective, is multiple or dialogical in nature – self as narrator, self as character, and so forth. Such a paradox is one of the many complexities, questions, or issues that accompany the lifestory construct. Over time, for instance, we may play a range of characters within our own lifestory: major and minor, central and supporting. As well, the events that are central to that story, or that comprise its plot, are events in our own lives. In that respect, we never just tell our stories; we live them. However, as narrator of those same events, we may not be entirely or consistently reliable. There is an inherent opacity associated with the living and telling of lives. In addition, a variety of life themes can surface across our life span, related to particular developmental tasks or particular characters we are living at particular times, and some of these themes recur. Finally, a lifestory is not one story so much as numerous stories in one, as is a novel. Indeed, because a lifestory both is unique to a particular individual and is emplotted – that is, is not merely a chronicle of event after event – then we could perhaps refer to the novelty of lives.

Dilemmas of Narrative

There are a cluster of dilemmas or issues that the construct of personal narrative brings into focus. They can be discussed in terms of time, interpretation, intertextuality, truth, and transformation.

Time To paraphrase Kierkegaard's famous observation, we live our lives forward but understand them backward. This is an inescapable paradox of story-time, which, on the inside of aging, we may live by much more so than clock time. In remembering or reviewing our lives, as in reading a story, we understand the past through the lens of the present, and we experience the present in light of the future (or futures) that we anticipate. In turn, we look to the future on the basis of what we recall having experienced in the past, or what we wish we had experienced, or what we are grateful we did not. Our sense of the past always includes stories about what might have been. In terms of time, autobiographical consciousness is thus a complex phenomenon, though fundamentally retrospective in nature. We read our lifestory from the end looking back to the beginning.

Interpretation Narrative, it is argued, is our principal mode of making meaning. It is by telling stories about events that we make sense of them, even if it is

only ourselves whom we tell. Human beings are interpretive beings, or hermeneutical beings. But the meanings we make of – or read into – events in our life will eventually be overlain, if not replaced, by the meanings we make of those events, and other events, tomorrow. Thus, like a kind of biographical capital, lifestory meaning continually changes and accumulates (or thickens) with time. This accumulation is an element of what some theorists call narrative development, which unlike physical development has no necessary end point. As with a great novel, even though the story ends, there is no end of meaning to be gleaned from it. Its meaning is indeterminate. As self-readers, however, perhaps most of us tend to underread our lifestories, or else overread particular passages while effectively ignoring the rest.

Intertextuality Making and remaking meaning is possible because, ontologically, we are creatures of language, and therefore of text. We can understand our lives only by textualizing them. Until we die, this textualization continues. Thus, our lives are open texts. Such textualizing occurs not in a vacuum, however, but amid a variety of interwoven contexts. These include family or community, culture, profession or discipline, gender, or creed and can be thought of as so many larger stories or narrative environments in which our personal stories are shaped, or misshaped, to the degree such contexts are, say, sexist or ageist or otherwise restrictive in nature. Such larger stories constitute interpretive communities that mediate what in narrative circles are referred to as narrative practices, forms of self-telling, life genres, ways of life, or storying styles. These underlie how we talk about and therefore experience our lives. Moreover, they influence what we remember, how we remember it, and how we feel about life in general, inasmuch as emotions have narrative roots. For better or worse, we textualize our lives, or our lives are (in part) socially constructed, through a constantly changing network of intertextual relationships and biographical encounters with others. These others co-author us into being (as we do them), though some, such as parents or therapists, structure our stories in especially deliberate ways. In a similar vein, and as noted by literary gerontologists, our stories are structured and our worldviews shaped through interactions with actual texts too, such as the novels we read, movies we watch, songs we hear, or, depending on our interests, works of history, religion, or science we may study.

Truth Because we make meaning of events by textualizing them – both at the time they occur and each time we recall them thereafter – and because this textualizing takes place amid particular relationships and environments, each of which affects the direction our tellings are slanted, the meaning-making process involves continual selecting and editing. However, unlike the text of a novel, which is written in black and white and in that sense is solid, the text of our life is highly unstable. With each telling and reading it is different, depending on who we are telling what, or for what reasons we are reading it. That we interpret the past through the present and future, and so on, only contributes to this instability. The point is that there is no straightforward connection between our life events and the stories we tell or internalize about them. The claim that people's stories are important to them is not a claim about the events of their lives per se but about how they interpret those events that, however creatively, they are able to recount. Inasmuch as our lifestory is true, its truth is less historical than narrative in nature. In this sense, lifestories not only contain answers to certain questions, but also are answers, insofar as they reflect what is meaningful to a particular person. In narrative research and practice, these meanings provide an understanding of a specific phenomenon and a basis for intervention.

Further, we can all tell multiple stories about our lives, but never the whole story. The whole story is never available for reading either, although particular episodes, or signature stories, may persist in standing out. In addition to being backward, autobiographical consciousness is incomplete, which renders the construct of autobiographical memory problematic. Remembering is not a matter of passively, let alone accurately, recording what happened and then recalling it later. It is always, in part, imagining. There is no such thing as the truth, the whole truth, and nothing but the truth.

Transformation Because we perceive the ever-thickening past through the lens of the ever-changing present in the light of an ever-shortening future, we are continually rewriting our selves. We are not just storying our lives but on some level are restorying them, too. As open texts, to which new events are steadily being added, our lifestories are capable of a number of possible tellings and readings, retellings and rereadings – depending on the contexts in which we tell them and live them. Indeed, from a narrative perspective, possibility as much as facticity is the hallmark of human experience. This suggests the particular possibility that in later life we can experience significant restorying, if not re-genre-ation, meaning a fundamental reformulation of the stories by which we understand who we are. Another possibility is that some may submit prematurely to a sort of narrative foreclosure and assume that – once

retired, for instance – their story is over, that there is little to be read in it, that nothing further of significance awaits them except death itself. Others, operating from a different master narrative, may view death not as the end but as the beginning, a segue to the next new chapter.

Future Applications

By considering the dynamics and dilemmas of self-narratives, we can appreciate the complexity of narrative development in later life, plus the implications of a narrative perspective for numerous areas of continuing interest for gerontological theory and practice. Some of these areas are discussed in relation to four interwoven categories: therapy (broadly defined), ethics, aesthetics, and spirituality.

Therapy

As mentioned previously, autobiographical memory is temporally complex, continually revisable, and inseparable from imagination. In short, the text of the past is far from fixed, but is capable of multiple versions, some more positive or life-affirming than others, depending on which metaphors are enlisted to access it and which themes are singled out to interpret it. Insofar as people's mental health is entwined with how they have storied their past, this is a critical realization, and an implicit starting point for most therapeutic interventions. From a narrative perspective, people are always, in principle, capable of changing their stories and thus, however modestly, of changing their attitudes, behaviors, and identities – even in later life. For example, such restorying could be triggered by becoming aware that a particular subplot, chapter, or theme in one's life, such as having cancer, being widowed, or getting older, is not the whole story of who one is. In fact, narrative research bears this insight out, namely, that it is necessary to understand a particular phenomenon in light of an entire lifestory. Among the interventions relevant here are reminiscence therapy, life review therapy, narrative therapy, psychotherapy, psychodrama, guided autobiography, and various forms of clinical care.

Ethics

Therapy is a controlled, highly intentional form of telling and listening. Yet even in everyday life, listeners unwittingly co-author tellers' lives and to a degree are agents of restorying. Little focus has been given, however, to the role played by the listening we experience in shaping the stories we tell and live. The nature, function, and ethics of good listening in later life deserve particular attention, especially in light of the possibility that, through bereavement, disability, or institutionalization, many older adults experience a dramatic constriction of the narrative environments in which they are accustomed to telling and interpreting their lives. This can contribute to their gradual 'destorying' just when they may otherwise be capable of a quality of narrative development that is perhaps possible only in later life, such as discovering and creating their unique wisdom story. Gerontologists could benefit, then, from considering what conditions would foster a wisdom environment in which, as in guided autobiography, older people are able to engage in deep telling and close reading of their lifestories, perhaps particularly their signature stories, and in deep listening to the stories of others. Such opportunities can be the route to integrating and even extending older people's sense of identity by expanding their repertoire of approaches to interpreting their life texts, thereby enriching their appreciation of the multiplicity of meanings, or truths, those texts contain. Two further ethical issues need to be noted: one is the necessity of acknowledging that everyone has or is a story, even the person who for whatever reason is unable to tell it in ways that others can readily comprehend, for example, someone who is dementing or dying. A second issue is that people should never be forced to tell their story against their wishes, however convinced we are that the process will be good for them.

Aesthetics

Across the centuries, numerous traditions have promoted understandings of, if not recipes for, the art of living. A narrative perspective holds the potential for acknowledging or re-covering the aesthetics of growing old, or what some refer to as the poetics of aging, whereby lives are viewed as quasi-literary texts that it behooves us to examine for the multiple meanings they can carry. The intersection of narrative gerontology and literary theory is thus an area that is currently being explored. A related area, of equal importance when approached from the perspective of therapy or ethics, concerns what criteria are appropriate for evaluating a good story in later life, as well as a satisfactory generativity script – that is, a picture of how one wants one's story to end. Such considerations could help link discussions of the aesthetics of aging with discussions of, for example, its spiritual dimensions.

Spirituality

Spirituality, broadly defined, concerns making meaning in, or of, our lives. However, spirituality is

experienced through, not despite, the stories of our lives. Thus, from a narrative perspective, spirituality and wisdom are closely linked. This experience can also involve an identification with elements of particular grand master narratives. However much their authority may have become eroded, such narratives are philosophical, political, or religious traditions, such as Christianity, communism, or existentialism, that provide plot lines, metaphors, and themes for making meaning of difficult life events, dramatic transitions, or the course of life as a whole, including death. Accordingly, a narrative perspective on spirituality in later life can shed light on such things as gerotranscendence. Gerotranscendence entails an expanded sense of time, past, present, and future, and a yearning for a story of the world that can encompass life and death alike, one that may even transcend the terms of the master narratives into which one has been born. Such yearning may also find expression in the urge felt by many older adults to understand their place in the broader narrative of the human community and to appreciate their roots as members of a particular family, community, or culture. Linked to this urge is generativity: the impulse to contribute to the well-being of the next generation and, in some small way, to bridge the gap between history and posterity.

Conclusion

The use of narratives in gerontology is expanding in relation to all four of the understandings of narrative indicated earlier, namely, as data, method, construct, and paradigm. Moreover, the range of topics that are of interest to narratively inclined gerontologists continues to expand. Contemporary gerontology is increasingly characterized by a collaboration among many approaches with the aim to understand both the inside and the outside of the complex and multifaceted story of aging.

Network Analysis

M Broese van Groenou and T van Tilburg, Vrije Universiteit, Amsterdam, The Netherlands

Glossary

Anchor – The central person within the network; the person providing information on who belongs to his or her network.

Full Personal Network – Network in which information is available on all the network relationships; also referred to as a complete network.

Network Analysis – Analytical methods used to compute measures of network structure and content.

Network Content – The type of interaction that takes place within pairs of network members.

Network Delineation – Procedure used to identify the personal network.

Network Structure – Aspects of the total network derived from combining features of individual relationships and the linkages between these relationships.

Personal Network – The group of persons (network members) with whom anchor has a direct relationship.

Star Personal Network – Network in which information is available on relationships between network members and the focal individual; also referred to as an ego-centric network.

Introduction

The personal networks of older people reflect their social opportunities and personal choices to maintain a specific set of relationships with relatives, neighbors, friends, acquaintances, and so on. Network analysis is the method used to identify and examine the structural and functional features of the network of the older adult. The conceptualization and operationalization of the personal network depend on the subject of research. Five approaches to defining personal network membership are presented and discussed. The five approaches differ regarding the part of the personal network that is mapped, and result in networks of different sizes and compositions. Regardless of the type of network delineation, a distinction can be drawn between the star network (data available on relationships with the focal person) and the full network (data available on all the network relationships). Features of the structure and content of both types of personal networks are presented. Finally, network analysis methods are presented and discussed, including ways to analyze hierarchical databases.

Aging and the Personal Network

The Personal Network of Older Adults: An Introduction

The personal network occupies an important place in the lives of individuals. The mere existence of a certain number of relationships has been shown to have beneficial effects; regular interaction with network members (children, relatives, neighbors, friends, and fellow members of organizations) enhances the feeling of being socially integrated and decreases feelings of loneliness. The positive effects of the network are also reflected in better health and a longer life.

Old age has often been associated with loneliness and with social isolation. However, numerous studies have shown over the past decades that the large majority of older adults have at least a few relationships available. The networks of older people usually encompass both kin and non-kin with whom regular contact is maintained. In general, the core of the network consists of close kin (e.g., spouse and children, siblings, parents) and close friends. Depending on the identification method of the network, other network members such as extended kin, neighbors, (former) co-workers, acquaintances, members from organizations, and so on may also be identified. The younger old who are socially active in many parts of society and who experience few physical restrictions in general have large networks that are composed of a large number of non-kin. The oldest old, who often experienced life transitions such as widowhood, retirement, and a decline in physical mobility, usually have smaller networks that enclose network members that are emotionally close (children, friends) or geographically close (neighbors).

In addition to the mere presence of relationships, interaction with others is important for daily functioning, coping with life events, and maintaining well-being. Feelings, information, services, and material goods can be exchanged between two individuals. These exchanges are often assumed to be supportive in nature. The support provided by network members helps protect individuals from experiencing negative outcomes, helps them in their efforts to improve their situation, and helps them respond to adverse events.

Social researchers have too often studied the personal relationships of individuals without taking the linkages between various network members into account. However, network members do not function independently of each other. It is crucial to regard the interaction between the focal individual and one network member in relation to the interaction with other network members. For example, which of the adult children is to provide support for an elderly parent might be the outcome of a family meeting at which they decide to take turns in caregiving. The study of personal relationships evolves into the study of the personal network if relationships are viewed as part of a large network and if linkages between these relationships are also taken into account. Combining the features of individual relationships leads to insight into the structural aspects of the network. Examples of structural aspects are size, composition (e.g., proportion of kin), and homogeneity (e.g., proportion of same-sex network members). Information regarding the content of the network can be obtained by aggregating the qualities of the individual relationships. Examples of network content are network interaction (e.g., number of frequent contacts) and support intensity (e.g., proportion of instrumentally supportive relationships).

The Impact of Aging on the Personal Network

Old age is often associated with shrinking network size and relationship losses. In the early days of social gerontology, these social losses were considered due to the loss of societal engagement and social activities. Currently, the diversity and changes in the personal network in later life can be understood from three different perspectives: (1) the changes in roles and transitions in later life, (2) the changes in the expected returns from relationships within the network, and (3) individual proactive management of personal relationships.

From early childhood to old age, an individual is surrounded by a variety of persons with whom he or she develops relationships, a so-called 'convoy' of relationships. During the life course some relationships end due to major (role) transitions (divorce, death of the spouse) or minor transitions (moving, changing jobs, entering or leaving organizations), while others may last a lifetime. New members may enter the network as a result of (re)marriage, a new job, or becoming a parent or grandparent. Thus, people enter old age with a personal network that reflects earlier transitions affecting their opportunities and individual choices to maintain and develop relationships. During old age, a phase lasting no less than 20 years for many people, people are in general in a position to exercise greater choices in their relationships. Unfettered by employment obligations and the responsibility for children at home, they generally have greater opportunities to organize and structure their social lives. On the other hand, a decline in health may impose restrictions upon older adults' capacities to engage in interaction with others. Hearing and memory problems can limit conversational exchanges, and reduced physical mobility can limit participation in shared activities. Role changes and restricted capacities in later life lead to a decrease in non-kin relationships and the growing importance of family relationships in the network.

From the second perspective, based on exchange theory, network change in later life results from changes within specific relationships. People constantly evaluate their relationships and prefer balanced support, i.e., they give support with the expectation of receiving something in return at some time. If the receiving party is not able to return the support and it is clear that this will not change in the future, the exchange of support may decline. Older adults may become more dependent on others, lacking the ability to perform certain tasks themselves. The existing balance in their relationships may be disrupted, introducing strain and discomfort. Imbalance results in the decline of supportive exchanges with older adults, in particular with less close relationships. Imbalance does not always end in the termination of a relationship, however, as overbenefiting of needy older adults can be normatively accepted and even desirable.

From the third perspective, based on the socioemotional selectivity theory, network change results from changes in an individual's motivation. With increasing age, the time horizon is limited, and emotional regulation becomes the most important drive for social interaction. As a result, older people disengage from peripheral relationships because the emotional engagement with core network relationships is more rewarding. This explains the selective shrinking in network size with age. People feeling near to death deliberately discontinue their less close relationships, reduce the emotional closeness with many others, and increase the emotional closeness with core network members such as kin and friends.

It can be concluded that dynamics in the personal networks of older people are related to changes in situational and personal characteristics. A network is the result of macro-social trends that create individual opportunities to maintain a personal network, but it also reflects individual transitions, relationship standards, and personal characteristics. In studying the networks of elderly people, it is recommended to relate changes in network features to changes in situational as well as personal characteristics of the elderly.

Personal Network Delineation

Methods for Network Delineation

A personal network is defined in general as the group of persons (network members) with whom a focal individual (anchor) has a direct relationship. There are various methods of delineating the social network. Some methods are based on the content of the relationships, some are based on the affective value of the ties, and other methods use the formal role relationship as a criterion for network membership. Research interests determine which method is used and which part of the larger social network will be identified.

The following five major methods can be used to identify networks of the aged: (1) the affective method, (2) the role relation method, (3) the exchange method, (4) the interactive method, and (5) the domain contact method. The five methods are conceptually unique and map different parts of the personal network. **Table 1** provides a summary of the main features of the five methods.

Table 1 Overview of network delineation methods

	Affective	*Role relation*	*Exchange*	*Interactive*	*Domain contact*
Conceptual definition	Network of significant others (affect based)	Network of formal role relations (role based)	Network of relations in which significant interactions occur (content based)	Network of persons with whom social interaction exists (contact based)	Network of socially active and important relations (contact and affect based)
Name generator(s) (examples)	"Who do you feel close to?"	"Name your spouse, children, neighbors, colleagues, friends"	"Who do you discuss personal problems with?" and "Who helps you with daily chores?"	"Name the persons you have contacted today for at least 10 minutes"	For each role relation (e.g., children, neighbors): "Who do you have regular contact with and who is also important to you?"
Number of questions asked	One or two	Depending on the roles of interest: five to seven	Three to 20	One (repeated every day for a certain period of time)	One for each role relation of interest (about seven)
Limits on period of time	No	No	Yes (past 6 months, past year)	Yes (2 weeks, one month, etc.)	No
Network size	Small (about three to nine)	Depends on the number of roles of interest	Large (10 to 22)	Large (16 to 26)	Medium (13 to 15)
Proportion of kin	Large (50 to 78%)	Depends on the roles of interest	Low (19 to 48%)	Low	Medium to large (66%)

The Affective Method

Conceptual framework The affective method identifies members who are of affective value to the focal individual, in other words, significant others or intimates. The underlying assumption is that these network members are potentially important sources of support for the focal individual. The method is commonly used by researchers who are interested in the 'psychological network,' defined as persons to whom the focal person feels attached.

Name generator This type of network is identified by asking one question: "Who do you feel close to?" or "Who are the persons who are important to you?" Some researchers set limits to the number of names to be mentioned; others apply a time frame (e.g., within the past 6 months). Sometimes a distinction is drawn in the degree of importance or the level of closeness of the network members.

Network features Typical of the affective network is a small size (about five to nine members), a large proportion of (close) kin (about 50 to 80%), a large number of long-standing relationships, and many supportive exchanges within the ties. The stability of this type of network is high, mostly because relationships that are stable, like those with close relatives and best friends, are cited.

Evaluation Crucial to this method is the subjective nature of the name generator. People are asked to evaluate relationships in terms of importance or closeness. This evaluation may be shaded by norms and obligations to mention relationships that are supposed to be important, for example, those with the spouse and children. A person is less inclined to mention relationships that are potentially supportive but not very important to the individual, for example, those with neighbors or colleagues. In addition, it need not be necessary to include persons with whom one interacts on a regular basis. As a result, this type of network can not be used to indicate the degree of social participation or integration of the focal individual. This type of network is positively related to the degree of well-being and negatively to feelings of loneliness of the central person. The major advantage of this method is that it has proven to be a robust method by yielding similar types of networks in different samples.

Role Relation Method

Conceptual framework The role relation method defines network membership purely on the basis of the formal role relationship maintained with the focal individual. Role relationships are derived from status variables such as marital status, employment status, type of living arrangements, friendship, and family status. The network accordingly includes the

partner, children, co-workers, friends, and members of the household. The underlying assumption is that the formal role relationship reflects norms and obligations with respect to the content of the relationship. The mere existence of relationships is expected to protect an individual from social isolation, illness, and loneliness.

Name generator Researchers using the role relation method do not always use a name generator. Inquiring after marital status, parental status, or job status will suffice if one is interested in the availability of a spouse, children, or co-workers. Researchers interested in the additional features of the role relationships have to use name generators. Examples include "Who is your partner?", "Who is your best friend?", and "Could you name two fellow members of your organizations?" The type of role relationship that is identified depends on the research objectives. Sometimes limits to the number of names to be mentioned are set.

Network features The size as well as other features of the network are completely dependent on the name generators used. The stability of the role network is high, since formal role relationships are not likely to change over a short period of time.

Evaluation The advantages of this method are that it is very easy to administer and it uses an objective measure for the identification of network members. Researchers interested in the social integration of individuals will be able to use this method successfully. One disadvantage is that relationships that have no formal role but that may nevertheless be important or supportive might be overlooked. The use of the role relation method in studies on support networks may therefore be limited.

Exchange Method

Conceptual framework The exchange method assumes that the relationships in which significant interaction occurs with network members are among the most important ones. Within this significant interaction, a regular exchange of emotional support, instrumental assistance, and material goods takes place. This interaction is considered to be of a supportive nature.

Name generator The exchange method uses several questions (usually six to ten) to identify members with whom significant interaction occurs. Examples include "Who do you talk about personal problems with?", "Who do you discuss problems at work with?", "Who helps you with daily chores around the house?", and "Who takes care of you if you are ill?" Often a limit to the number of names to be identified in response to each question is set. The number of questions asked is related to the number of persons to be identified, but there is a certain limit. It has been noted that asking five questions about different types of support (emotional and instrumental support and companionship) identifies about 80–85% of the persons who are mapped with ten questions. Some researchers distinguish between questions indicating the receipt of support ("Who helps you with daily chores?") and questions indicating the provision of support ("Who do you help with daily chores?"). This results in a larger number of identified persons compared to non-directive questioning about exchange relations.

Network features The typical exchange network is rather large, varying from about ten to 20 names. The proportion of kin within the network is rather low, varying from 35 to 50%. In general, the exchange network contains many relationships that are socially active at the time of measurement. A relatively large proportion of more superficial relationships is identified, based on a (temporary) sharing of the same workplace, organization membership, neighborhood, etc. The stability of the exchange network is relatively low compared to the affective and role relation networks, since many unstable non-kin relationships are identified.

Evaluation The exchange method is easy to administer and of a rather objective nature. The interactions are specific and not multi-interpretable. The exchange method can map different parts of the network. In contrast to the affective method, non-kin relationships are more likely to be identified. One disadvantage is that ties that are potentially supportive but not actually supportive at that moment are overlooked. In addition, persons one is socially involved with but with whom no significant interactions are exchanged (e.g., more distant relatives) are also excluded from this network. Crucial to this method is the fact that it focuses on the content of a tie rather than the formal role relationship or the degree of contact frequency.

The Interactive Method

Conceptual framework The interactive method identifies the persons with whom one engages in social interaction within a given period of time (e.g., 2 weeks, a month). The assumption is that the interactive network indicates the degree of social participation. It is found to be unrelated to support or well-being.

Name generator The interactive method requires a systematic recording of the people one has contact with on a daily basis. Usually this is done by having respondents maintain a diary or by contacting them daily by telephone. Respondents have to indicate whom they interacted with on that day for at least 10 minutes.

Network features The size of the interactive network depends on the period used for monitoring social interaction. The longer the period, the more different persons are identified. The interactive network may contain a large proportion of non-kin relationships, depending on the living situation of the respondent (married, employed, with children, etc.). The interaction network is apt to be sensitive to changes in daily contacts. Many superficial contacts that are part of the interaction network in a given period may not be included in another period of time.

Evaluation The interactive network is a good indicator of the degree of social participation, since it records daily social interaction. Comparing this method to other methods reveals a very small overlap between the networks. The affective and exchange networks are far more psychological, and their members usually do not meet every day. However, enlarging the monitoring period of the interactive network will eventually decrease the differences with the exchange network. A major advantage of daily monitoring is that it provides a reliable picture of the social interaction of the respondents.

The Domain Contact Method

Conceptual framework The domain contact method combines the different roles an individual performs with the frequency of contact and the importance of the relationships as criteria for the identification of network members. The main objective of this method is to identify the socially active relationships in the larger network. A central assumption is that this type of network constitutes the structural vehicle for the ties in which various types of support can be exchanged. In this line of reasoning, the potential or actual support exchanged is not a criteria for delineation, but an object of research on the delineation of the personal network.

Name generator Network members are identified in various domains of the network, e.g., household members (including the spouse), children and their partners, other relatives, neighbors, school or job acquaintances (including voluntary jobs), members of organizations (sport, church, political parties), and others (friends, acquaintances). All the household members are included in the network. As to the other domains, the respondents are asked, "Name the persons (e.g., in your neighborhood) you have frequent contact with and who are also important to you." No limits are set on the number of names to be mentioned.

Network features The domain contact network is medium to large (an average of 13 members, ranging from 0 to 75), with about two-thirds of the relationships being with relatives. Since that contact frequency is used as a criterion for identification, the average contact frequency with these network members is relatively high, between about once every 2 weeks and weekly.

Evaluation Using several criteria for network membership leads to a medium-sized network (compared to the smaller affective network and the larger exchange network) that contains a large range of role relationships. The method combines objective criteria (role relationship and contact frequency) and subjective criteria (importance) for the delineation of network relationships. As a result, the domain contact network indicates the actual degree of social participation as well as the availability of potentially supportive relationships.

Choices in Network Research

The examination of the personal networks of older adults requires several choices to be made by the researcher beforehand. The first choice concerns the type of method to be used for network delineation. This necessitates a clear description of the research objective. Usually, two types of research objectives can be distinguished: (1) the network has to indicate the degree of social participation of older adults, and (2) the network has to reflect the actual support reservoir of older adults. The first type of objective requires the use of the role relation method, the interactive method, or the domain contact method in the delineation of the network. The affective method and the exchange method are more appropriate if one has the second type of objective in mind.

The second choice within network research focuses on how many network members and relationships additional information will be collected on. In most network research (particularly large surveys), there is no time to collect information on all the network members who are identified. Some researchers have solved this time problem by setting limits to the number of names to be identified by the name generator. However, limits of this kind distort the

identification of the network because they leave uncertainty about the true size of the personal network. Since network size is crucial for the calculation of other structural and functional network features (e.g., proportion of kin), it is strongly recommended to set no limits on the number of persons to be identified. A better solution is to add an extra objective criterion such as contact frequency or traveling distance to the identification procedures. If interview time is of the essence, additional information can be asked about a selection of the network members. The selection criterion can either be objective, e.g., the ten persons contacted most frequently, or subjective, e.g., the six persons who are the most important. The disadvantage of the subjective option is that respondents have to choose between certain network members, which may be a difficult task.

The third choice in network research pertains to the type of information to be collected on some or all of the identified network members. Again, this choice is guided by the research objectives. Yet there seems to be a general consensus among network researchers that it is advisable to collect information on the type of relationship and sex of as many network members as possible. Researchers interested in the degree of social participation also inquire about the contact frequency with each network member, whereas support researchers are more interested in the support exchanged within the relationship.

A final choice the network researcher has to make involves who is to serve as a respondent in the study. Usually, the information on network members and relationships is obtained only from the focal individual, the anchor of the network. The identified network is then called a star network, and only information on the ties between the anchor and his or her network members is available (**Figure 1**). Yet it is also possible to include network members as respondents and ask them about the tie characteristics with the anchor and with the other identified members of the network. If members of a personal network report about identified ties with other network members, data are available on a full network (**Figure 2**).

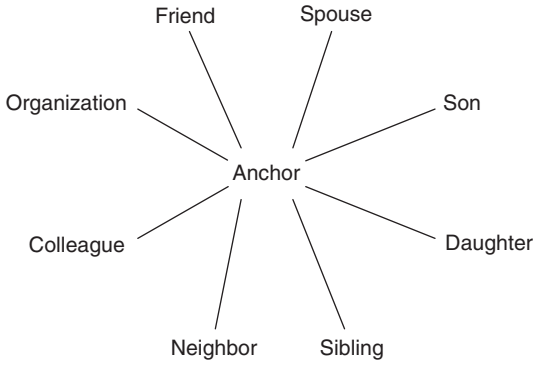

Figure 1 Graphic representation of a star network.

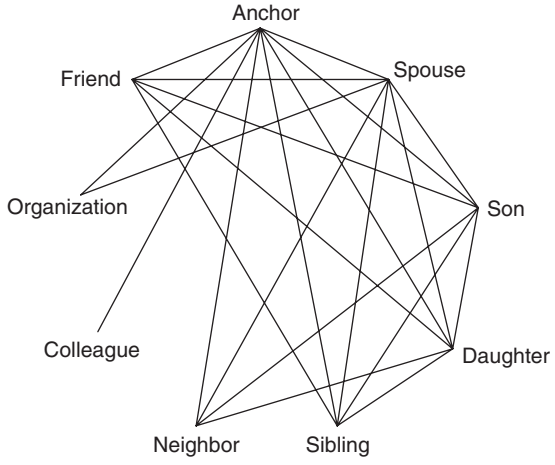

Figure 2 Graphic representation of a full network.

Features of the Personal Network

In a star network, the older adult is the focal person, the anchor. All the features of the network and the relationships can be linked with his or her behavior and state of mind. The following sections provide an overview of features of the network structure and content associated with aging. As people age, these aspects of the network are subject to changes and are therefore relevant to the study of the networks of older adults. **Tables 2** and **3** give examples of network structure and content based on information about relationship features.

Network Structure

The size of the network indicates how many relationships one is involved in, whether affect-based, role-based, or contact-based. Involvement in a larger network is associated with a larger degree of social participation and a greater exchange of support and well-being.

The network composition indicates the available proportions of kin and non-kin. The distinction between kin and non-kin is often too global, and it is wise to differentiate between relationships with a spouse, children, other kin, neighbors, friends, and other non-kin.

If information on the personal characteristics of the network members is available, it is possible to compute the homogeneity of the network with respect to sex, age, parental status, and so forth. It has often been reported that individuals like to associate with people who have similar backgrounds and who

Table 2 Features of network structure

Network structure	*Operationalization at the network level*	*Information on the dyad*	*Information on the network member*
Size	Total number of identified network members		
Composition	E.g., number of children, friends; proportion of kin	Role or type of relationship	
Homogeneity	E.g., total number of females in the network; percentage of members within the same age category	Similarity between characteristics of anchor and network member: e.g., same-sex or cross-sex	E.g., sex, age, race, partner status, employment status
Density	Total number of pairs who know each other of the total number of available pairs		How many of the other network members are known
Stability	Average years of network membership	Duration of the relationship	
Role complexity	Number of multiplex relationships	Number of different roles shared with the network member	
Geographical dispersion	E.g., number of persons living within 15 minutes; mean traveling time	Traveling time from anchor to network member	

Table 3 Features of the network content

Network content	*Operationalization at the network level*	*Information on the dyad*
Interaction	E.g., proportion of network members contacted at least weekly, mean frequency	Frequency of contact
Support intensity	E.g., total amount of emotional support received and given, proportion of ties with large social support intensity	Receiving and giving support (emotional, instrumental, social, material goods)
Support complexity	E.g., total number of multiplex relationships	Exchange of one versus more types of support
Reciprocity	E.g., average number of reciprocal relationships, proportion of unbalanced ties, ratio of given and received support	Balance between giving and receiving of support

are assumed to have similar life experiences. In particular, non-kin network members are expected to exhibit marked similarities in sex, age, and level of education with the focal individual, resulting in a large homogeneous non-kin network.

The density of the network refers to the interconnectedness between network members. Large networks usually have a low overall density, meaning that fewer network members interact with each other without the anchor being present. However, large networks may also contain specific parts that are very high in density (neighbors or close relatives). Networks that are low in density are generally found with younger persons who are highly educated and participate in various social organizations that are only loosely connected to each other, if at all. Small networks usually have a high density and are generally more prevalent among elderly people with a relatively low level of education. Dense networks are generally composed of persons who have been interacting for many years, indicating a high stability within the network.

Network members may have more than one formal role relationship with the focal person. A neighbor may also be a friend, and a second-degree relative may also be a member of the same club. At the network level, role complexity is indicated by the number of uniplex (one formal role) or multiplex relationships. Networks with a high role complexity are usually also small and densely knit.

The geographical dispersion within the network indicates the extent to which network members live in the same neighborhood or region by the proportion of network members who live less than 15 minutes' drive away. The geographical dispersion of the network demonstrates the availability of potential supporters in the vicinity of the older adult.

Content of the Network

The overall interaction of the older adult with the network members is often used as a token of social participation. Network interaction may vary among different parts of the network. Interaction is higher

with the spouse, children, and neighbors than it is with distant relatives and acquaintances. The more frequently one interacts with network members, the more likely the exchange of support. The support intensity of the network refers to the exchange of support between all the network members and the focal person. Various types of support can be distinguished: emotional support, instrumental support, social support (companionship), material support, and so on. Furthermore, a distinction can be drawn between giving and receiving support. The types of support vary among the types of relationships, and among older men and women. Men are known to exchange instrumental support, whereas women are known to give and receive emotional support to an old age.

The exchange of two or more types of support within the network relationships indicates the support complexity of the network. Some network members provide emotional as well as instrumental support, whereas others exchange only material goods.

Last, the balance between the overall provision and receipt of support indicates the support reciprocity within the network. In general, elderly people receive more support than they provide. This is particularly the case after there is a strong decline in their physical capacities. Giving and receiving support is usually more balanced for women than men. An unbalanced support network has a negative impact on the well-being of the elderly. The imbalance created by being in debt to many network members leads to feelings of guilt, whereas providing support to many relatives and friends without receiving much in return can lead to feelings of being exploited.

Methods of Network Analysis

Data Storage

Network data are hierarchically constructed. There are two levels of star network data. The elderly person as the anchor of the network is the higher level, with such characteristics as sex, age, network size, and well-being. Inside of it, characteristics of the network members such as sex, and characteristics of their relationships with each other such as traveling time and support received by the elderly person are on the lower level. There are three levels of full network data: the network as a whole, for example, its size; the characteristics of the network members including the elderly person; and the features of their relationships with each other. The data are stored in accordance with this hierarchic structure.

Analysis of Network Data

One of the attractions of having network data at one's disposal is that data on different levels can be linked to each other. There are two methods for simultaneously analyzing the data on both levels: aggregation and disaggregation.

In aggregation, data from the lower level of the separate network members and/or relationships are transferred to the higher level of the elderly person. For each elderly person, a researcher can take the mean of the contact frequency within his or her relationships and introduce the average contact frequency as variable in an analysis to explain the differences in the well-being of elderly people. A variant on aggregation as the average frequency of contact across relationships would be to count the number of network members with whom there is contact at least once a week. Statistical software has capacities for aggregation of this kind.

In disaggregation, data from the higher level of the elderly person are related to the lower level of the separate network members and/or relationships, for example, when the researcher wants to find out whether more support is exchanged in same-sex relationships than in cross-sex relationships. Data from different cases are not independent of each other, so this violates an assumption of many analysis techniques. The application of multi-level analysis is appropriate. In this analysis technique, a linear regression equation is formulated for explaining variance in a variable on the lower level from the perspective of other variables on the lower level. The support received by an elderly person is then predicted on the basis of, for example, the sex of the network member and of the elderly person. Interaction effects can be added to the model. A crucial aspect is that the magnitude of the effect of explanatory variables on the relationship level may differ between respondents. Therefore, the intercept as well as the slopes of the different independent variables in this equation are then explained with different regression equations from the perspective of independent variables on the higher level, such as the age and health of the elderly person. Multi-level analysis techniques are available as specific software.

Summary and Conclusions

The personal network is considered a social resource and is important for daily functioning, coping with life events, and maintaining well-being. The impact of aging on the personal network becomes evident in the changes within the structure as well as the content of the network. The personal network of the elderly can be studied with different objectives. The researcher can focus on the content of the network, e.g., the relation between support and well-being, or on structural aspects of the network, e.g., the relation of

marital status to its size, composition, and density. In every network study, several methodological choices are made beforehand: which network delineation method is to be used, whether additional information is to be collected on some or all of the identified network members, which information is to be collected, and who will provide this information (only the older adult or all the members of the network).

Neuroimaging (MRI, PET)

A C Burggren and S Y Bookheimer, University of California, Los Angeles, CA, USA

Glossary

Activation Imaging – An imaging technique that identifies brain regions that show increased cerebral blood flow, which is tightly coupled to neural activity, during ingoing mental operations.

Functional Magnetic Resonance Imaging (fMRI) – An imaging technique that monitors blood flow indirectly and requires comparison of two states such as memory task performance and a baseline control task.

Magnetic Resonance Imaging (MRI) – An imaging technique that allows for observation of structural differences in the brain, noninvasively.

Positron Emission Tomography (PET) – An imaging technique that monitors glucose metabolism and blood flow that can identify functional brain changes in patients.

Introduction

Neuroimaging is widely used in the evaluation of Alzheimer's disease (AD). Traditionally, imaging in AD has been used to exclude other diseases and neurological conditions that produce similar cognitive symptoms. Recently, however, neuroimaging has been explored for its potential in predicting clinical outcomes in subjects before the onset of AD or as surrogate markers for monitoring the course of treatment. While these experimental uses tend to be more exploratory than of current clinical application, the diagnosis of AD has unquestionably been advanced

with the inclusion of neuroimaging. In particular, positron emission tomography (PET) imaging has gained wider usage, as characteristic patterns of hypometabolism appear strongly related to AD. As the science progresses, several imaging measures may aid not only in diagnosis of current disease but also in prediction of incipient disease. Imaging is predicted to impact the field of AD management in three ways: first, by increasing the specificity of disease diagnosis; second, by allowing AD to be detected earlier in patients with only mild cognitive impairment or, even earlier along the disease continuum, in patients without apparent clinical symptoms; and third, by following disease progression and treatment once it is diagnosed in predementia stages. However, the clinical application of imaging in AD has not yet been fully maximized and, in the future, the contribution of neuroimaging is likely to be critical to the understanding of both pathophysiology and therapeutic intervention.

PET Studies in AD

PET has proven to be a sensitive and specific tool for identifying functional brain changes in patients with AD as well as those in preclinical stages, including genetic risk and mild cognitive impairment (MCI). PET uses positron-emitting radionucleotides (commonly used isotopes include oxygen-15 [^{15}O], nitrogen-13 [^{13}N], carbon-11 [^{11}C], and fluorine-18 [^{18}F]) to monitor both glucose metabolism and blood flow after these molecules enter the central venous system and are detected by crystal scintillation detectors in the PET scanner. The most commonly used ligand binds ^{18}F to deoxyglucose, producing the moderately long (110 min) half-life compound ^{18}FDG, which measures resting glucose metabolism with great sensitivity. ^{18}FDG imaging of resting metabolism in AD patients demonstrates a consistent pattern of reduced blood flow and metabolism throughout the middle temporal region, cingulate cortex, and the parietotemporal association cortex. This pattern of altered blood flow and metabolism spreads in a superior to inferior fashion, beginning typically in the superior parietal cortex, and then spreading inferiorly and anteriorly to involve the inferior parietal, superior temporal, and prefrontal cortices (**Figure 1**). As the disease progresses, frontal cortices become more affected, while the primary motor and sensory areas remain preserved until the final stages of the disease, following closely the pattern of plaque and tangle distribution as detailed by Braak and Braak in their landmark 1991 paper. The extent of hypometabolism correlates with the severity of cognitive impairment and often shows right/left hemispheric asymmetry. More recent studies using higher-resolution PET scanning have reported marked hypometabolism of the hippocampal head and amygdala in AD. A longitudinal study determined that measuring regional brain metabolism in subjects presenting with early signs of dementia was a sensitive indicator of

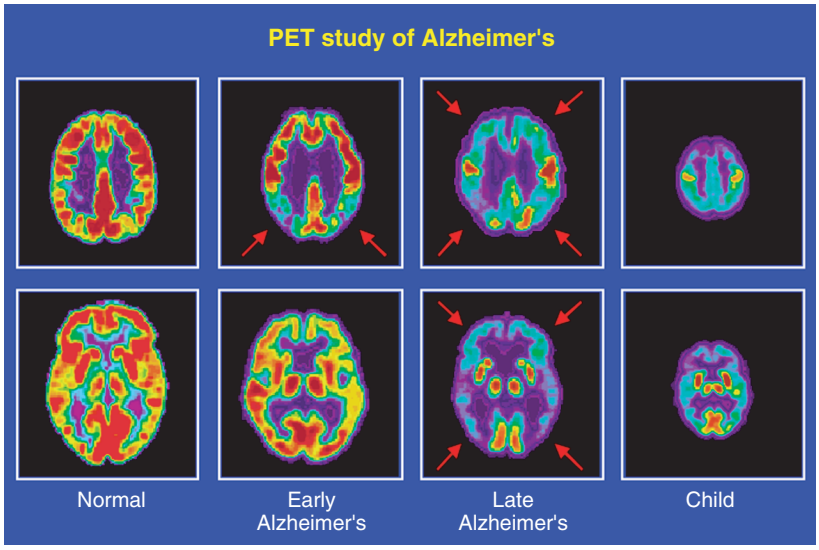

Figure 1 A PET study of glucose metabolism in Alzheimer's disease. The early Alzheimer's study was performed at the stage of questionable Alzheimer's disease and illustrates the characteristic metabolic deficits of Alzheimer's in the parietal and temporal memory centers of the brain (arrows). Over time, the metabolic deficit spreads throughout the brain. At the late stage of disease, metabolic function of the brain in Alzheimer's is similar to that of the child shown to far right, which corresponds to their similar behavior and functional capacity. Baltimore MD: Williams & Wilkins.

subsequent AD. PET identified AD patients with a sensitivity of 94% and a specificity of 73%.

PET Studies in MCI

Patients with MCI, considered to be of considerable clinical interest because of the 50% rate of conversion from MCI to AD over a 4-year period, typically show hypometabolic patterns similar to AD patients but reduced in magnitude and extent. Current clinical practices now focus on MCI as a prodromal phase of AD. The reduced metabolism seen in MCI patients is typically restricted to the medial temporal cortex. In longitudinal studies of MCI patients, the conversion of MCI to AD may be predicted by specific patterns of hypometabolism. For example, in those MCI patients destined to convert to AD within a year, hypometabolic patterns were detected within the temporoparietal association areas as well as the posterior cingulate cortex. However, the reduction of cerebral metabolism within prefrontal cortical areas was the most highly correlated with the transition from MCI to AD. This was interpreted to represent the course of disease progression. Compared to normal controls, MCI subjects demonstrate reduced cortical metabolism primarily in temporal regions including the entorhinal cortex (ERC), the hippocampus, the lateral temporal lobe, as well as the dorsolateral frontal cortex. In addition, the reduction of glucose metabolism at baseline in normal subjects within the ERC predicted with high accuracy (84%) the decline from normal aging to MCI. Overall, these findings suggest the utility of reduced glucose metabolism within the medial temporal lobe (MTL) as a predictive measure of decline from MCI to AD. This also suggests the possibility of the recognition of AD in non-demented stages, leading to more effective disease intervention.

PET Studies and Genetic Risk

Identifying genetic polymorphisms that are overrepresented in AD has proven a successful way of identifying individuals with a significant risk for AD and, in combination with imaging, may increase our ability to detect AD in preclinical stages. In particular, discovery of the relationship between the Apolipoprotein E e4 allelle (APOE-4) allele on chromosome 19 and AD is one of the best-replicated findings in complex human genetics. APOE-4 significantly decreases the age of onset of the disease in a dose-dependent manner and is associated with higher β-amyloid (Aβ) plaque burden.

Early imaging studies made use of the newly discovered gene to reveal subtle alterations in brain function among non-demented carriers. In a study designed to monitor progression of metabolic changes over time, Small and colleagues used PET imaging, in combination with genotyping, to reveal subtle alterations in cerebral metabolism among older, non-demented carriers of APOE-4 in 2000. They found a decline in left posterior cingulate metabolism and inferior parietal and lateral temporal regions in APOE-4 carriers after a 2-year follow-up PET study. The authors suggested that combining PET imaging with genetic risk factors provides a method for preclinical detection of AD that will assist in response monitoring during experimental treatments (**Figure 2**). Several other groups have also identified alterations in glucose metabolism similar to AD patterns in genetic risk subjects without clinically apparently cognitive impairment. This type of study holds the potential for increasing the efficacy of therapeutic treatments.

Activation Imaging with PET

An alternate approach to imaging brain function in AD uses activation imaging, in which subjects perform a cognitive task, such as a memory test, in comparison to a control or resting state, during scanning. These methods identify brain regions that show increased cerebral blood flow (CBF), which is tightly coupled to neural activity, during ongoing mental operations. In principle, brain regions with impaired neural activity will show less CBF when engaged in a task than those unaffected and have the potential for identifying deficits more sensitively. In practice, however, activation imaging is more complicated: first, PET ligands used in activation imaging, typically H_2[15-O], have a short half life, necessary for experiments involving multiple conditions but producing images with significantly lower signal, and thus reduced ability to detect differences among individuals. In addition, activation studies have shown evidence of increased brain activity in some regions, likely attributed to compensation. For instance, in normal subjects, increasing task difficulty also increases regional CBF (rCBF) in regions critical for the particular task performance, and individuals with less cognitive ability appear to show an increase in brain metabolism. Thus, it is not surprising that activation imaging studies with PET have yielded mixed results in studies of AD.

In a study of normal aging published in 1993, scientists compared CBF in older and younger subjects while they performed visuoperceptual tasks. Both older and younger subjects showed similar CBF increases in superior visual pathways; however, young subjects showed greater activation of prestriate cortex,

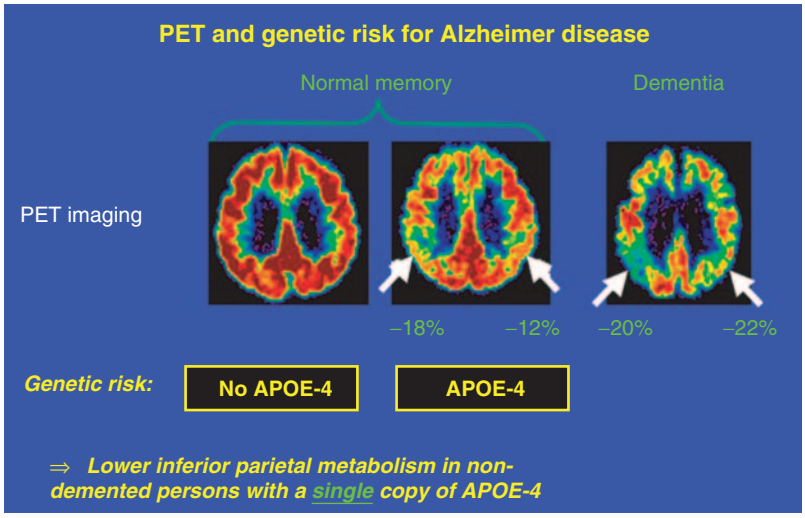

Figure 2 The first two PET scans were performed on people in their 60s – both had only minor memory complaints. This shows how someone with normal memory performance may have deficits in brain function revealed by the PET scan, especially if they have the APOE-4 genetic risk for Alzheimer's disease. Adapted from Small GW, Ercoli LM, Silverman DH, *et al.* (2000) Cerebral metabolic and cognitive decline in persons at genetic risk for Alzheimer's disease. *Proceedings of the National Academy of Sciences USA* 97(11): 6037–6042.

while older subjects had greater rCBF increases in visual recognition areas in occipito-temporal cortex. Older subjects also had greater activity in the prefrontal cortex, which may be consistent with their need for increased effort to perform the task. Comparing older controls with AD, the same group reported that the pattern of rCBF activation observed in normal older subjects during a perceptual matching task is maintained in patients with AD of mild to moderate severity. Such results are similar to other findings that normalized glucose metabolism in occipital areas increases during behavioral task performance in patients with AD, but does not differ in magnitude from that in controls. In contrast, Kessler and associates reported a similar pattern of regional glucose utilization in 1991 in patients with AD and control subjects during a visual recognition task, with patients demonstrating increases of lower magnitude than control subjects. However, these subjects were more demented, which could explain the reduced activation.

Several authors have suggested that subjects use compensatory strategies that produce increased activity in regions less affected by the disease. Small and colleagues found an association between patients' use of mnemonics and cerebral glucose metabolism; subjects who used more frequent mnemonic strategies had lower rates of glucose metabolism in inferior frontal cortex. The results suggest that in early AD, patients attempt to compensate for subtle cognitive impairments by employing compensatory strategies that invoke the use of more intact cortical structures.

Amyloid Imaging

There is a keen interest in developing more direct measures of AD-specific pathology, which has led to the emergence of several new PET ligands to measure amyloid deposition. Amyloid plaques, which are composed of Aβ, and neurofibrillary tangles (NFTs) are the pathological hallmarks of AD. NFTs are correlated with the stage of AD, and both pathological deposits appear before symptoms show themselves, perhaps decades before. This observation suggests that these deposits may be a good early marker for the disease. Based on the presence of diffuse plaques in neurologically normal individuals, it may be that Aβ accumulation precedes other pathological features of AD. Controversy exists as to the chain of events in this Aβ cascade. However, evidence suggests that accumulation and aggregation of Aβ is related to brain inflammation, disruption of neuronal metabolism and ionic homeostasis, altered neuronal kinase/phosphatase activities resulting in hyperphosphorylation of tau and paired helical filament (PHF) formation, and finally, neuronal death in AD. Thus, a biological marker of NFTs and plaques as well as specific hippocampal neural function would have great potential for early detection of AD.

[^{18}F]DDNP

In 2002, results were published that used 2-(1-{6-(2-[F-18]fluoroethyl) (methyl)amino-2-napthyl}ethlidene)malononitrile ([^{18}F]DDNP) as a molecular

imaging probe for the localization of pathological disease features in living AD patients (NFTs and senile plaques) using PET (**Figure 3**). [^{18}F]DDNP binds to plaques and tangles in a manner analogous to receptor–ligand interactions. However, it is likely that the binding reflects a complex process involving multiple binding sites. Receptor–ligand interactions are governed by the dissociation constant, binding affinity constant, and receptor density constant. PET visualization of *in vivo* probe binding to brain receptor sites with a receptor density of approximately 20 nM requires dissociation constant values in the nanomolar range in order to get specific binding. [^{18}F]DDNP has two such sites. In addition, it crosses the blood–brain barrier in proportion to blood flow in a manner similar to ^{18}FDG. The scientists who conducted the study measured the relative residence time (RRT) of the molecular imaging probe in areas known to be associated with AD (the subiculum, entorhinal, and transentorhinal regions; hippocampus; basal temporal lobe; basal frontal lobe; isocortical regions; supramarginal and supratemporal gyri regions) compared to the pons, an area known to have limited lesions due to AD. Higher RRT times denote higher NFT (receptor) density based on binding to the probe, [^{18}F]DDNP, and were also associated with poorer memory performances as measured by the Mini-Mental State Examination (MMSE). Specifically, the hippocampus–amygdala–entorhinal regions were associated with the highest RRT values and generally matched the lowest MMSE scores. It is noteworthy that the authors validated [^{18}F]DDNP binding to senile plaques and NFTs through postmortem analysis of an AD patient.

PIB

Another promising compound, 2-(4′methylaminophenyl)-6-hydroxy-benzothiazole (referred to as Pittsburg compound B or PIB) showed promising results in labeling Aβ deposits. Multiphoton microscopy was used to capitalize on the fluorescent properties of PIB and observe the contrast agent crossing the blood–brain barrier within seconds and specifically label amyloid plaques and cerebral amyloid angiopathy, or protein deposits in blood vessels, within minutes. The compound was used in transgenic mice models of Aβ deposition (Tg2576 and PDAPP mouse lines), indicating the labeling was not specific to one model of the disease. The first human PIB study demonstrated a robust difference between the retention pattern of PIB in AD patients and the healthy controls. The AD

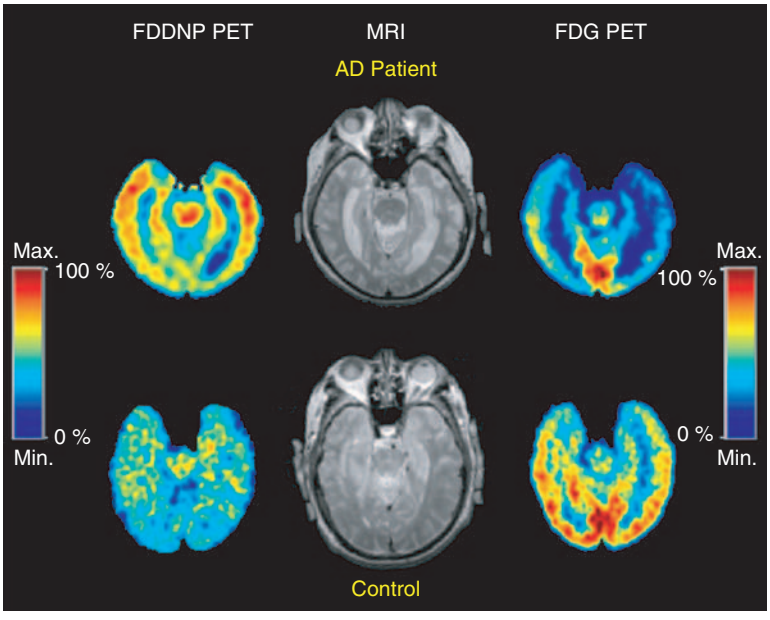

Figure 3 FDDNP PET, MRI, and FDG PET images of an AD and control normal subjects. The FDDNP PET of the Alzheimer's patients (AD; upper scans) shows increased signal (red) in temporal memory regions compared with the control (below). The FDDNP chemical marker is attracted to the plaques and tangles in the brain, which is the physical evidence of Alzheimer's disease in the living patient. The FDG PET shows glucose metabolism indicating how well the neurons are firing. In the Alzheimer's case, the FDG PET shows decreased neuronal activity in the brain regions where FDDNP shows increased activity (i.e., high concentrations of plaques and tangles). The MRI scans show brain structure but no signal for plaques and tangles. Reproduced with permission from Shoghi-Jadid K *et al.* (2002) Localization of neurofibrillary tangles and beta-amyloid plagues in the brains of living patients with Alzheimer's disease. *American Journal of Geriatric Psychiatry* 10(1): 24–35.

patients showed marked retention of PIB in association areas known to contain large amount of amyloid in AD. In areas that remain relatively unaffected by amyloid deposition in AD, however, the control subjects and AD patients showed equivalent retention rates of the amyloid marker. These areas included white matter, pons, and cerebellum. The authors suggested that the study demonstrated the ability of the PET tracer to provide quantitative information on amyloid deposits in living patients. They also suggested the utility of this technique as an *in vivo* technique to assess the efficacy of anti-amyloid drug studies as novel therapies are developed.

[^{18}F]MPPF

The cell loss caused by the neuropathological processes in AD mostly occurs in the vulnerable populations of large pyramidal neurons in the cortex. These neurons form the neuronal circuits responsible for memory and cognition. Serotonin 1A (5-HT1A) receptors are primarily located in limbic areas, particularly those temporal lobe areas affected in early stages of AD. Pyramidal neurons in the hippocampus have high levels of 5-HT1A receptors expressed on their cell bodies through which they receive modulatory serotonergic inputs, suggesting that quantification of receptor density would be useful in monitoring neuronal loss within the MTL in AD. The loss of these pyramidal neurons in the hippocampus has been correlated with 5-HT1A receptor densities. Partial antagonism of 5-HT1A affects cholinergic transmission and affects memory as well. These receptors may be mapped in the hippocampus and other brain areas by using [^{18}F]MPPF, a selective molecular imaging probe that permits the quantification of 5-HT1A receptor densities in the human brain with PET. Mapping of these receptors has been shown *in vivo* in both the rat model and the human brain. Labeling with the ligand in humans matches the known distribution of 5-HT1A receptors, with high binding in the hippocampus, cingulate cortex, entorhinal cortex, dorsal raphe nucleus, and interpeduncular nucleus and low binding in the cerebellum.

Recently, the 5-HT1A ligand has been used to measure neural loss in patients with MCI and AD as well as control subjects. Initial [^{18}F]MPPF PET Logan graphical analysis using cerebellum as a reference tissue in AD patients demonstrates the decrease in hippocampal binding (binding potentials [BPs]) by 40–60% when compared with values for control subjects. Based on these results, it is possible that [^{18}F]MPPF may add information about hippocampal neural integrity above measures associated with aging, providing additional clues to changes in AD independent of APOE status.

Structural MRI in AD

Magnetic resonance imaging (MRI) provides an excellent tool for observing structural differences noninvasively. In aging generally, MRI may show enlarged ventricular size and generalized brain atrophy; however, many of these changes may be nonspecific to AD. Thus, among the goals of MRI research in AD are to identify structural changes that appear early in the disease, including preclinical stages, and that are specific to AD as opposed to normal aging or other dementia disorders. In most cases of AD, MRI-evident atrophy of the MTL is markedly disproportionate to the rest of the brain, and most investigators agree that the first brain structure affected in AD is the MTL, making memory decline one of the earliest cognitive symptoms of the disease. Structural brain imaging studies of AD have revealed that measurements of the MTL are the most sensitive and specific to differentiating AD from normal aging. More specifically, reduced hippocampal volume within the MTL was found to provide a sensitive marker for dissociating AD from normal elderly. From these results, MR volumetry measures of the hippocampus were found to be comparable to the accuracy of a pathologically confirmed clinical diagnosis in distinguishing AD patients from healthy elderly controls. Indeed, the prevalence of hippocampal atrophy in advanced AD may be as high as 96%, with no relation to age. Such significantly reduced volumetric measurements found in the temporal lobe were also correlated to declining performance on neuropsychological exams typically used in the diagnosis of AD.

Within the MTL, pathological studies of changes in synaptic integrity, reduction in density, and the formation of neurofibrillary tangles in AD all point to the ERC as the first target of AD. The ERC receives most of its projections from the perirhinal cortex and the parahippocampal cortex, with some input also coming from polymodal cingulate/retrosplenial cortex, orbitofrontal cortex, dorsal superior temporal sulcus, olfactory bulb, and parainsular cortex. The ERC is the gateway to the hippocampal circuit, including dentate gyrus and cornu ammonis subfields (CA1, CA2, and CA3), and the subiculum. Thus, damage to the ERC affects the entire hippocampal memory system. MRI studies specifically measuring the ERC show that reduction in ERC volume appears to precede other MRI changes in AD and MCI. In contrast, studies of non-AD processes in aging suggest a sparing of the ERC with selective targeting of other hippocampal regions.

Patients with MCI display significant hippocampal atrophy when compared to normal aged controls. Among those MCI subjects retroactively examined for correlates to future AD conversion, MRI results revealed that reduced temporal association neocortex volume combined with reduced hippocampal volume may be the best structural predictor for conversion from MCI to AD. These results suggest that volumetric measurements of the subregions within the MTL, including both the entorhinal cortex and the hippocampus, can correctly distinguish MCI patients from healthy controls.

High-Resolution MRI and Advanced Techniques

To determine change in brain structure with MRI, investigators have relied traditionally on volumetry with user-defined region of interest analysis. While such techniques have provided extremely useful data, they typically emphasize whole-brain image acquisition, yielding pixel dimensions that are at best 1–1.2 mm^3. Higher in-plane resolution methods offer many options for exploring subtle structural abnormalities. Such methods are unnecessary for most volumetry studies, since cortical regions are defined by relatively large boundaries (e.g., sulcal landmarks that are 1–2 cm apart). In some subcortical structures, and in particular the hippocampus, this general rule does not hold: the entire width of the hippocampus perpendicular to the long axis is 1 cm or less; most importantly, the structures within the hippocampus (dentate gyrus, CA fields, ERC, and subiculum) are much smaller than that in the perpendicular axis. Of greatest importance is the known heterogeneity of hippocampal function within these substructures. For instance, neural loss in CA fields 1 and 3 is associated specifically with impairments in acquiring new associations. In addition, recent functional imaging studies have suggested specific roles for subiculum, anterior and posterior hippocampus and parahippocampal gyrus. These findings suggest an important need to identify abnormalities in hippocampus structure and function at a finer level than whole-structure volumes.

Recently, some groups have focused on measuring the thickness of the cortical ribbon rather than the global size of the structure. Overall cognitive function in AD patients correlates with synaptic density in lamina III of the frontal and parietal cortices. Such a pattern of neural loss may suggest that the thickness of the cortical ribbon may change prior to the overall volume of the structure. In a recent study, the thickness of the entorhinal cortex was reduced in genetically at-risk normal volunteers with normal performance on psychometric measurement of memory and cognition. Interestingly, the differences between groups remained stable across age; genetic group differences in ERC thickness were as large in the 45-year-old subjects as in the elderly subjects. This may suggest that APOE-4 subjects have a longstanding vulnerability in the ERC; alternatively, loss of subjects to memory complaints and AD in the APOE-4 group may have masked an interaction between age and genetic status. Thompson *et al.* used an automated, voxel-based technique to determine cortical thickness in AD, showing significant thinning in cortices also known to be hypometabolic.

Structural MRI and Genetic Risk

The atrophic patterns seen in AD and MCI using MRI have been found in reduced magnitude in genetic risk subjects. A study of structural MRI scans from early AD subjects genotyped for APOE status revealed that although all AD patients had significant atrophy of the medial temporal structures, atrophy was greatest among those homozygotes for APOE-4. Large decreases in the volume of the entorhinal cortex of AD patients with APOE-4 compared to APOE-3 carriers have been found; this difference is highest for female patients and correlated with memory decline. In APOE-4 subjects without AD, however, no significant differences in gross structural MRI measures, which included sulcal and ventricular enlargement, were found. However, APOE-4 subjects performed worse on neuropsychological tests. In contrast, significant decreases in the size of the entorhinal cortex and hippocampal head in genetically at-risk volunteers with only mild cognitive impairment have also been found. Similarly, hippocampal volume loss in APOE-4 subjects without AD is associated with memory loss. While structural MRI results in asymptomatic genetic risk subjects have been variable, it is possible that MRI may not be sufficiently sensitive to observe changes prior to signs of memory decline. However, based on the presence of prodromal symptoms as measured by other techniques such as PET or fMRI, it is more likely that measures such as whole-structure volume or ventricular size are not sufficiently sensitive to detect group differences. The effects of the APOE-4 allele may be very subtly expressed early in development of the disease (e.g., initially in the entorhinal cortex), making whole-volume measurements of the hippocampus not sufficiently sensitive to detect differences early in progression of the disease. If subtle deterioration occurs on a smaller scale, subregional volumetry, or measuring the volumes of individual areas within the

hippocampus, may be a more useful methodology for the detection of AD pathology.

Monitoring Change

While numerous studies have identified group differences in imaging measures among MCI or at-risk populations, there are very few studies demonstrating the predictive ability of these methods. Absolute measures of hippocampus and ERC size are vulnerable to baseline differences in overall and regional size that are unrelated to decline, as well as to differences in measuring technique. An alternative approach to morphometric analyses uses a rate of change metric, reasoning that the speed with size decreases may more accurately reflect a declining process than a single time point measure. Several groups have taken this approach. Fox and colleagues, in 2004, used automated and semiautomated serial imaging to map atrophic rates and patterns of gray matter loss in AD, MCI, and normal aging, using the rates to successfully differentiate between the groups and as a marker of disease progression. They also suggest the potential usefulness of serial MRI in determining the efficacy of future disease-modifying treatments and detecting disease onset.

With powerful computing hardware, subvoxel image registration allows repeat MRI scans to be precisely digitally overlaid. This makes it easier to assess longitudinal brain change and create detailed maps of degenerative processes. Gray matter loss in AD has been mapped using powerful image analysis techniques to compare gray matter distribution in AD patients' and controls' MRI scans over time. In a longitudinal study published in 2003, a dynamically spreading wave of gray matter loss was detected in the brains of patients with AD, visualizing the loss pattern in four dimensions as it spread over time from temporal and limbic cortices into frontal and occipital brain regions, sparing sensorimotor cortices. These shifting deficits correlated strongly with progressive cognitive decline ($P < 0.0006$). The potential for this technique in calculating exact rates at which AD and control subjects lose gray matter and, therefore, identifying differences between the two may help in identifying patterns of loss in subjects before the onset of clinical AD symptoms.

Activation Imaging and Functional MRI

Functional MRI (fMRI) is another activation imaging technique that offers several distinct advantages over PET, including non-invasion, increased spatial and temporal resolution, and repeatability, as it does not require radiation exposure. This functional imaging procedure monitors blood flow indirectly, taking advantage of the difference in magnetic susceptibility between oxygenated and deoxygenated blood, whose relative concentrations change during neural activity. The resulting MRI signal change defines the blood oxygen level-dependent (BOLD) response. Like activation PET, fMRI requires comparison of at least two states, such as memory task performance and a baseline control task.

fMRI studies have identified a variety of functional activation differences between AD patients, normal elderly volunteers, and other dementias. Differences in neural activation in patients with AD compared to normal elderly controls have been identified during both visual and language processing tasks. It is important to take into consideration subject performance in such studies: if patients are unable to perform tasks with the same level of accuracy as the comparison group, differences in brain activation patterns may reflect those performance differences rather than regional brain pathology. Matching for performance is much easier in preclinical studies of at-risk subjects. An fMRI study of performance-matched normal volunteers who were asymptomatic but at genetic risk for AD took this approach. Despite equal performance on the fMRI task, which required rote memory for unrelated words, the APOE-4 carriers showed large increases in both the magnitude and spatial extent of activation in frontal and parietal neocortex as well as in medial temporal regions. Further, the extent of these fMRI increases correlated with memory decline after a 2-year follow-up. These results were specific to memory challenge; genetic groups performing a very challenging task that did not include an episodic memory component showed no differences in fMRI activation. Similarly, a study by Smith and colleagues, using a word fluency task, also demonstrated a pattern of increased brain activation while maintaining performance in subjects at risk for AD. These results suggest that individuals with incipient cognitive decline might utilize compensatory strategies, drawing on intact brain resources to perform challenging tasks early in the AD process (**Figure 4**).

In contrast, data on impaired subjects suggests that as cognition declines, patients rely increasingly on primary sensory and motor areas that are less affected by the disease. This notion is supported by the findings of Reiman and others that hippocampal volume loss was detected in only those at-risk subjects showing memory decline. It is likely that an observed compensatory response, e.g., an increase in blood flow or glucose metabolism during task performance, will occur before neural loss and subsequent memory decline; in contrast, significant neural

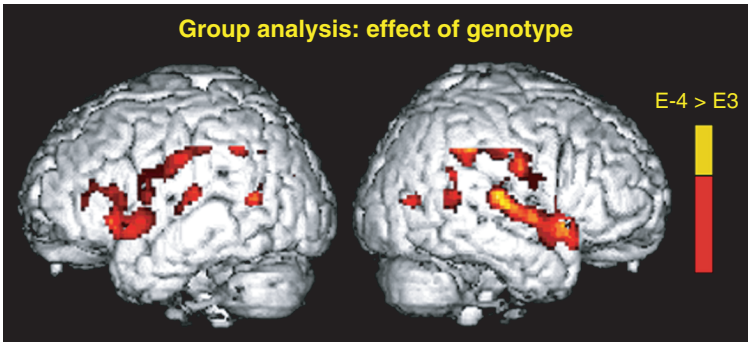

Figure 4 fMRI activation maps of neural activation differences between APOE-4 and APOE-3 subjects during a paired-associate word task. Both the magnitude and the extent of brain activation during memory activation tasks in regions affected by Alzheimer's disease, including the left hippocampal, parietal, and prefrontal regions, were greater among the carriers of the *APOE-4* allele than among the carriers of the *APOE-3* allele. Adapted from Bookheimer SY, Strojwas MH, *et al.* (2000) Patterns of brain activation in people at risk for Alzheimer's disease. *New England Journal of Medicine* 343(7): 450–456.

death in a region will lead to decreased activation. fMRI studies that examined AD patients compared to healthy elderly controls revealed the expected results: reduced activation in the neural network involved in completion of the task. In another fMRI study, patients with mild AD failed to activate either temporal lobe or prefrontal regions that did show activation in normal controls on the same visual learning task.

These studies highlight the potential for detecting functional differences in activation patterns not only between Alzheimer's patients and healthy controls, but also between normal elderly controls before they display cognitive symptoms of the disease. Future applications of this technique may include monitoring functional activation differences longitudinally in a group of normal elderly subjects to assess progression of the disease from the very earliest warning signs (seen as activation differences in the absence of overt memory deficits as measured by neuropsychological tests) to severe deficits in functional activity during later stages of the disease. Taken as a whole, these advances show that functional neuroimaging is developing a prominent role in *in vivo* monitoring of progression of AD (including early detection) and therapeutic intervention.

Effects of Drug Therapies on Neuroimaging

The current standard of clinical care for mild to moderate AD is treatment with cholinesterase inhibitors. Four are currently available: donepezil, tacrine, rivastigmine, and galantamine. These treatments may slow cognitive decline or may reduce the emergence of new behavioral manifestations of the disease but are not considered a cure for the disease. Nevertheless, the prevalence and importance of understanding the physiological effects of these drugs in the treatment of AD is not to be underestimated. In fact, the evaluation of the effects of these drugs on imaging measures has become its own area of specialized research. Some imaging studies suggest the maintenance of cognitive performance by these drugs through increased regional cerebral blood flow. Structurally, the neuroprotective effects of these drugs have been suggested with the finding of reduced atrophy in the hippocampus using MRI. Functionally, fMRI has been used to link the clinically observed increase in cognitive performance after treatment with a cholinesterase inhibitor to altered brain activation. The authors suggest that the modified firing rates observed via differences in the BOLD signal using fMRI reflect altered neurotransmitter status in the brain. Taken as a whole, these studies suggest the utility of neuroimaging measures as a surrogate marker for therapeutic interventions, suggesting the use of imaging measures as a faster measure of pharmacological-induced cognitive benefits in the disease.

Concluding Remarks

The field of neuroimaging in AD is rapidly leaving its indelible mark on the clinical field of AD diagnosis. PET scans have recently been approved for limited coverage under Medicare policies. Several other neuroimaging techniques are promising tools for an earlier diagnosis than is currently possible with behavioral testing alone. The field of research in neuroimaging and AD holds the potential for diagnosing not simply the behaviorally affected AD patient, but perhaps the patient who has yet to display cognitive manifestations of the disease. With several new lines of treatment under research, the most promising methodology for reducing the incidence of AD in the population is an earlier diagnosis, taking

advantage of future interventions that may slow disease progression. It is apparent that as imaging methods have become more sophisticated, they have detected brain changes occurring much earlier in life than previously assumed. By combining higher resolution structural and functional imaging methods, emphasizing change analysis, with genetic risk factors, there is promise in being able to identify brain changes as they first emerge and to identify a trajectory of change likely to lead to AD.

Glossary

Contractile Proteins – Actin (thin filament) and myosin (thick filament) interact to form the sliding filament mechanism of muscle contraction. The heavy chain isoforms are central in the regulation of muscle shortening speed.

Contraction – Muscle can contract with (dynamic) or without (isometric) movement. During movement, an active muscle can either shorten (concentric contraction) or lengthen (eccentric contraction).

Muscle Strength – The maximum force that can be produced by a muscle, which is specific to the type of contraction.

Plasticity – The ability of muscle to adapt to changes in usage. This can be at all levels, from changes in the expression of contractile proteins to its metabolism.

Power Output – The product of muscle force and speed of movement.

Sarcopenia – Age-related loss of muscle mass. The decline in muscle mass is closely associated with the decline in muscle strength in old age.

Introduction

Old age in both men and women is characterized by a reduction in muscle mass, which relates to a reduction in both the number and size of muscle fibers. This loss of contractile tissue is accompanied by a decline in muscle force production (strength) and power output. A loss of motor nerves in the spinal cord results in a reduction in the number of functioning motor units, while in those motor units remaining the number of muscle fibers is increased, as some of the fibers that have been lost become reinnervated. The proportion of fast myosin isoforms may be reduced in aged muscle as a consequence of a selective atrophy of the type II fibers, resulting in a slowing in the speed of muscle movement, amplifying the decrease in power-producing capability. With only small changes in body mass, functional ability and mobility are reduced as the muscle power to body mass ratio decreases. While the decline in physical performance seems an intrinsic part of the aging process, the aged neuromuscular system remains sensitive to improvements in muscle mass, strength, power, fatigue resistance, and coordination.

Properties of Skeletal Muscle

Contractile Properties

To understand the effects of the aging process on the neuromuscular system it is important to identify the factors that determine the mechanical properties of a muscle. The force–velocity relationship describes how, as a muscle contracts and actively shortens against an external load, the force that it can generate decreases in a hyperbolic manner with velocity of contraction. In contrast to traditional experiments undertaken by muscle physiologists on isolated muscle, in the body there are many factors that have an influence on contractile output; these include the activation of muscle and the role played by elastic structures in series with the muscle fibers, namely, tendons.

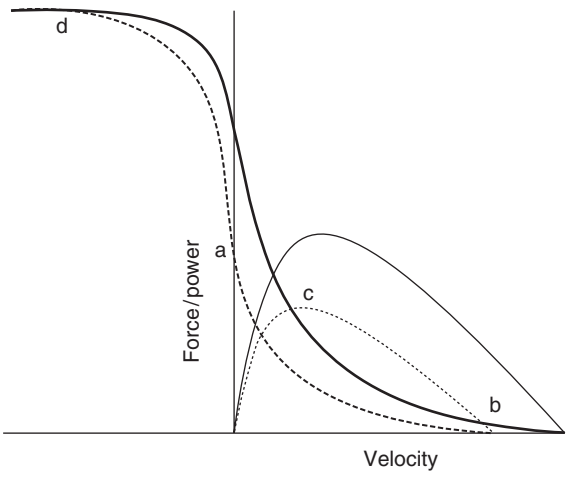

Figure 1 Schematic diagram showing the force–velocity and power–velocity relationships for a hypothetical young (continuous) and old (dashed) muscle. The older muscle may demonstrate lower isometric force (a), reduced maximum velocity of shortening (b), lower power output (c), but maintained function during stretch (d).

Strength, which can be defined as the amount of force that can be generated during a single maximal isometric (or static) contraction, is determined by the physiological cross-sectional area of a muscle, which is ultimately a reflection of the number of functioning subunits within muscle, the sarcomeres, working in parallel with one another. In contrast to isometric contractions, when a muscle is allowed to shorten, or contract concentrically, mechanical work is performed and the rate at which this work is performed is equivalent to power output. In other words, power is the product of force and velocity. As can be seen in **Figure 1**, power rises with increasing speed of movement until a velocity of shortening at approximately 30% of V_{max} is reached; here peak power is obtained. Power then declines with further increases in the speed of movement. As all movements of the body involve components of force generation and speed of movement, any changes in either of these variables will have an effect on the power that can be generated. Ultimately, it is the force-producing ability, the rate at which force can be produced and the power-generating capacity of the muscle, that will determine the ability of older people to perform a given physical tasks.

Contractile Proteins and Function

As mentioned previously, the isometric force that can be generated during a contraction relates most closely to muscle or fiber size, specifically to its cross-sectional area. This in turn is a reflection of the number of myosin cross-bridges, the molecular motors, that are

working in parallel. However, there is evidence to suggest that type II fibers are capable of generating ~20–30% higher force per unit area and thus have a higher specific tension. During movement, the implications for fibers expressing different myosin isoforms are marked. Fibers that contain MHC-I isoforms (type I, or slow fibers) are considerably slower, and as a consequence generate less power, than the two other types (MHC-IIA and MHC-IIX). Type I fibers are on average one-quarter to one-third slower than the other two types and also have a slower rate of force development. MHC-IIX isforms are the fastest to shorten and are capable of generating the highest power outputs.

Human skeletal muscles are not homogeneous; rather, each muscle comprises a mixture of fast- and slow- contracting fibers depending on the myosin isoforms, which are expressed and thus show differences in their contractile characteristics. This relates in large part to their functional roles. The calf muscle, for instance, is a postural muscle with the soleus muscle being dominated by slow-contracting, but fatigue-resistant, MHC-I fibers. For activities that require the generation of large power outputs, a large muscle with a higher proportion of fast myosins is obviously an advantage. Unfortunately, as we shall see later, the reverse situation exists in aging muscle, which is both smaller and slower.

Reprinted with permission from Lexell J, Taylor C, Sjostrom m (1988) What is the cause of the ageing muscle? Total number, size and proportion of different fiber types studied in whole vastus laterals muscle from 15- to 83- year- old men. *Journal of the Neurological Sciences* 84: 275–294.

Properties of Aged Muscle

Muscle Mass and Force Production

As the force generated by a skeletal muscle relates most closely to its size, a large decrease in whole muscle cross-sectional area will have a dramatic effect on muscle force production. Muscle cross-sectional area can be estimated using various techniques, such as ultrasonography, computed tomography scanning, and magnetic resonance imaging, while whole body potassium and nitrogen and the 24-hour excretion of creatinine have been used as markers of whole body muscle mass. The numerous studies that have been performed in relation to increasing age clearly show that there is a marked decrease in muscle mass (sarcopenia) in aged muscle (**Figure 2A**). The similarity between the effects of disuse and those of aging on skeletal muscle has led to the suggestion that many age-related changes in muscle may relate to a disuse atrophy phenomenon, such as that seen in a leg that has been immobilized. Indeed, the extent to which the decline in muscle mass results from a preprogrammed loss of contractile tissue, or from a reduction in overall activity resulting in disuse atrophy, is one of the important questions still to be resolved in aged muscle. Studies that have analyzed whole sections of the vastus lateralis muscle indicate that the reduction in skeletal muscle size is due to both a loss of muscle fibers (**Figure 2B**) and a reduction in fiber size, particularly in the size of type II fibers. The latter factor, however, plays a relatively minor role. Associated with this decline in muscle mass is a decline in muscle strength. Data in this regard have primarily come from cross-sectional studies in which muscles from aged individuals have been compared with those of young and middle-aged adults. This method does have intrinsic limitations given differences in nutritional status and health care between generations. However, the findings of numerous studies are reasonably consistent. They show that a decrease in strength can occur in muscles of the upper and lower limb, in both distal and proximal locations, and that for both males and females the reduction in strength across the adult

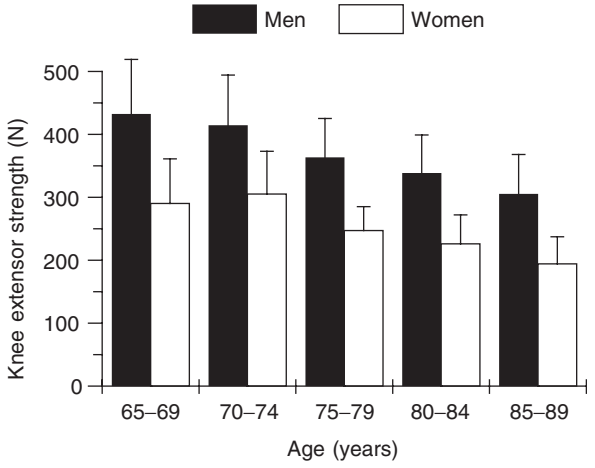

Figure 3 The effects of age on voluntary isometric knee extensor strength (±SE) in men and women ($n = 10$ in each age group). Data from Skelton DA, Young A, Greig CA, and Malbut ke (1995) Effects of resistance training on strength, power, and selected functional abilities of women aged 75 and older. *Journal of the American Geriatrics Society* 43: 1881–1887.

range tends toward being curvilinear, with the onset of the seventh decade being a turning point for an accelerated decline (see **Figure 3**). Between the ages of 30 and 80, deficits in muscle strength have generally been found to be in the region of 30% for the arm muscles and 40% for the leg and back muscles.

It has been suggested that the decline in force production in elderly muscle may relate, in part, to the ability of elderly subjects to activate fully the total muscle mass during a maximum voluntary contraction. However, even when the muscle is activated by direct electrical stimulation, aged muscle has been shown to be markedly weaker than that of young muscle. Indeed, the decline in force production has been shown to be greater than the decrease in muscle mass. This decrease in specific tension has partly been attributed to the increased content of fat and connective tissue in elderly muscle, resulting in overestimates of aged muscle cross-sectional area. However, there are reports that single muscle fibers obtained from human muscle biopsy samples and studied *in vitro* also produce less force per unit area than those from younger counterparts. In aged rodents, paramagnetic resonance studies of chemically activated fibers have revealed a lower proportion of myosin cross-bridges in the strong-binding high force (22%) compared with young fibers (32%). Furthermore, in aged rodents there is also evidence to suggest that the force loss is absent during stretching or eccentric contractions. There are similar observations in studies comparing young and elderly people, although the mechanisms underlying this phenomenon are as yet not clear.

Contractile Characteristics and Muscle Composition

The force–velocity properties of homogeneous muscles (comprising either virtually all type I or all type II fibers) of aged rodents have been reported to be essentially unchanged, but human muscles are far from homogeneous. As the shortening properties of skeletal muscle are closely regulated by the MHC isoforms they express, a reduction in the relative proportion of the fast myosin isoforms will have a reducing effect on the velocity at which the muscle will contract. A reduction in the ability of the muscle to shorten quickly, coupled with a decline in muscle force production, will have a marked effect on the power-producing ability of the muscle. Muscle fibers are traditionally determined on the basis of their ATPase histochemical staining properties. The question of whether there is a change in the distribution of histochemically determined fiber types with old age has been controversial. In studies in which whole muscle cross-sections of the vastus lateralis have been examined, it has been suggested that there is not a reduction in the proportion of slow, type I fibers, but a decrease in the area occupied by the fast, type II fibers. The histochemical technique, however, does not clearly show fibers that express more than one MHC isoform. Using single-fiber electrophoresis, elderly muscle has been shown to possess more of these 'hybrid' fibers. Furthermore, irrespective of a switch in myosin isoforms, the reduced volume of type II fibers means that there is a reduction in the relative amount of fast myosin in the muscles of elderly people.

Implications for Changes in Contractile Function

A decrease in force production in old age coupled with a slowing in shortening characteristics has a dramatic effect on muscle power production. Furthermore, the rate at which force can be developed is also slowed, relating in part to alterations in the Ca^{2+} release-repute kinetics from the sarcoplasmic reticulum. This results in impaired functional ability reflected in increased difficulty in performing everyday tasks such as rising from a chair or climbing stairs. As well as a decrease in power-generating capacity, a slowing of contraction results in a reduced capacity for the rapid production of force in protective reflexes, thus amplifying the impact of muscle weakness on mobility and increasing the risk of falls. Importantly, these changes are worse for an elderly person than they would be for a young person losing an equivalent amount of strength. This is because despite the loss of muscle mass, the older person's whole body mass remains relatively unchanged as fat

mass increases. This has implications for power output during physical tasks. A weaker muscle contracting against a similar load, whether it be an unchanged body mass or a 20 kg bag of potatoes, must use a greater proportion of its maximum force-generating ability. The force–velocity relationship of muscle dictates that this must be at a slower speed. Thus, for high force contractions, this slower speed of movement means less power.

Changes in the Nervous System and Motor Unit Properties

A key question regarding the loss of muscle mass with increasing age is whether this is a change intrinsic to the muscles themselves, of neural origin, or a combination of both. It is known that there are a reduced number of alpha motor neurons in the spinal cord of elderly people and that nerve conduction velocity decreases, with the peripheral segment reflex loop being significantly delayed in aged individuals. Furthermore, impaired neuromuscular transmission and reduced muscle membrane excitability seem to be further consequences of old age. Electrophysiological evidence also suggests that there is a loss of functioning motor units, but with an increase in the size of those motor units remaining, that is, each remaining motor unit contains more muscle fibers. This phenomenon has implications for fine control of movements and coordination.

There is experimental evidence that in this reinnervation process there is a preference for a specific fiber to be reinnervated by its own type of motor nerve. Type grouping is found in muscles of elderly humans ($> \sim 75$ years), which is probably a sign of a less effective reinnervation procedure. Of note is the extent to which these neurological phenomena vary between muscles, with the anatomically more distal regions seemingly most affected.

Skeletal Muscle Metabolism

With a weaker muscle, the relative forces and power outputs required to perform tasks that require given absolute loads (such as body weight) are higher. Thus, in one sense the older muscle might appear to be more fatigable. In addition, age-related mutations in mitochondrial DNA might suggest a cause for reduced endurance of the aged muscle. However, there is little evidence to suggest that the intrinsic fatigue resistance of the aged muscle is lower than that of a young muscle. Muscle fatigue is determined by a number of physiological and metabolic phenomena relating to the type and intensity of exercise. The activation of fatigued muscle, as indicated by neuromuscular transmission, does not seem to be the limiting factor in old age, although there is some evidence of a decrease in the amount of Na^+-K^+ pumps in elderly muscle, which might reduce the clearance of K^+ during exercise-induced hyperkalemia.

Oxygen availability to individual muscle fibers is determined, in part, by the degree of capillarization. Similar capillary densities are observed in elderly men and women as compared with younger people (**Table 1**). During low-intensity exercise, ATP production occurs from the aerobic metabolism of glycogen and fat. Thus, despite reports of mutations in mitochondrial DNA, measurements of the enzymes responsible for the aerobic breakdown of glycogen in the Krebs cycle (e.g., citrate synthase, succinate dehydrogenase) and of fat through beta oxidation (e.g., 3-hydrox Co-A dehydrogenase) have been shown to be unchanged, or in some instances only slightly reduced, in old age (**Table 1**). Enzymatic capacity is inextricably linked to activity pattern, making interpretation of the effects of aging per se difficult; however, studies examining the muscles of activity pattern, or training status, in matched older and young individuals suggest no effect of the aging process. In contrast to low-intensity exercise, the demand for ATP is greatly accelerated during high-intensity exercise, such that its supply by aerobic metabolism cannot be maintained. During high-intensity exercise ATP is generated initially from the breakdown of phosphocreatine (PCr) and from anaerobic glycolysis. The enzymes regulating PCr

Table 1 Capillary density and oxidative enzyme capacity in muscle

	Young			*Elderly*			
				Sedentary			
	Sedentary	*Joggers*	*Athletes*	*(> 60 yr)*	*(> 80 yr)*	*Joggers (> 60 yr)*	*Athletes (> 70 yr)*
Capillaries (cap. fiber^{-1})	1.2	1.6	2.7	1.4	1.5	1.7	2.5
Citrate synthase (μmol g^{-1}min^{-1})	31	42	82	34	39	34	61
3-Hydroxyacl-CoA-dehydrogease (μmol g^{-1}min^{-1})	27	36	76	29	32	32	58

breakdown (creatine kinase) and glycolysis (phosphorylase, hexokinase, lactate dehydrogenase, phosphofructokinase) do not appear to be adversely affected by aging in sedentary humans. Moreover, the availability of the high-energy substrates (ATP, PCr) is similarly not affected.

What Causes the Change in Aging Muscle?

The mechanisms underlying changes in skeletal muscle are unclear. Whether the aging process represents a cell- and organ-specific response to genetic preprogramming, or whether other factors relating to a decrease in usage, either coupled to a general reduction in physical activity or to a reduction imposed by other factors not directly related to the neuromuscular system, is not known. For example, changes in the amount of or sensitivity to different circulating hormones may be responsible for some of the alterations observed in aged muscle. It has been suggested that the decrease in muscle mass and thus force-generating capacity may be at least partly related to changes in the amount of anabolic hormones such as growth hormone (GH), insulin-like growth factor-I (IGF-I), and testosterone. In women, a significant decline in muscle force production has been shown to correspond to the time of onset of menopause, when estrogen levels are falling, independent of a loss of muscle mass. This specific strength loss can be offset by hormone replacement therapy. The thyroid hormones may also be of importance, as in rats they have been shown to have a marked influence on the expression of myosin isoforms and on contractile characteristics. However, the extent to which the effects of aging per se and the effects of various experimental interventions reported in animals can be extrapolated to humans remains unclear.

Under the microscope, aged skeletal muscle exhibits features of both neuropathy and myopathy with a predominance of neuropathic alterations. These neuropathic alterations include the presence of small angulated fibers and increased fiber type grouping. Myopathic-like changes include dilation and proliferation of the sarcoplasmic reticulum–transverse tubular (SR-T) system, myofilament disorders, streaming of the Z band and rod formation, accumulation of lipofuscin and lipid droplets, infoldings of the sarcolemma, aggregation of muscle nuclei, and alterations in the amount and structure of mitochondria.

Several hypotheses have been proposed for the deterioration of muscle and muscle function. These include the theory that as a result of random damage (wear and tear) or due to damage from free radicals, errors occurring in the duplication of DNA increase, so that when a significant number of errors accumulate, abnormal mRNA and protein molecules are formed that do not function normally. Free radicals are produced from the oxidation of free fatty acids. These oxygen molecules that bear free electrons are highly reactive and can easily tie up and weaken proteins and cause damage to DNA. This theory has particular relevance for skeletal muscle, given the large aerobic energy metabolism in exercising muscle. Another theory suggests that there is an inherent biological clock: just as some genes control embryonic development, so other genes program the aging processes. The changes associated with old age may thus result from the normal expression of a genetic program that begins at conception and ends in death.

Adaptability of Aged Muscle to Physical Activity

As mentioned previously, an unresolved question is whether the alterations observed in the muscles of elderly people are solely a function of age or whether usage of muscle when growing old also plays a role. Human skeletal muscle is very plastic, and disuse and usage are critical determinants of both the size of a muscle fiber as well as its qualitative characteristics, such as the isoform pattern of contractile proteins, energy-related enzymes, and membrane-bound regulatory proteins. This plasticity appears to be present not only in muscles of the young, but also in elderly people.

Increasing Muscle Size and Strength

Both cross-sectional and longitudinal studies have shown the efficacy of high-resistance strength training in improving muscle mass and function in older people. In 70-year-old men who have been physically active through strength (high-resistance) training, muscle force and muscle cross-sectional area are comparable to those of sedentary young adults. Muscle cross-sectional areas of both arms and legs can also be maintained in these elderly people. This is accomplished by a larger mean fiber size to compensate for a reduced number of muscle fibers. Studies of elite master weightlifters show that they have superior strength and power output when compared with non-trained, healthy, age-matched individuals. However, the age-related rate of decline is actually similar for both (**Figure 4**).

In recent years, several well-controlled longitudinal studies have been performed to evaluate the effect of increased usage through strength training by elderly people. The general finding is that, as with young adults, task-specific muscle function can be

vastly improved in just a few months by regular training (**Figure 5**). At the same time, the changes in maximum isometric strength and muscle cross-sectional area as a result of training are, as is the case with young people, not as impressive. This suggests that the elevation in, for example, 1RM (one repetition maximum) is primarily a function of improved neural drive. The positive effects of strength straining appear to be similar even in those subjects considered to be the oldest-old (>85 years). A critical factor for obtaining these marked improvements is that the training is characterized by a regime of high-resistance loading with few repetitions. Thus, the total time for training may amount to only 10 min per day. It appears favorable to use training loads exceeding 70% of 1RM. Such high muscle force developments can be sustained by elderly people. This has been shown repeatedly, not only in small studies with small numbers of selected elderly subjects, but also in population-based samples (**Figure 6**).

The mechanisms by which muscle mass is increased in response to strength training are becoming better understood. For a muscle to get larger there must be a net gain in protein, by an increased rate of synthesis, a reduction in degradation, or both. The older muscle has a slower rate of muscle protein turnover as determined by studies in which labeled amino acids are infused and their rate of incorporation into muscle

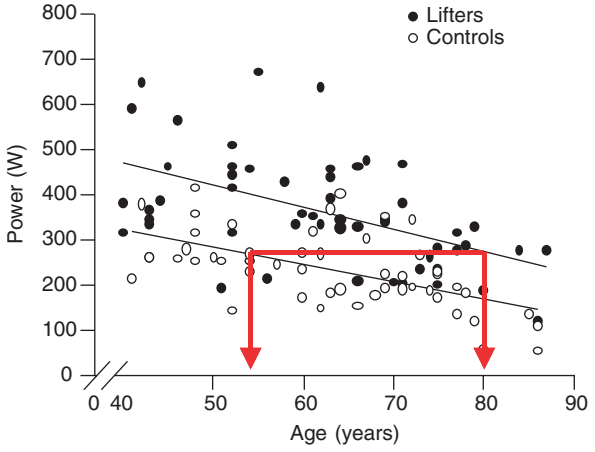

Figure 4 Power output from the lower limb extensor muscles in master weightlifters and non-active but healthy control subjects. The data show that on average the weightlifters were 35% more powerful, and that both groups had a similar 1.6% per annum decline. The red arrows indicate that power output from an 85-year-old weightlifter is equivalent to that of a non-active subject 25 years younger. Adapted from Pearson *et al.* (2002) Muscle function in elite master weightlifters. *Medicine and Science in Sports and Exercise* 34: 1199–1206.

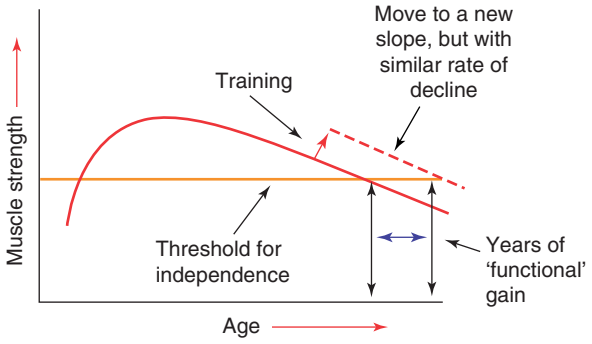

Figure 6 A hypothetical diagram showing the change in muscle strength with increasing age and the potential for improving function through strength training.

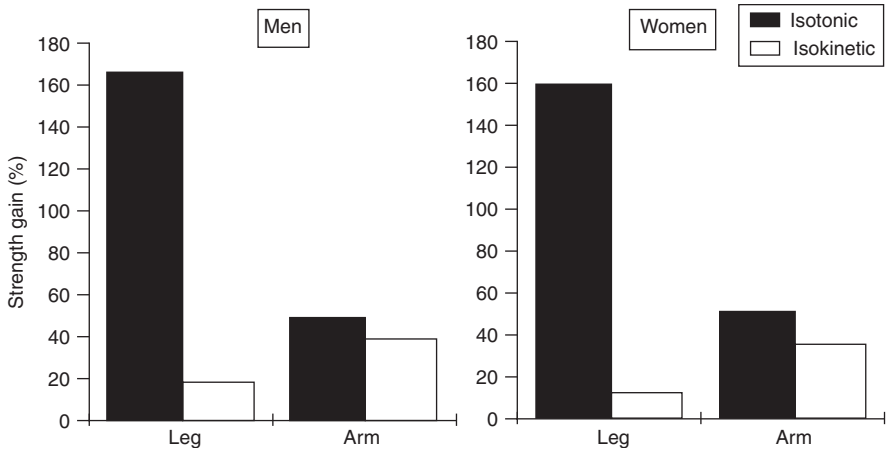

Figure 5 The effects of high-load (free weights) resistance training on the isotonic and isokinetic (constant speed at $30^{\circ}\,s^{-1}$) strength of the knee extensors and elbow flexors in elderly men and women aged 70–77 years. Note the similarity in responses between men and women, the greater improvement in isotonic, compared with isokinetic strength and the greater improvement in the leg compared to the arm muscles, despite similar training loads (three sets of six repetitions at 85% 1RM, three times per week for 11 weeks). Data from Lexell J, Dowham DY, Larsson Y, Bruhn E and Morsing B (1995) Heavy-resistance training for Scandinavian men and women over 70: short and long-term effects on arm and leg muscles. *Scandinavian Journal of Medicine and Science in Sports* 5: 329–341.

measured. However, older muscles seem as responsive to increasing rates of protein synthesis as young muscles when undertaking high-resistance exercise. The intracellular events that initiate increased protein synthesis are also becoming understood and relate to the upregulation of local growth factors in muscle such as IGF-I, which have autocrine and paracrine actions. These stimulate increases in protein synthesis by activating intracellular signaling events to initiate and facilitate translation and by activating the satellite cells. These are the muscle stem cells, which when activated by overload can either differentiate into myoblasts and ultimately form functioning contractile proteins, or remain in the mononucleate state and function as new nuclei to manage the enlarged muscles fibers. Older people have been shown to upregulate IGF-I and its splice variants (IGF-IEa and mechano growth factor, MGF) as a result of high-resistance exercise training, although there is some evidence to suggest that they may be less able to do so than younger people. Older people are also able to increase satellite cell number in response to strength training. In healthy elderly subjects, nutritional supplementation per se does not add to the improvement in strength, but the appropriate timing of protein intake shortly after exercise may help to facilitate the adaptation process.

Muscle Fiber Number

The role of physical activity in retarding the rate by which muscle fibers are lost with age is not clear. Indirect estimates based on measurements of cross-sectional area of the muscle and mean muscle fiber size suggest that active muscles of elderly people may contain more fibers ($\sim$15%). No thorough evaluation has been performed to estimate muscle fiber number with brief periods of training in elderly subjects. With small and similar changes observed in mean muscle fiber area and whole muscle cross-sectional area, it is unlikely that the training has an effect on the number of muscle fibers. It may, however, if the training period is extended. With daily strenuous muscle usage, muscle fiber number has been shown to be maintained at a 30% higher level in active compared to inactive rats. Thus, slowing the rate by which muscle fibers are lost may be a significant factor in maintaining muscle mass in the elderly. It needs to be demonstrated whether the less marked loss of muscle fibers observed with muscle usage is due to the death of fewer spinal motor neurons or to an increased reinnervation activity of the remaining functional peripheral motor nerves.

Muscle Fiber Types

Lifelong physical activity may affect muscle fiber type composition. Strength-trained elderly men have been shown to have the highest percentage of type II fibers, in both leg and arm muscles. In contrast, elderly joggers have the highest percentage of slow fibers in the leg muscles. Similar observations are available on elite master athletes who had been runners all their lives. Notably, however, muscles that have been dynamically active for a lifetime may have 20–30% more slow-twitch fibers. More specific methods to characterize the isoform pattern of the contractile proteins such as immunocytochemistry and single-fiber electrophoresis give a similar pattern of change as the one described previously.

Differences in muscle fiber composition comparing young and older sedentary people tend to be more marked in the leg than in the arm muscles. Whether this is due to differences in muscle usage is not known. In a small number of very active elderly runners studied, the coexpression of MHC isoforms in the leg muscles was found to be similar to that found in young subjects, while strength training also reduces the degree of coexpression. It is a possibility than an exercise stimulus aids in more proper regulation of gene transcription in the elderly.

No change in muscle fiber types has been observed in longitudinal studies as a result of training, but that does not exclude the possibility that changes could occur, provided that the duration of the training is longer (many months), and techniques more sensitive than traditional histochemistry are used to identify the MHC isoforms.

Capillaries and Mitochondrial Enzymes

Muscles of endurance-trained elderly men contain a very high number of capillaries, and their mitochondrial enzyme activity levels are high (**Table 1**). Indeed, these men are at a level similar to young endurance athletes. Less regular and strenuous endurance activities are also effective, although the absolute level of adaptation is smaller than that in top-trained athletes, but nevertheless is above that observed in young sedentary men.

Oxygen delivery to muscle during exercise is reduced in elderly subjects due to a drop in maximal heart rate and stroke volume. This also occurs even in very active elderly subjects, as the reduction in maximal heart rate is unaffected by the level of physical activity. With a maintained capacity of the muscle to receive a given blood flow and to utilize oxygen, there is a relative overcapacity for aerobic metabolism in the muscle of the elderly. The functional significance is a more favorable muscle metabolism during exercise, as indicated by a low blood lactate accumulation and a low respiratory exchange ratio, that is, a large lipid oxidation, even at quite high exercise intensities.

Little is known about the effect of short-term training on aged muscles in humans, as it has not been a focus of many studies. As the successful training programs for improving strength incorporate few repetitions and each session is of short duration, it is highly unlikely that muscle capillaries or mitochondrial enzymes would be enhanced. Rather, if there is fiber enlargement, a dilution effect may occur, with less capillaries and mitochondria present per unit area or volume.

In endurance training studies on rodents, there is an increase in both the number of capillaries and mitochondrial capacity, clearly demonstrating that aged skeletal muscle maintains its capacity to adapt to demands in regard to aerobic metabolism.

Membrane-Bound Regulatory Proteins

Na^+-K^+ pumps and Ca^{2+}-ATPase of the SR system are affected by physical activity, and as for other muscle characteristics, the effect is specific to the type of muscle usage. High-resistance activities over a lifetime maintain the Na^+-K^+ pump better than endurance activities, whereas the reverse is true for Ca^{2+}-ATPase. These maintained capacities are likely to have a functional role by retarding the rate at which fatigue develops during high-intensity and endurance exercise.

In rodents, a training-specific effect is observed for both Na^+-K^+ pumps and Ca^{2+}-ATPase of the SR system, confirming the finding in cross-sectional studies. Resistance training is needed to affect the [^{3}H]ouabain binding sites, and repetitive monotonous activation affects the Ca^{2+}-ATPase. Studies have also shown that the age-related slowing in the rate of Ca^{2+} reuptake by the sarcoplasmic reticulum can be reduced in older people by strength training.

Conclusion

The progressive decline in muscle force (strength) is primarily related to a loss of muscle mass (sarcopenia). The loss of muscle power is even greater, as the effects of a loss of muscle mass are exacerbated by a relatively greater loss of the fast (type II) myosins. From an anatomical perspective, the loss of muscle mass is caused by a reduction in muscle fiber and motor unit number. However, skeletal muscle retains the ability to adapt to overload, even in very old age. But the evidence from older individuals who have maintained very high levels of physical activity suggests that there are age-related changes in muscle, which are independent of changes that may occur as a result of lower levels of physical activity in later life. In other words, the capacity of muscle to improve its function is retained. This will improve function, but not ultimately prevent an age-related decline. Nevertheless, what this means in absolute terms is the 'buying back of years.' Although master weightlifters appear to have a rate of decline in muscle power similar to non-active individuals, in absolute terms they are far superior, such that their lower limb extensor power-generating ability is equivalent to non-active individuals some 25 years younger then themselves (see **Figures 5 and 6**).

Other qualities of skeletal muscle, such as capillaries, substrate availability, and energy-related enzymes, in elderly people are kept at levels comparable to young adults, and the response to training is similar to that observed in young people. As with young people, there is a very high degree of specificity in the response to training. High-load strength training affects mainly muscle fiber size and fiber number as well as ion pumps, whereas endurance training primarily affects capillary proliferation, mitochondria, oxidative enzyme activity, and the Ca^{2+}-ATPase of the SR system.

Finally, it is clear that some of the alterations that are observed in the muscles of healthy elderly people relate to a lack of muscle usage. The good news is that muscle remains sensitive to increased activity even in very late life.

Glossary

Age-Related Neurodegenerative Diseases – Diseases in which age is a primary risk factor and that are characterized by atrophy or death of nerve cells; examples are Alzheimer's disease and Parkinson's disease.

Neurotransmitters – Chemicals mediating the transfer of information between nerve cells at synaptic junctions.

Neurotrophic Factors – Proteins regulating survival and morphological plasticity of nerve cells.

Introduction

Neurotransmitter release and the receptor mechanisms stimulated by them are key determinants of brain function and ultimately serve to modulate a variety of complex body functions such as movement, learning, memory, mood, and sensory processing. By comparison, neurotrophic factors are proteins that regulate the survival of nerve cells and are required for normal development and maintenance of structural integrity of the nervous system. The function of neurotransmitters and neurotrophic factors changes during aging. However, such changes are selective, and there is no evidence of global decline. Neurotransmitters and neurotrophic factors are also affected by neurodegenerative disease and play a central role in the pathophysiology of the disease process. Current therapies and approaches to future therapy of such diseases are based on influencing neurotransmitter and neurotrophic factor mechanisms.

Role of Neurotransmitters in Brain Function

Nerve cells are the functional units of the nervous system and form physical contacts with one another to facilitate intercellular communication throughout the brain and spinal cord. The concept that neurons are independent units and can form close functional contacts to permit the transfer of information from one cell to another is called the neuron theory of brain function. This theory was first proposed by the Spanish neuroanatomist Santiago Ramon y Cajal at the end of the nineteenth century and has formed the basis of understanding how the brain functions for over 200 years. The chemical signal that transfers information from one neuron to another is called the neurotransmitter, and in the early 1900s Sir Charles Sherrington, the English Nobel Laureate, coined the term synapse to describe the site at which two neurons come into contact.

Synapses in which neurotransmitters communicate information from one cell to another are called chemical synapses. Presynaptic information is carried by the axon as an electrical impulse from the cell body to the axon terminal of the presynaptic cell, where it is converted into a chemical signal. This chemical signal, or neurotransmitter, is released in small quanta from membrane-bound vesicles (synaptic vesicles) and crosses a physical gap (about 20 nm) between the pre- and postsynaptic neurons, called the synaptic cleft (**Figure 1**). Transport of the neurotransmitter across the synaptic cleft is carried out by simple diffusion and does not require the use of an energy-dependent mechanism. Upon arrival at the postsynaptic cell, the neurotransmitter combines with a protein receptor embedded in the cell membrane that is specifically designed to bind with the neurotransmitter. Binding of the neurotransmitter to the receptor initiates a series of postsynaptic cellular events that ultimately serve to modulate a variety of complex body functions such as movement, learning, memory, mood, and sensory processing. Local postsynaptic effects last as long as the neurotransmitter remains bound to the receptor. Neurotransmitters are eventually deactivated by a degrading enzyme or transporter protein that takes the neurotransmitter back into the presynaptic nerve terminal. In this way, transmission of information between nerve cells is unidirectional and does not involve the direct transfer of the electrical signal from one cell to another.

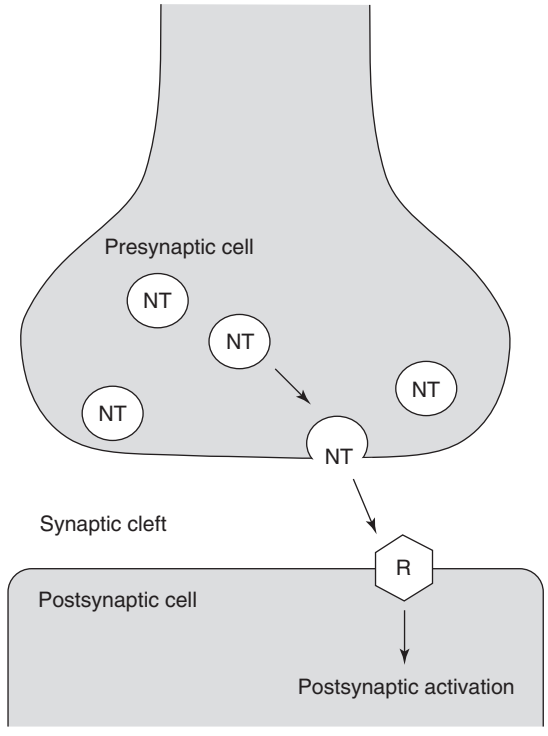

Figure 1 Schematic drawing of chemical synapse. Neurotransmitter (NT) is released in small quanta from synaptic vesicles at the presynaptic terminal. The neurotransmitter diffuses across the synaptic cleft and binds to the receptor (R) in the postsynaptic membrane.

A molecule is considered a 'classical' neurotransmitter if it meets several criteria. First, the molecule must be synthesized and released by the presynaptic neuron. Second, it reproduces the same effects in the postsynaptic cell as when the presynaptic neuron is independently stimulated. Third, postsynaptic effects of the molecule can be blocked by competitive antagonists, and fourth, there is an appropriate mechanism to inactivate the molecule in the synaptic cleft. Although more than 100 small peptides have been shown to be biologically active in both the central and peripheral nervous systems at the level of the synapse and can alter the electrophysiological state of the postsynaptic cell, few have passed the rigorous criteria for being considered a classical neurotransmitter. These include the biogenic amines (dopamine, norepinephrine, epinephrine, serotonin, histamine), acetylcholine, γ-aminobutyric acid (GABA), glycine, and glutamate.

Individual neurons contain only one type of neurotransmitter, but these neurotransmitter-specific cells are distributed across various regions of the brain and spinal cord. Like dopamine neurons of the substantia nigra (SN), they can be clustered in specific ganglia or nuclei, or, like glutamate neurons, can be spread out ubiquitously across the nervous system, serving as a component of multiple neuroanatomical pathways. In addition, based on previous clinical, neuropathological, and experimental studies, it is clear that certain biological functions can be linked to specific neuroanatomical pathways that use a particular neurotransmitter to communicate information between neurons. Examples of this functional/biochemical correlation include the dopaminergic neurons of the SN in the regulation and coordination of movement and cholinergic neurons of the basal forebrain in learning and memory. The obvious corollary to this anatomical organization is that damage to a neurotransmitter-specific neuroanatomical pathway as part of aging or disease can underlie primary characteristics of the disease. This is most readily seen in Parkinson's disease, in which loss of dopamine neurons is directly involved in symptomatic movement problems, and Alzheimer's disease, in which cognitive impairment is linked with loss of acetylcholine activity. However, it is apparent from the neuropathological literature that neurodegenerative diseases of the central nervous system (CNS) are not the result of the loss of a single neurotransmitter system but are composites of global neurotransmitter deficits and other neuropathologies that

result in the generation of the range of behavioral characteristics typical of a particular disease state (*see* Brain and Central Nervous System).

Role of Neurotrophic Factors in the Nervous System

Neurotrophic factors are proteins that regulate the survival and developmental growth of nerve cells. Although the adult brain does not undergo the same degree of morphological change as it does during development, most adult neurons retain the ability to modify their morphology as a way to adapt to changes in their surrounding environment. This adaptive process, generally referred to as neural plasticity, is essential to the formation and maintenance of the wide network of limbic, striatal, and cortical circuits that regulate the complex array of human behaviors. Like neurotransmitters, neurotrophic factors act as chemical signals between cells and can effect short-term changes in synaptic activity as well as long-lasting changes in neuron morphology and neuron survival. However, neurotrophins are not directly involved in the propagation of signals along neural pathways in the manner that neurotransmitters are. Neuronal trophic support does not follow the unidirectional flow that neurotransmission does, but rather is derived from both antero- and retrograde sources, from other neurons as well as glia and other cell types (**Figure 2**).

Known neurotrophic factors include the neurotrophin family, consisting of nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), neurotrophin-3, and neurotrophin-4/5. Other factors that function as neurotrophic factors are ciliary neurotrophic factor and the family of glial cell-derived neurotrophic factor (GDNF) proteins, which include GDNF, neurturin, artemin, and persephsin. In addition, there are proteins with neurotrophic factor functions among the members of the fibroblast growth factor family, epidermal growth factor family, transforming growth factor (TGB-β) family, and insulin-like growth factors (IGFs). Growth factors act by stimulating specific receptor molecules embedded in the cell membrane and provide trophic support for responsive cells.

A biological role for the neurotrophins is particularly well established in the development of the peripheral nervous system. There, neurotrophins play an essential role in regulating the fate of precursor neurons of the neural crest and in the development of sensory neurons of the dorsal root ganglia. In the CNS, neurotrophins provide trophic support for the survival of neurons during embryonic development and can elicit short- and long-term adaptive changes in synaptic efficacy and neuronal morphology in the adult. It is believed that the maintenance of high levels of neurotrophins and their receptors in specific regions of the adult brain, such as the cortex and hippocampus, corresponds to areas that demonstrate a high level of neuroplasticity associated with learning, memory, and motor learning. Likewise, evidence suggests that when the adult brain is damaged by trauma or disease, these developmentally regulated neurotrophic mechanisms are brought back into play and form the basis for compensatory repair mechanisms critical for determining the limits of functional recovery that can be expected after brain injury.

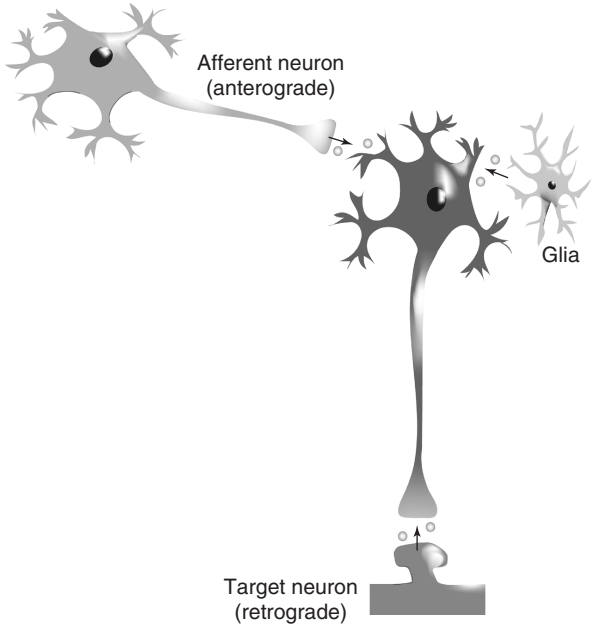

Figure 2 Possible sources of neurotrophic support. Neurotrophic support does not follow the traditional unidirectional flow that neurotransmission does, but rather is derived from both anterograde and retrograde sources as well as from adjacent glia. Sources include afferent neurons that synapse with other CNS and PNS neurons (anterograde), target neurons or tissues in other parts of the CNS or PNS (retrograde), and glial cells such as astrocytes adjacent to CNS neurons that produce growth factors.

Neurotransmitters and Neurotrophic Factors in the Aged Brain

Two of the most prominent principles that underscore gerontologic research in general and neurotransmitter and neurotrophic factor studies in particular are the following: (1) organisms age at different rates, as do different biological systems in their bodies, and (2) identifiable differences can be demonstrated between biological and chronological age among individuals of like age. The divergence between biological and chronological old age is most

obvious in the human population but is not limited to the human experience. Functional variability with age is a consistent feature across species and is closely tied to the variability in neurotransmitter and neurotrophin changes found in different regions of the nervous system. In addition, research conducted during the 1980s has forced us to reevaluate the traditional view that age-related changes in brain function can be represented by simple cell loss. Rather, it is now widely accepted that the aging nervous system functions as a composite of various adaptive responses in neurotransmitter and neurotrophin neurons that together preserve and repair the nervous system's neural networks against a background of progressive age-related cell dysfunction. In addition, it is well established that screening animals of like age for common behavioral characteristics and correlating behavioral changes with the anatomical and biochemical changes in specific neurotransmitter and neurotrophin systems is an extremely useful approach for studying mechanisms of 'usual aging,' abnormal aging, and disease.

The degree to which age-related changes occur in neurotransmitter systems that form the anatomical neural circuitry of the brain and spinal cord is variable at best. Studies that have reported on age-related morphological changes in neurons suggest that advancing age has a differential effect on cell loss and the biochemical content in different populations of neurotransmitter neurons in the same region of the brain. For example, it has been reported that aging in the SN of rodents is associated with a decline in the number of GABAergic neurons in the pars reticulata, but not dopaminergic neurons of the adjacent pars compacta. In addition, evidence suggests that the degree to which cell loss occurs in the same region of the brain for a particular population of neurotransmitter neurons varies in rodent, non-human primate, and postmortem human brain. For example, the lack of dopaminergic cell loss in the rat pars compacta of the SN is consistent with previous biochemical studies that reported small and inconsistent losses of dopamine and tyrosine hydroxylase activity in the nigrostriatal system of aged mice and rats. Similarly, anatomical studies in squirrel monkey have reported no difference in total cell number of dopaminergic neurons of the substantia nigra between young, middle-aged, and old experimental groups. In contrast, comparison studies in young and aged rhesus monkeys found a significant age-related decrease in nigral neurons accompanied by a substantial impairment in motor function. In postmortem human brain anatomical studies, dopamine cell loss is generally comparable to that found in the rhesus monkey. Specifically, cell loss ranges from 7 to 10% per decade up to 90 years of age; however, cell loss is not always accompanied by significant cognitive and motor deficits. Although the reason for the dissociation between the degree of cell loss and the onset of clinical symptoms is unclear, it has been suggested that while some dopamine neurons show signs of age-related atrophy or cell death, neighboring neurons may increase their rate of synthesis in order to compensate for this metabolic decline. This compensatory process, hypothesized to maintain the content within the normal range despite the metabolic decline in some cells, is similar to what has been reported in experimental studies of rats following acute neurotoxic lesions of the SN using the dopamine neurotoxin 6-hydroxydopamine (6-OHDA). Following an injection of 6-OHDA, some dopamine neurons of the SN show continual signs of neurotoxicity, atrophy, and cellular degeneration, while others increase their rate of dopamine synthesis to offset the death of neighboring cells. It may be suggested that a similar compensatory phenomenon occurs in normal aging and that individual neurons within the SN may be differentially sensitive to the effects of the aging process. However, the time over which these adaptive responses can compensate for age-related cell dysfunction is limited. Recent studies of this compensatory response in aging rats found that in the oldest animals, the capacity to increase dopamine turnover is lost. Similarly, following unilateral damage to the dopamine system in monkeys following intracarotid administration of the neurotoxin MPTP, increased turnover is maintained through middle age but is completely absent in older animals. These studies suggest that while the compensatory mechanisms designed to adapt to age-related neuronal damage are active during youth and middle age, they substantially decline in old age. Studies to determine whether lifestyle changes such as alterations in diet and exercise can push back the time when these compensatory mechanisms are no longer effective are only just beginning, but have shown promise. In particular, evidence suggests that an active lifestyle including structured programs involving mental and physical exercise can enhance personal well-being, increase cognitive function, improve cardiovascular health, and reduce the risk for developing dementia in old age. In addition, it is believed that the specific signaling pathways in the brain thought to be important determinants for maintaining a healthy brain include the neurotrophins BDNF and IGF and the neurotransmitters dopamine, norepinephrine, and serotonin.

The degree to which neurons that contain the same neurotransmitter are affected by age in different regions of the nervous system is also variable. For

example, studies have consistently reported a loss of cholinergic interneurons and activity of choline acetyltransferase, the rate-limiting enzyme for the synthesis of acetylcholine, in the striata of aged mice, rats, and humans. This may suggest that cholinergic neurons may be particularly vulnerable to the aging process. However, age-related cholinergic cell loss is not a general characteristic for cholinergic neurons of the basal forebrain, a region of the brain particularly involved in learning and memory. Most revealing, however, is the demonstration of the close association between functional and biochemical changes that occur in neurotransmitter neurons regardless of the age group examined. Previous studies used a variety of behavioral tests to divide rats of like age into behaviorally impaired and unimpaired age groups and have correlated cell number and biochemical content for a number of neurotransmitter systems with functional performance. Among the most robust relationships revealed by this approach is the correlation between changes in performance on spatial learning and memory tasks (e.g., Morris water maze, radial arm maze) and age-related changes in the hippocampus, in particular with age-related degenerative changes in cholinergic neurons. In addition, age-related impairments in learning and memory on inhibitory avoidance tasks have been correlated with the loss of norepinephrine from the locus coeruleus. Deficits in motor performance, as assessed by performance on a rod balance task, have been linked with an age-related increase in the number of atrophic GABAergic neurons in the striatum. Consistent with this evidence is the premise that the variability in functional performance increases with age and that deficits in specific behavioral parameters may or may not be correlated with alterations in selective neuroanatomical pathways in the brain. In addition, evidence suggests that age-related behavioral deficits, such as changes in cognition and motor function, are species specific. Thus, when data from neurogerontological studies are analyzed with age as the only independent variable, the ratio of functionally impaired versus unimpaired animals that constitute a specific sample population may directly confound the outcome of the experiment in terms of the relationship between age, behavioral performance, and neurobiological substrates. Furthermore, neurobiological changes that occur profoundly in some aged animals can be masked by the variability across old animal populations and can be parceled out only by relating neurobiological measures to behavioral performance.

The situation is further complicated by possible changes at the level of neurotransmitter receptors in the aged brain without significant cell loss or decreases in neurotransmitter content. Previous studies have found that the loss of neurotransmitter receptors is one of the more common characteristics of normal aging and is often correlated with age-associated changes in learning and memory, motivation, and motor function. Age-related changes in neurotransmitter function attributed to alterations in postsynaptic receptors have been described in varying degree in multiple neurotransmitter systems, including glutamate, dopamine, norepinephrine, GABA, and acetylcholine. A decrease in the NMDA glutamate receptor is one of the most consistent findings of neurogerontologic research, occurring across a variety of brain regions in species ranging from rodents to non-human primates. The magnitude of the decrease is routinely reported as between 20 and 50% and has been strongly correlated with hippocampal memory deficits in rats and monkeys. Likewise, decreases in the D1 and D2 dopamine receptors have been described in the striatum of rodents, non-human primates, and humans. In addition, in humans, an age-dependent decline in dopamine receptor activity has been confirmed in the cortex, striatum, and thalamus using non-invasive nuclear medicine techniques such as positron emission tomography (PET) and single photon emission computed tomography (SPECT). However, decreases in dopamine receptors do not always correlate with a functional decline across species. While loss of D1 receptors in the frontal cortex has been associated with age-associated cognitive deficits in executive function in humans, decreases in cognitive function mediated by the frontal lobe are not linked to loss of D1 receptors in aged rhesus monkeys. The variability between structural and functional change in aged animals again points to the necessity to screen aged animals so that behaviorally impaired animals are evaluated as a separate group from those that are not behaviorally impaired so as not to introduce unwanted confounds to the data analysis.

Much of the work regarding neurotrophins and aging has examined trophic effects at the cellular level. Evidence to support the hypothesis that mechanisms related to neurotrophic factors are involved in senescence is still emerging. Previous studies showed that the decline in the proliferative capacity of certain cells in culture seems to be associated with alterations in their response to growth factors. For example, the expression and functional response of receptors mediating the biological actions of epidermal growth factor (EGF) decline during the proliferative senescence of endothelial cells in culture. In addition, the effects of aging on trophic activity derived from striatum and relevant to the dopamine system have been studied in aging rats and non-human primates. For rats, striatal

trophic activity declines significantly in old age; at least part of this decline is attributable to decreased levels of GDNF. Following a unilateral 6-OHDA lesion, young rats increase their striatal trophic activity as a form of compensation, but this capacity is absent in old rats. In contrast, a different pattern of effects is seen in aging non-human primates. Advancing age correlates with an increase in combined striatal trophic factor activity, and this change is already present in middle age. Thus, primates may have an ongoing compensatory trophic reaction to aging-related changes in the dopamine system, but this mechanism does not appear to operate in aging rats. Dopamine system lesions in young adult non-human primates resulting from MPTP treatment, as with young rats, increases striatal trophic activity, but a further lesion-induced increase is not found in older animals above their elevated age-related baseline levels. These effects in non-human primates are not attributable to changes in either GDNF or BDNF. Taken together, these findings suggest the possibility that neurotrophic factor-related mechanisms are altered during the aging process and that a reduced sensitivity to neurotrophic factors may be responsible for some of the age-related declines in neuronal and behavioral function (*see* Models of Aging: Vertebrates).

Neurotransmitters and Neurotrophic Factors in Neurodegenerative Disease

The question of how changes in neurotransmitter or neurotrophin systems, considered to be part of normal aging, may contribute to the onset and progression of human neurodegenerative disease is the topic of much debate. Although it is well known that most degenerative diseases of the brain have a characteristic age of onset, it is unclear what role natural age-related changes in morphological and biochemical properties of neurotransmitter or neurotrophin neurons play in the progression of disease, or to what degree aging may affect different areas of the diseased brain. What are clear, however, are the facts that neurodegenerative diseases of the brain result from a composite of multi-neurotransmitter and possible neurotrophin deficits that are characteristic of a particular disease state and that classic neurodegenerative diseases of the brain, such as Parkinson's and Alzheimer's disease, should not be considered the natural endpoints of normal aging but rather represent disease states for which risk factors increase with age.

Another basic concept that is crucial for understanding the pathophysiology of neurotransmitter systems in human neurodegenerative disease is the notion that neurotransmitter neurons can compensate for disease-associated cell loss that can delay the onset of clinical systems for several decades after cell loss begins. The phenomenon of functional compensation was first observed in dopaminergic neurons of the nigrostriatal system in Parkinson's disease in the early 1970s when investigators reported that mild clinical symptoms were associated with a disproportionately large decrease (up to 80% loss) of striatal dopamine. Subsequent to this observation, numerous investigators have developed models and theories regarding the etiopathology of transmitter systems as a causal factor for the development of neurodegenerative diseases of the CNS. Common to all theories regarding the pathology of neurotransmitter systems and human disease are the hypotheses that (1) clinical symptoms become evident only when the neurotransmitter content of a critical brain region is substantially depleted (i.e., by 80% in the case of Parkinson's disease), and (2) in the early stages of the disease, neurotransmitter cell loss or dysfunction is offset by adaptive changes in both pre- and postsynaptic neurons that functionally compensate for the death of neighboring neurons. The notion that neurotransmitter neurons can functionally compensate for cell death has led to the idea that the onset and progression of human neurodegenerative disease can be characterized by two stages of the disease process. Stage 1, or presymptomatic disease, spans the time from when disease-associated neurotransmitter cell loss begins (i.e., disease inception) to when cell loss and neurotransmitter depletion is sufficient to induce clinical symptoms (i.e., symptomatic threshold). As in the case of Parkinson's disease, presymptomatic clinical disease can last as long as 20 to 40 years prior to when the disease becomes clinically manifest. In comparison, stage 2, or symptomatic disease, is characterized by the progressive increase in the severity and complexity of clinical symptoms characteristic of the disease process and is positively correlated with the degree of neurotransmitter loss. Understanding the underlying mechanisms that relate to the loss of neurotransmitter neurons in human disease and how they relate to brain function is a prerequisite for developing new strategies to ameliorate age-related behavioral impairments and neurodegenerative diseases of the CNS. In addition, knowing that the brain retains a high level of functional reserve so that early neuron degeneration can occur without clinical symptoms challenges researchers to develop preventive therapeutic strategies that can be started before symptoms appear. Thus, a major goal of current clinical research is not just to treat the disease after it becomes debilitating, but to develop new tools that can improve early detection and identify at-risk groups. In this way preventive therapies can be

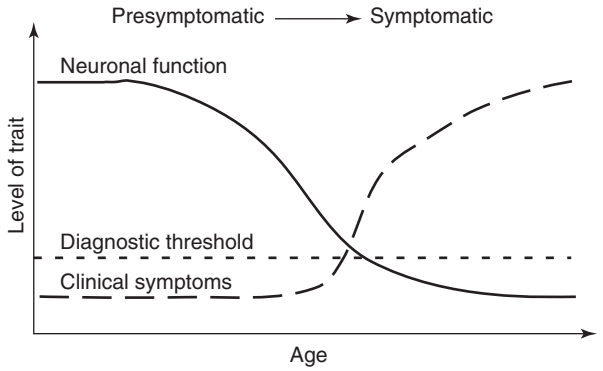

Figure 3 Schematic diagram of the progression of neuron loss and dysfunction in neurodegenerative disease. The presymptomatic phase is characterized by loss of neuron function without clinical symptoms. This period may last 20 or more years before the clinical symptoms of disease become manifest. By comparison, the symptomatic phase occurs when cell loss and neurotransmitter depletion are sufficient to induce clinically significant symptoms (i.e., diagnostic threshold).

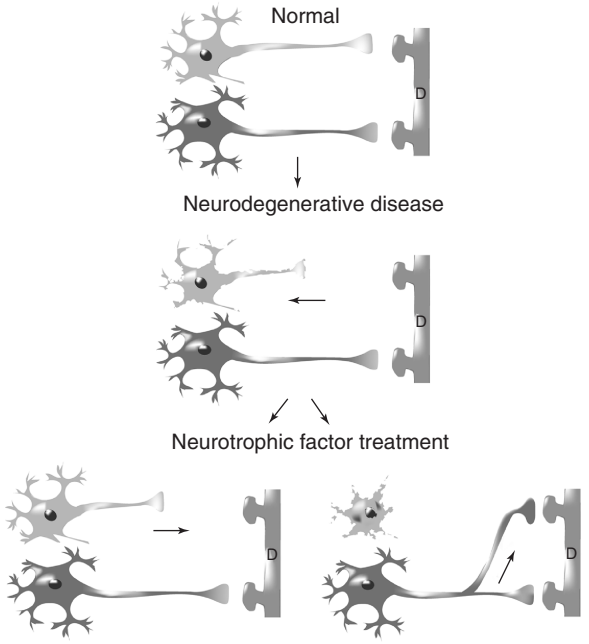

Figure 4 Schematic drawing depicting two nerve cells with synaptic contacts on target neuron dendrite (D). In neurodegenerative diseases such as Alzheimer's or Parkinson's there are atrophic changes in some neurons, including shrinkage of the cell body, retraction of the axon terminal, and loss of synapses. Two therapeutic approaches that have been proposed for neurotrophins as neuroprotective agents are shown. First, neurotrophins can reverse cell body and synaptic atrophy in the affected neuron and promote synthesis of proteins necessary for cell survival and axon growth. Second, neurotrophins may promote axon sprouting and reinnervation of lost synapses by neighboring neurons to compensate for cell loss and maintain functional performance.

directed at individuals in the preclinical phase of the disease in order to prevent or slow the progression of the disease process (see **Figure 3**).

Neurotrophic regulation has been linked to the degeneration that occurs in the age-related neurodegenerative diseases. Basic research indicating that these proteins regulate the survival and growth of neurons has created opportunities for using them therapeutically as neuroprotective agents. To date, three therapeutic approaches have been proposed for neurotrophins as neuroprotective agents. First, since it is known from developmental studies that neurotrophic factors are essential for cell survival, it is believed that treatment with neurotrophic factors in the presymptomatic phase of the disease may reverse the atrophy of the nerve cell's synthetic machinery and stimulate synthesis of proteins essential for cell survival, neurotransmitter release, and, perhaps, reestablish lost synaptic contacts (**Figure 4**). Second, since studies have shown that neurotrophins can modulate neural plasticity in the adult brain and that neighboring neurons can compensate for cell loss and atrophy of neighboring neurons, it is believed that activation of developmentally regulated neurotrophic mechanisms in response to aging or disease can form the basis for the compensatory repair mechanisms needed to slow or prevent the progression of the disease process. This hypothesis forms the basis not only for the development of new neurotrophin treatments but also for the promising new changes in lifestyle strategies that promote mental and physical exercise to enhance personal well-being, increase cognitive function, improve cardiovascular health, and reduce the risk for developing dementia in old age. Third, studies have reported that neurogenesis (i.e., forming new neurons) is not limited to the development, but continues throughout life in a few areas of the brain such as the hippocampus and subependimal zone of the ventricular system. In addition, data suggest that neurogenesis is modulated, in part, by the neurotrophin BDNF. It is believed that treatments targeting BDNF upregulation in the hippocampus may be useful therapeutic approaches to preserving brain function by stimulating cell division in part of the brain important for learning and memory.

Several strategies are currently being pursued to deliver neurotrophic factors to the brains of patients with age-related neurodegenerative diseases. In one example, NGF is provided by gene therapy to acetylcholine-producing neurons in the brains of patients suffering from Alzheimer's disease. These studies are based on a wealth of data from animal studies that predict that this approach will be safe and beneficial. Initial clinical observations have provided encouraging results. In a second approach, GDNF is being delivered to DA neurons in the brains of Parkinson patients by infusions through cannulas

implanted into the brain. Early observations in patients are encouraging. These early clinical experiences paint an optimistic picture for the future of neurotrophic factor therapy. However, many years of careful observations on a small number of patients will be necessary to establish the safety and efficacy of these experimental treatments.

O

Obesity

E Rudin, M Rincon, J Bauman, and N Barzilai, Albert Einstein College of Medicine, Bronx, NY, USA

Glossary

Body Mass Index (BMI) – A measure of body weight adjusted for height determined by a person's weight in kilograms, divided by height in meters squared.

Metabolic Syndrome (also known as Syndrome X, and the Insulin Resistance Syndrome) – A constellation of abnormal metabolism including glucose intolerance, abdominal obesity, dyslipidemia, and hypertension.

Obesity – Refers to an excess of body fat relative to lean body mass, typically with a BMI of 30 or higher.

Visceral Fat (VF) – The fat accumulated within the abdominal wall and around internal organs such as intestines and kidneys, resulting in abdominal adiposity.

Background

The prevalence of obesity is increasing at an alarming rate. Although it is difficult to estimate the actual numbers of overweight and obese people, data from the latest National Health and Nutrition Examination Survey (NHANES) show that about 33% of American adults are obese, and ~66% are either overweight or obese (see **Figure 1**), a 119% increase over the past three decades. Other continents show similar trends. The obesity epidemic is not limited to industrial countries; the increase is often faster in developing countries.

Obesity is independently associated with an increase in deaths from all causes. Additionally, obesity has been linked to many diseases that carry significant morbidity, mortality, and shortened life span, including diabetes and the metabolic syndrome, stroke, gall bladder disease, some cancers, obstructive sleep apnea, osteoarthritis, and stroke. Indeed, obesity-attributable US medical spending in 2002 has been estimated at $61 billion, accounting for 4.6% of total annual medical expenditures. This does not include the substantial indirect cost to society, including disability and lost time from work, which is estimated to be $51 billion. The growing prevalence of obesity thus has important public health implications.

Aging is often associated with an increase in adiposity, especially abdominal obesity, which can be increased even in the absence of a significant increase in body mass index (BMI), a measure of body weight adjusted for height. In developed areas of the world,

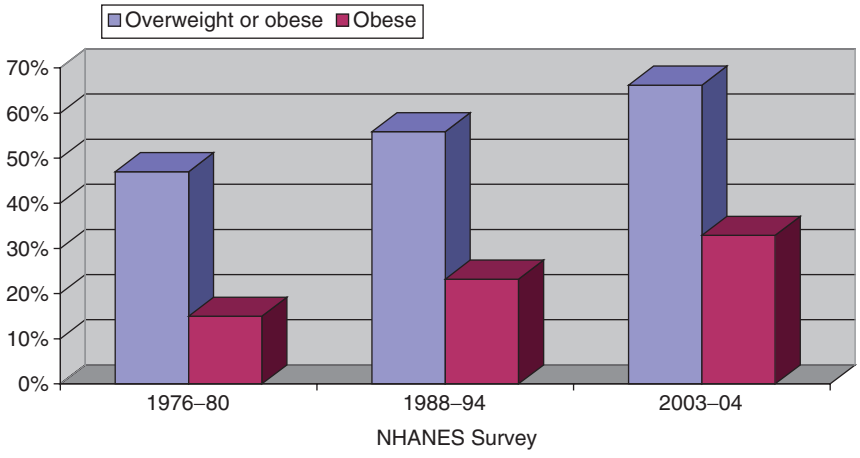

Figure 1 Age-adjusted prevalence of overweight and obesity among US adults, age 20–74 years. Adapted from the Centers for Disease Control and Prevention website (http://www.cdc.gov).

people tend to gain weight until about 60 years of age, and then their BMI begins to decline. However, in the elderly, the ratio between fat mass and lean body mass is usually increased. In addition, fat infiltrates other tissues, such as muscle and liver, and accumulates substantially at the visceral (abdominal) region. This increased visceral adiposity is largely due to an increase in visceral fat (VF). VF is defined as the fat accumulated within the abdominal wall and around internal organs such as intestines and kidney, resulting in abdominal adiposity. VF may have important health implications, as it is linked to the development of poor health outcomes and has a central role in the metabolic syndrome of aging. As the population ages and the obesity epidemic grows, our understanding of the relationship between increased adiposity and the poor health outcomes associated with the metabolic syndrome becomes increasingly important.

Definition of Obesity

The definition of obesity is arbitrary but generally refers to an excess of body fat relative to lean body mass. The problem of defining obesity arises because weight is a continuum, so an absolute cutoff dividing normal from overweight from obesity is difficult to determine. Several techniques are available for measurement of fatness. The gold standard technique for estimating body fat is called densitometry and involves underwater weighing of patients using the underlying principle that fat and non-fatty tissues have different densities. Using one of several available formulas, an estimate of body fat can be obtained. Another method is to estimate lean body mass based on nuclear isotope studies. These methods are not readily available, so other indirect estimates need to be used to estimate body fat.

Indirect methods for estimating body fat are more commonly used and more practical. They include skin fold measurements and tables that provide weight for height values that have been developed by life insurance companies to determine the lowest mortality risks. Currently the most widely accepted indirect measure of obesity is BMI. This value is defined as a person's weight in kilograms divided by the height in meters squared. The Center for Disease Control and Prevention defines overweight as a BMI between 25 and 29.9 and obesity as a BMI of 30 or higher. Healthy weight is defined as a BMI between 18.5 and 24.9.

What Causes Obesity?

Obesity results from an imbalance between caloric consumption and caloric expenditure over a prolonged period. Weight gain occurs when there is a greater consumption of calories than expenditure. The expenditure of calories is complex and results from likely combinations of metabolic, genetic, and individual factors. Genetics and environment may predispose to weight gain, but it is only the consumption of calories in excess of utilization that can cause weight gain.

In the developed world, there is easy access to large quantities of low-cost, high-calorie, high-fat foods. Over the last 20–30 years portion size has also dramatically increased. The combination of increased availability to nutrients and sedentary lifestyle has resulted in decreased energy expenditure with increased caloric intake. This combination is likely the main reason for the dramatic increase in obesity occurring worldwide. Additionally, medical care has advanced so that the average life span is rising despite the age-associated increase in body fat and obesity-related disease.

Although energy imbalance is the underlying reason for the obesity epidemic, there are some medical conditions, genetic diseases, and medications that may cause the imbalance to occur or worsen. Problems such as hypothyroidism (inadequate production of thyroid hormone) and Cushing's syndrome (an excess of endogenous steroid production) are examples of medical problems that can be associated with weight gain. Examples of genetic diseases associated with obesity include leptin deficiency (a hormone involved in the energy balance and discussed in detail later) and Prader-Willi syndrome (a complex disorder resulting in decreased muscle tone, short stature, mental retardation, behavioral problems, and excessive eating resulting in obesity). Some examples of medications that are associated with weight gain include antipsychotic medications (especially newer-generation medications) and steroids (chronic use), which may be given for a variety of inflammatory conditions. However, the aforementioned factors are rarely the primary cause of obesity and combined do not significantly contribute to the obesity epidemic.

Obesity and the Metabolic Syndrome

Concomitant with the global increase in obesity is the increase in the metabolic syndrome. The metabolic syndrome, also known as the metabolic syndrome of aging, syndrome X, and the insulin resistance syndrome, is a constellation of abnormal metabolism including glucose intolerance (impaired glucose tolerance, impaired fasting glucose, and type 2 diabetes), central (abdominal) obesity, dyslipidemia, and hypertension. All of these metabolic abnormalities are well-established cardiovascular (CV)

Table 1 NCEP: ATP III criteria for metabolic syndrome[a]

Risk factor	*Defining level*
Abdominal obesity	Waist circumference
Men	>102 cm (>40 in)
Women	>88 cm (>35 in)
Triglycerides	≥1.7 mmol/l
HDL cholesterol	
Men	<1.0 mmol/l
Women	<1.3 mmol/l
Blood pressure	≥130/≥85 mmHg
Fasting glucose	≥6.1 mmol/l

[a]Diagnosis is established when three or more of these risk factors are present.

disease risk factors. A low level of inflammation may coexist and contribute to, or serve as markers of, this increased risk.

The definition of the metabolic syndrome remains controversial. There are currently two well-established definitions of the syndrome using slightly different criteria. The World Health Organization (WHO) criteria are often limited to the research setting since they involve multiple glucose measurements or clamp studies. The National Cholesterol Education Program: Adult Treatment Panel III (NCEP: ATP III) guidelines (see **Table 1**) are more often used clinically because they require only a single glucose measurement. Based on the NCEP: ATP III definition of the metabolic syndrome, it is not surprising that the presence of the syndrome correlates well with the development of diabetes and death from coronary disease.

Future criteria for the metabolic syndrome may take into account racial or age-related differences in risk for disease. For example, Asians may have equivalent risk for the poor outcomes associated with metabolic syndrome at BMI of 23–24 compared to Caucasians with BMI of 30, and the elderly may have increased visceral fat despite normal BMI.

Fat Distribution, Caloric Restriction Principles, and Experimental Models

Not all fat is equally bad for your health. It is widely known that fat distribution is extremely important. There is increasing evidence for the deleterious effects of VF on aging. Waist-to-hip ratio (WHR) is an epidemiological tool that demonstrates a correlation between VF and development of diabetes mellitus, stroke, coronary artery disease, and mortality. This ratio is easily determined by dividing the measurement of waist circumference by hip circumference. A ratio greater than 1.0 for men and 0.9 for women correlates with adverse outcomes. People with higher WHR probably have a more central fat pattern and have body fat distributions sometimes described as android, apple-shaped, or having a 'beer belly'. People with a lower WHR probably have more fat distributed in the lower body, are referred to as gynecoid, or pear-shaped, and seem to have less risk from obesity-related diseases than those with central fat. The fact that different body distribution of fat may be worse than others partially explains why it is difficult to simply define obesity.

Experimental data in rodent models further support the relationship of VF to obesity-related illness. For example, caloric restriction (referring to a diet containing all of the necessary nutrients and vitamins but only a fraction of the calories of a diet with free access to food) reversed the age-related increases in plasma insulin, glucose, and glycosylated hemoglobin (a serum marker of glucose control over an extended period of time) to youthful levels. In fact, it restored liver and muscle insulin sensitivity to youthful levels independent of age. Furthermore, surgical removal of VF in rats has dramatically reversed the defects in insulin action. In a recent human study, removal of subcutaneous fat did not provide the same improvement in insulin sensitivity seen, underlining the importance of visceral fat as the biologically more active fat depot.

Fat as a Dynamic Organ

Adipose tissue is not simply a reservoir for excess nutrients, but rather an active and dynamic organ capable of expressing biologically active fat-derived peptides (FDPs). At times of acute injury, macrophages contribute to the release of these peptides and the term inflammatory markers is often applied, but in the basal state, adipose tissue is the predominant source of production. Some of these FDPs may have a role in the development of the metabolic syndrome of aging and other obesity-related diseases.

Leptin, a peptide derived from adipose tissue, acts through a cytokine receptor and is expressed and secreted in direct proportion to fat mass. Leptin exerts its effect predominantly through receptors in the central nervous system, specifically the hypothalamus, but it may also have peripheral actions. Genetic models of leptin deficiency are associated with marked obesity and diabetes. Leptin serves as a marker of energy sufficiency by rapidly decreasing during starvation and weight loss. With the development of increased VF during aging, leptin levels are increased in proportion to fat mass, but its activity to decrease appetite seems reduced. This failure of leptin action may be partially due to human eating behavior in which meals are eaten regularly regardless of plasma leptin levels, degree of appetite, or degree of obesity.

Tumor necrosis factor-α (TNF-α), previously known as lymphotoxin and cachetin, is thought to be involved in the wasting that occurs during illness and malignancy. In the basal state TNF-α level is proportional to fat mass and has been shown experimentally to be involved in the development of insulin resistance. *In vitro* studies have demonstrated that TNF-α decreases the insulin receptor tyrosine phosphorylation and downregulates several steps in the insulin signaling pathway. Additionally, TNF-α antagonists have been shown to improve insulin resistance in some models.

Adiponectin is highly expressed in adipose tissue and is one non-cytokine FDP that is thought to be protective. Unlike most FDPs, circulating levels are inversely proportional to obesity. Levels tend to be low in obesity and increase with weight loss. Animal models have shown that low adiponectin levels increase smooth muscle proliferation in response to injury, increase free fatty acid levels, and cause insulin resistance, while adiponectin administration improves insulin sensitivity. The pro-diabetic and pro-atherogenic effects of low adiponectin levels seen in the metabolic syndrome provide another link between inflammation and obesity.

Plasminogen activator inhibitor-1 (PAI-1) is the primary inhibitor of fibrinolysis and is highly expressed in adipose tissue, and may have a significant role in thrombosis. PAI-1 levels are correlated with adiposity and are significantly overexpressed in the adipose tissue of obese compared to lean animals. The relationship of PAI-1 to obesity provides a link between obesity and acute coronary events.

Interleukin-6 (IL-6) is another cytokine derived from adipose tissue. Its expression and circulating levels correlate directly with fat mass. Elevation of circulating IL-6 is a predictor of the development of cardiovascular disease and diabetes. Infusion of IL-6 results in hyperlipidemia, hyperglycemia, and insulin resistance in experimental models. Additionally, IL-6 decreases the expression of adiponectin.

Angiotensinogen (AGT), as well as the other peptides in the renin-angiotensin system, are produced in adipose tissue. The strong correlation between obesity and hypertension suggests that adipose tissue may play a role in blood pressure regulation. The correlation between circulating AGT levels and obesity/hypertension has been shown in animal studies in which overexpression of AGT results in hypertension while underexpression of AGT results in decreased blood pressures.

Other inflammatory cytokines, including serum amyloid A interleukin-1, interleukin-8, and interleukin-18, also increase with increasing body weight and may have a yet-undetermined role in the development of obesity-related disease.

Weight Loss

Weight loss improves many of the adverse health outcomes associated with obesity, including preventing or delaying the onset of diabetes, improving blood sugar control in those with diabetes, reducing low-density lipoprotein (bad cholesterol), raising high-density lipoprotein (good cholesterol), improving hypertension, improving symptoms of osteoarthritis, and providing an improved sense of well-being. Individuals must only lose a small percentage of their weight (~5–10%) to begin seeing these improved health outcomes. As many people know from their personal experiences, weight loss is difficult and lost weight is often regained for a variety of reasons. Returning to the original concept of energy balance, the formula for weight loss is predictable. To lose weight, energy expenditure must be greater than energy consumption. The first recommendation therefore is lifestyle modification with a combination of increased exercise and decreased intake (diet modification).

The amount of exercise needed to lose weight is variable. Current recommendations from the US Surgeon General is for adults to engage in an activity of moderate intensity (such as brisk walking) for 30 min daily or more strenuous activities (such as jogging) for 15–20 min daily. Additional exercise will increase energy expenditure and may result in further favorable health outcomes.

Caloric restriction through dieting is also essential for losing weight. The ideal diet has not yet been established, but the principle of reducing caloric intake along with ease of long-term compliance remains the cornerstone of any diet. The American Dietetic Association currently changes their recommendation periodically in an effort to determine the most helpful, practical diet, based on current data. The problem with short-term dieting is that weight loss can rarely be maintained once the diet has ended. Exercise may help maintain some of the weight loss.

Some medications exist for weight loss. These medications are moderately effective, although they often have side effects that limit their widespread use. The history of diet medications has been plagued with adverse health outcomes, including valvular heart disease and heart arrhythmias. Many of these medications have focused on increasing the metabolic rate or suppressing appetite.

One such medication that has been approved for use in the United States for weight loss is orlistat. This medication uses a novel mechanism to prevent the body from digesting a portion of the fat that has been ingested, thereby lowering the number of

calories absorbed. The undigested fat is excreted out of the body via bowel movements. This medication has minimal systemic side effects since there is little absorption; however, it results in uncomfortable changes in bowel movements such as oily discharge and increased frequency of bowel movements.

Another medication available for weight reduction is sibutramine. The mechanism of action is inhibition of norepinephrine, dopamine, and serotonin reuptake, resulting in weight loss from appetite suppression, possibly combined with an increase in thermogenesis from stimulation of adipose tissue. Use of this medication combined with diet and exercise results in modest reduction ($\sim$7%) in weight at 1 year, although sustained weight loss at 2 years is less robust.

Because of the high failure rates of lifestyle modification and medical therapies, surgical approaches for weight loss are becoming widely available. The most successful of these surgeries is the gastric bypass. It works by decreasing the size of the stomach, to achieve satiety earlier, as well as by bypassing part of the small intestine, which results in fewer calories being absorbed. This surgery is very effective in achieving weight loss and improving many of the obesity-related diseases. Complications include nutritional deficiencies, postoperative wound infections, leaks at the surgical sites, and postoperative mortality ($\sim$1.5%). Due to these risks, this therapy should be reserved for patients who are morbidly obese (BMI $>$40 or BMI $>$35), who have obesity-related diseases, and who have failed behavioral modification therapies.

Special Considerations in the Elderly

Obesity in the elderly is a major health crisis facing our population that may predispose the elderly to the same adverse health outcomes facing the younger, obese population. However, several studies have suggested that the risk of obesity on life span is less in the elderly and may even become insignificant. However, these studies have found an increase in disability in older subjects with obesity. Before concluding that obesity is not a risk factor in the elderly, there are a few considerations that help explain the data. First, because obesity is a risk for death in younger age, it is the survivors who are protected from the adverse effects of obesity that are being followed, i.e., those with obesity-related illnesses tend to die before reaching old age. Second, as mentioned earlier, people begin to decrease their lean body weight with age, thereby lowering their BMI despite the fact that they continue to acquire and/or redistribute VF preferentially. This increased VF in the elderly can lead to poor health outcomes. If BMI is the only index associated with obesity in the elderly, then the true risk might be missed. Third, a subgroup of elderly who are losing weight rapidly due to illnesses such as the frailty syndrome, sarcopenia, cancer, or pulmonary or cardiovascular diseases are at greater risk of dying than obese people, an observation that masks the independent effect of obesity.

Considering the preceding confounding variables, how to apply standards for ideal weight is unclear in elderly populations. Medications used for weight loss have not been sufficiently studied in the elderly population, and surgical options may be limited in the elderly because of comorbidities that increase the risks of surgery.

Conclusions

The prevalence of obesity is increasing at alarming rates. This increase in obesity is resulting in epidemic increases in obesity-related disease including diabetes, hypertension, and cardiovascular disease. The distribution of fat is of key importance, with VF seemingly worse than subcutaneous fat, and this is supported by experimental data. This is well illustrated in humans by the fact that the elderly, who are at high risk for obesity-related disease, tend to accumulate VF despite the fact that their BMI can decrease. In fact, it is not clear how to interpret BMI in the elderly population since being overweight does seem to correlate well with mortality.

Indeed, these trends suggest that for the first time in modern history, the life expectancy of people in developed societies will begin to decrease, unless the rapid increase in the prevalence of obesity can be reversed.

Obsessive Compulsive Disorders

R Kohn, A G Yip, and M C Mancebo, Brown University, Providence, RI, USA

Glossary

Compulsive Hoarding – A behavioral syndrome that involves acquiring a large number of possessions, storing of items and not discarding unused objects, and keeping or storing them in such a way that it interferes with daily living.

Diogenes Syndrome – Syndrome characterized by extreme self-neglect, domestic squalor, and social withdrawal, as well as refusal of help.

Exposure and Response Prevention – In this behavioral therapy, patients are systematically exposed to their obsessions while trying to resist their compulsions.

Obsessive-Compulsive Disorder – An axis I psychiatric disorder characterized by the presence of either obsessions or compulsions, which cause marked distress, are time-consuming, and interfere with functioning.

Obsessive-Compulsive Personality Disorder – An axis II personality disorder that is associated with an obsessive concern for details, perfectionism, and rigidity with ego-syntonic behaviors.

Introduction

Obsessive-compulsive disorder (OCD) is a common neuropsychiatric condition that is frequently unrecognized and untreated, resulting in significant personal suffering and functional impairment. This article reviews the current state of knowledge of OCD epidemiology, clinical features and natural history, differential diagnosis, and treatment options, focusing on how OCD affects the elderly.

Diagnosis and Epidemiology

Obsessive-compulsive disorder is defined by the presence of either obsessions or compulsions, which cause marked distress, are time consuming, and interfere with functioning. Obsessions are anxiety-provoking repetitive and intrusive thoughts, impulses, or images. Compulsions are characterized by repetitive and ritualistic behaviors or mental acts aimed at reducing anxiety. Adult patients recognize symptoms of OCD as unreasonable – although there is great variability in insight, both across individuals and in a given individual over time. The current diagnostic criteria for OCD are described in **Table 1**.

OCD has not been well studied among elderly patients. Much of what is known about aging and OCD comes from the National Institute of Mental Health (NIMH) Epidemiological Catchment Area Program (ECA) using the Diagnostic Interview Schedule (DIS) based on the *Diagnostic and Statistic Manual of Mental Disorders*, 3rd edition (DSM-III) conducted in the United States. The 1-year prevalence for individuals over 65 years was 0.85%, 0.75% for men and 0.93% for women, in contrast to 1.65% for all ages combined. Analysis limited to the eastern Baltimore site of the ECA found a prevalence rate of 1.3% in those between the ages of 65 and 74 years, and 0.6% in those older than 75 years. Interestingly, when incidence rates were estimated for the ECA study based on the 1-year follow-up, a bowl-shaped curve was found with an increase in incidence for women over the age of 64, whereas the incidence rate for OCD fell for men with increasing age. The incidence rate for those over the age of 64 was 0.63 per 1000 person-years, due primarily to women. The ECA estimated that only one-twelfth of individuals with OCD are initially afflicted after the age of 50, with a mean age at onset between 21.9 and 35.5 years. A cohort effect, differential mortality, differences in symptom endorsement, or differential recall

Table 1 DSM-IV-TR diagnostic criteria for obsessive-compulsive disorder

A. Either obsessions or compulsions:
Obsessions as defined by (1), (2), (3), and (4):
(1) Recurrent and persistent thoughts, impulses, or images that are experienced, at some time during the disturbance, as intrusive and inappropriate and that cause marked anxiety or distress.
(2) The thoughts, impulses, or images are not simply excessive worries about real-life problems.
(3) The person attempts to ignore or suppress such thoughts, impulses, or images, or to neutralize them with some other thought or action.
(4) The person recognizes that the obsessional thoughts, impulses, or images are a product of his or her own mind (not imposed from without as in thought insertion).
Compulsions as defined by (1) and (2):
(1) Repetitive behaviors (e.g., hand washing, ordering, checking) or mental acts (e.g., praying, counting, repeating words silently) that the person feels driven to perform in response to an obsession or according to rules that must be applied rigidly.
(2) The behaviors or mental acts are aimed at preventing or reducing distress or preventing some dreaded event or situation; however, these behaviors or mental acts either are not connected in a realistic way with what they are designed to neutralize or prevent or are clearly excessive.
B. At some point during the course of the disorder, the person has recognized that the obsessions or compulsions are excessive or unreasonable. Note: this does not apply to children.
C. The obsessions or compulsions cause marked distress, are time consuming (take more than 1 h a day), or significantly interfere with the person's normal routine, occupational (or academic) functioning, or usual social activities or relationships.
D. If another axis I disorder is present, the content of the obsessions or compulsions is not restricted to it (e.g., preoccupation with food in the presence of an eating disorder; hair pulling in the presence of trichotillomania; concern with appearance in the presence of body dysmorphic disorder; preoccupation with drugs in the presence of a substance use disorder; preoccupation with having a serious illness in the presence of hypochondriasis; preoccupation with sexual urges or fantasies in the presence of a paraphilia; or guilty ruminations in the presence of major depressive disorder).
E. The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.
Specify if:
With poor insight: if, for most of the time during the current episode, the person does not recognize that the obsessions and compulsions are excessive or unreasonable.

Adapted from *Diagnostic and Statistical Manual of Mental Disorders* (APA, 2000).

may explain the lower rates of OCD in elderly patients because OCD is a chronic disorder.

A study conducted in Edmonton, Canada, using the DIS and DSM-III, found the 6-month prevalence rate for those over the age of 65 was 1.5% and the lifetime rate was 2.5%. Men had a 6-month prevalence rate of 0.9% and a lifetime prevalence of 2.2%, and women had rates of 1.9 and 2.7%, respectively. A prevalence study conducted in Turkey using the Composite International Diagnostic Interview (CIDI) found unusually high rates of OCD in those over the age of 65 using *International Classification of Diseases* (ICD-10) diagnoses. The overall 1-year prevalence rate in the elderly was 4.3% compared to 3.0% for the general population. The Turkey study found no cases of OCD in elderly men, but found a prevalence rate of 9.3% for women. In Colombia the 1-year prevalence rate for those 61 and older using the CIDI and DSM-IV was 2.0% for lifetime and 0.6% for 1-year prevalence, while the overall population had rates of 3.6 and 3.1%, respectively. In Iran the Schedule for Affective Disorders and Schizophrenia (SADS) was used to ascertain cases of DSM-IV-defined OCD in a national sample. That study obtained a current prevalence rate of 1.0% among those age 65 and older, with a predominance in women of 2.8% in contrast to men with 0.1%; the rate in those over the age of 18 for comparison was 1.8% total, 2.8% in women and 0.7% in men.

The Longitudinal Aging Study Amsterdam (LASA) is the most extensive community-based study to have examined anxiety disorders in adults age 55 and older, using the DIS and DSM-III diagnoses. The authors found a 6-month overall rate of OCD of 0.6%. The disorder was found exclusively in women in this study, as in the Turkish study, which is unusual because in most epidemiological studies there is a near-equal gender distribution with women having a higher prevalence among the elderly. The rates were 2.7% among 65- to 74-year-olds and 0.8% for those aged 75–85. The LASA study found few related risk factors for OCD among the elderly other than a positive family history and loneliness. A strong comorbidity with major depression, but not with any of the other anxiety disorders, was found. In addition, an increased risk was found among those with heart disease and incontinence.

Most recently, the National Comorbidity Survey Replication (NCS-R) study conducted in the United States, based on the CIDI, found a lifetime rate of DSM-IV OCD among those over the age of 60 of only 0.7%, in contrast to 1.6% in the overall

population. In addition, 90% of those in the NCS-R had an age of onset prior to age 50, with more than half by the age of 19.

However, most studies using diagnostic criteria developed for use in geriatric mental health research have found much lower rates in the elderly. A number of studies examining current prevalence of obsessive neurosis in the elderly have been conducted using the Geriatric Mental State Interview (GMS) with diagnoses made with the Automated Geriatric Examination for Computer Assisted Taxonomy (AGECAT). In Liverpool, UK the rate was found to be only 0.1%. In the United Arab Emirates the rate among individuals 60 and older was 1.8%. In Edmonton, Canada it was 1.0% in males, 0.9% in females, and 0.9% for the total sample of individuals over the age of 64. In Dublin, however, no cases were found in a population of 1232 persons age 65 and over.

OCD has a higher prevalence in institutional settings compared to the general community. Elderly nursing home patients using the DIS in Edmonton, Canada, had a 6-month prevalence of 1.4% for men and 4.7% for men.

Clinical Characteristics in the Elderly

Only about 5–12% of people attending specialty OCD clinics are 60 years or older. However, OCD is rarely diagnosed in general outpatient settings in the elderly, as noted in a study of the Kaiser Health Maintenance Organization in which only 29 cases per 100 000 patients were reported. OCD seldom begins in late life, and most elderly people with this disorder who present for treatment have had symptoms for decades. A study of consecutively evaluated outpatients found only 1% of those in an OCD clinic had the onset of the disorder after age 50. There are few reported cases of onset after the age of 70. The first contact in treatment among the elderly with OCD is also later than in younger patients, 43 compared to 25 years of age.

The clinical presentation of OCD does not significantly differ between younger and older patients. Older patients have more hand-washing rituals and less obsessions with symmetry, concerns about checking paperwork, preoccupation about remembering insignificant details, counting rituals, fear of not saying the right thing, checking things a certain number of times, and systems of lucky and unlucky numbers. Common obsessions in older patients are fears of contamination, harming others, being responsible for things going wrong, having sinned, and obsessions with symmetry. The most common compulsions in the elderly are hand-washing rituals, concerns with avoidance of contamination, checking things around the house to make sure they are safe, needing to confess, and doing and undoing rituals (see **Tables 2** and **3**). In addition, the severity of OCD symptoms does not differ with age based on the Yale Brown Obsessive-Compulsive Scale (YBOCS).

Recently, intake data were analyzed from the Brown Longitudinal OCD Study (BLOCS), the only observational study in the literature in which subjects were recruited concurrently from multiple clinical settings, with assessments conducted by trained interviewers following a structured research protocol. Results suggested few differences among patients who were 60 years or older at intake ($n = 19$) and younger adults ($n = 274$). As in the previous study, the average age of first seeking treatment for OCD was considerably later in the elderly, 46 ± 17.8 years compared to 28.8 ± 10.6 years. However, there was no difference in severity of OCD symptoms on the YBOCS. Current and lifetime obsessive and compulsive symptom presentation showed few differences between the younger and older groups. The elderly did report fewer lifetime checking rituals and somatic obsessions. The most common obsessions found in the elderly were aggressive obsessions, while in the younger cohort they were obsessions of contamination. Cleaning rituals were the most common in the elderly, and checking rituals were the most common in the younger group. The rate of axis II personality disorders also did not differ using the SCID-II, with obsessive-compulsive personality disorder being the most prominent across age groups. As for comorbidity with axis I disorders based on the SCID, this sample of elderly patients had no current comorbid affective disorders in contrast to 17.5% among the younger cohort; however, there were no significant differences in lifetime affective disorder comorbidity. In addition, lifetime substance use disorders were lower among the elderly with OCD. Consistent with the lack of affective disorders among the elderly, the Hamilton Depression Scale scores were lower in the elderly sample, although this difference was not statistically significant.

Only one study has followed patients with OCD from their initial presentation to old age. This 40-year follow-up study found that an episodic course of OCD was more common during the initial years (about 1–9 years) but a chronic course was more common afterward. The study found that over time, 39–48% of people had symptomatic improvement. Compulsive symptoms were found to be less tractable than obsessions, and changes in the content of obsessive and compulsive symptoms are common.

Table 2 Common current and lifetime obsessions in OCD in elderly ($N = 32$) compared to younger adult patients ($N = 601$) (%)

Obsession symptoms	*Current*			*Lifetime*		
	< 60 years	*⩾ 60 years*		*< 60 years*	*⩾ 60 years*	
Aggressive obsessions	57.9	56.3		61.6	56.3	
Fear that one might harm or has harmed others	33.6	37.5		36.9	40.6	
Fear that one will be responsible for things going wrong	35.9	28.1		38.3	28.1	
Violent or horrible images	13.5	12.5		16.1	15.6	
Fear of hitting something or someone while driving one's car	16.5	9.4		21.5	12.5	
Fear that one will act on unacceptable impulses	9.8	9.4		11.6	9.4	
Fear that one might harm self	11.5	6.3		13.8	12.5	
Contamination obsessions	56.4	65.6		60.4	65.6	
Concerns with dirt or germs	44.8	56.3		50.9	56.3	
Concerns or disgust with bodily waste or secretions	23.1	18.8		25.1	18.8	
Excessive fear of contracting AIDS	16.0	12.5		19.8	12.5	
Excessive concern with household items	17.6	6.3		19.3	6.3	
Excessive concern with environmental contaminants	14.6	6.3		17.0	9.4	
Somatic obsessions	32.6	18.8		36.6	21.9	
Fear of developing a serious illness	32.6	18.8		36.6	21.9	
Sexual obsessions	24.1	21.9		26.6	21.9	
Forbidden or perverse sexual thoughts or images	21.5	21.9		23.3	21.9	
Unacceptable sexual impulses connected with images or thoughts	11.5	18.8		13.5	18.8	
Content involves homosexuality	7.0	6.3		8.0	6.3	
Content involves masturbation	3.5	3.1		4.3	3.1	
Content involves children	3.2	3.1		3.5	3.1

Another study comparing retrospective reports of the course of OCD in younger adult and elderly patients found that the elderly had a more steadily deteriorating course with fewer periods of waxing and waning or remission.

Differential Diagnosis

A number of primary medical disorders can produce syndromes that resemble OCD. The phenomenological similarity between idiopathic OCD and OCD-like disorders that are associated with basal ganglia diseases, such as Sydenham's chorea and Huntington's disease, is well established. Hence, neurological signs of such basal ganglia pathology must be assessed when considering the diagnosis of OCD in a patient presenting for psychiatric treatment, especially among older individuals. Parkinson's disease also has been reported to have an association with OCD, although more recent studies do not support this relationship. Repetitive behaviors that are unrelated to OCD are frequently seen in Alzheimer's disease, such as repeatedly putting on and removing clothing, opening and closing drawers, and insistent repeating of questions. OCD symptoms also have presented for the first time among elders who have acquired brain injury, including cerebrovascular disease and infarcts.

OCD is also closely related to Tourette's syndrome; the two conditions frequently co-occur, both in individuals over time and within families. In its classic form, Tourette's syndrome is associated with a

Table 3 Common current and lifetime compulsions in OCD in elderly ($N = 32$) compared to younger adult patients ($N = 601$) (%)

Compulsion symptoms	*Current*			*Lifetime*		
	< 60 years	*⩾ 60 years*		*< 60 years*	*⩾ 60 years*	
Somatic compulsions	11.5	3.1		13.6	3.1	
Checking the body over again for a serious illness	11.5	3.1		13.6	3.1

Miscellaneous compulsions	45.1	40.6		48.1	40.6	
Need to tell, ask, or confess	34.6	34.4		34.6	34.4	
Need to touch	16.6	6.3		21.3	6.3	*

Based on the YBOCS checklist adapted from data used in Kohn *et al.* (1997) *Fisher exact test $P < 0.05$. Lifetime = past and current combined.

pattern of recurrent vocal and motor tics that bears only a slight resemblance to OCD. However, many of the more complex vocal or motor tics are very similar to compulsions. Unlike compulsions that are actions aimed at relieving anxiety or preventing a feared consequence, tics are involuntary.

Pharmacologically precipitated OCD has been reported in the elderly. Case reports have been published of OCD being induced by methylphenidate and oral corticosteroid treatment.

Obsessive-compulsive behavior is also found in a number of other psychiatric disorders, which the clinician needs to rule out when diagnosing OCD. Psychotic symptoms often lead to obsessive thoughts and compulsive behaviors that can be difficult to distinguish from OCD with poor insight, in which obsessions border on psychosis. A substantial proportion of elderly with schizophrenia have comorbid OCD. OCD can be difficult to differentiate from depression, as the two disorders often co-occur, and major depression is often associated with ruminative thoughts that may appear to be obsessions. Ruminations are typically repetitive, mood-congruent thoughts that occur only during depressive episodes and are concordant with the patient's views of self. Comorbidity of OCD among those with major depression is rare. In a series of 336 elderly patients who either participated in treatment studies or were inpatients in a geriatric psychiatry unit with major depression, DSM-III-R OCD was found in 0.3% and 0.6% had a lifetime diagnosis. However, comorbidity of OCD in the elderly with other psychiatric disorders has been reported to be as high as 41% in clinical samples, primarily with major depression.

Cognitive deficits are seen in OCD regardless of age, and in the elderly they may be misinterpreted as age-related changes rather than characteristics of the disorder. Patients with OCD show significant impairments in visuospatial memory and verbal fluency, in particular in the accuracy of immediate and delayed recall on complex figure tests, the numbers of responses on category fluency tests, the response time

on the trail's A test, and the number of perseverative response and perseverative errors on the Wisconsin card-sorting test. The memory impairment seen in OCD is due to problems with organizational strategies in encoding information, executive function deficits, in non-verbal memory rather than actual memory deficits, suggestive of frontal-striatal dysfunction.

OCD shares some of the clinical features of obsessive-compulsive personality disorder (OCPD), which is associated with an obsessive concern for details, perfectionism, rigidity, and other similar personality traits. The conditions are distinguished by the fact that only OCD is associated with a true syndrome of obsessions and compulsions, while OCPD is associated with ego-syntonic behaviors (e.g., the individual derives pleasure from arranging items 'perfectly' in his or her home). One study found that community residents in the oldest age group reported more obsessive-compulsive personality characteristics using a self-report dimensional measure compared to one or more of the younger age groups. Another study of a sample of anxious elderly individuals and non-anxious elderly controls found OCPD in 39%, with higher symptom scores in the anxious group and non-anxious elderly compared to a younger adult anxious group. OCPD is also highly prevalent among the elderly with affective disorders. A report of elderly outpatients with dysthymic disorder found that 31.2% had OCPD and in major depression 11.0%. A retrospective chart review suggested that OCPD was the most prevalent of the personality disorders among geriatric inpatients with major depression.

Compulsive Hoarding

Compulsive hoarding consists of three components: acquiring a large number of possessions, storing of items and not discarding unused objects, and keeping or storing them in such a way that it interferes with daily living, with possible severe neglect of living space. This behavior was first described in 1975 in a sample of 30 individuals, all of whom were elderly and demonstrated extreme neglect of their home, appearance, and health, and was termed Diogenes syndrome. Although extreme hoarding, syllogomania, is frequently but not necessarily seen in Diogenes syndrome, it is characterized by extreme self-neglect, domestic squalor, and social withdrawal, as well as refusal of help. Diogenes syndrome may be present in 0.5 per 1000 elderly in the community and may be both a primary or secondary problem, with the latter being related to an axis I psychiatric disorder and the former being attributed to lifestyle choices or personality.

Hoarding is a behavior that brings the elderly to the attention of the authorities. Hoarding behavior is chronic and starts in childhood or early adolescence; treatment seeking is not evident until much later, around age 40 or 50. Based on a survey of health officers in Massachusetts, the researchers estimated that the rate of hoarding that presented to the Health Department in the community was 26.3 per 100 000 over a 5-year period. In that study, 40% of the cases were reported to authorities by the Department of Aging. A third of cases reported to authorities involved hoarding of animals. Those who hoard frequently are uncooperative with the authorities, resulting in multiple visits and reoccurrence of the problem. In Dublin, a study of service refusal by individuals offered meals-on-wheels, home help, house cleaning, and medical care found the majority (69.5%) to be elderly, and of those, 54.1% demonstrated hoarding behaviors.

Hoarding symptoms occurring at least several times a week have been found to be highly prevalent in nursing homes and in community senior adult day care, with rates of 15 and 25%, respectively. Among nursing home residents, hoarding behavior was related to a larger appetite, taking fewer medications, higher social functioning, comparatively less impairment in activities of daily living, and manifestations of physically non-aggressive, agitated behaviors. In both nursing homes and adult day care settings, persons who manifested hoarding behavior were those with relatively fewer health and functional disabilities.

A debate exists in the literature as to whether hoarding is actually OCD, a syndrome distinct from other psychiatric disorders, or a specific subtype of OCD. Hoarding is found as an obsession or compulsion in approximately a quarter of individuals with OCD. In an OCD clinic sample, 19% of the elderly had hoarding symptoms. Hoarding in the elderly has been found among patients with schizophrenia, bipolar mania, and dementia. Among these patients, it is usually not associated with OCD. A study of 133 dementia patients on a geropsychiatric unit found that 22.6% showed symptoms of hoarding. Hoarding was found in various types of dementia. Patients with hoarding and dementia had a higher prevalence of repetitive behaviors, hyperphagia, and pilfering. Hoarding behavior is associated with frontal lobe damage. In the original sample published in 1975 predating DSM-III, half did not meet the criteria for a specific psychiatric disorder.

One study examined the clinical characteristics of elderly hoarders who did not have dementia. Most elderly hoarders were female, were unmarried, and lived alone. Extensive clutter was associated with

significant impairment, interfering with basic hygiene and posing a serious physical threat. These patients were rarely insightful about their collecting and often resisted change, rendering interventions generally ineffective. Never being married was associated with more severe hoarding, greater impairment, and possibly with worse outcomes.

Treatment

Because there are no placebo-controlled treatment studies of OCD in the elderly, treatment guidelines are generally extrapolated from studies of younger populations and case reports of treated elderly. Selective serotonin reuptake inhibitors (SSRIs) are the drugs of first choice for OCD. The appropriate dose for treating OCD in the elderly has not been established, although it is widely believed that older patients generally require a lower dosage range for OCD than that used for younger adults. The efficacy of paroxetine, nefazodone, and venlafaxine in treatment of OCD in the elderly has not been reported, and evidence for the efficacy of sertraline for OCD in younger patients has not been consistent. Fluvoxamine has been studied in a very small sample open-labeled study in the elderly with OCD. Elderly patients on clomipramine have been found to reach a therapeutic steady state at doses lower than those reported for midlife patients, suggesting the need for plasma clomipramine monitoring and lower dosages. Although effective in younger patients, its use in the elderly may be more limited by anticholinergic, antihistaminergic, sedative, and sexual dysfunction side effects. At least one case of treatment-resistant major depression with comorbid OCD in the elderly with both disorders responding to electroconvulsive therapy has been reported.

In addition to pharmacological therapy, psychotherapy is an integral component in treating OCD in younger patients. Behavioral and cognitive-behavioral approaches dominate research into OCD psychotherapy, with exposure and response prevention (ERP) being the most commonly employed technique. ERP is clearly effective, but the evidence suggests that it results in a reduction rather than a removal of symptoms in a significant proportion of patients. This caveat notwithstanding, there is good maintenance gain for many patients. Several case reports using ERP also suggest that this treatment modality may be of benefit in the elderly with OCD. A comparative study of cognitive-behavioral therapy with ERP in 11 elderly OCD patients, mean age 68.7 years, compared to 11 younger patients, mean age 30.3 years, was conducted. These investigators found comparable improvement between the elderly group and younger group, with 72 and 63% improvement, respectively. A number of case reports have illustrated the benefits of combined ERP and psychopharmacological therapy in the elderly. ERP may need to be modified for the elderly due to increased medical comorbidity, cognitive deficits, and decreased stamina. For example, an elderly person with hearing deficits might need videotaped or written descriptions of exposure scenes to administer imaginal flooding rather than audiotapes. For those with mild cognitive impairments, written reminders to resist rituals can be strategically placed in the patient's environment to help with adherence to the response prevention protocol. Pacing treatment may be necessary to prevent some patients from becoming overwhelmed.

Most treatment outcome studies that have examined symptom subtypes have found that compulsive hoarding symptoms are particularly resistant to pharmacological or standard ERP interventions. More recently, this issue has been addressed by integrating motivational enhancement, organizational skills training, and cognitive and ERP techniques. Outcome data in the elderly are limited to a case report of successful treatment of an elderly woman using this approach.

Summary

OCD is more common than previously thought, with prevalence rates across studies in older adults ranging from 0.1 to 4.3%. Disease onset often occurs in young adulthood and its course lasts into old age. Prevalence studies suggest that, unlike in younger adults, the rates in the elderly may be somewhat higher in women than men. Compulsive hoarding is a problem that brings the elderly to the attention of the authorities. What limited data exist suggest few differences in the clinical features, comorbidity, and treatment options of OCD between elderly and younger patients.

Organizations On Aging

P S Liebig, University of Southern California, Los Angeles, CA, USA

Glossary

Advocacy – Urging society to attend to and act on the needs of elders. Elders can act as their own spokespersons, or others, such as service providers (the 'aging enterprise'), can speak and act on their behalf.

Age Consciousness – Identification of oneself with others on the basis of chronological age, as opposed to other kinds of group identification such as race, gender, or religion.

Coalition – An alliance, often temporary, of age-based groups with each other (the 'aging coalition') or with non-age-based groups sharing similar concerns about a variety of issues, such as long-term care, mental health, home modification, or transportation.

Interest Groups – Organizations that seek collective benefits from policy makers through grass roots mobilization and lobbying. Participants (or 'players') in a complex political system, they are based on mass membership or private philanthropies or made up of professionals, business or industry groupings, or consumer subgroups.

Politics of Aging – The process by which aging groups make demands on the policy system by bargaining, persuading, competing, or allying with other interest groups and/or bureaucrats, thereby creating a policy subsystem, and sometimes threatening the re-election prospects of elected officials.

Public Policy for the Aged – Policies that are enacted by governments at all levels to benefit older persons, often with chronological age as the determining factor. They include Social Security, Medicare, state tax preferences, and local zoning benefiting older persons.

Social Movements – Grass roots mobilization of like-minded individuals, often by a charismatic leader, to voice grievances. While characteristically disorganized initially, they can evolve into interest groups. Examples include civil rights and women's and senior groups.

Introduction

Organizations on aging are stable, non-profit collective entities that are distinguished by their advocacy for the betterment of older adults in society through research, education, and service. Most are 501(c)(3) organizations and are tax exempt. They are not necessarily identifiable by the words 'age' or 'aging' in their names; the majority, however, do include those terms or related ones, such as retired, older, or senior. Several types exist. Mass membership groups composed of older adults are often driven by age consciousness. They and other age-based entities, composed of researchers, consumers, practitioners, and businesses providing services to the aged, focus on ensuring that public policies and private activities benefit the elderly.

Social Movement and Interest Group Theory

Both social movement and interest group theory have been used to explain the rise and greater visibility of

organizations on aging. Social movements involve collective actions to aggregate interests on a broad scale and are often characterized by three stages. The first, or developmental, stage consists of erratic expressions of grievances by individuals who feel left out or left behind by the larger society in terms of economic or political benefits. These disgruntled feelings are often catalyzed by a populist leader into an ad hoc organization that focuses heavily on political solutions to perceived wrongs. The second, or institutional, phase consists of a large membership base and a stable organization with economic and political resources, division of labor and hierarchy, and connections with government officials. United States history is replete with such social movements from the mid-nineteenth century on, some of which have evolved into political parties or interest groups. A third stage may include decline and death of the movement, either because the cause espoused is no longer relevant or the organization loses its clout or even becomes dysfunctional due to leadership, finances, and other internal problems.

Interest group or pluralist theory posits that politics is characterized by dispersed power, competition, and bargaining over specific goals by multiple groups or factions, and the responsiveness of decision makers to a wide range of societal interests and the voting public. Interest groups operate within a complex milieu of macroeconomic development, political parties, government officials, and policy professionals, as well as prevailing values and public attitudes toward the role of government or other societal institutions.

A Brief History of Organizations on Aging

The history of organizations on aging can be divided into three periods: the 1920s–1950s, an incubation stage; the 1960s–1970s, a proliferation period; and the 1980s–1990s, a specialization and consolidation era. These groups grew out of the state-level movement for old-age pensions, initially led by non-aging groups, such as the Fraternal Order of the Eagles and the Ham and Eggs movement. Between 1923 and 1933, 25 states enacted old-age assistance laws.

Incubation

The first age-based group was started by Francis Townsend in California, a hotbed of old-age politics. He had a plan for a national pension of $200 per month – a substantial sum in those days – to be paid to everyone age 60 and over, financed by a national sales tax. This plan led to a national movement, by early 1935, of more than 3000 clubs nationwide. After Social Security passed later that same year, the organization's membership and support began to decline because the new law met some of the needs identified in Townsend's mass appeal to elders who were especially hard hit by the Depression. Even so, the Townsend movement went on to sponsor congressional candidates in 1938; 147 Townsend endorsees were elected. After that peak, the movement subsided and disappeared, partly due to problems with leadership and the handling of funds.

The enactment of Social Security initiated a direct relationship between the federal government and the elderly, based on social insurance against the economic risks of old age as a matter of right. Despite the new law, older persons were still at a disadvantage. Still, no other mass membership organization came into being; instead, two professional organizations composed of practitioners and academics were created: the American Geriatrics Society (AGS) in 1942 and the Gerontological Society of America (GSA) in 1948. Two other United States organizations on aging were created in the late 1940s. One was a mass membership entity, the National Retired Teachers Association (NRTA), led by Dr. Ethel Percy Andrus, a former high school principal. The NRTA focused on the lack of pensions for public school teachers and their need for benefits such as life insurance that were otherwise difficult to obtain. The other was the National Association of Retired Federal Employees, whose agenda emphasized pensions for federal civilian retirees. Advocacy by both groups centered on the economic needs of specific employee groups.

The pace of formation of new organizations on aging picked up slightly in the 1950s. The 'new kids on the block' included the National Welfare Assembly; the precursor to the National Council on Aging and the Western Gerontological Society (later to become the American Society on Aging), both composed largely of practitioners; and the American Association of Retired Persons (AARP), a second creation of Dr. Andrus that was destined to become the primary mass membership organization in America. The AARP advocated against age discrimination and in favor of the contributions to be made by the aged to society. International organizations on aging also were initiated during this decade: the Canadian Geriatric Research Society and the International Association of Gerontology, whose membership comprised the growing number of national gerontological organizations, such as the GSA. By the time the turbulent 1960s began, only a handful of organizations on aging existed.

Proliferation

The 1960s and 1970s ushered in a proliferation of interest groups in general, and age-based groups in particular. These decades also generated a 'golden age' in the politics of aging. The Senior Citizens for Kennedy thrust age-related issues into the arena of presidential politics. The 1961 and then the 1971 White House Conference on Aging (WHCoA) provided a forum for discussing the needs of the aged, and new public policies benefiting elders were enacted: Medicare, the Older Americans Act (OAA), Medicaid, and Supplemental Security Income. Although the extent to which age-based groups were primarily responsible for these entitlements is controversial, their ability to work with other established groups, especially labor unions, was an important factor. They also developed age-based coalitions to encompass the different agendas of mass membership organizations (e.g., AARP), professionals (e.g., NCoA), and academics (e.g., GSA) and a wide array of organizations such as the Older Women's League and the National Caucus and Center on Black Aged to represent the concerns of specific subgroups of the elderly, such as women and minorities. In many instances, OAA grants helped fund these new groups. The increase in federal and state programs for elders also gave rise to trade associations (e.g., the American Association of Homes for the Aging) and other entities composed of providers and practitioners (e.g., National Association of State Units on Aging) serving the elderly, dubbed the 'aging enterprise.' This huge increase in organized groups led to the creation of the Leadership Council of Aging Organizations in 1978 to unify the divergent perspectives expressed by the various age-based organizations. Another international umbrella organization, the International Federation on Ageing, was established, with its members drawn primarily from professionals and consumers.

Specialization and Consolidation

In the 1980s and 1990s, the rapid increases in the numbers of programs for the aged slowed markedly, as did growth in the numbers of new major organizations on aging. Instead, these two decades marked a shift toward more specialized organizations in research, education, and practice. New 'splinter' groups that focused on research included the Alliance for Aging Research and the Alzheimer's Association. Other groups represented the wider range of careers in aging, such as professional geriatric care managers, service coordinators in group housing, nursing home and home care administrators, psychologists in long-term care, and assisted living owners and managers.

The late 1980s and 1990s also were accompanied by a political backlash against elders, signaling an end to the easy public policy gains of earlier decades and a need to consolidate those gains. A few new major organizations were created in response to debates over generational equity and emerging threats to Social Security and Medicare. They included the National Committee to Preserve Social Security and Medicare and Generations United, who countered the arguments put forth by the National Association of Senior Citizens (NASC) and Americans for Generational Equity. In addition, the passage and subsequent repeal of the Medicare Catastrophic Care Act (MCCA) revealed the non-monolithic advocacy stances of age-based groups, as did the growing influence of other organizations (e.g., the NASC) that were more attuned to the agenda of the new Republican majority in the House of Representatives. In spite of these changes, national policy makers had come to view older people as a political force in their own right, beyond their high levels of participation in elections.

Current Status and Characteristics

As of 2005 there are more than 1000 age-based groups at the national, state, and local levels advocating for collective benefits for a highly diverse and growing old-age population. In Washington, D.C., many have achieved insider status, especially AARP, the Alzheimer's Association, and Families/USA, which often join forces on issues such as long-term care. The 'gray lobby' commands many resources necessary for access and influence: leadership stability, consistent sources of income, hierarchical structure, expertise in particular areas, geographic dispersion, and skillful professional lobbyists and public relations capabilities. Some organizations on aging have developed technological capacity, beyond websites, to enhance their advocacy activities, such as listservs designed to remind members to contact policy makers within the relatively short time frames during which bills are voted on.

However, with few exceptions (largely due to their tax-exempt status), age-based groups have not created political action committees (PACs) that increasingly affect electoral politics. Additionally, while some aging groups, particularly AARP, continue to exercise substantial influence on crucial legislation (e.g., the enactment of the Medicare Modernization Act), the political climate in Washington, D.C. is overall less welcoming to any new programs for the elderly compared to earlier decades. Furthermore,

most age-based groups lack the financial resources to engage in lawsuits that increasingly affect pensions, retiree health benefits, and other issues affecting the well-being of the elderly. Finally, the majority of these groups have yet to develop the same kind of sophistication and influence at the state level that they have at the national level. (AARP and the Alzheimer's Association are notable exceptions.) With more responsibilities being devolved to the states, this lack of advocacy structure in state capitals can lead to fewer positive outcomes for older persons.

The Future of Organizations on Aging

In the current policy climate of entitlement cutbacks and continued devolution to the states that got underway in the 1990s, organizations on aging will find it more difficult to promote major new programs, such as national social insurance for long-term care. Both employers and the federal government are pursuing policies that place more responsibility on individuals for their retirement years. The 1995 WHCoA resolutions were quite modest in number (50) and content compared to the hundreds of demands for major programs made at earlier conferences, reflecting the realities of today's politics of aging. The 2005 conference also has been restricted to a maximum of 50 resolutions, and it is likely that many of those will be blocking actions designed to maintain existing programs. If, as has been proposed in the past decade, more federal programs are funded through block grants to the states in such areas as housing, health, and long-term care, age-based groups will need to sharpen and organize their lobbying skills at the state and often local levels. This kind of mobilization can be very expensive, especially for small organizations representing subgroups of the elderly. Monitoring the implementation of block grants in 50 states also will require considerable effort.

Organizations on aging, similar to other constituencies that have benefited from national programs, also will continue to be challenged by the more than decade-long shift in party dominance in Congress and many statehouses. The Republican majority in Congress, with its emphasis on less government, has made it more difficult for the dominant age-based groups to exercise the same kind of influence that they have in the past. For example, while the Medicare Modernization Act resulted in a prescription drug benefit, the final outcome was not endorsed by all organizations on aging, and even AARP, despite having played an important role in its enactment, has gone back to the legislative drawing board to try to correct perceived defects in the new program. Conservative organizations on aging that had little influence on the Democrats have found that they continue to have increased access in the policy process since the Republicans became the majority party in Washington, D.C.

Similarly, the strong showing of Republicans in state elections has resulted in party shifts that may lead to increased influence of traditional state interest groups such as business and industry, which are often at odds with the consumer focus of aging advocates. Term limits for state legislators and executives may also result in age-based groups having less clout as legislators become less driven by the need to assuage older voters to get reelected. Term limits may also increase the influence of groups such as the insurance industry that, unlike nearly all aging groups, contribute heavily to political campaigns.

The backlash against the aged at the national level has not fully subsided, with the likely result that age-based groups will increase their coalition-building activities with non-aging groups, as well as other advocates for the elderly, as they have done since the late 1980s. AARP has, in keeping with its membership demographics, focused more on those aged 50 and over (not 65+) and officially changed its name to AARP, since a substantial proportion of its membership is not retired and is composed of persons younger than age 65. Similarly, AARP, Families/USA, and other well-positioned advocate groups with listserv capacity and other major resources are likely to become the most prominent voices among the numerous organizations on aging. This, coupled with disparate levels of interest in globalization and its impacts on the aged and ever-increasing diversity among the older population, opens the possibility of important differences in advocacy techniques and positions taken among organizations on aging, even beyond what has occurred in the past. The ability of age-based groups to forge strong links with other organizations may very well be the key to retaining current programs – recent skirmishing over Social Security reform is a case in point – and to developing new programs at the federal and/or state level. Whatever the future holds for age-based organizations, new programs that benefit only the aged are less likely to happen than in the past.

Osteoporosis and Aging Related Bone Disorders

S H Gueldner, T N Grabo, G Britton, C Pierce, and B Lombardi, Binghamton University, SUNY, Binghamton, NY, USA

Glossary

Osteoporosis – A systemic skeletal disease characterized by a low bone mass and a microarchitectual deterioration of bone tissue, with a consequent increase in bone fragility and susceptibility to fracture (WHO, 2003: 27).

Introduction

Osteoporosis is among the most common health problems facing elders worldwide.

Globally, the elderly are increasing at a dramatic rate with the number of individuals 65 years or older predicted to rise from 431 million in 2000 to 696 million by the year 2020. During this same period of time, the number of persons 75 years and older is expected to rise from 163 to 269 million. Since the incidence of osteoporotic hip fracture increases exponentially with age, this demographic shift could dramatically increase the number of hip fractures, posing a devastating increase in disability and cost for elders worldwide. Faced with other pressing and acute health problems such as tuberculosis, AIDS, and malaria, there is concern that the more innocuous-appearing problem of osteoporosis may be relegated to a low priority in many countries. For these reasons, it is imperative that an algorithm be developed and instituted worldwide to support lifestyle changes and early diagnosis of osteoporosis, in time to avoid fractures if at all possible. But the first and perhaps most difficult challenge that must be addressed is to change the prevailing misperception that osteoporosis and fracture are inevitable conditions of growing old. Toward that purpose, the World Health Organization (WHO), in collaboration with organizations concerned nationally and internationally with bone health, has declared 2002–11 as the Decade of the Bone and Joint, uniting nations throughout the world in the commitment of energy and resources to accelerate progress in bone health and prevention of fractures. Keeping in mind this global context, this article focuses primarily on the incidence of osteoporosis within the United States, noting risk by specific demographic features when that information is available.

Given that osteoporosis and osteoporotic fractures represent the most widespread and devastating bone health problem, this article focuses primarily on osteoporosis, with a subsection on other bone disorders that affect elders. Discussions include information about the prevalence and impact of osteoporosis, pathology (including bone remodeling), factors that place individuals at risk for developing osteoporosis, screening and diagnostic measures, and treatment. Encouraging information is also provided about recent innovative technological developments that may enhance our ability to detect and treat osteoporosis in time to reduce and better manage its unwelcome sequelae. The *2004 Surgeon General's Report on Bone Health and Osteoporosis*, prepared by the US Department of Health and Human Services under the direction of the Office of the Surgeon General, represents the most definitive document available on this

topic, and serves as a primary source of information for this article.

Prevalence

Osteoporosis is defined as a skeletal disease characterized by low bone mass and deterioration of bone tissue, with a consequent increase in bone fragility and susceptibility to fracture. Osteopenia refers to a decrease in bone mass below normal, but not low enough to be classified as osteoporosis. The WHO measures prevalence directly by using bone mineral density (BMD) data, and measures incidence indirectly as the number of fractures resulting from the disorder. However, since most data are from developed countries, there is a deficit of standardized criteria on the prevalence of osteoporosis on a multinational basis. Different measurement techniques are used to collect BMD data at varied skeletal sites, on subjects of different age groups, limiting generalizations. In addition, the WHO criteria base the standard BMD scores on the mean scores of young White women, making it difficult to generalize findings to groups other than Caucasian women. In the United States, prevalence of osteoporosis ranges from 3.9% in Caucasian American women who are 50–59 years old, increasing to 47.5% for those older than 80. The National Osteoporosis Foundation (NOF) estimated that 55% of all Americans aged 50 and older in the year 2002 had either osteoporosis or osteopenia (low bone mass). Based on the 2000 census, prevalence estimates increased to 52 million women and men for the year 2010 and to 61 million in 2020. In the United Kingdom, it has been estimated that 23% of women 50 years or older are osteoporotic, with increases proportional to age. The percentages of Swedish women who have osteoporosis range from 7% of women 50–59 years of age to 36% of those 80–89 years. The prevalence of osteoporosis is higher for women in Norway than anywhere else in Europe, and the risk of hip fracture among Norwegians is four times that of Southern Europeans and double that of Americans.

Prevalence varies by gender, race, and ethnic group. Both men and women experience a decline in BMD starting in midlife, with women experiencing more rapid bone loss in the years immediately after menopause. Of the 44 million people in the United States estimated to have osteoporosis in 2002, 32% were men and 68% were women, confirming that osteoporosis is not just a problem among women. Asian and White non-Hispanic women have the lowest bone mineral densities throughout life, and African American women have the highest. Mexican American women have bone densities that are intermediate between the two groups. Limited data suggest that Japanese and Native American women attain a peak BMD that is lower than for White non-Hispanic women.

Virtually all fractures occur in persons 35 years and older, with 80% occurring in women. The highest incidence rates are reported in northern Europe, the northern part of the United States, and among Southeast Asian populations, with the lowest rate from African countries. It is of note that the differences in incidence of hip fractures between countries are greater than differences between gender.

Impact

Osteoporosis is identified as a major public health concern for Americans aged 50 years and older. More than 75% of those affected by osteoporosis are women, and the WHO estimates that up to 70% of women older than 80 years of age have osteoporosis. One in every two women and one in every five men over 50 years of age experience an osteoporotic fracture during their lives, and more women die from the after-effects of osteoporotic fractures than from cancers of the ovaries, cervix, and uterus combined. There are 1.5 million osteoporotic fractures in the United States each year; 20% are hip fractures, 50% are vertebral fractures that lead to height loss, and 30% are at the wrist and other sites. One-fourth (25%) of all postmenopausal women will develop a vertebral deformity, and another 15% will sustain a fractured hip, numbers that could triple by 2040.

Hip fractures are the most severe consequence of osteoporosis and are associated with lengthy hospital admissions, difficulty in performing activities of daily life, nursing home placement, and a high rate of mortality. In 1998, more than 339 000 hip fractures occurred in men and women aged 65 and older in the United States, and the annual worldwide incidence is projected to grow to 2.6 million by 2025 and to 4.5 million by 2050. Virtually all persons in the United States with hip fracture are hospitalized, and 25% of those who sustain hip fractures require long-term nursing home care. Hip fractures account for 140 000 nursing home admissions annually. Spine fractures are considerably less problematic in terms of cost, with only 10% requiring hospitalization and less than 2% being admitted to a nursing home. However, they account for 66 000 physician office visits and at least 45 000 hospital admissions each year.

The economic burden of osteoporosis to society is immense. In the United States, osteoporotic fractures result in more than half a million hospitalizations,

800 000 emergency room visits, more than 2.6 million physician office visits, and the placement of nearly 180 000 individuals into nursing homes. It is estimated that each hip fracture represents approximately $40 000 in total medical costs. The annual direct care costs associated with osteoporotic fractures is estimated to be as high as $18 billion, and indirect costs (i.e., lost productivity for patients and caregivers) add billions of dollars to this amount. Care to White women comprises the majority of these costs, but men and non-White women of all ages account for $1 billion in direct costs of osteoporotic fractures. Due to the late age at which the expenses related to care occur, osteoporosis accounts for 14% of all days spent in nursing homes. Given that 75% of all hip, spine, and distal forearm fractures occur in persons 65 years and older, the direct costs are largely borne by society, in the form of social reimbursement programs. In the United States, Medicare pays approximately one-half of these costs, and Medicaid covers an additional one-fourth of the expense.

But the impact of osteoporosis on the personal lives of the patients and their families is even greater. Nearly one in five persons who sustain a hip fracture end up in a nursing home, and 20% will die before a year has passed. Two-thirds of hip fracture patients never return to their prefracture level of function, and many lose their ability to walk. Reports from the Established Populations for Epidemiologic Studies of the Elderly (EPESE) confirm that 37% lose the ability to dress themselves, 58% lose the ability to move from their chair to standing, and 60% lose the capacity to walk across the room. The sequelae of bone disease can also affect an individual's self-esteem, body image, and mood and may result in other serious psychological consequences. In a survey conducted by the NOF, 89% of the women who had sustained an osteoporotic fracture said they were afraid of breaking another bone, 80% feared losing their independence, 80% feared they would not be able to perform their daily activities, and 68% were afraid that they would have to go to a nursing home if they had another fracture. Approximately half of the individuals who sustain hip fractures never walk independently again, even if they were ambulatory before their fracture.

Pathology

There is general consensus that BMD accounts for 70% of bone strength, is measured as grams of mineral per area, and reflects both peak bone mass and the amount of bone loss. Osteoporosis is not only the result of accelerated bone loss during aging, but it may also develop because of suboptimal bone growth in childhood and adolescence or from the use of certain medications (most notably steroids) for the treatment of other health problems. Bone quality is not well understood, but is thought to result from the bone's micro and macro structure, biochemical composition, distribution and integrity of material components within bone, turnover, and microdamage accumulation. Fracture risk is currently estimated by measuring BMD. The risk of fracture rises sharply as BMD declines. The estimated lifetime risk for wrist, hip, and vertebral fractures is 15%. The majority of these fractures in persons over 50 years of age are a result of osteoporosis, and the hip fracture rate is used to calculate the osteoporosis fracture burden. Since most individuals who have a low density have also lost bone structure, a low T score is usually accurate. However, it should be noted that the BMD only measures bone density and does not assess the quality of the bone structure. Therefore, some individuals with high bone density may sustain fractures, because they have lost bone structure. Conversely, not all persons with low bone density sustain fractures, because they may have retained good bone structure. Prior fracture is one of the most important predictors of future fracture. The risk of hip fracture after a wrist fracture was increased 1.4-fold in US women, 1.5-fold in Swedish women, and 1.8-fold in Danish women. Wrist fracture is an even stronger predictor of hip fracture in men; US men who had a wrist fracture were found to be 2.3 times more likely to sustain a hip fracture, and Swedish men with wrist fracture were 2.8 times more likely to sustain hip fracture.

Bone Remodeling and the Development of Osteoporosis

Although an individual's height and unique bone structure are developed by late adolescence, new bone continuously replaces old bone throughout life in a process referred to as bone remodeling. Bone remodeling helps one's skeleton maintain its structural integrity; it is estimated that approximately 10% of the skeleton is remodeled annually, with most of the adult skeleton being replaced every 10 years. Eighty percent of the skeleton is cortical (compact) bone, which is located predominantly on the outer surfaces of the bone, and 20% is inner trabecular (spongy) tissue, which forms a large part of the vertebrae, proximal femur, and distal radius. If less new bone is formed than the amount of old bone removed, a net loss of bone occurs, and the more fragile bone is more likely to break with less trauma, as is the clinical problem with osteoporosis. It should

also be noted that remodeling bone is inherently weaker, and is therefore more susceptible to fracture. Remodeling occurs in both types of bone, but most (80%) occurs in the trabecular bone. Thus, fractures are more likely to occur in regions of high trabecular area such as the hip, spine, and wrist.

In the complex bone remodeling sequence, bone cells lie quiescent until osteoclasts (bone-resorbing cells) are stimulated to resorb a small volume of bone. While some of the details of the actual remodeling process remain unclear, it is thought that this osteoclast (resorbing) activity is increased by a number of factors, including parathyroid hormone (PTH) and thyroxine, and that it is decreased by estrogen, testosterone, vitamin D, calcium, high phosphorus levels, and sometimes by cytokines from osteoblasts (bone-forming cells). Localized prostaglandins and interleukins may also exert a stimulatory or inhibitory effect on this remodeling process. A low calcium intake stimulates the secretion of PTH, which activates the osteoclasts to release lysosomal enzymes that digest bone matrix, causing the release of calcium and other bone minerals and proteins. After the resorption cavity is formed, a cement line is laid down by macrophage-type mononuclear cells, limiting further resorption on bone in that particular area. The cement line is rich in osteopontin, which may serve to shut off osteoclast (resorption) activity and stimulate osteoblast (rebuilding) activity. A growing number of pharmaceutical modalities have been developed with the goal of reducing bone loss or increasing bone formation to maintain bone health by inhibiting osteoclast action on bone resorption or by allowing formation to continue.

Predictors and Risk Factors

Factors associated with low bone density and/or risk for fracture have been identified in several large prospective studies:

- Female gender
- Advancing age
- Traditionally defined Caucasian and Asian populations
- Estrogen deficiency due to menopause, especially early or surgically induced. Sometimes categorized as a secondary cause
- Low weight and body mass index (i.e., small frame)
- Personal history of fracture after age 50
- Family history of osteoporosis
- Cigarette smoking
- Low lifetime calcium and vitamin D intake
- Inactive lifestyle
- Insufficient exposure to sun (reducing production of vitamin D, which is essential for calcium absorption).

Other suspected predictors of low bone mass, including use of alcohol and caffeine-containing beverages, have proven to be inconsistent in their association with the development of osteoporosis. Higher body mass index, African American heritage, sufficient estrogen levels, and stress-applying exercise are viewed as BMD protective factors, while age, personal or family history of fracture, Asian or Hispanic heritage, smoking, and cortisone use are significant predictors of osteoporosis.

Secondary (modifiable) causes are believed to contribute to 30–60% of osteoporosis in men and more than 50% in perimenopausal women. Among men, hypogonadism, glucocorticoid therapy, and alcoholism are the most common secondary causes. In perimenopausal women, hypoestrogenemia, glucocorticoid therapy, thyroid hormone excess, and anticonvulsant therapy are the most common secondary causes.

- Exogenous glucocorticoid use as a treatment for a coexisting condition (i.e., for treatment for asthma, or in conjunction with transplants) is the most common cause of secondary osteoporosis, and its long-term use is associated with high rate of fracture. Glucocorticoids suppress bone formation and increase bone resorption by affecting local regulatory factors, suppressing collagen synthesis, and inhibiting calcium absorption. An emerging population affected by this risk are persons with organ transplants, who rely on steroid therapy to minimize the risk of rejection.
- Hypogonadism affects osteoblastic cell functioning in both women and men. Production of estrogens maintains bone mass. In women, the timing of menarche and menopause influences the attainment and preservation of peak bone mass, and in men estrogens similarly play an important part in building and maintaining the male skeleton. Androgens are also important regulators of bone metabolism, including cellular effects on bone remodeling. Hypogonadism distinct from postmenopausal status in women and age-related decline in men may be caused by diseases such as hyperprolactemia, hemochromatosis, Klinefelter's syndrome, mumps orchitis, anorexia nervosa, and excessive exercise-induced hypogonadism.
- Hyperthyroidism has detrimental effects on the skeleton, especially in females. Thyroid hormones stimulate bone resorption, decrease calcium intestinal absorption, and increase hypercalciuria,

resulting in a decrease in bone density and an increase in risk of fracture in individuals with a history of thyrotoxicosis.
- Drug therapies associated with reduced bone mass in adults include pharmaceutical preparations that contain aluminum, anticonvulsants (phenobarbital, phenytoin), cytoxic drugs, gonadotropin-releasing hormone agonists, lithium, long-term heparin use, long-acting parenteral progesterone, supraphysiological thyroxin doses, tamoxifen (premenopausal use), and total parenteral nutrition.

Presenting Symptoms and Sequelae

While the skeletal changes in osteoporosis result in significant chronic morbidity and mortality, the changes in bone mass and quality occur without symptoms and are usually not detected until a fracture occurs. Fractures of the proximal femur (hip), vertebrae (spine), and distal forearm (wrist) are the most clinically apparent complications of osteoporosis and may profoundly affect quality of life. Bone loss, in the presence of risk factors and age-related changes such as compromised vision, hearing, proprioception, and balance, may lead to greatly increased risk of fracture due to falls. Vertebral fractures, often called crush fractures, result in the characteristic physical changes often associated with osteoporosis, most notably kyphosis or dowager's hump. This collapsing of the vertebral column onto itself impacts other body systems: gastrointestinal, respiratory, genitourinary, and craniofacial, and produces concomitant morbidity: height loss, abdominal protuberance and fullness, inhibited breathing patterns, back pain, and functional limitations in walking, bending, and reaching.

Diagnosis and Treatment

Guidelines for Screening

Osteoporosis is a silent disease and usually remains asymptomatic until a fracture occurs. It may present as a spontaneous fracture or collapse of a vertebra or as a backache of varying degrees of severity. Height loss is also common. Osteoporotic fractures are preventable; therefore, appropriate diagnostic tools are crucial in the assessment and treatment of osteopenia and osteoporosis. Bone densitometry has made it feasible for health-care providers to diagnose osteoporosis before the first fracture occurs and to reliably predict fracture risk in postmenopausal women, men, those at high risk, and those receiving glucocorticoids. It can also be used as a surrogate marker to determine the effectiveness of therapies and to evaluate those patients that might not respond to osteoporosis therapy. There are several methods currently available to determine bone mass. Currently, dual energy X-ray absorptiometry (DXA) has become the measurement of choice for osteoporosis. The results are reported in T scores and Z scores. The WHO classifies normal bone density as a T score of -1 or above, osteopenia as a T score between -1 and -2.5, and osteoporosis as a T score of -2.5 or below. Less commonly used are Z scores, which classify the type of osteoporosis and may be helpful in identifying those in need of testing for secondary osteoporosis. Z scores of –1.5 and below indicate primary osteoporosis that is age related, and a score of –1.5 and above indicates secondary osteoporosis. Once osteoporosis has been diagnosed, a history is carefully taken and a physical examination is performed to determine the cause.

The National Osteoporosis Foundation and the US Preventive Services Task Force (USPSTF) have established recommendations on screening for osteoporosis (**Table 1**). A number of reliable portable bone scanners have also become available, making low cost detection of low bone density increasingly feasible as a more widespread screening procedure for osteoporosis.

BMD measurements correlate strongly with the load-bearing capacity of the hip and spine, detect osteoporosis before a fracture occurs, predict fracture risk, assess the rate of bone loss with repeated measures, and monitor the effectiveness of treatment

Table 1 Recommendations on screening for osteoporosis

National Osteoporosis Foundation	*US Preventive Services Task Force (USPSTF)*
Bone mineral density testing should be performed on: 1. All women aged 65 and older regardless of risk factors 2. Younger postmenopausal women with one or more risk factors 3. Postmenopausal women who present with fractures (to confirm the diagnosis and determine disease severity)	Screening summary: 1. Women aged 65 and older should be screened routinely for osteoporosis 2. Routine screening should begin at age 60 for women at increased risk for osteoporotic fractures 3. The USPSTF makes no recommendation for or against routine osteoporosis screening in postmenopausal women who are younger than 60 or in women aged 60 to 64 who are not at increased risk for osteoporotic fractures

for osteoporosis. Several different techniques are now available to assess BMD at multiple skeletal sites.

DXA of the hip and spine is presently considered the gold standard in assessing fracture risk. Used to measure BMD of the hip, spine, or wrist, the DXA takes about 10 min to perform with low radiation exposure (one-tenth that of a standard chest X-ray). However, DXA is not universally available for screening for osteoporosis, partly because the equipment is large and expensive and is not portable. Additionally, the National Institutes of Health (NIH) has concluded that the value of universal screening, especially in perimenopausal women, has not yet been supported by compelling evidence. Perhaps for this same reason, the costs are not consistently covered by insurance companies and other third-party reimbursement programs.

Prevention, Risk Management, and Treatment

Calcium and Vitamin D Over a lifetime, inadequate supply of calcium in the diet is thought to play a significant role in the development of osteoporosis. The literature supports the need to develop healthy behaviors early in life to build and maintain strong bones. This includes consuming a healthy diet, maintaining normal weight, and exercising regularly. Calcium is the specific nutrient required for achieving peak bone mass and for preventing and treating osteoporosis. Calcium absorption is incomplete, usually about 10–12%, and vitamin D is needed for the best possible absorption. Vitamin D is not a normal constituent of most foods but is usually endogenously produced by a photosynthetic reaction. Few foods contain or are fortified with vitamin D; more than 90% of the required vitamin D comes from sunlight exposure. Short (15 min) exposure of hands, face, or arms and legs to sunlight, before the application of sunscreen, may produce an adequate amount of vitamin D. Adequate calcium and vitamin D intake provided through eating a diet high in low-fat dairy products and calcium-fortified foods is preferred to supplements, since other beneficial nutrients including phosphorus and magnesium are also found in these foods. Supplemental calcium and vitamin D is recommended for individuals who are unable to consume a sufficient amount of foods rich in calcium. The Institute of Medicine of the National Academy of Sciences recommends a calcium intake for healthy individuals over 50 years of 1200 mg/day and a vitamin D intake of 400–800 IU/day. However, the NOF advises all individuals to obtain a dietary intake of calcium of at least 1200 mg/day, including supplements if necessary. A single dose of calcium should not exceed 500–600 mg of elemental calcium per dose to ensure absorption. Individuals with established osteoporosis, pregnant or nursing women, those using glucocorticoids, and those over 65 require 1500 mg/day of calcium with 600–800 mg/day of vitamin D. Women who lack adequate sunlight exposure should receive up to 800 IU/day of vitamin D. The recommendations of the Institute of Medicine of the National Academy of Sciences for calcium and vitamin D intake are listed in **Table 2**.

Table 2 Dietary calcium and vitamin D recommendations

Age	*Calcium (mg/day)*	*Calcium for women who are pregnant or lactating (mg/day)*	*Vitamin D*
4–8	800		200 IU (5 μg)
9–18	1300	1300	200 IU (5 μg)
19–50	1000	1000	200 IU (5 μg)
51–70	1200		400 IU (10 μg)
>70	1200		600 IU (15 μg)

From the Institute of Medicine of the National Academy of Sciences (1997).

Hormone Therapy Estrogen is essential in the maintenance of bone mass in women, and it has been well established that after menopause, some women experience rapid bone loss due to increased bone resorption. Specifically, there is an accelerated period of bone loss during the early menopausal years during which women may lose bone mass at the rate of up to 3–5% per year for approximately 5–7 years. In 1984 the NIH Consensus Conference on osteoporosis stated that estrogens were the most effective way to prevent bone loss in postmenopausal women. The main estrogen in use was Premarin (conjugated equine estrogen [CEE]); a progestin was added to prevent endometrial hyperplasia in women with an intact uterus. Estrogen and progestin use increased and was effective in preventing osteoporosis.

However, in 2002 the Women's Health Initiative (WHI) reported greater potential harm than benefit from the use of CEE plus a progestin. This report changed the way that health-care providers managed the treatment of postmenopausal women in terms of osteoporosis prevention. The WHI study was a large, well-publicized, placebo-controlled randomized trial of healthy postmenopausal women ages 50 to 79 who received daily oral CEE/medroxyprogesterone (E + P), Prempro (0.625 mg/2.5 mg). The positive results showed an overall 24% reduction in all fractures after 5.6 years of follow-up and a 33% decrease in hip fractures in women receiving E + P(B). However, the WHI findings also demonstrated that Prempro increased the risk of breast cancer, myocardial

Table 3 FDA-approved drugs for the prevention of osteoporosis in postmenopausal women

Hormones	*Dosage*
Activilla (estradiol/norethindrone acetate)	1 mg/0.5 mg qd
Femhrt (norethindrone acetate/ethinyl estradiol)	0.5 mg/2.5 μg, prevention: 1 mg/5 μg qd
Ortho-Prefest (estradiol/norgestimate)	1 mg/d for 3 days, then 1 mg/0.09 mg/qd for 3 days repeated
Premphase (conjugated equine estrogens/ medroxyprogesterone [MPA])	0.625 mg/day 1–14, then 0.625 mg/mg/day 15–28 0.3 mg/1.5 mg/day
Prempro (conjugated equine estrogens/MPA)	0.3 mg/1.5 mg/day, 0.45 mg/1.5 mg/day, 0.625 mg/2.5 mg/day Prevention: 0.3 mg/1.5 mg/day
Estrace (estradiol)	0.5 mg, 1 mg, 2 mg
Ogen (estrone sodium as estropipate)	0.625 mg, 1.25 mg, 2.5 mg Prevention: 0.625 mg qd
Ortho-est (estropipate)	0.75 mg, 1.5 mg qd Prevention: 0.75 mg
Premarin (conjugated equine estrogens)	0.3 mg, 0,45 mg, 0.625, 0.9 mg, 1.25 mg, 2.5 mg Prevention: 0.3 mg/day
Alora (transdermal) (estradiol)	0.025 mg/day, 0.05 mg/day, 0.075 mg/day, 0.1 mg/day Prevention: 0.05 mg/day patch applied 2/week
Estroderm (transdermal) (estrodiol)	0.05 mg/day, 0.1 mg/day Prevention: 0.05 mg/day patch applied 2/week
Vivelle (transdermal) (estradiol)	0.05 mg/day, 0.1 mg Prevention: 0.025 mg/day patch applied 2/week
Vivelle Dot (transdermal) (estradiol)	0.025 mg/day, 0.0375 mg/day, 0.05 mg/day, 0.075 mg/day, 0.1 mg/day Prevention: 0.025 mg/day patch applied 2/week
Climar (patch) (estradiol)	0.025 mg/day, 0.0375 mg/day, 0.05 mg/day, 0.06 mg/day, 0.075 mg/day, 0.1 mg/day Prevention: 0.025 mg/day patch applied 1/week
Menostar (transdermal) (estradiol)	0.014 mg/day patch applied 1/week

infarction, stroke, pulmonary emboli, and deep vein phlebitis. As a result of this report, many health-care providers promptly discontinued hormone therapy, fearing the increased risk of these serious side effects. In addition, women themselves stopped the use of hormone therapy after hearing about the report, which was widely publicized. As a result, there has been a precipitous decrease in estrogen and progesterone use and a critical re-examination of the use of menopausal hormone therapy. The report has also fostered an increased interest in alternative methods to managing menopausal symptoms, and the use of bioidentical hormones and herbal therapies has ensued. In addition, the Food and Drug Administration (FDA) guidelines concerning treatment to control menopausal symptoms and osteoporosis prevention have resulted in a variety of estrogen and progesterone formulations, doses, and routes of administration, affording various options for women who seek conventional therapy (**Table 3**).

Phytoestrogens, plant-derived natural estrogens, have mild estrogen-like effects in epidemiological and cell line research, but no reduction in fracture incidence has been demonstrated. Human intervention studies to assess the clinical effects of phytoestrogens are needed.

Bisphosphonates (FDA Approved) Bisphosphonates are non-hormonal drugs that decrease bone resorption. Currently there are three bisphosphonates approved by the FDA for the prevention and treatment of osteoporosis. Alendronate (Fosamax) and risedronate (Actonel), in randomized controlled trials, demonstrated an increase in BMD and decrease in the risk of vertebral and non-vertebral fractures in both early postmenopausal women and those with established osteoporosis. The dosing for alendronate is 5 mg daily or 35 mg weekly (prevention), 10 mg daily or 70 mg weekly (treatment), and it is 5 mg daily or 35 mg weekly for risedronate. They must be taken with 8 oz of water 30 min after an overnight fast. In addition, the patient must remain upright for 30 min after ingesting the pill to reduce esophageal irritation (**Table 4**).

Ibandronate (Boniva) is the newest bisphosphonate that can be dosed daily or monthly. It is dosed at 2.5 mg daily or 150 mg once monthly on an empty stomach with 8 oz of water 60 min before other medications, fluids, or food. Again, the patient must be able to remain upright for 60 min after taking the pill. Ibandronate has been shown to decrease vertebral fractures in women with osteoporosis and a history of previous vertebral fracture. There is no

Table 4 FDA-approved non-hormonal drugs for the treatment and prevention of osteoporosis in postmenopausal women

Bisphosphonates
Fosamax (alendronate): 5 mg, 10 mg, 35 mg, 40 mg, 70 mg, 70 mg/75 ml (oral solution); prevention: 5 mg/day or 35 mg/week; treatment: 10 mg/day or 70 mg/week
Actonel (risedronate): 5 mg, 30 mg, 35 mg; prevention and treatment: 5 mg/day or 35 mg/week
Boniva (ibandronate): prevention and treatment: 2.5 mg/day or 150 mg/month
Boniva (ibandronate sodium): treatment: 3 mg quarterly IV
Selective estrogen receptor modulators (SERMS)
Evesta (raloxifene): prevention and treatment: 60 mg/day
Calcitonin
Miacalcin nasal spray (salmon calcitonin): treatment: 200 IU intranasal spray, one spray in nostril daily (alternate nostrils)
Miacalcin injection (salmon calcitonin): treatment: 100 IU SC or IM q other day
Fortical nasal spray (salmon calcitonin): treatment: 200 IU intranasal spray
Parathyroid hormone
Forteo (teriparatide): treatment: 20 μg SC/day

evidence showing that it reduces hip fracture or other non-vertebral fracture, nor that it reduces fracture in women without previous fracture. An intravenous formulation, ibandronate sodium, that is administered quarterly was recently approved by the FDA for the treatment of postmenopausal osteoporosis. Boniva injection is administered over 15–30 s and provides an alternative for patients who are unable to tolerate oral bisphosphonates or who are unable to remain upright for 30 to 60 min (**Table 4**).

Other Bisphosphonates (Non FDA Approved) Other bisphosphonates, while not FDA approved to treat postmenopausal osteoporosis, are available off-label for patients who are unable to tolerate approved preparations. One preparation is zoledronic acid (Zometa), an intravenous (IV) bisphosphonate (4 mg once yearly or less) FDA approved to treat hypercalcemia of malignancy. Generally side effects are mild and of short duration. Current thinking includes the future use of zoledronic acid to treat postmenopausal osteoporosis in patients unable to tolerate oral preparations. Another antihypercalcemia preparation is pamidronate (Aredia), given IV for hypercalcemia, Paget's disease of bone, and bone metastasis. Etidronate (Didronel) is an oral preparation used to treat hypercalcemia and Paget's disease.

Calcitonin Salmon calcitonin (Miacalcin), Calcimar, or Fortical is a peptide hormone approved by the FDA for treatment of osteoporosis in women who are 5 years postmenopausal; it is not approved for prevention. Most commonly it is administered intranasally once daily (200 IU); it may also have an analgesic effect.

This preparation is also available for subcutaneous injection. Calcitonin increases BMD at the lumbar spine and decreases vertebral fracture risk, but it has not been shown to alter non-vertebral fracture rates. It is generally well tolerated, and side effects include rhinitis and, rarely, epistaxis (**Table 4**).

Selective Estrogen Receptor Modulators (SERMS) Raloxifene (Evista) and tamoxifen (Nolvadex), similar in magnitude to that of estrogen, are a class of drugs called selective estrogen receptor modulators (SERMS). Raloxifene exerts estrogen-like effects on bone and blocks estrogen effects on breast and uterus. Raloxifene's use in osteoporosis prevention and treatment is recommended in women >60 years of age at a dose of 60 mg daily. Raloxifene, however, increases the risk of deep vein thrombosis, pulmonary emboli, leg cramps, and hot flashes. Tamoxifen, used in breast cancer therapy, also positively affects bone mass in postmenopausal women (**Table 4**).

Parathyroid Hormone Parathyroid hormone is an anabolic agent that increases bone density by stimulating bone formation. Terparatide (Forteo), the 1-34 sequence of PTH, is approved by the FDA for the treatment of osteoporosis for up to a period of 2 years in postmenopausal women and men at high risk for fractures. The drug is administered by subcutaneous injection of 20 μg daily. Headaches, dizziness, nausea, and leg cramps are adverse effects experienced by some patients. An increase in the incidence of osteosclerosis and osteoscaroma has been observed in rats receiving high doses. This has not been the case in humans receiving therapeutic doses for approximately 3 years (**Table 4**).

Strontium Ranelate Strontium ranelate 2 g/day is a new, well-tolerated oral anabolic agent to treat osteoporosis in postmenopausal women. Originally used in the 1950s to treat osteoporosis, strontium fell out of favor due to a concern regarding mineralization defects. Inappropriate dosing and dietary calcium deficiency may have caused these defects. However, later studies of strontium on bone tissue cultures demonstrated an increased bone formation. This promising research led to renewed interest in the potential application of strontium in the treatment of osteoporosis. Recent studies demonstrate its effectiveness in reducing vertebral fractures in women. Data support the use of strontium ranelate in preventing both vertebral and non-vertebral fractures.

However, strontium ranelate is not FDA approved for the treatment or prevention of osteoporosis at this time.

Overlooked and Emerging Modalities

There exist two useful concepts that are not new, but that have been generally unattended in the search for ways to detect the presence of osteoporosis and prevent hip fracture. Recent studies have confirmed the importance of height loss of more than 1 inch as a reliable indicator of osteoporosis. Yet health-care providers are much more likely to measure weight and blood pressure than they are to measure height. While it is not a new indicator, accurate height measurement is a low-cost marker that merits serious reconsideration for its importance in osteoporosis screening. Likewise, padded hip protectors have shown some promise for decreasing fracture during falls in elderly populations and should be revisited for their value in fracture prevention in persons with severe osteoporosis.

A number of pharmaceutical preparations for treating osteoporosis are in the research phase and are becoming available for treatment. Likewise, community awareness, screening, and education programs are beginning to have an impact in teaching women and their primary care providers about the importance of early diagnosis of osteoporosis and the timely institution of treatment. But for best results, the education and awareness need to be directed toward the young girls and boys who are presently building their peak bone mass, for it is only through their generation and following generations that the problem of osteoporosis can be solved. Osteoporosis is a lifelong condition that manifests itself in old age, and the best treatment is to engage in healthy lifestyles from childhood on, to prevent or reduce bone loss.

Finally, there are a growing number of innovative, non-pharmaceutical biomedical devices under study that hold potential for helping to reduce bone loss and stimulate bone growth non-pharmaceutically. Perhaps the best known such innovation is a vibrating platform device that resembles a laptop computer that delivers a high-frequency, low-magnitude (30 Hz) mechanical signal (perceived as a gentle vibration) to the femur and spine of the standing human. It is thought by its developers to have the capacity to boost bone mass by increasing lower limb circulation of the individual as they stand on the device. Safety of the device has been demonstrated in a 6-month study of children with disabling conditions and in a 1-year randomized clinical trial (opposite a placebo device) in postmenopausal women, with no adverse effects reported. In animal models, the intervention has been shown to inhibit disuse osteopenia. The instrument has also been tested in US Army recruits, and NASA is presently testing the device with astronauts, who are known to lose bone mass while in the weightless environment of space. The treatment is currently being tested using a daily 10-min intervention.

Other Bone Diseases Associated with Aging

Paget's disease is the most common bone disease after osteoporosis. It is a progressive and sometimes crippling disorder of bone remodeling that can affect any bone, but most often involves the spine, pelvis, legs, or skull. Persons with this condition experience an increase in bone loss at the affected site, due to excess numbers of overactive osteoclasts. Bone formation increases to compensate for the loss, but the resulting bone becomes enlarged and is associated with increased formation of blood vessels and connective tissue in the bone marrow, leading to deformity or susceptibility to fracture. The disease can be transmitted across generations, and 15–40% of those affected have an affected relative. However, some studies have suggested that Paget's disease may result from a slow virus infection with measles. If diagnosed early, it can be treated, but it often goes undiagnosed until later in life, when there is pain and thickening or bowing of the affected body part.

Osteomalacia (the adult equivalent of rickets) is a condition in which calcium phosphate is not deposited in the bones correctly. In adults, the condition can lead to fractures in weight-bearing bones such as the pelvis, hip, and feet. Many patients experience bone pain, and some complain of severe muscle weakness. It is a relatively uncommon disease in the United States, since it can usually be prevented with the adequate administration of vitamin D. Osteomalacia can also be caused by disorders that cause loss of phosphorus from the body, and it is sometimes inherited as a mutation of the gene that produces the enzyme necessary to the production of vitamin D. Patients with chronic renal disease are at risk for developing osteomalacia and other bone disorders.

There are also a large number of genetic and developmental disorders of the bone, including a group of usually inherited disorders referred to as osteogenesis imperfecta (OI). The defects associated with this group of diseases interfere with the production of type I collagen (the underlying protein structure of the bone), resulting in low bone mass

leading to recurrent fractures and possible skeletal deformity. Those with type I or type IV, the mildest forms of the disease, may have relatively few fractures, mild to moderate bone deformity, and sometimes dental problems and hearing loss. They may also develop a distinctive blue, purple, or gray discoloration in the whites of their eyes. A more severe form of the disorder (type III) results in more frequent fractures, short stature, hearing loss, and dental problems. Individuals who have the most severe form (type II) typically have numerous fractures and severe deformity, leading to early death. Another group of developmental bone disorders known as oseopetroses causes an increase in bone mass resulting from a genetic defect that impairs the ability of osteoclasts to resorb bone, leading to excessive bone accumulation. Although dense in appearance, the bone fractures easily. In addition, the expanded bone compresses various nerves, causing neurological symptoms such as deafness or blindness. Individuals with this disorder may also suffer from anemia, as blood-forming cells in the bone marrow are crowded out by the excess bone. Two types have been identified in humans, one that is relatively asymptomatic, and another that is usually present at birth and fatal in infancy or early childhood.

One of the most common acquired skeletal disorders is tumor of the bone. Bone tumors may originate in the bone (known as primary tumors) but more commonly result from the seeding of bone by tumors outside the skeleton (metastatic tumors). Primary tumors can be benign (non-cancerous) or malignant (cancerous). Osteochondroma is the most common benign bone tumor, and osteosarcoma and Ewing's sarcoma are the most common malignant bone tumors. Metastatic tumors often result from breast or prostate cancer that has spread to the bone. Bone destruction also occurs with multiple myeloma, which is malignancy of the plasma cells that produce antibodies and cytokines that stimulate osteoclasts and inhibit osteoblasts. Bone-resorbing cytokines are also produced in acute and chronic leukemia, Burkitt's lymphoma, and non-Hodgkins's lymphoma. Other infiltrative processes that affect bone include infections and marrow fibrosis (myelofibrosis).

Finally, the prevalence of oral bone loss is a significant problem among adult populations worldwide. Oral bone, like the rest of the skeleton, comprises both trabecular and cortical bone and undergoes formation and resorption throughout the life span. When oral bone loss exceeds gain, it can cause a loss of tooth-anchoring support or diminish the remaining ridge in those areas where partial or complete tooth loss has occurred. Oral bone loss with resulting tooth loss is associated with estrogen deficiency and osteoporosis and may create the need for periodontal and prosthetic procedures. Oral examination, including radiologic findings, may assist in the diagnosis of extra-oral bone loss.

Summary

Osteoporosis is a devastating public health problem that affects all strata of the global community. The good news is that healthy women and men 50–65 years of age still have time to engage in osteoporosis-preventing behaviors to reduce bone loss and eventual height loss. Concerted effort must be directed toward community education and the development of new treatment modalities to rid towns and communities worldwide of the ravages of osteoporosis, as our predecessors spared modern society from the devastation of polio, smallpox, and rickets. Though less common than osteoporosis, there are also a number of other bone disorders that create serious problems for older adults. It is important that additional research be conducted to find effective treatment measures and that both professionals and the general public be better informed about bone health.

Oxidative Damage

A K Balin and M Vilenchik, The Sally Balin Medical Center, Media, PA, USA

Glossary

Enzymatic Antioxidant Defense System – Enzymatic antioxidants (antioxidative enzymes) that provide protection against oxidative damage to biological molecules.

Free Radicals and Reactive Oxygen Species – Any chemical species that contains one or more unpaired electrons in the outer atomic or molecular orbitals. Free radicals are normal metabolites and are usually very reactive. Biologically the most important are carbon-centered radicals, produced during lipid peroxidation; sulfur-centered thiyl radicals; nitrogen-centered radicals; and, in particular, oxygen-centered radicals. The terms free radical, oxygen free radical, and reactive oxygen species (ROS) are often employed in biological and medical publications as synonyms. ROS also include the non-radical species H_2O_2 and singlet oxygen, which can be produced through radical reactions and/or can produce free radicals, thereby contributing to oxidative stress. Thus, ROS includes radical and non-radical species. They are usually lumped together because of the increased reactivity of ROS with biomolecules, even if they are non-radical species. Also, free radicals of biological importance include reactive nitrogen species such as nitric oxide that is a free radical synthesized by a family of enzymes called nitric oxide synthases.

Free Radical Theory of Aging – Initially proposed by Denham Harman in 1954, this theory suggests that free radical-inducing and/or -producing biochemical reactions can damage the tissue's major molecular components and that the damage is a cause of aging and is involved in the pathogenesis of many aging-related common chronic diseases.

Lipid Peroxidation – A series of free radical reactions, which usually are initiated in membranes from the interaction of ROS with polyunsaturated fatty acids and which can result in a chain reaction producing aldehydes and hydroperoxides.

Oxidative Damage or Oxidative Injury – Uncontrolled reactions of ROS with the prime targets being bases in DNA, amino acids in proteins, and unsaturated lipids in cell membranes.

Introduction

A variety of reactive oxygen species (ROS) are produced during normal metabolism. They can react with proteins, DNA, and other biomacromolecules, either directly or through a chain of free radical

reactions, which usually are initiated in the membranes by lipid peroxidation. Oxidative damage to biomolecules is limited by antioxidant defenses. But the defenses are not 100% effective. A small percentage of ROS such as superoxide radical and H_2O_2 have been found to escape before contact with deactivating enzymes. Additionally, certain levels of these reactive species are necessary for normal cellular function. Kinetically, ROS can escape from normal cellular metabolic pathways, particularly if present in nonphysiological amounts. Thus, ROS can induce various alterations, including difficult to repair damage to oxidizable biomolecules. These include key molecules, such as tumor suppressor genes, mitochondrial DNA, transcription factors, and DNA repair enzymes. Dysfunction of these molecules may be involved in the pathogenesis of senescence and some of the common chronic diseases.

Chemical and Biochemical Aspects

Important Sources and Mediators of Oxidative Damage

There are endogenous and external sources of 'natural' oxygen free radicals and other ROS. Thus, under normal conditions endogenous ROS are generated in living cells as a by-product of normal metabolism and during cellular/physiological signaling and in connection with inflammatory responses. Specifically, the established endogenous sources of superoxide anion radical and hydrogen peroxide include the mitochondrial electron transport chain, endoplasmic reticulum (microsomal electron transport chain) peroxisomes, nuclear and plasma membranes, and phagocytic cells. Cigarette smoke, sunlight, and dietary factors such as certain metals and substances that oxidize glutathione are among the main exogenous sources of ROS production in the human body. The contribution of each of the ROS-producing cell compartments (cytosol, mitochondria, microsomes, and peroxisomes) to a total 'ROS load' is dependent on the cell type.

Until the beginning of the 1990s, it was generally believed that only phagocytes can generate ROS through events catalyzed by a membrane-associated respiratory NADPH oxidase. But NADPH oxidase-like enzymes, which can be activated by growth factors and which produce $^{\bullet}O_2^-$, have been found in many other cells. Another important source of free radicals is the metabolism of L-arginine, which can result in the production of the free radical nitric oxide, $NO^{\bullet}$.

Biologically relevant production of ROS in human skin by ultraviolet A is well documented. However, some of the biological effects of the sun's UVB (wavelength component 290–320 nm) have been connected with the enhanced generation of ROS. Although the exact source of ROS produced by UVB has not been clearly revealed, it has been demonstrated using human keratinocytes that NADPH oxidase and cyclooxygenase mediate the UVB-induced generation of ROS. This observation reveals that an external 'natural' inducer of ROS produces them in exposed human cells through activation of an endogenous source of ROS, such as NADPH oxidase.

There are three main types of radical reactions *in vivo*: (1) radical addition reactions, (2) electron transfer reactions, and (3) atom abstraction reactions. The chemical reactivity of the superoxide radical is less than the hydroxyl radical. The half-life of the superoxide radical ranges from 0.4 μs to 1 ms. For comparison, the half-life of the hydroxyl radical is 0.3 ns.

Hydrogen peroxide is a weak oxidizing agent and is the most stable intermediate of oxygen's reduction products. However, H_2O_2 can oxidize sulfhydryl groups of enzymes and other proteins such as transcription factors. The effects of very low concentrations of H_2O_2 and $^{\bullet}O_2^-$ are potentiated in the presence of transition metal ions, because extremely reactive hydroxyl radicals, $^{\bullet}OH$, are generated from H_2O_2 by means of transition metal ion-catalyzed reactions called the Fe-catalyzed Haber-Weiss reaction or the Fenton reaction.

Catalysts of $^{\bullet}OH$ radical production can be bound to proteins and membrane lipids and can initiate site-specific protein oxidation and lipid peroxidation if H_2O_2 is formed and/or transported to these sites.

Singlet oxygen is an electronically excited form of oxygen and is a strongly electrophilic molecule produced in tissue as a result of dismutation of superoxide radical. In the skin, singlet oxygen is additionally produced as a result of various photochemical reactions. Nevertheless, the biological role of the production of this 'neglected' ROS under normal conditions or during accelerated aging remains unclear. Singlet oxygen, in addition to the hydroxyl radical, can attack DNA directly. Also, singlet oxygen can damage various enzymes through amino acid modification and may lead to oxidative damage in membranes and blood plasma because it has high reactivity with double bonds in unsaturated fatty acids.

Primary Molecular Defense Mechanisms against Oxidative Damage

Enzymatic Antioxidants Certain enzymes and many small water-soluble and lipid-soluble molecules can

intercept and destroy free radicals and other ROS. Important components of cellular enzymatic protection include catalase, superoxide dismutase (Mn, Cu/Zn, extracellular), glutathione peroxidase, glutathione reductase, glutathione S-transferase, glucose-6-phosphate dehydrogenase, and thioredoxin reductase.

Non-enzymatic Antioxidant Proteins and Low-Molecular-Weight Antioxidants There exist proteins that are not traditionally considered as antioxidants but that have important antioxidant functions. Among them are metallothioneins, low-molecular-weight sulfhydryl-rich Zn/Cu proteins, which are natural scavengers of superoxide and hydroxyl radicals. Important non-enzymatic macromolecular antioxidant defense mechanisms include metal binding proteins such as ferritin and ceruloplasmin, which remove iron and copper ions, respectively. These ions can catalyze the production of $^{\bullet}OH$ and other ROS such as alkoxyradicals.

The antioxidant proteins are supplemented by a number of low-molecular-weight molecules that protect against oxidative damage in tissue. These include (1) endogenous antioxidants, such as reduced glutathione, cysteine, and some other sulfhydryl-containing molecules; ubiquinol 10 in reduced state; bilirubin; uric acid; and lipoic acid in reduced state; and (2) essential antioxidants, vitamin C (ascorbic acid), the principal and terminal scavenger of radicals in the aqueous phase; vitamin E, the principal chain-breaking antioxidant in membranes; vitamin A (retinol), a peroxy radical and thiyl radical scavenger; beta carotene, a precursor to vitamin A and a singlet oxygen quencher; and lycopene, the non-vitamin precursor carotenoid with extremely high singlet oxygen-quenching activity.

Among water-soluble scavengers of free radicals, reduced glutathione (GSH) is one of the most abundant biological antioxidants that function to maintain redox homeostasis *in vivo*. Reduced GSH can scavenge various free radicals. Vitamin C also scavenges various oxy radicals, including thiyl radicals.

Repair of Oxidative Damage One of the most prevalent and best-studied oxidative damage products in DNA is 7,8-dihydro-8-oxo-2′-deoxyguanosine (8-oxodG) (or its base form, 8-oxoguanin [8-oxoG]). This DNA damage is repaired through two pathways. The major pathway, base excision repair (BER), consists of removing the oxidized guanine, while some mammalian cells utilize another pathway, the nucleotide excision repair (NER) pathway. Oxidative damage to DNA, specifically 8-oxoG, may be one of the molecular determinants of aging and may also be involved in the pathogenesis of a number of chronic diseases associated with aging.

Base excision repair is performed by (1) a specific DNA glycosylase that recognizes and removes this damage, resulting in an abasic site; (2) an apurinic-apyrimidinic endonuclease that cleaves the phosphodiester backbone; (3) DNA polymerase, which fills the nucleotide gap, and (4) DNA ligase, which seals it.

Oxidized DNA base repair primarily occurs by this base excision repair pathway, which is important to know in order to properly interpret the results of measurements of 8-oxo deoxyguanosine in human and rodent urine. This nucleoside is primarily excised through the NER pathway, while the glycosylase removes the base but not the nucleoside.

In vivo Measurement of Free Radicals and Markers of Oxidative Stress

An increase in the concentration of free radicals, measured using electron spin resonance (ESR) spectroscopy, can reflect the degree of oxidative stress. An *in vivo* ESR spectroscopy technique has been developed to measure free radical reactions even in the whole animal non-invasively using nitroxide free radicals, which are sensitive to both redox state and ROS. Rates of penetration of nitroxide free radicals into the skin and their distribution in the skin have been measured by the ESR technique. Thus, the generation and distribution of radicals produced during normal metabolism or induced after irradiation of the skin by sunlight can be measured.

However, there are significant limitations to the use of ESR to detect radical intermediates in association with oxidative damage in cells and tissues. Some radicals have very short lifetimes under normal conditions. These very reactive radical species will be less likely to accumulate, because their measured steady state concentrations are dependent on the rates with which they react with surrounding molecules. Thus, more reactive radicals are less readily observed by standard ESR techniques. To measure concentrations of very reactive radicals, spin-trapping agents such as α-phenyl-N-tert-butylnitron (PBN) and 5,5-dimethyl-1-pyrroline-N-oxide (DMPO) are used *in vivo*. But interpretation of the data concerning concentrations of the trapped radicals *in vivo* is complicated due to unknown mechanisms of metabolism of the spin traps and their respective radical adducts. The degradation of radical adducts of DMPO in cells can be very rapid.

There are specific markers of the attack of $^{\bullet}OH$ radical (DNA adducts, aromatic probes, amino acid

hydroxylation, and salicylate hydroxylation products) that are used for measuring $^{\bullet}OH$ *in vivo*. Of these and other biomarkers that indicate the intensity of an oxidative stress (aging-associated or associated with exposure to radiation or to other stressful environmental facts), measurements of 8-oxoG (or 8-oxodG) have become increasingly popular. Until quite recently, however, there were problems with the measurement techniques. In particular, earlier studies of the levels of induction and repair of this type of DNA damage used DNA that was isolated using either phenol or other organic solvents, which resulted in a high background level of the damage, while the use of sodium iodide indicated at least a 10-fold lower background level of the damage. The immunohistochemical detection of 8-oxodG allows detection of this damage *in situ*, therefore avoiding DNA damage during the DNA isolation and preparation for analysis. It is worth noting, however, that the published data on 8-oxodG are in agreement with the major conclusions derived from earlier studies, i.e., there is accumulation of 8-oxodG in DNA of cells and tissues with chronological age.

One of the most important pathways of oxidation of proteins by the ROS is conversion of side chain amino groups to carbonyl derivatives called protein carbonyls. Measurements of the levels of protein carbonyls in human body fluids have been used to estimate the levels of oxidative stress *in vivo*. Various tests have been developed to measure lipid peroxidation in human tissues and body fluids. The older method of measurement, the thiobarbituric acid assay, can be improved upon by a more accurate and sensitive method, which is based on the non-enzymatic production of a group of prostaglandin-like compounds arising from ROS attack on phospholipids.

Molecular-Physiological and Pathological Responses of Mammalian Cells to Oxidative Damage

Regulatory Role of Reactive Oxidants and Antioxidants

Cellular Response to Oxidative Stress and Sensitivity of Transcription Factors to ROS That Determine the Response It is established that control of gene expression is required for proper response to stress and that transcription factors play a crucial role in regulating these processes. Modification of the redox state of certain transcription factors can contribute to or inhibit the formation of specific complexes between these factors and their cognate DNA elements in mammalian cells. This mechanism is similar to the mechanism of regulation of gene expression in response to oxidative stress in bacteria through a change in the DNA-binding specificity of the bacterial transcriptional regulatory protein, OxyR. For example, formation of a regulatory disulfide bond in OxyR transcription factor activates it *in vitro*, while studies of the *in vivo* oxidation of this protein indicate its oxidation within 30 seconds in response to hydrogen peroxide. The oxidation is transient and is associated with activation of transcription of OxyR-regulated genes. In mammalian cells, there are several pathways of regulation of transcription factors by ROS.

Role of the Nrf2-Keap 1 Complex of Proteins in the Induction of Genes Encoding Antioxidant Proteins in Response to an Oxidative Stress A molecular defense system provides cytoprotection against oxidative stress and against electrophiles by the expression of antioxidant proteins and phase 2 detoxifying enzymes, respectively. A key element of this system that regulates the resistance of cells to ROS or electrophiles is a cis-acting element called the antioxidant responsive element (ARE) or electrophile responsive element (EpRE), which is located within the regulatory region of a number genes that are induced upon exposure to low levels of ROS or electrophiles. During the past 10 years, it has become evident that among the ARE/EpRE binding transcription factors, Nrf2 plays a major role. This protein was first isolated by two independent groups of researchers in the mid-1990s as a protein closely related to p4 NF-E2. Therefore, its complete name is NF-E2-related factor 2.

Another important element in the response to oxidative stress or electrophiles is Keap1 (Kelch-like ECH associating protein 1). Keap 1 determines the intracellular localization of Nrf2 by binding and thus sequestering Nrf2 in the cytoplasm (recall that Nrf2 is a transcription factor that can function only upon reaching its cognate DNA sequences). However, ROS or electrophiles can induce the release of Nrf2 from its inhibiting 'partner' Keap 1 and allow Nrf2 to accumulate in the nucleus and then interact with the cognate DNA elements to enhance the expression of a number of cytoprotective genes, in which these elements are placed.

Cell Replication and Differentiation Oxidants can regulate cell replication in a dose-dependent manner. Usually, low levels of exogenous oxidants stimulate cell replication, whereas high levels of oxidants inhibit it. Endogenously generated ROS, such as superoxide radical and hydrogen peroxide, can act in various cells as signals augmenting the proliferative response. Transcription factors and/or kinases

involved in growth signal transduction pathways can mediate these effects through regulation of the expression of genes and the activity of proteins that control the cell cycle.

For example, in human hepatoma cells, ROS-induced proliferation correlated well with the extracellular signal-regulated kinase (but not JNK or p38) activity. Studies using mitogen-activated protein kinase (MAPK) inhibitors have shown that the MAPK signaling pathway can lead to activation of cell proliferation, which can be triggered by ROS.

Since Allen and Balin demonstrated that manganese superoxide dismutase (MnSOD) activity increased by as much as 46-fold during the differentiation of *Physarum polycephalum*, this enzyme has been found to be increased as differentiation proceeds in various other biological systems. Moreover, transfection of rodent cells with MnSOD promotes their differentiation. Liposomes containing SOD can induce differentiation in some tumor cells, such as Friend erythroleukemia cells. Thus, factors controlling redox state such as the levels of SOD can be involved in the mechanisms of differentiation.

Paradoxically, not only the antioxidant enzymes, but also the oxidant H_2O_2 can induce cell differentiation in some systems. This paradox can be partially resolved if one remembers that SOD is involved in the mechanisms of production of intracellular H_2O_2. On the other hand, oxidative stress induced by H_2O_2 can result in an adaptive response, resulting in an increased activity of SOD.

Pathophysiological and Gerontological Aspects

Primary Targets of Oxidative Injury, Physiological Aging, and Diseases Associated with Aging: Rationale for Prevention of These Disease by Optimal Use of Antioxidants

Oxidative Damage to Nuclear DNA and Replicative Cell Aging and Initiation of Carcinogenesis Even under normal conditions, the cell's DNA is bombarded by many ROS each minute. Most spontaneous oxidative DNA damage is removed by DNA repair systems. But, as shown in many radiobiological studies, these repair systems are not 100% effective. Thus, oxidative damage to DNA and, in particular, the difficult to repair complex DNA damage that can be produced by hydroxyl radicals might accumulate during aging.

After it was discovered in the mid-1980s that the major oxidative damage to DNA in cells exposed to ionizing radiation is 8-oxodG, a number of studies demonstrated that normal aging of human and rodent tissues is associated with an accumulation of this oxidative DNA damage product.

8-oxodG is a strong mutageneic and (pre)carcinogenic oxidative lesion, and DNA damage can be a major player in the mechanisms of the aging-associated carcinogenesis and pathogenesis of chronic diseases, including atherosclerosis and some neurodegenerative disorders. Studies in which DNA was isolated by a more gentle sodium iodide technique showed that there is a significant increase in the levels of 8-oxodG in DNA in tissues of mice and rats with age. For example, there was an 84% increase in 8-oxodG in nuclear DNA isolated from liver and a 37% increase in 8-oxodG in nuclear DNA from the hearts of male F-344 rats.

Oxidative Damage to Lipids, Proteins, and Lipoproteins and Promotion of Carcinogenesis and Degenerative Diseases The classical model of carcinogenesis has been operationally divided into initiation (mutation and formation of a transformed clone), promotion (expansion of the clone), and progression (malignant evolution of tumor cells toward increased malignancy). It is established that H_2O_2 and some organic peroxides stimulate the promotion of skin cells to develop into papillomas. These oxidants can also stimulate progression of papillomas into carcinomas. Agents that generate ROS are also tumor promoters and/or can mimic the biochemical action of tumor promoters in a variety of other cells and tissues besides the skin. On the other hand, various antioxidants inhibit tumor promotion.

Data obtained using biophysical, biochemical, and histochemical methods indicate that lipofuscin is a lipid-protein adduct complexed with metal ions, including copper and iron. These metals may be involved in the pathogenic mechanisms of age-dependent accumulation of lipofuscin by activation of lipid peroxidation. Direct or metal-catalyzed reactions of oxygen and unsaturated fatty acids also contribute to the age-related accumulation of lipofuscin. This accumulation may play a role in the functional decline of postmitotic cells.

One of the more serious end points of the activation of lipid peroxidation and the formation of oxidative damage to lipoproteins is the atherosclerotic lesions that develop in blood vessels. A significant decrease in the activity of antioxidant enzymes, in particular, superoxide dismutase and glutathione peroxidase, has been found in atherosclerotic tissue, while ROS can induce oxidative damage to both the lipid and protein components of low-density lipoprotein (LDL) and other lipoproteins.

Accordingly, oxidative modification changes the properties of LDLs and high-density lipoproteins in ways that are known to promote atherogenesis. Furthermore, lipoprotein particles with physicochemical properties similar to oxidized LDL have been found in human atherosclerotic lesions. Oxidized amino acids have been found in proteins isolated from atherosclerotic lesions. The pattern of these amino acids implicates reactive intermediates generated by myeloperoxidase, a major phagocyte enzyme. This suggests that myeloperoxidase promotes LDL oxidation *in vivo* and that this oxidation is involved in the formation of atherosclerotic lesions.

The atherogenic potential of LDLs is increased through the non-enzymatic binding of glucose to the protein component, that is, by glycation of the protein. The combined effect of oxidation and glycation, which is exaggerated in diabetic individuals, can foster the development of atherosclerosis.

However, studies of cohorts of humans with a high risk of atherosclerosis have not shown significant benefit from vitamin E or other antioxidants. At the moment, there is no clinical evidence demonstrating that antioxidant supplements are of value in the prevention of cardiovascular diseases in subjects at high risk, as was thought previously. However, the picture is complicated by the observation that even the most popular antioxidants may, under certain conditions, become pro-oxidants. This may be why the use of beta carotene for the prevention of cancer in smokers led to an increase in cancer in the subjects studied.

There is some evidence, obtained on preclinical models of Alzheimer's disease (AD), Parkinson's disease, and Huntington's disease, for the primary role of protein oxidation in the initial steps of these neurodegenerative diseases. Aging is a risk factor in the development of these diseases. The increase in oxidized proteins isolated from the brains of humans suffering from these diseases can reflect a mechanism of initiation of a cascade of biochemical events that results in the neurodegeneration.

Indeed, almost all amino acids in proteins are potential targets for oxidation by ROS. Methionine and cysteine residues are particularly sensitive to oxidative damage, while the formations of carbonyl derivatives of cysteine as well as lysine, arginine, proline, histidine, and threonine residues comprise the most widely studied oxidative modifications of proteins. Multiple studies have confirmed the initial observation by E. R. Stadtman of the aging-related increase of protein carbonyls in human cells and tissues. Furthermore, elevated levels of carbonyl proteins have been observed in the two major human progeroid syndromes and in some of the aging-related common diseases, including Alzheimer's disease.

Thus, oxidatively damaged DNA, lipids, and proteins accumulate in human and animal tissues with chronological age. In addition to the age-related increase in the level of protein carbonyl content, there is also an increase in the amount of oxidized methionine and cross-linked and glycated proteins. These observations help explain the earlier discovery of David Gershon of the aging-related accumulation in mammalian tissues of a fraction of less active or inactive enzymes, which have increased susceptibility to heat inactivation.

However, the mechanisms leading to the aging-related increase in the levels of oxidatively damaged proteins remain obscure. It is hypothesized that one such mechanism is increased ROS production associated with reduced functioning of proteasome-based mechanisms of degradation of oxidized proteins. It is still not known whether ubiquitylation is necessary for the degradation of such 'aged' *in vivo* proteins.

Oxidative Injury-Dependent Pathway of the Apoptotic/Programmed Cell Death Mechanisms Programmed cell death plays an important role during aging of various tissues and cells *in vivo*. For example, age-dependent apoptotic cell death has been documented in the aged brain. However, human fibroblasts aged *in vitro* are resistant to apoptosis. But unlike aged fibroblasts, human endothelial cells undergo age-associated cell death during *in vitro* senescence, which is also associated with a significant increase in the intracellular concentration of ROS. Thus, a link between aging-related ROS production (and therefore oxidative damage to biomolecules) and aging-associated apoptotic cell death exists, although this link seems to be a cell type-specific phenomenon.

Oxidative Damage to Intracellular Components of Connective Tissue and Skin Aging ROS such as hydrogen peroxide modulate the activity of signaling molecules that induce expression of extracellular matrix-degrading metalloproteinases (MMPs). This signaling in human skin can be blocked by antioxidants, confirming suggestions that redox reactions are involved in the regulation of MMP expression. On the other hand, UV light, which is responsible for human skin photo-aging, increases the activity of MMPs, in particular, MMP-1. Thus, systemic degradation of collagen by MMPs has been implicated in premature skin aging and a number of other disorders associated with accelerated aging.

Oxidative Damage to Mitochondrial DNA and Limit of Life Span of Animals and Humans Only mitochondrial DNA (mtDNA) is vulnerable to a direct attack of hydroxyl radical produced in the mitochondria, because hydroxyl radical has a very short half-life (0.3 ns) and diffuses less than 10 molecular diameters before it reacts. Therefore, this radical causes DNA lesions near its origin.

Superoxide radical or H_2O_2 can react with unsaturated lipids, which are enriched in the inner mitochondrial membranes. It has been shown that lipid peroxidation of these membranes is associated with damage of mtDNA. The vulnerability of mtDNA to oxidative damage is amplified by a lack of histones, which can partially protect nuclear DNA in chromatin. The nucleotide excision DNA repair pathway, which could contribute to repair of oxidative damage, is absent in mitochondria.

The content of 8-oxodG measured in mtDNA isolated from autopsied myocardium of Japanese patients increases exponentially with age and in parallel with the accumulation of mtDNA that contains a 7.4 kbp deletion. The age-dependent increase in both these mtDNA alterations is correlated with an age-dependent increase in the death rate in Japan.

An age-dependent increase in the proportion of mtDNA with a common 5-kb deletion compared to normal mtDNA has been found to occur in the skeletal muscles of American patients. This mtDNA deletion increases exponentially and in parallel with the age-dependent increase in the human death rate in the United States. In all cases, the ratio of altered mtDNA to normal mtDNA and the death rate in both countries double each 7–8.8 years after age 30–40.

It is generally believed that the major mechanisms limiting the proliferative life span of replicative cells aged *in vitro* involve telomere shortening. It is interesting that telomeric DNA (tDNA) is particularly vulnerable to various sources of oxidative damage. The special features of instability and repair of mtDNA and tDNA suggest the possibility that together they might play a role in limiting the life span of human postmitotic and replicative cells, respectively.

Oxidative Stress and Premature or Accelerated Aging

The Late Biological Effects of Ionizing Radiation Exposure to ionizing radiation results in an increase in oxidative damage to DNA, protein, and lipids in a dose-dependent manner. This increase is mainly the result of the increased rate of production of ROS and their direct attack on biomolecules.

Late biological effects of ionizing radiation include accelerated aging on different levels. For example, an increase in the rate of the age-dependent accumulation of DNA damage in brain cells and of cross-links in collagen molecules has been observed in rodent tissues many months after they were exposed to ionizing radiation.

Photo-aging of the Skin and Accelerated Aging of Collagen Connected with Diabetes The rate of aging of human skin is related to the combined effects of chronologic aging and actinic damage, referred to as photo-aging. The destruction of several antioxidant enzymes, including SOD and catalase, occurs in UV-irradiated keratinocytes *in vitro* and in the epidermis and dermis of skin exposed to UV light *in vivo*. Thus, skin proteins are vulnerable to UV light, and this vulnerability is amplified by the decline in enzymatic antioxidant defenses.

Exposure of skin to UV light results in lipid peroxidation and is associated with the production of singlet oxygen. In addition, UV-induced oxidative damage in human skin can be mediated by sensitized molecules, including tryptophan, riboflavin, and pyridoxine. There is direct evidence, obtained by measurement of free radical signal intensity using ESR techniques, that UV radiation produces ROS and carbon-centered radicals in human skin. Photochemically generated ROS induce various alterations, including cross-links in collagen that contribute to the molecular mechanisms of photo-aging of mammalian skin.

In addition, there is evidence that certain skin metalloproteinases are involved in photo-aging and are induced by ROS leading to the degradation of collagen types I, II, and III. For example, induction of a major enzyme (MMP-1) in human skin by UV light requires production of hydrogen peroxide. Therefore, ROS could contribute to the reduction of collagen content in human skin with chronological age and/or photo-aging, indirectly through the induction of MMPs in the skin, specifically MMP-1.

The content of lipid peroxidation products is increased in the aged epidermis of animals and humans. Accordingly, in the senescence-accelerated mouse model, an increase in lipid peroxide levels in the skin precedes the accelerated senescent clinical signs of mutant mouse skin.

Skin senescence and aging-related skin diseases may be associated with a combination of oxidative modifications in addition to the non-enzymatic glycation of skin proteins. Glycation of collagen is substantially elevated in diabetic patients as compared with age-matched controls. This phenomenon can be referred to as accelerated aging of collagen, because collagen glycation increases almost linearly with normal aging. Collagen isolated from tissues of

long-term diabetics is more stable in comparison with age-matched controls. Mechanisms of the stabilization of collagen molecules during normal and diabetes-accelerated aging include cross-linking of the molecules via glucose.

Summary

Of the numerous modifications of various biomolecules induced by ROS, a few can be identified as oxidative damage associated with the process of aging. One of these oxidative damage products is 8-oxoguanine. Its steady accumulation with age in mitochondrial DNA of hearts and brains, and in nuclear DNA of replicative cells, can be correlated with the age-dependent increase in the risk of chronic heart and brain disease and cancer, respectively. These observations lend a strong credence to Harman's free radical theory of aging. But the picture that emerges is more complex than one simply due to damaged products.

First, different ROS play a specific role in many processes, including intracellular signal transduction, cell proliferation, differentiation, and apoptotic cell death mechanisms, which are required for both normal development and maintenance of adult health. Different ROS are endowed with different biophysical and biochemical characteristics, such as half-life, affinity to certain receptors, and chemical reactivity with certain groups in macromolecules including bases in DNA. These characteristics influence the physiological role of the different ROS.

Second, the physiological role of at least some of the ROS can be mediated by transcription factors, which are both sensors of the levels of ROS and/or of redox state and regulators of genes that determine cellular response to oxidative stress. These genes are among those that modulate cell replication and differentiation. This provides a mechanism in which ROS are involved in both the regulation of cell replication and differentiation and in the pathogenesis of diseases connected with deregulation of these processes.

Pain and Presbyalgos

S W Harkins and R B Scott, Virginia Commonwealth University, Richmond, VA, USA

This article is reproduced from the previous edition, volume 2, pp 247–260, © 1996, Elsevier Inc.

Glossary

Nociception – Sensory properties of pain and pain perceptions. Determined, in part, by type, intensity, location, duration of the stimulus and resulting activity in nociceptive pathways in most cases. Central pain and other conditions involving referred pain, reflex sympathetic dystrophy, or causalgia are accepted as involving activity in nociceptive pathways. Sensory qualities of different nociceptive events may differ.

Nociceptor – A receptor preferentially sensitive to a noxious stimulus or to a stimulus that would become noxious if prolonged or sufficiently intense.

Pain – An unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage. Pain is always subjective. Activity induced in the nociceptor or nociceptive pathways by a noxious stimulus is not pain, which is always a psychological state.

Pain Affect – Pain can elicit two distinct emotional components. One, the primary affective component, is associated with the immediate sensory/perceptual experience and is strongly related to cotemporal sensory pain experience (nociception). Another, the secondary affective component of pain, is determined more by past history of the painful experience, personality, cognitive appraisals, and meaning of the pain to the individual. This dimension of pain can be equated with suffering (see **Table 1**).

Presbyalgos – (*presby*, old; *algos*, pain) A general term used to describe age changes in pain sensitivity, perception, affect, and behavior. It differs from the terms employed to describe age changes in vision (presbyopia: *opia*, vision) or audition (presbycusis, *cusis* or *acusis*, hearing), which are restricted to losses in sensory acuity. Presbyalgos includes sensory, cognitive, affective, and behavioral components and is not a generalized decrease in sensitivity to pain in old age, a phenomenon that likely does not exist. Social cohort influences on meaning of pain to the individual, individual differences in definition of pain and its properties, as well as individual differences in definition of acceptable pain behaviors must not be interpreted as age differences in nociception.

Introduction

The topic of geriatric **pain** has not received attention in the field of gerontology until recently. This article reviews what is currently known about pain in relation to age in the later years of life. Pain is defined and a preliminary definition of **presbyalgos** is presented. The relations between old age and different types of the human experiences of pain are reviewed. These include experimental pain, acute procedural and clinical pain, postsurgical pain, atypical pain, and chronic pain. Considerations for pain assessment in the geriatric population are discussed, and needs for future research to improve pain assessment in specific populations of elderly pain patients are suggested.

There are at least four factors that might influence pain perception in the later years of life. These include loss of receptors for pain (nociceptors), changes in conduction properties of primary nociceptive (pain) afferents, changes in central mechanisms subserving the coding and sensation of pain, and psychosocial influences affecting the meaning of pain to the individual. The psychosocial influences that may differ between younger and older adults include those due to experiences with pain over the lifetime (developmental effects) and those due to social history or secular change (birth cohort effects) (*see* Touch and Proprioception).

Currently, it is unclear whether pain perception is influenced by age in the later years of life. This is due

in large part to confusions concerning not only the definition of what pain is, but also questions by some as to whether pain can be measured. As for pain, no discrete physiological markers exist for old age. Yet, this difficulty in definition and measurement of age has not deterred research related to the phenomena of biological, psychological, and sociological aging. Therefore, other reasons must account for the limited understanding of the effects of age on pain.

The field of pain research has expanded enormously in the past decade. This is in part due to (1) successful efforts to define the phenomenon of pain; (2) recognition that different types of pain exist (pain is not a unitary phenomenon); (3) a better understanding of some of the neural mechanisms of specific pain-related phenomenon; and (4) insights into both the impact of pain on the individual as well as the impact of individual differences (i.e., personality) on expression of pain symptoms and behaviors. Nevertheless, the psychophysical evaluation of the effect of age on pain has a history differing considerably from that of almost all other sensory modalities.

Although the physical, physiological, and psychological attributes of most sensory modalities have been carefully characterized, those defining pain are far less well documented. There are at least four reasons for the comparative lag in the understanding of the effects of old age on pain. The *first* reason relates to the precision to which stimuli that activate the various sensory modalities can be controlled and quantified. For example, in auditory or visual psychophysics, the ease of quantification and control of stimuli has facilitated precise definition of the effects of aging on hearing and vision. In contrast, quantification and control of stimuli that produce pain are far less precise. This is due, in large part, to the fact that these stimuli are potentially damaging and difficult to present repeatedly with the same effect, and many lack a natural physical counterpart (i.e., electrical shock).

The *second* reason relates to attitudes about pain. The human experience of pain has sensory-discriminative, motivational-emotional, and cognitive-evaluative dimensions. The operational definitions for measurement of these dimensions, however, remain a topic of considerable debate. Some, wrongly, even consider that pain is a private experience that is not measurable.

A *third* reason is the magnitude of the effort that has been directed toward the study of the other sensory modalities versus the study of pain in relation to age. The number of researchers exploring the effects of age on the psychophysics of other sensory modalities has been far greater than that devoted to the study of adult age differences in pain.

A *final* reason is that it is often simply assumed that age results in a loss of pain perception. In the clinical setting, particularly multidisciplinary pain clinics, it has also been assumed that the older adult with a chronic pain complaint is not a good candidate for treatment. Such ageist attitudes, combined with the view that pain is not measurable and the perceived difficulty in stimulus presentation and control, have limited advances in our understanding of adult developmental factors that may influence pain perception.

Definition of Pain

Pain is defined according to Mersky and by the International Association for the Study of Pain as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage" (Mersky, 1986: S217). It must be explicitly recognized that pain is an experience, not simply a response to a stimulus. Thus, "activity induced in the nociceptor and nociceptive pathways by a noxious stimulus is not pain, which is always a psychological state, even though we may well appreciate that pain most often has a proximate physical cause" (Mersky, 1986: S217). Two situations in which the proximate physical causes of pain are more clearly and quantifiably specified are in acute, procedural pain (e.g., injection, third molar extraction) and in experimental studies of pain in the laboratory. To our knowledge there are no systematic studies of age differences in procedural pain. A number of laboratory studies of the effects of age on pain sensation have been published, and these are reviewed below.

Dimensions of Pain

Human pain has been described as having sensory, emotional, and cognitive dimensions. The sensory components of pain are described in terms of location, temporal properties, quality, and quantity. Quantity in terms of pain intensity is the property most frequently studied, usually by verbal descriptor scales such as the widely used McGill Pain Questionnaire or by visual analog scales (VAs).

Effects of aging on the motivational-emotional dimension of pain has received less attention than the sensory-discriminative dimension. Recently it has been shown that two quite different emotional components of pain exist. One is associated with the immediate unpleasantness of pain. This emotional component (stage 1 pain affect) usually does not exist in the absence of the sensory qualities of a painful event and is primarily, but not uniquely, determined

by pain intensity. The second emotional component of pain (stage 2 pain affect) is associated with broader feelings or moods that are in large part determined by interactions of the history of pain with cognitive-evaluative processes (meanings, expectancies, memories, social context, and pain-related limitations in activities of daily living [PRL-ADLs]). Stage 2 pain affect represents suffering that often occurs in the absence of the nociceptive event or that occurs for any threat to personal integrity. The effect of age on stage 2 pain affect has not been systematically studied.

The cognitive-evaluative dimension of pain has received even less attention in relation to aging. The cognitive aspects of pain involve the meaning of the pain to the individual and expectancies concerning the pain, as well as the contexts in which it occurs, its impact on voluntary or obligatory ADLs (PRL-ADLs) and its effects on social, family, and occupational activities. The cognitive dimension of pain is now recognized to have a greater impact on the two emotional components than on the sensory dimension of pain, with a larger effect on stage 2 than stage 1 pain affect.

Figure 1 serves as a model to review the known effects of age on pain. The different dimensions of pain are illustrated in this figure. In this figure, a nociceptive event results in specific sensations that can be appreciated in terms of intensity, location, temporal quality, as well as other qualities. Cognitive appraisals, combined with the sensory quality of the nociceptive sensation(s) and autonomic arousal, condition the immediate unpleasantness of the painful event (stage 1 affect). The second type of emotional response to pain (stage 2 affect in **Figure 1**), however, is mediated by more complex cognitive events that are influenced not only by the sensory quality and primary affective response but also by the current context and past history with the same or similar pains.

Presbyalgos

Table 1 summarizes possible age effects on the different dimensions of the human pain experience as shown in **Figure 1**. A common view is that the elderly have reduced sensitivity to pain that parallels the well-documented changes that occur in the major senses. Presbyopia (*opia*, vision) is the most common physiological marker for onset of old age for the eye. Presbyopia begins in the later fourth and early fifth decade of life and results in decreased ability to focus on near objects. It is due to loss of flexibility and accommodation ability of the lens. Presbycusis (*cusis*, hearing) is a decrease in hearing that is characterized psycho-physically in terms of increased thresholds for pure tones. It is bilaterally symmetrical, progressive, and irreversible and affects higher before lower frequencies. Although presbycusis is, as presbyopia, almost universal, it affects men to a greater degree than women. Its onset, which is often

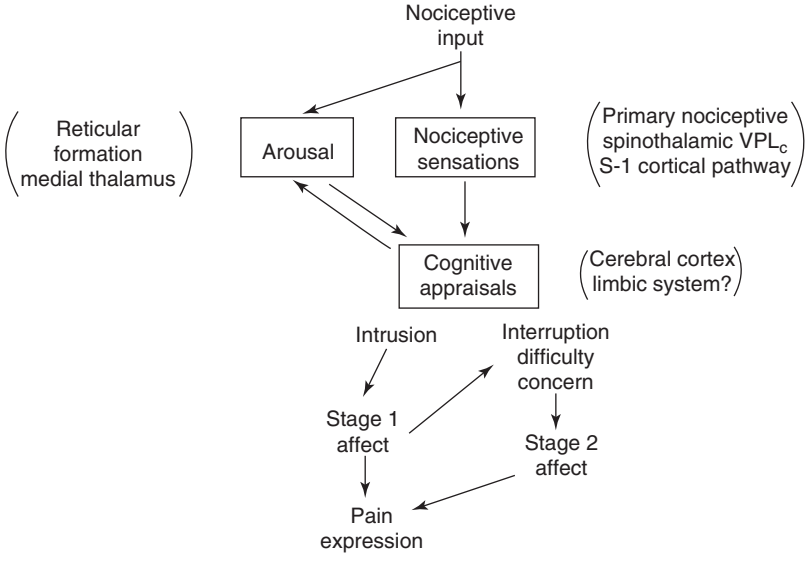

Figure 1 A schematic illustrating the interactions among the various dimensions of pain. Nociceptive input (a painful event) has specific sensory properties that are dependent on the type of pain. The perceived qualities of pain interact with cognitive evaluative processes influencing, to differing degrees stage 1 (immediate unpleasantness of pain) and stage 2 (pain-related suffering) pain affect. Adapted from Price DD and Harkins SW (1992) The affective-motivational dimension of pain: A two-stage model. *American Pain Society Journal* 1: 229–239.

Table 1 Characteristics of presbyalgos

I. Sensory components: Nociception
  A. Characteristics
    1. Determined by stimulus intensity, location, duration, type
    2. Sensory qualities differ for types of pain (e.g., superficial versus deep pain)
  B. Possible age effects
    1. Increased pain thresholds (Not likely)
    2. Increased pain tolerance (Not likely)
    3. Reduced ability to discriminate between pain of various intensities (Not likely)
    4. Reduced ability to discriminate among different pains (Difficult to assess)
    5. Increased frequency of atypical pain as a symptom of disease processes (Definitely)
    6. Increased frequency of chronic pain (Definitely)
II. Primary affective components: Stage 1 pain affect
  A. Characteristics
    1. Strongly related to pain intensity and autonomic nervous system
    2. Related to appraisal of the present and short-term future
    3. Mediated by meaning and cognitive appraisal
  B. Possible age effects
    1. Reduced unpleasantness of pain, due to reduced sensory intensity of pain in general (Not likely)
    2. Reduced unpleasantness of pain due to decreased arousal, exteroceptive (sight, sound), and interoceptive (startle, autonomic) responses resulting in reduced segmental responses to painful injury (No evidence exists for acute pain, may be true of chronic pain)
    3. Reduced general aversiveness of nociceptive stimuli (Unlikely)
    4. Decreased perception of threat, distress, annoyance associated with the intensity of the painful sensation and its accompanying arousal (Unlikely for acute pain)
    5. Differences or changes in cognitive appraisal (Likely)
III. Secondary affective components of pain: Stage 2 pain affect
  A. Characteristics
    1. Related to past and long-term future
    2. Cognitive appraisal
    3. Related to or representative of suffering
    4. Not measurable in experimental studies of pain
    5. Stage 2 pain affect shares many properties of emotional suffering. Suffering is defined here as the state of severe distress associated with events that threaten the intactness of the person. There is confusion between chronic pain and suffering because disease models dominate thinking concerning pain
    6. Unameliorated pain-related suffering (stage 2 affect) requires different interventions than those traditionally used for control of the sensory intensity or the primary affective components of pain
  B. Possible age effects
    1. No systematic studies exist concerning effects of age on the secondary affective component of human pain, but the results shown in **Figure 5** suggest a reduction in stage 2 pain affect with age

a little later than that of presbyopia, indicates the beginnings of old age for the ear. It is due to damage to the hair cells (cilia) of the cochlea and, likely secondarily, to loss of first-order neurons in the acoustic portion of the eighth cranial nerve (sensorineural hearing loss) (*see* Hearing, Vision).

Types of Pain

A phenomenon parallel to presbyopia and presbycusis that would adversely influence ability to perceived painful stimuli could be termed presbyalgos (*algos*, pain). However, a decrease in pain sensitivity with age and associated reduction in either nociceptors or in conduction properties of nociceptive afferents has not been consistently demonstrated in experimental studies of pain.

Experimental Pain

The question of whether age influences the way in which pain is perceived can be assessed in the laboratory. A number of studies have evaluated the effects of aging on experimental pain, employing the psycho-physical end points of threshold, reaction, tolerance, and discriminability. These studies are untidy. Some indicate that there is a loss of pain sensitivity with age, whereas others indicate that the elderly are more pain sensitive compared to younger adults. A third grouping of these studies indicates

that age has no effect on pain sensitivity. These studies are summarized in **Table 2**.

The various outcomes in experimental studies of pain (**Table 2**) reflect number of substantive differences between the studies. These studies vary in stimuli employed, psychophysical end point and method, the age and gender of subjects, as well as subject selection and screening criteria. The instructions and degree of practice on the psychophysical task also likely influence variability among these experimental studies.

It is likely that aging per se has minimal effect on sensitivity to superficial, acute pain. This conclusion is based largely upon recent studies employing contact thermal stimulation. This method of study of cutaneous pain in the laboratory has been demonstrated to be particularly powerful for assessing individual differences in acute pain sensitivity. **Figure 2** presents results from one of these studies. The results of this study indicated a significant, but trival, difference in pain ratings between younger, middle-aged, and older volunteer subjects.

Some earlier studies do indicate increased thresholds for radiant heat-induced thermal pain, whereas others indicated no effects of age (see **Table 2**). We agree with those researchers who have found that pain intensity ratings are similar in older and younger adults if care is taken in subject selection, instructions, and practice. Instructions are critical. When they have clearly indicated that responses are to be made to the pricking or first pain sensation in studies employing thermal stimuli, no age effects have been found.

Acute Procedural Pain

As mentioned earlier, there are, to our knowledge, no systematic studies of age differences in procedural pain in older adults. Procedural pain is defined here as pain resulting from a specific, limited, invasive procedure. Procedural pain has been systematically studied in evaluation of neonatal and pediatric pain (e.g., studies of reaction to heel prick in neonates or to allergy injections in young children). It is surprising that so little research has focused on this area in geriatric patients. There may well be significant hyperalgesia and allodynia in the frail elderly that would be demonstrable by carefully conceived and excuted studies of pain in the old-old and oldest-old.

Postsurgical Pain

Currently available information indicates that the intensity of postsurgical pain in different age groups is similar in quantity and quality. Some researchers, however, found that older adults received less analgesia than younger adults and that this may contribute to a longer hospital stay during post surgery recovery in geriatric patients. Further research is sorely needed in this area and should focus on quality and quantity of procedural and postsurgical pain in relation to age in the later years of life. Long-term follow-up would indicate whether the elderly are differentially at risk for postsurgical causalgia.

Cancer Pain

Cancer pain is a form of acute pain that is related to the type and status of the cancer. Pain in cancer patients occurs frequently. In the elderly cancer patient, any apparent decrease in sensitivity to pain is likely due to less effective report of pain than to actual losses of sensorineural processes subserving pain sensibilities. This impact of cultural inhibition on complaining of pain, and less effective reporting of pain in the old has not been systematically evaluated. Nevertheless, pain in the elderly is more likely to produce significant impairment of psychological, social, and physical function than in younger individuals (*see* Cancer and Age).

Management of cancer pain begins with efforts to control the underlying disease with standard modalities. An important principle of pharmacotherapy is to suppress the pain before it becomes severe, and to give continuous effective doses rather than to attempt to treat episodically. Elderly patients are more responsive to smaller doses than younger persons because of a somewhat diminished metabolism of the drugs (pharmacokinetic effects) and an enhanced effect at the cellular level in the central nervous system (pharmacodynamic effects) (*see* Pharmacology).

In the elderly it is best to use drugs with a short half-life, prescribe one drug at a time, begin with low doses, and continue trial for an adequate period. In addition to the usual analgesics, other non-pharmacological measures frequently used to aid pain control in younger cancer patients may be helpful. These include various forms of nerve stimulation, physical and occupational therapy, sectioning of nerves surgically, or psychotherapy.

Atypical Pain Presentation

Although the evidence is untidy concerning experimental pain sensitivity in old age, there is no question that important age differences exist with regard to acute pain as a symptom in the older patient. Silent or painless acute myocardial infarction (MI) occurs more frequently in the elderly (up to 30%) than in younger patients (23%). Pain consequent to MI develops when sufficient levels of afferent impulses are reached and when an appropriate

[a] From Harkins et al., 1992, as modified from Harkins SW and Warner MH (1980) Age and pain. In: Eisdorfer C (ed.) *Annual Review of Gerontology and Geriatrics*, Vol. 1, pp. 121–131. New York: Springer Publishing Company.

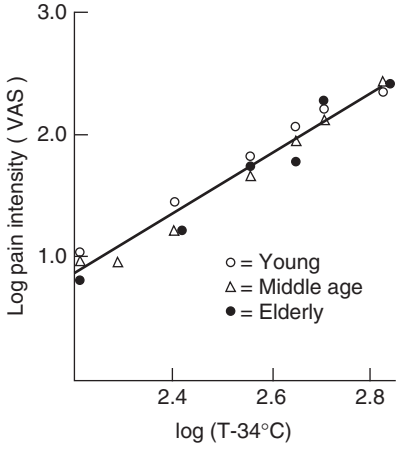

Figure 2 Psychophysical representation of reported pain intensity to brief heat pulses (43°C to 51°C; from an adapting temperature of 34°C) in young ($M = 25$ years), middle age ($M = 53$ years), and older ($M = 73$ years) community-dwelling, healthy individuals. Stimuli were delivered to the inner surface of the forearm. Stimulus intensity in natural log units on the ordinate and pain intensity (by visual analog scales; VAS) on the abscissa. Statistical results indicated a significant groups effect, with older individuals rating the intensity of the lower level stimuli as less intense compared to older subjects. At higher levels of stimulation, age groups were not different in their pain ratings. The significant age effect at lower intensities accounted for less than 1% of the variance in VAS pain ratings. Redrawn from Harkins SW, Price DD, and Martelli M (1986) Effects of age on pain perception: Thermonociception. *Journal of Gerontology* 41: 58–63.

activation of central ascending pathways has been established. In patients with a silent MI, such levels are apparently not reached, perhaps because of insufficient stimulation of the myocardium, decreased capacity for cephalad transmission, or for other unknown pathophysiological reasons affecting peripheral transmission.

Such age differences in presentation of pain as a symptom have been cited as evidence for a general decline with aging in pain sensitivity. This is inappropriate. First, pain does occur with acute MI in the majority of older heart attack patients. Stress testing suggests that depression of the S-T segment, without pain, occurs relatively frequently in both young and elderly adults. Thus, silent MIs may well reflect individual differences or pathophysiological changes in processes subserving referred pain and not generalized age changes in mechanisms subserving pain. Pain from deep structures and superficial pain represent quite different phenomena. Age differences in the one should not be generalized to the other without supporting empirical evidence.

Nonetheless, it is important clinically to recognize the increased prevalence of atypical presentation of pain as a symptom in the elderly. The direction of this is toward reduced not augmented pain. This reduction in incidence of acute pain, associated with certain conditions (e.g., myocardial ischemia) in the elderly, does not appear to hold true for recurrent or chronic pain.

Recurrent and Chronic Pain

Chronic pain has been defined as a pain that has not responded to treatment and that, according to different authorities, has lasted at least 1, 3, or 6 months. Chronic pain can be defined as pain that outlasts the normal healing period following tissue damage by 1 month. A time of approximately 1 month is preferred because failure to intervene will, in some cases, result in irreversible changes, increasing the likelihood that the pain will not be successfully treated.

There are many conditions causing pain that are treatable only to a certain point. It has been suggested that any pain that recurs with some regularity (whether there is or is not evidence of associated pathophysiological process that may give rise to pain), that can be expected to recur, that responds only to a degree to currently available interventions, and that negatively impacts on the quality of life of the individual in pain should be considered chronic and appropriate for referral to a multidisciplinary chronic pain diagnostic and treatment center.

The pattern of painful conditions in relation to old age with population-based survey studies indicating that aging is associated with an increase in musculoskeletal-related pains and a decrease in headaches and back pain typically seen in multidisciplinary pain clinical settings.

Figure 3 shows frequency of several chronic pains and **Figure 4** the intensity of these pains in younger and older community-dwelling individuals. Although the elderly may underutilize the multidisciplinary pain clinic, the population-based findings, shown in **Figures 3** and **4**, indicate that older adults are at increased risk for chronic pain compared to younger individuals (**Figure 3**).

Herpes zoster and the associated risk for postherpetic neuralgia increase with age and represent a major source of suffering in the elderly. The pain associated with postherpetic neuralgia is thought to arise from peripheral neurons that were damaged during the herpes zoster eruption. Another source of pain of unknown etiology is associated with parkinsonianism, a condition that increases with age in the later years of life. Approximately 50% of patients with parkinsonian's type movement disorders have significant pain, particularly in the lower limbs. Current thinking is that this pain is central in origin, but mechanisms and best modes of treatment are unclear.

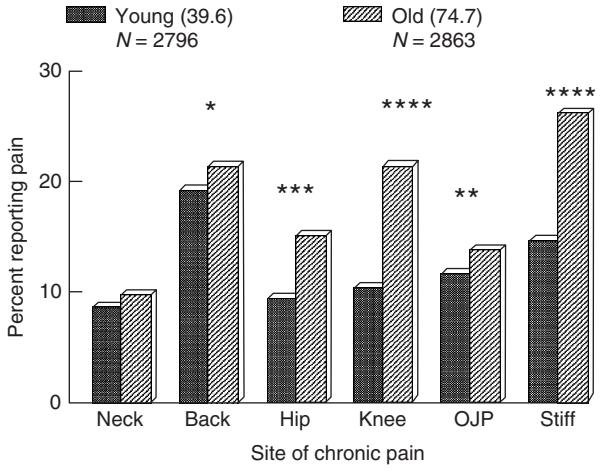

Figure 3 Chronic pain frequency in the general population in relation to age. Note that older individuals are at greater risk of pain from the back, hip, and knee compared to younger individuals. The older respondents also reported other joint pain (OJP) and stiff joints upon awakening compared to younger individuals. Chronic pain was defined here as a pain in the specified location lasting at least 1 month, which was present in the past week. From Harkins SW, Price DD, Bush FM, and Small R (1994) Geriatric pain. In: Wall PD and Melzack R (Eds.) *Textbook of Pain*. Edinburgh: Churchill Livingstone. (*$P<0.05$; **$P<0.01$; ***$P<0.001$; ****$P<0.0001$.)

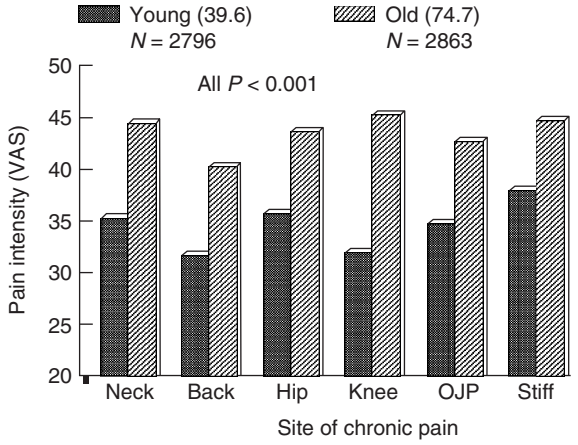

Figure 4 Chronic pain intensity in the general population in relation to age. Intensity ratings are for pains lasting at least 1 month that were present during the past week as in **Figure 3**. Fain intensity was greater in older compared to younger individuals (all $P<0.001$). Pain intensity based on visual analog scale (VAS) labeled 'no pain' at one extreme and 'very severe pain' at the other. Pain severity ratings range from 0 to 60 and were recorded in this figure as percent (i.e., 0 to 100%) of the original scale. Individuals reporting 0 pain over the past week were eliminated from this analysis. OJP, other joint pain; Stiff, stiff or swollen painful joints. Data from subjects as in **Figure 3**.

There is no convincing evidence that pain systems are influenced by the major cause of dementia in later life, dementia of the Alzheimer's type (DAT). Given the widespread effects of this central degenerative disease and its impact on attention, memory, and semantic abilities, it would not be surprising to find that perceptual aspects of pain were influenced by such disorders. More critical is the fact that ability to communicate is restricted in patients with DATs, and this will influence ability to communicate critical information concerning pain in these patients (*see* Dementia).

The epidemiology of pain in patients with age-related neurological degenerative disorders or in older individuals in long-term care settings, particularly the frail elderly, has not been the subject of focused study and merits attention. Considerable unnecessary suffering likely exists in these individuals.

The characteristics of presbyalgos (shown in **Table 1**) can be summarized in terms of the sensory, affective, and cognitive dimensions of pain as follows:

1. *Sensory dimension of pain*: As indicated in **Table 2** (see **Figure 1**), it is not likely that the elderly have increased thresholds, tolerance, and reactions, or decreased discriminability of pain intensity as determined in the laboratory. The elderly are at risk for atypical presentation of pain as a symptom and are more likely to suffer from chronic pain compared to younger individuals.

2. *Primary affective component of pain – Stage 1 pain affect*: Stage 1 pain affect in the model shown in **Figure 1** and **Table 1** is strongly influenced by the concurrent intensity of the noxious event, accompanying autonomic nervous system (ANS) activation (arousal), as well as a combination of situational and predispositional factors. It is unlikely that the primary affective component of pain is reduced with normal aging. There have been no studies of age differences in ANS arousal to acute pain. Empirical demonstration of such age differences, however, would not be strong evidence for age differences in pain perception because both sympathetic and parasympathetic control of end organs differ with age. Demonstration of age differences in ANS response to nociceptive stressors and no such differences for nonpainful stressors, or vice versa, could lead to informative research in this regard.

Similarly, as indicated in **Table 2**, it is unlikely that the elderly have a generalized reduction in the immediate unpleasantness (stage 1 pain affect) of a painful stimulus. That is, there is no substantive evidence that the elderly can be characterized as anhedonic for pain.

It is more likely that there are age differences in perception of threat, resulting distress, and accompanying general arousal and anxiety for previously experienced pain that is mediated by age-related

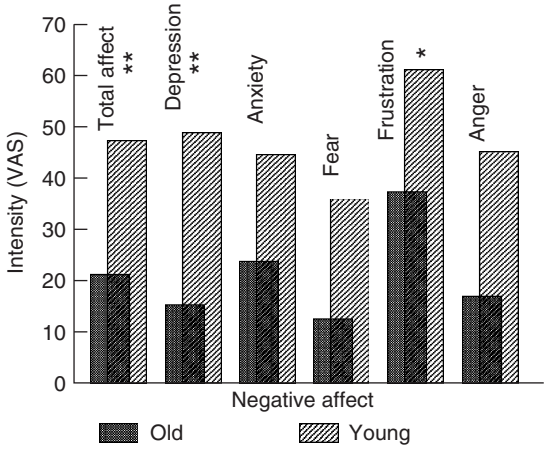

Figure 5 Stage 2 pain affect in younger and older chronic pain patients (see **Figure 1** and **Table 1**). Stage 2 pain affect is defined here as depression, anxiety, fear, frustration, and anger specifically related to the chronic pain. Total affect is the sum of the individual domain-specific affect ratings. Ratings were made on 150-mm visual analog scales (VASs) for each emotion. VASs were labeled 'no depression' (or anxiety, etc.) on the left and 'the most extreme depression imaginable' (or anxiety, etc.) on the right of the VAS. Care was taken to ensure that patients were rating their mood or affect specifically related to their chronic pain. These results indicate that domain-specific affect related to chronic pain differs with chronological age in adults and is not due to age differences in pain intensity or immediate unpleasantness of pain (stage 1 pain affect, in **Figure 1** and **Table 1**). Pain ratings made on the Virginia Commonwealth University Pain Inventory. Reproduced with permission from Harkins SW, Price DD, Bush FM, and Small R, (1995) Geriatric Pain. In: Roy R (ed.) *Chronic Pain in Old Age*, pp. 127–163. Toronto: University of Toronto Press.

changes in cognitive appraisal. Such a change in the meaning of a pain, across a lifetime, likely accounts for the reduction in stage 2 pain affect in elderly chronic pain patients discussed below (see **Figure 5**).

3. *Secondary affective component of pain – Stage 2 pain affect*: The characteristics and factors influencing stage 2 pain affect (**Figure 1**) are summarized in **Table 2**. As indicated, this secondary affective component of pain is a property of the suffering that accrues to a chronic pain. It is the distress associated with a threat to the intactness of the individual. This stage 2 pain affect is not a component of experimental pain for obvious reasons. It must be, therefore, studied in the real world in relation to the stress and suffering associated with a pain problem.

There have been no systematic studies of this dimension of pain in the elderly. Preliminary evidence (**Figure 5**) indicates that the older chronic pain patients report less stage 2 pain affect compared to younger chronic pain patients. This occurs even when the intensity and stage 1 pain affect are identical in younger and older chronic pain patients and suggests that there is a difference in meaning of the pain to younger compared to older chronic pain patients.

Special Considerations in Assessment of Geriatric Pain

There are a number of issues that must be considered in geriatric pain assessment. Some of these are summarized in **Table 3**. The major issues that merit attention are presence of comorbidities, mental status, depression, limitations in ADLs, medications, and the importance of family and other support systems (*see* Depression; Social Networks, Support, and Integration).

Eighty percent of the elderly have at least one chronic, degenerative process. Many of these degenerative processes predispose one to chronic pain (e.g., osteoarthritis, osteoporosis, parkinsonism-type movement disorders, non-insulin-dependent diabetes mellitus). Additionally, these conditions exist in the presence of acute and other chronic morbidities that may interact with the pain-related degenerative disease.

An aspect often overlooked is the *functional* consequence of the pain in the older person. Older persons may have several limitations affecting their daily activities, and the addition of pain may accentuate this. The elderly have less reserve capacity to adapt to functional stresses than do healthy young persons, and the consequence of pain on functional status may be very severe in an older person. The clinician must also be sensitive to the perceived needs of the individuals with differing wishes for the outcome of pain treatment. A patient at the end of life may wish only to die free of pain and even be heavily sedated by the medication, whereas another patient may prize the ability to effectively communicate with loved ones and want pain medications balanced so that sedation is minimized.

In dealing with the elderly patient, there is always the recognition that adverse effects of potent medicines are commonplace, and the adage start low and go slow must guide the treatment plan.

Although intensity and frequency of chronic pains, particularly those related to the musculoskeletal system, actually increase with age, presentation of pain in the very old is frequently characterized by multiplicity (multiple overlapping signs and findings), duplicity (unusual symptom presentation – particularly for acute pain of recent origin), and chronicity (new pains are especially suspicious in the elderly).

Mental status represents a challenging issue for pain assessment in the elderly. Between 50 and 60%

Table 3 Special considerations in geriatric pain assessment

1.	General considerations a. Recognize that age itself does not reduce pain sensitivity. b. Recognize that there is no evidence that age, per se, influences qualitative properties of pain. c. Recognize the importance of encouraging patient to discuss the pain.
2.	Comorbidity: Illness and symptom presentation in the elderly, particularly the frail and the old-old, is often characterized by multiplicity, duplicity, and chronicity.
3.	Mental status: Assess for cognitive impairment: Dementia of the Alzheimer's type, pseudo-dementia secondary to depression, multi-infarct dementia. Refer if necessary.
4.	Depression: Pain is likely a major source of depression in the elderly.
5.	Activities of daily living (ADLs): Differentiate between limitations caused by non-pain-related dysfunction and limitations in activities due to the fact that their performance is painful. Pain-related dysfunctions and limitation in ADLs is likely a significant source of depression in the old.
6.	Medications: Assess all current and recent medications: (look in the 'brown bag of pills'). Start low and go slow.
7.	Family and social support systems: Maintain these systems in the physically or mentally impaired elderly.

of older individuals in long-term care settings have a dementing illness. It is also estimated that up to 40% of community-dwelling individuals 80 years of age and over score in the at risk for dementia range on mental status examinations. Social skills may be well maintained and the presence of a possible dementia may only become suspected upon specific mental status evaluation. Screening instruments for evaluation of mental status exist, but because chronic pain reduces cognitive abilities, norms for such instruments are needed for older chronic pain patients.

Assessment of pain in patients with a clinical diagnosis of DAT represents a special challenge. No studies of the magnitude of this problem or the best methods for assessment of pain in dementia patients have been made. More is known about pain assessment and control in the very young than in the frail dependent or cognitively impaired elderly.

Summary and Conclusion

Four factors were identified that may influence the perception of and reactions to pain across the life span. These included changes in receptors for pain, changes in primary nociceptive neurons, changes in central mechanisms subserving pain, and psychosocial influences. The information summarized indicates limited effect of age on perceived intensity of acute, superficial pain. This would suggest that changes, at least in cutaneous pain receptors, primary nociceptive afferents, or central mechanisms subserving pain sensory processes, are not dramatically changed with age. The same cannot be said for deep or referred pains. As the mechanisms of pain from the viscera, joints, and muscle are better understood, control of pain associated with acute deep tissue injury and chronic degenerative processes in the elderly will improve.

The primary affective response (stage 1 pain affect) to pain does not change with age. Stage 2 pain affect is less in older compared to younger chronic pain patients (**Figures 1** and **5**). This likely reflects experience of the patient with this or a similar pain as well as age–cohort effects.

The properties of *presbyalgos* are defined more by similarities between younger compared to elderly individuals (**Table 2**). There is an increase in chronic pain in the old, and this is associated with greater pain intensity in the community-dwelling population, but not necessarily the pain clinic population, which is likely the result of self-selection and referral filters.

Considerable care must be exercised in evaluation and treatment of the older patient with significant comorbidity, particularly the metabolically compromised. Assessment of pain in the old-old and the frail individual is a particular challenge, which is made even more difficult if there is evidence of a dementing disorder. It is unfortunate that the very old, the frail elderly, the dementia patient, and the cognitively intact but physically challenged because of pain have not been systematically evaluated for pain and pain control. Considerable unnecessary discomfort, pain, and suffering currently exist in these subpopulations of geriatric patients.

Parkinson's Disease

P Chand and I Litvan, University of Louisville, Louisville, KY, USA

Glossary

Bradykinesia – Slowness of body movement.

Deep Brain Stimulation (DBS) – Surgical treatment of choice for severe Parkinson's Disease not responsive to medication. A programmable stimulator is implanted in the chest wall to deliver continuous stimulation to the brain.

Parkinson's Disease – Progressive neurodegenerative disorder characterized by bradykinesia, tremor at rest, and rigidity.

Introduction

Parkinsons disease (PD) is a progressive neurodegenerative disorder initially described in 1817 by Dr. James Parkinson in "An Essay on the Shaking Palsy." PD is characterized clinically by the asymmetric and slowly progressive onset of parkinsonism benefiting from dopaminergic medication, and pathologically by the loss of dopaminergic cells and occurrence of Lewy bodies in the substantia nigra and specific brain stem areas. Typically, PD presents in the 60s with a slowly progressive bradykinesia (slowness) tremor at rest, and rigidity affecting one of the limbs, that benefits from dopaminergic medication, in the absence of atypical features (i.e., falls, dementia, or autonomic features early in the course of the disease). The prevalence of PD is 200–300 cases per 100 000 people, and in the United States about 1 million persons are affected. The annual incidence is approximately 20 new cases per 100 000 people, and about 60 000 Americans are diagnosed with PD each year. The likelihood of developing PD increases with age. PD typically develops in the 60s, but can occur at younger ages. Approximately 10% of all patients develop symptoms before age 40. PD is usually a sporadic disease but is hereditary in 10% of the patients. Men are slightly more frequently affected than women.

Etiology

PD is a neurodegenerative disorder affecting the basal ganglia circuitry and is unique in that most of the motor symptoms result from a single neurotransmitter deficit that is due to a loss of dopaminergic neurons in the substantia nigra pars compacta. When PD is clinically manifest, about 70–80% of the nigrostriatal neurons cease functioning. However, at later stages, most symptoms in PD (i.e., loss of balance, cognitive, autonomic and sleep disturbances) are due to non-dopaminergic neuronal degeneration. The cause of neuronal loss in sporadic PD is not clear and is likely a mix of genetic, environmental, and biological factors combined with the aging process, but PD can also be familial.

Genetics

Several gene mutations have been shown to cause PD, but they account for a small minority of patients and have not been found in most individuals with sporadic PD. Epidemiological studies indicate a

genetic contribution to the occurrence of sporadic PD. The World War II Veteran Twins Registry study shows that genetic factors play a role in sporadic PD when the disease manifests at or before age 50. Using positron emission tomography (PET) with ^{18}F-DOPA and longitudinal evaluation, 75% concordance of PD has been demonstrated in monozygotic twins versus 22% in dizygotic twins. Lazzarini et al. found in a New Jersey study that the chance of having PD by age 80 was estimated to be 2% for the general population, about 5–6% with an affected parent or sibling, and 20–40% if both a parent and sibling were affected.

There are now 11 PARK loci, each representing a genomic region linked with varying degrees of evidence to PD-like disorders (**Figure 1**). PARK-1 presents with a familial autosomal dominant PD due to mutations in the alpha-synuclein gene on chromosome 4q21.3-23. Alpha-synuclein is normally a soluble protein, but in PD it aggregates to form insoluble fibrils that are the primary structural component of the neuronal Lewy body inclusions. Putative mechanisms by which the mutated alpha-synuclein causes PD include mitochondrial damage, impaired protein disposal, and toxic build-up of protein leading to cell death.

PARK-2 presents as an autosomal recessive trait due to a gene mutation on chromosome 6q25.7-27. PARK-2 is a common genetic cause of PD but still accounts for less than 1% of all cases. The gene

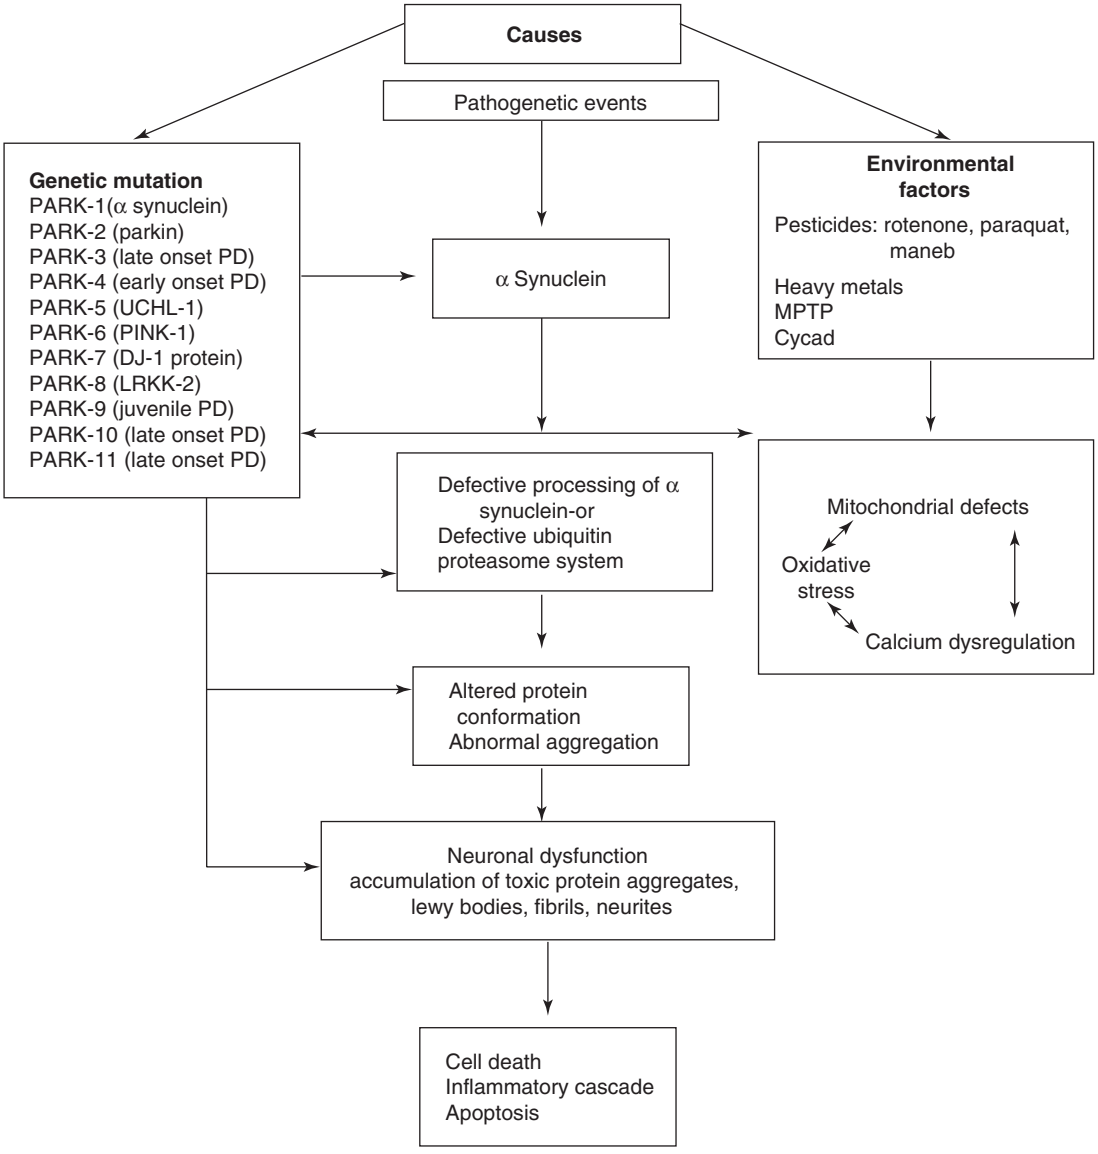

Figure 1 Pathogenesis of Parkinson's disease.

product, the protein Parkin, is a part of the ubiquitin-proteasome system, which breaks down defective proteins in the cells. Patients with the Parkin gene mutation have a young-onset PD, with symptoms beginning usually in the fourth decade of life. Those with the Parkin mutation in just one copy of the gene have a higher risk of getting PD as they get older than those without the mutation. Parkin accumulates in Lewy bodies and may be important in both inherited and sporadic forms of the disease.

PARK-3 is due to an autosomal dominant trait and a gene mutation on chromosome 2p13. Patients with PARK-3 have a relatively late age of onset, much like sporadic PD, but with rapid progression. PARK-4 is due to an autosomal dominant trait and is due to a gene mutation on chromosome 4p15. Patients present with an early-onset PD with rapid progression, autonomic dysfunction, dementia, and postural tremor. PARK-5 is an autosomal dominant trait due to a mutation in the ubiquitin carboxy-terminal hydrolase L1 (UCHL1) gene on chromosome 4p14-16.3. UCH-L1 is an important member of the ubiquitin-proteasome system that performs ubiquitination, a process that tags proteins for breakdown and is critical for the proper handling of misfolded proteins. PARK-6 is caused by mutations in a gene located on chromosome 1p36 for a mitochondrial kinase (PTEN-induced kinase 1 [PINK1]). It has been identified in several families with autosomal recessive PD of early onset and slow progression. PARKm-7 is a rare form of autosomal recessive young-onset parkinsonism due to mutations on chromosome 1p 35-36 within the gene encoding DJ-1, a 189-residue protein.

PARK-8 is the most frequent genetic cause. It has been identified in families with autosomal dominant late-onset PD and is due to mutations in the leucine-rich repeat kinase 2 gene (LRRK2, protein product dardarin), located on chromosome 12p11.2-q13.1. LRRK2 mutations have also been found in sporadic PD cases and are significantly more frequent in the Arab and Jewish population. PARK-9, due to a gene mutation on chromosome 1p36, presents as an autosomal recessive early-onset juvenile PD. Patients have spasticity, supranuclear gaze palsy, and dementia. PARK-10 and PARK-11 are chromosomal regions that have been implicated in families with PD; the genes are yet to be identified. PARK-10 locus on chromosome 1p has been linked to PD of late onset in Icelandic families. PARK-11 locus on chromosome 2q36-37 was identified in pairs of siblings with late-onset autosomal PD and appears to affect the susceptibility to the disease in North American Parkinson families.

Impairment in the capacity of the ubiquitin-proteasome system to clear unwanted proteins has been implicated in the cell death that occurs in PD. In support of this concept, defects in proteasomal structure and function as well as protein aggregates and increased levels of oxidized proteins are found in the substantia nigra of PD patients. Inhibition of proteasome activity in mesencephalic cultures induces degeneration of dopaminergic neurons coupled with the formation of proteinaceous intracellular inclusions.

PD patients have more mitochondrial DNA variations than patients with other movement disorders or Alzheimer's disease. Mitochondrial DNA mutations as the cause of PD have been actively investigated in families with maternal inheritance of PD, and potentially important mutations in the genes ND2, ND4L, and ND5 are associated with an increase risk of PD. The age at onset of PD has wide variability (even within the same family), ranging from juvenile to very late (80s to 90s), with average age at onset of 60 years. The gene for brain-derived neurotrophic factor (BDNF) may also influence PD onset age in familial PD. The gene GSTO-1 and the adjacent gene, GSTO2, appear to affect the age at onset for PD and Alzheimer's disease.

Environmental Factors

Environmental toxins, infections, and other triggers can provoke excessive production in the body of oxygen free radicals, damaging particles that may play a major role in the neuronal degeneration leading to PD (**Figure 1**). The toxin MPTP (1-methyl-4-phenyl-1,2,5,6-tetrahydropyridine), a contaminant of street drugs, has a breakdown product (MPP+) that is toxic to dopaminergic substantia nigra neurons and produces a severe, permanent parkinsonian syndrome. The relative risk of PD is higher in industrialized countries and in farmers and other agricultural workers. Rotenone, a common organic chemical in pesticides, may induce oxidative injury that targets dopaminergic, cholinergic, and GABAergic neurons. In rats, chronic rotenone exposure leads to pathological, biochemical, and behavioral features seen in PD and in atypical parkinsonian disorders. The herbicide paraquat and the fungicide maneb and their combination can lead to an irreversible and progressive dopaminergic neurotoxicity in mice. Many toxins, including MPTP and rotenone, can affect mitochondrial complex I and increase the production of free radicals. Neurotoxins in flour from cycad plants in Guam can (when fed to mice)

lead to behavioral changes and neuronal loss much like those seen in PD.

Biological Factors

Aging Process Aging is the most important risk factor for PD. The frequency of PD increases markedly with age in people older than 50. Dopaminergic neurons in the substantia nigra show about 20% cell loss in normal aging, whereas in PD more than 60% of these cells may die before the disease becomes clinically evident. Changes associated with normal aging may interact with the pathogenic processes of PD and lower the threshold for symptom expression.

Apoptosis In PD, there is some evidence that there is abnormal neuronal apoptosis. Three molecules are critical in the development of inherited PD – parkin, alpha synuclein, and ubiquitin, which all interact in the normal brain. Parkin normally causes alpha-synuclein to bind ubiquitin, which then triggers apoptosis, causing this compound to self-destruct. In the PARK-2 variety of inherited PD, Parkin is abnormal and fails to bind alpha-synuclein to ubiquitin. Apoptosis does not take place, and alpha-synuclein accumulates in Lewy bodies.

Complex I and Oxygen Free Radicals Some PD patients have a 30 to 40% reduction in the mitochondrial enzyme complex I, making nerve cells vulnerable to unstable oxygen free radicals that can modify alpha-synuclein and cause it to aggregate or clump together into fibrils.

NMDA Receptors In PD there are changes in the subthalamic nucleus, as glutamatergic N-methyl-D-aspartate (NMDA) receptors become constantly overstimulated and produce high levels of calcium ions within neurons. This in turn leads to a cascade of events that trigger oxygen free radicals and cell damage.

In summary, it is currently thought that PD is attributable to an interaction of genetic and environmental factors and that a combination of the mechanisms of oxidative damage, environmental toxins, genetic predisposition, and accelerated aging may ultimately be shown to cause the disease.

Pathology

The gross appearance of the brain in PD may show mild frontal cortical atrophy. On sectioning the brain stem, there is visible loss of neuromelanin pigmentation in the substantia nigra in the midbrain, which may associate with a rust color in the pars reticulata of the substantia nigra due to increased iron deposition. Histopathology reveals neuronal loss in the substantia nigra pars compacta and locus coeruleus along with compensatory astrocytic and microglial proliferation. Hyaline cytoplasmic inclusions-Lewy bodies (**Figure 2**) are found in the residual neurons in the substantia nigra, locus coeruleus, dorsal motor nucleus of the vagus, basal nucleus of Meynert, limbic cortex, and amygdala. Lewy bodies are proteinaceous inclusions often accompanied by abnormal neuritic filaments called Lewy neurites that on electron microscopy appear as densely aggregated filaments. Immunohistochemical studies show that the chemical composition of Lewy bodies is a mixture of proteins, including alpha-synuclein, neurofilament, and ubiquitin. Extensive serial studies by Braak in more than 400 autopsy brains have recently shown that there are stages in PD and that the substantia nigra is not affected initially. At preclinical stages there are Lewy bodies in the olfactory bulb and vagus nerve, whereas at later stages the cortex is affected, supporting the presence of olfactory and gastrointestinal disturbances at presymptomatic stages and dementia at advances stages.

Pathophysiology

In PD the loss of dopaminergic neurons projecting from the substantia nigra to the striatum (caudate and putamen) results in altered function of the motor striatal–pallidal–thalamic–cortical circuits that mediate normal movement, resulting in bradykinesia and rigidity. The striatum controls the activity of basal ganglia output neurons via two major routes: the direct pathway and the indirect pathway. There are at least five dopamine receptors that can be separated into two distinct families, D1 (made up of D1 and D5) and D2 (made up of D2, D3, and D4). The effect of dopamine and dopamine agonists on D1 receptors is excitatory, whereas their action on D2 receptors is inhibitory.

Direct Pathway

Striatal neurons containing D1 receptors project to the globus pallidus interna (GPi) and induce an inhibition via GABA and substance P upon the GPi neurons, which then in turn inhibit target neurons in the motor thalamic nuclei (**Figure 3**). This leads to disinhibition of the motor thalamus and to an increase in the firing rate of its cells. Activation of

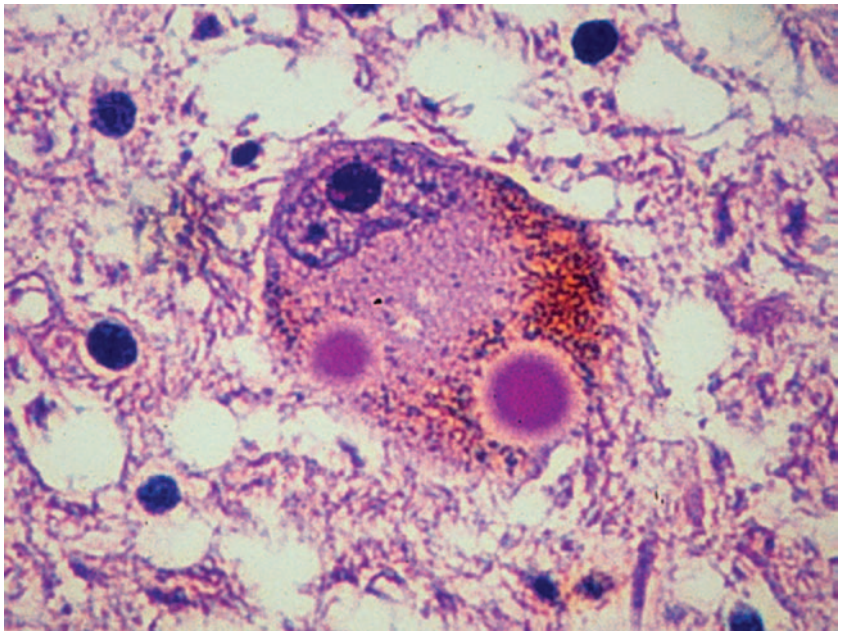

Figure 2 The Lewy body. Reproduced with permission from Mackenzie IRA (2005) Neuropathology of Atypical Parkinsonian Disorders. Litvan I, ed. In: Atypical Parkinsonian Disorders. New Jersey: Humana Press.

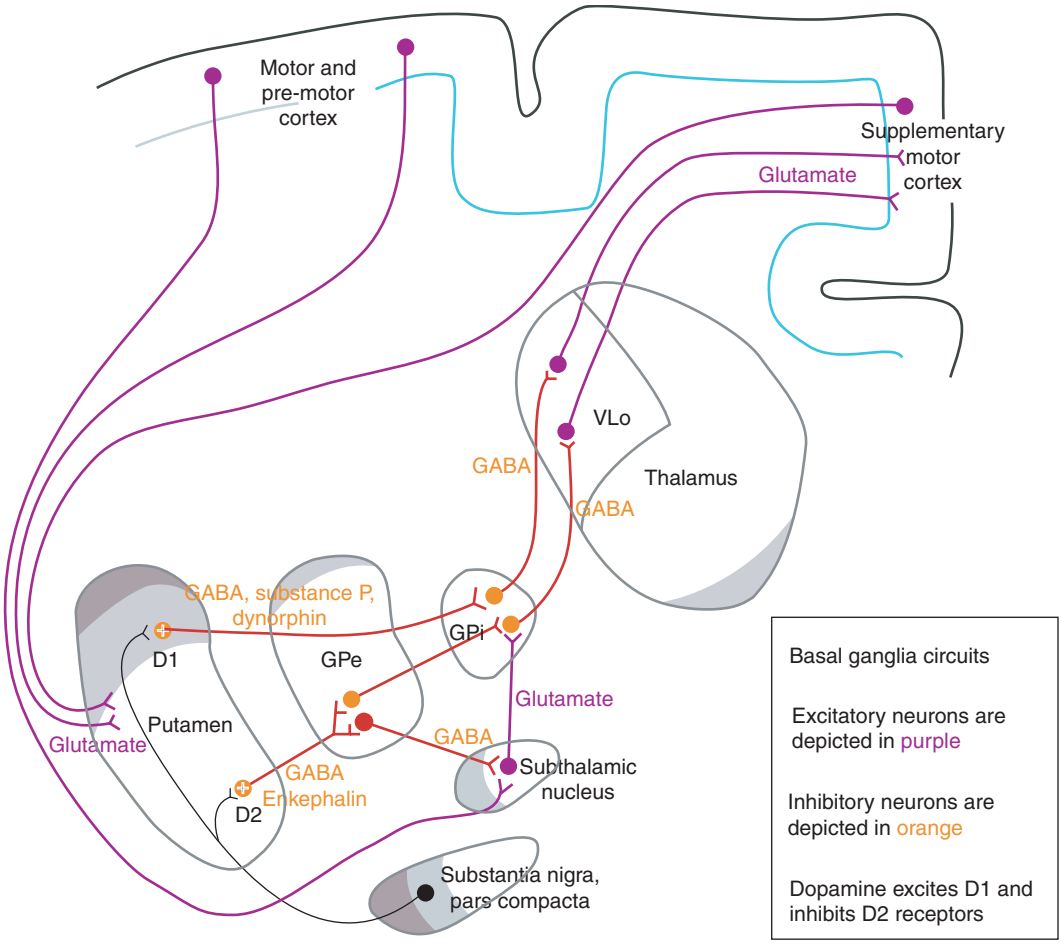

Figure 3 Diagram of basal ganglia circuitry. Courtesy of Jen-Luc Dreyer.

the direct pathway facilitates initiation or ongoing movements. In PD, the depletion of dopamine from the nigrostriatal projection to D1 receptors on the striatal neurons (excitatory) results in the direct pathway being underactive, leading to decreased firing of thalamic neurons and inhibition of initiation of movement.

Indirect Pathway

Striatal neurons containing D2 receptors project to the globus pallidus externa (GPe), which then projects to the GPi via the subthalamic nucleus (**Figure 3**). Dopamine here acts as an inhibitor of the striatum, which in turn releases GABA and enkephalin that in turn inhibit the GPe neurons, which in turn disinhibit the subthalamic nucleus. The subthalamic nucleus increased firing leads to activation of the GPi and the substantia nigra pars reticulata neurons. Since the output from the GPi to the thalamus is inhibitory, there is a reduction of excitatory thalamic input to supplementary motor areas. Thus, the indirect pathway is thought to inhibit unwanted movements. In PD, depletion of dopamine in the nigrostriatal neurons projecting to D2 receptors on the striatal neurons results in the indirect pathway being overactive. In patients with PD, ^{18}F-fluorodeoxyglucose PET studies show an abnormal metabolic brain network in the resting state characterized by relative lentiform and thalamic hypermetabolism associated with metabolic reductions in motor cortices. The combined hyperinhibitory outflow from the GPi may account for the negative symptoms of PD (rigidity and akinesia). Reduction of this excessive inhibitory outflow, by lesioning or stimulating the GPi or the subthalamic nucleus, reverses these symptoms, which is the basis of surgery in PD. Tremor activity is thought to be generated in the ventral lateral nucleus of the thalamus. On the other hand, dysregulation of the D1 pathways, in levodopa-treated patients, leads to the development of dyskinesias, a side effect of dopaminergic therapy.

Diagnosis of PD

Though the clinical features of PD are characteristic, three large clinicopathological studies show that specialists misdiagnose 25 to 40% of patients with PD in clinical practice. An early accurate diagnosis is relevant because the prognosis and treatment of patients with PD is markedly different from those with atypical parkinsonian disorders (APDs). The survival of patients with early PD is almost the same as that of the US population, particularly when appropriately treated; APD patients have a shorter survival (usually less than 10 years).

Clinical History

Patients with PD usually present over age 50 with a variety of motor complaints – tremor at rest, micrographia, slowness or poverty of movements, stiffness, or pain. Typically, the onset is insidious, and the progression is slow, affects one limb, and then spreads to the others, although the asymmetric involvement persists. Lack of associated movements and rigidity are also symptoms at onset. Tremor usually is at rest, increases in periods of anxiety, and disappears during activities or sleep. Slowness when walking may occur relatively early in the disease, but instability or falls occur later. Speech volume reduction and monotony may occur relatively early, but sialorrhea secondary to dysphagia develops at later stages. Similarly, faintness, impotence, or urinary disturbances are not early PD problems. While depression may antedate motor symptoms or associate with them, dementia is not an early feature in PD. The patient's drug treatment history should be carefully reviewed. Drug-induced parkinsonism is frequently secondary to dopamine receptor blockers used primarily as antipsychotics and antiemetics, less commonly, calcium channel blockers (e.g., flunarizine) or cardiac antiarrhythmic agents (e.g., amiodarone).

Non-motor symptoms of PD include pain, autonomic dysfunction, depression, anxiety, dementia, and sleep disorders. Pain is a common symptom, affecting as many as 46% of patients and is often related to motor dysfunction seen in the off state. Olfactory dysfunction with a reduced sense of smell may be one of the earliest PD symptoms. Autonomic dysfunction can lead to orthostatic hypotension, erectile dysfunction, excessive sweating, constipation, and urinary disturbances but these are all late symptoms.

Depression is common and can affect up to 50% of patients at any stage of the illness. It could be both reactive as well as endogenous to the neurodegenerative process with depletion of monoamines. Anxiety (generalized or panic attacks) is also common in PD and is often related to the off state. Dementia occurs late in PD, and the overall prevalence ranges from 30–40%, but prospective studies have shown that after 8 years of follow-up, up to 80% of the patients with PD may develop dementia. Pathological studies correlate dementia in PD with a significant loss of neurons in the nucleus basalis of Meynert and loss of choline acetyl transferase as well as Lewy bodies and Alzheimer-type changes in the

cerebral cortex and limbic areas. The dementia in PD could also be due to associated Alzheimer's or vascular diseases. Sleep disorders in PD include sleep-onset delay, sleep fragmentation, sleep apnea, periodic leg movements, and REM sleep behavioral disorder. Polysomnography is often required to diagnose the type of sleep disorder.

Neurological Examination

Akinesia may be assessed by having the patient tap the index finger to the thumb repeatedly or by foot tapping. Rigidity can be tested by flexion–extension of the neck and each extremity. Tremor should be assessed at rest, while performing an activity, and by maintaining a posture. Evaluation of eye movements, particularly the speed of vertical and horizontal saccades (rapid movement of the eyes between two stimuli), aid in ruling out other disorders. Parietal signs such as visual and sensory neglect can be assessed with the presentation of one or two simultaneous stimuli. Balance should be assessed with the pull test (maintaining balance while being pulled backward). The pull test is abnormal only at later stages. To effectively rule out orthostatic hypotension, blood pressure should be taken lying and after 1 and 3 min standing. The Hoehn and Yahr staging and the Unified Parkinson's Disease Rating Scale (UPDRS) are useful clinical tools for following the progression of the illness and response to therapeutic interventions.

Diagnostic Criteria

Several clinical criteria for the diagnosis of PD have been proposed. The main features required for the diagnosis of PD are the presence of akinesia (slowness, decreased amplitude of movements) associated with either rigidity or a 4–6 Hz rest tremor in addition to an excellent and maintained response to levodopa therapy and absence of atypical features. In fact, akinesia is universal in PD, but a rest tremor ultimately develops in about 75% of patients with PD. The presence of rest tremor is very highly suggestive of PD in patients with akinesia.

When a patient presents with tremor, one needs to evaluate the type of tremor (at rest, with action, postural) and determine if akinesia is present (**Figure 4**). If akinesia is not present, one should determine whether the characteristics of the tremor are those of an essential tremor (postural and with action) or cerebellar tremor (mostly an intention tremor, associated with dysmetria and other cerebellar features). If akinesia is present, one needs to determine whether the parkinsonism is due to a secondary cause (medications such as neuroleptics, amiodarone; metabolic disorders such as Wilson's disease; vascular causes; infections, etc.). If there are

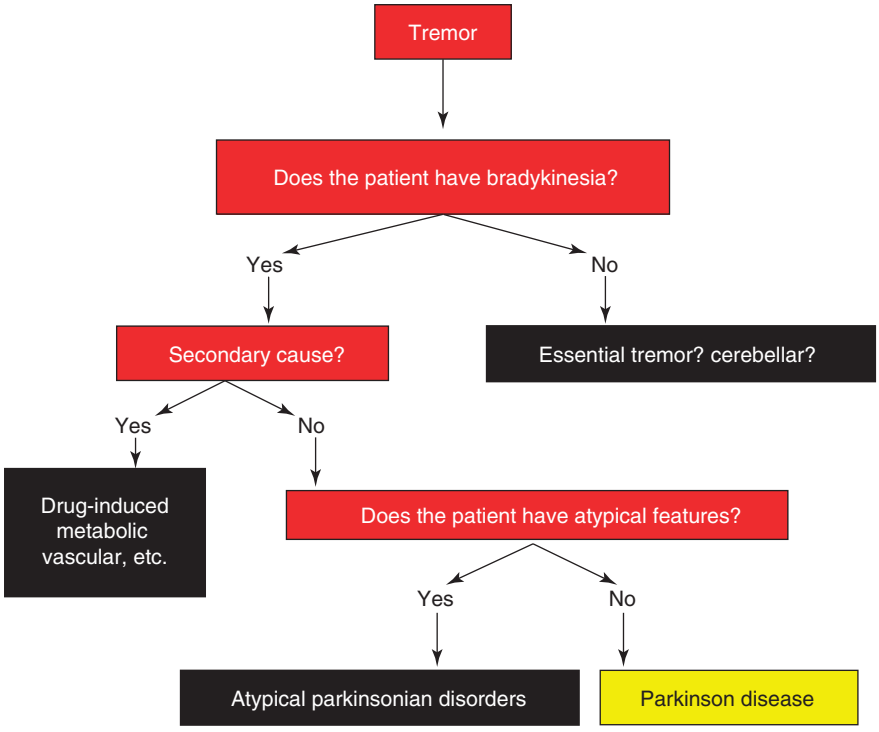

Figure 4 Diagnostic algorithm.

no identifiable causes, one should determine whether there are atypical features. Atypical features that call into question the diagnosis of PD include rapid symptom progression, early (within 3 years) postural instability, poor or transient response to dopaminergic therapy (900 mg of levodopa for at least 1 month), myoclonic jerks, supranuclear gaze palsy, early autonomic failure (i.e., orthostatic hypotension, impotence in males, neurogenic bladder), pyramidal or cerebellar signs, ideomotor apraxia, and prominent early or severe speech and swallowing difficulties. These latter features suggest an APD (progressive supranuclear palsy, multiple system atrophy, corticobasal degeneration, or dementia with Lewy bodies). If there are no atypical features, one can make the diagnosis of PD.

Laboratory Studies

The diagnosis of PD remains a clinical one. Laboratory testing is not usually needed except to rule out treatable diseases such as Wilson's disease or normopressure hydrocephalus. PD patients may benefit from a neurology consultation early in the disease to establish the most appropriate management and should always be referred when an APD is suspected.

Neuroimaging

Neuroimaging, computed tomography (CT), or magnetic resonance imaging of the brain usually aid in ruling out other diagnoses but rarely confirm PD. *In vivo* neuroreceptor imaging using radioactively labeled dopaminergic ligands in single photon emission computerized tomography (SPECT) and PET have emerged as tools to assist in the accurate diagnosis, monitor disease progression, and evaluate potential neuroprotective therapies for PD. Specific presynaptic dopaminergic markers include ^{18}F-DOPA for PET and dopamine transporter (DAT) ligands 123Iβ-CIT for SPECT. These studies demonstrate a specific pattern of asymmetric putamen greater than caudate loss of dopaminergic uptake that is progressive in PD and correlates with bradykinesia but not tremor. APDs are associated with more symmetric and diffuse reduction in uptake, affecting both caudate and putamen equally. Postsynaptic dopamine receptor imaging with IBZM-SPECT, ^{11}C-raclopride PET, and others also shows reduced uptake in APD but not in PD.

Longitudinal imaging studies estimate the onset of PD symptoms at 70–75% of normal dopaminergic activity and a preclinical phase of 4–8 years. Preclinical identification of PD may allow interventions to slow progression of the disease. PET scans are also useful to rule out PD in patients with symptoms and signs that are due to dopamine-blocking drugs.

PD also affects other neurotransmitter systems, and imaging with a serotonin receptor ligand shows reduced uptake in the cerebral cortex of PD patients with depression and a correlation with tremor scores. Ligands to SP/NK1 receptor show reduction in thalamic activity in PD patients with dyskinesia. Nicotinic acetylcholine receptors have close interactions with the dopaminergic system and play a critical role in cognitive function. SPECT imaging shows a significant decrease in nicotinic acetylcholine receptors in both cortical and subcortical regions in PD patients and is one of the substrates of the cognitive impairment in PD.

Treatment

Pharmacological Treatments

Pharmacological therapies for PD include agents that work directly or indirectly to increase the level of dopamine in the brain, delay the development of motor fluctuations, and affect other neurotransmitters to reduce some of the symptoms of PD and agents that treat the non-motor symptoms of the disease. Neuroprotective and neurorestorative therapies are still experimental.

Levodopa Levodopa was FDA approved in 1970. Dopamine does not cross the blood–brain barrier (BBB) and cannot be used as therapy for PD, but levodopa does, and its transport across the gut mucosa and BBB involves an energy-dependent carrier-mediated system. Large neutral amino acids in high-protein food compete with dopamine at both sites, and levodopa is hence best taken on an empty stomach. Levodopa is converted to dopamine in the brain and at other peripheral sites by dopadecarboxylase. Combination of levodopa with a dopadecarboxylase inhibitor, carbidopa or benserazide (these do not cross the BBB), increases the plasma half-life of levodopa from 50 to 90 min and reduces the amount required for an adequate response by 75%. Levodopa preparations in combination with decarboxylase inhibitors remain the most powerful dopaminergic agents. Initially patients have an excellent response to dopaminergic medication (honeymoon phase). Unfortunately, the short half-life of levodopa and neuronal degeneration contribute to the early development of motor fluctuations. Over time, several patterns of motor fluctuations occur with levodopa therapy. The earliest is the end of dose wearing-off phenomena in which parkinsonian symptoms occur prior to the next dose of medication.

Dyskinesias (non-rhythmic movements) may occur at the maximum effect of a dose of levodopa (peak dose), at the beginning and end of each dose (diphasic), throughout the on period (square wave dyskinesia), or they may fluctuate abruptly from immobility to severe dyskinesia (yo-yoing). Later, patients experience random on periods and off periods unrelated to dose or delayed on response to levodopa due to difficulties with gastric emptying.

Catecholamine-O-methyltransferase (COMT) is an enzyme that degrades dopamine by methylation predominantly in peripheral tissues. Two Catechol-O-methyl transferase-inhibitors (COMT-Is) are currently available for use as adjunctive therapy in PD patients who have developed motor fluctuations with inhibitors wearing-off phenomena. Tolcapone is the more potent of the two, but its hepatotoxicity has restricted its use. Entacapone has a dose-dependent effect on COMT activity. It does not cross the BBB and exerts its effect in the periphery. It also reduces homocysteine plasma levels, which could provide a mechanism to reduce cell death in PD. Currently, the combination levodopa–carbidopa–entacapone is particularly indicated for the treatment of wearing-off phenomena.

Extensive research shows that motor fluctuations can be delayed by the use of continuous dopaminergic stimulation, which is the current standard of treatment for PD. Experimental evidence in animal model studies suggests that early treatment with levodopa–carbidopa–entacapone may substantially ameliorate the incidence of motor fluctuations. Although one study showed that there were no differences between immediate release and controlled release (CR) levodopa with regard to development of motor fluctuations (continous release (CR) first study over 5 years), the controlled release doses in the study were administered only twice a day, thereby not fulfilling the principle of continuous dopaminergic stimulation.

Since immediate-release levodopa leads to the earlier development of motor fluctuations, it is not currently indicated as a first treatment in young patients with PD who tend to easily develop dyskinesias. Disease progression with loss of nigrostriatal neurons and the short half-life of dopaminergic agents are the cause of motor fluctuations, and delaying levodopa therapy may delay motor fluctuations, but once motor fluctuations are present they occur with any treatment.

Despite the evidence that levodopa is toxic in cell culture studies, there is no evidence of neurotoxicity in human or animal studies. In the ELLDOPA study, the clinical outcomes indicate that levodopa is effective in a dose-dependent manner in overcoming the signs and symptoms of PD; the drug does not worsen or hasten disease progression, but rather may slow down the rate of the disease. However, a β-CIT SPECT substudy showed that levodopa may cause a more rapid decline in the integrity of the dopamine transporter located in the nigrostriatal nerve terminals in the striatum. Further studies are needed to better understand these findings.

Dopamine Agonists Dopamine agonists, unlike levodopa, do not need to be metabolized to reach neurons. They delay the development of motor fluctuations, but are less potent and have more side effects (hallucinations, orthostatic hypotension, edema, sleep attacks, pathological gambling) than levodopa. There are two major groups of dopamine agonists: ergot derivatives (bromocriptine, cabergoline, pergolide) and non-ergot derivatives (pramipexole, ropinirole). Ergot compounds can lead to pleural, retroperitoneal fibrosis and heart valvular restrictive disease.

Apomorphine is a short-acting potent D2 agonist with high D1 receptor affinity and emetic properties. A subcutaneous preparation is FDA approved as rescue medication in patients with unpredictable off episodes, but this therapy requires prior treatment with an antiemetic drug (i.e., trimethobenzamide, domperidone). Subcutaneous administration of apomorphine has been found to have long-term efficacy in patients treated for as long as 8 years.

Bromocriptine is a partial D2 agonist, mild adrenergic agonist, with a mild D1 and serotonin antagonist properties. A number of studies have demonstrated that in the treatment of early and also advancing PD, bromocriptine is beneficial in improving disability and delaying motor fluctuations.

Cabergoline, a long-acting, more expensive, once-daily dopamine agonist, has been shown to improve motor scores and reduce levodopa dose in early and advanced PD. It has an efficacy similar to bromocriptine, but more side effects (dyskinesia and confusion). Currently, it is not FDA approved for use in PD.

Pergolide has high D2 affinity and mild D1 agonist and alpha-adrenergic activity, and has 10 times the potency of bromocriptine and similar side effects. Pergolide has been demonstrated to be effective in both early- and late-stage PD in several trials and superior to bromocriptine in regard to improvements in motor function and disability. A more recent PELMOPET trial compared pergolide to levodopa and found motor complications and dyskinesias to be three times more frequent in the levodopa-treated patients; reduction of ^{18}F-DOPA uptake on PET scans was less in pergolide-treated patients. However, pergolide frequently induces heart valvular

restrictive disease and should be avoided or used with caution.

Pramipexole is a synthetic dopamine agonist active at the D2 receptor with affinity for alpha- and beta-adrenoreceptors, acetylcholine, and serotonin receptors. A number of studies have shown the efficacy of pramipexole in PD. In levodopa-treated patients, the use of pramipexole resulted in significant benefits in activities of daily living, motor scores, off time, and levodopa dose reduction. Side effects are similar to other dopamine agonists; unexpected sleep episodes and pathological gambling were also reported side effects. The CALM-PD study using pramipexole showed significantly less motor fluctuations as compared to levodopa, but levodopa had better efficacy in reducing PD clinical scores. The SPECT imaging studies showed a 40% reduction in the rate of loss of dopamine transporter, suggesting a neuroprotective effect.

Ropinirole has affinity for D2 receptor and is effective in early and advanced PD. The REAL-PET study in early PD showed that ropinirole-treated patients at 5 years had significantly less dyskinesias than those who received levodopa. The PET studies showed that ropinirole-treated patients had significantly less reduction in ^{18}F-DOPA striatal uptake over 2 years as compared to the levodopa-treated group. The CALMPD and REALPET studies have suggested a neuroprotective effect for DAs; however, there may be alternative explanations for this observed effect.

Rotigotine, a novel dopamine agonist delivered by the transdermal route, has been demonstrated to be safe and effective in Europe and is pending FDA approval. In PD patients significant reduction in levodopa dosage was recorded at the two highest daily dosage levels. Some patients receiving rotigotine were able to completely discontinue levodopa. Adverse effects were generally mild; the most common were typical for a dopamine agonist. In patients with advanced PD, transdermal routes of administration of medications such as rotigotine may be able to diminish both the peak dose adverse effects such as dyskinesia and the wearing-off fluctuations that so often develop with the more pulsatile oral drug delivery.

Amantadine Amantadine is an antiviral drug that has multiple antiparkinson mechanisms that include dopamine synthesis, reuptake inhibition and release, D2 receptor modulation, as well as glutamate blocking activity at the NMDA receptor. It has mild beneficial effects on rigidity and bradykinesia. Its reported side effects are few and include pedal edema, livedo reticularis, and cognitive changes. Its major use has been in the treatment of early PD and as an adjunctive agent in moderate PD, but currently it is mostly used in late PD as an adjunct to reduce levodopa-induced dyskinesias attributed to an effect on NMDA receptors.

Monoamine Oxidase-B Inhibitors (MAO-BI) Selegiline is a selective irreversible inhibitor of MAO-B (an enzyme involved in the breakdown of dopamine). Selegiline has mild symptomatic benefit and has been used in early PD and also as an adjunct to levodopa. It improves UPDRS scores, thus allowing reduction in levodopa dosing. It may also benefit freezing of gait, but may worsen dyskinesias. Side effects include nausea, constipation, sweating, and hallucinations. There is no evidence that its use is associated with increased mortality in PD. A new preparation of selegiline pending FDA approval, Zydis selegiline, dissolves with contact with saliva, avoiding gastric absorption, and provides high plasma concentrations.

Rasagiline is an irreversible MAO-BI five times more potent than selegiline that is also pending FDA approval. In large clinical trials, rasagiline was effective as monotherapy in early PD, as well as adjunctive therapy to levodopa in advanced disease. A disease-modifying neuroprotective effect has also been suggested in animal models of PD and in a clinical trial.

Anticholinergics A number of drugs – trihexyphenidyl, biperiden, benztropin, and procyclidine – were used to treat PD prior to the advent of levodopa and dopamine agonists. They have troublesome central and peripheral anticholinergic side effects, especially in the elderly. They have a beneficial effect in tremor and dystonia in PD mediated through the central muscarinic acetylcholine receptors. Currently the use of anticholinergics is mainly to treat severe tremor in young-onset PD.

Non-motor Symptoms of PD Pain may be due to dystonia and responds best to optimization of dopaminergic medications to reduce off time. Orthostatic hypotension can be treated with compression stockings, by switching dopamine to levodopa preparations, or by adding fludrocortisone or midodrine. Nocturia and urgent micturition require a urological evaluation, as they may be secondary to a neurogenic spastic bladder that may respond to oxybutynin or tolterodine, to a neurogenic atonic bladder, or to obstructive causes such as benign hypertrophy of the prostate. Sildenafil may be useful for erectile dysfunction. Depression can be treated with selective serotonin reuptake inhibitors (SSRIs). Anxiety related to off periods can be treated by tailoring

dopaminergic drugs, but also improves after deep brain stimulation; generalized anxiety can be treated with alprazolam, gabapentin, or SSRIs. The symptoms of dementia in PD may respond to anticholinesterase inhibitors such as rivastigmine and donepezil, the former is FDA-approved for this use.

Surgical Treatments

The early brain operations for PD were pallidotomy and thalamotomy, which destroyed parts of the globus pallidus and thalamus, respectively. These procedures were irreversible and often led to complications. In recent years, deep brain stimulation (DBS) has been found to mimic the effects of pallidotomy and thalamotomy and has now replaced these procedures as the surgical treatment of choice for PD. These procedures are usually reserved for severely afflicted PD patients who have not had adequate relief from medications. DBS is much safer than pallidotomy or thalamotomy because the stimulation can be adjusted to match the patient's needs and turned off if adverse events occur. DBS leaves electrodes in the brain connected by wires (tunneled under the skin in the neck and scalp) to a programmable stimulator implanted in the chest wall to deliver continuous stimulation. The stimulator can be turned on and off by a magnet waved over the surface. Batteries in the chest wall can be replaced as needed, generally after 5 years. The exact mechanism of action of DBS is unknown. It is postulated that high-frequency stimulation may block neuronal output from the stimulated site or that stimulation changes the irregular neuronal activity to a tonic activation pattern.

Adjusting the stimulator and medications after electrode implantation is a major time commitment on the part of the neurological team and patient. The maximum effect of the procedure is achieved once that adjustment occurs, which may be weeks or even months after the procedure itself. Risks for DBS procedures include surgical risks (hemorrhage, infection) as well as hardware complications. These include leads breaking, electrode malfunction, stimulator failure, and battery failure.

Thalamic DBS is primarily effective against tremor but is not commonly indicated in PD. Bilateral procedures have a higher risk of adverse effects. DBS of the subthalamic nucleus has become a major procedure of choice for control of PD, but its preeminence over GPi DBS is being questioned. Both lead to improvement of all major motor features of PD, with improvement of motor scores of 40 to 60% in the off state and 10% in the on state that last for several years on follow-up. Levodopa dosage can be reduced typically around 30%, with resulting improvement in dyskinesias. Bilateral procedures appear to be superior to unilateral, with only a slightly increased risk of complications. F-DOPA PET has shown that DBS does not stop the continuous decline of dopaminergic function in patients with advanced PD. The rates of progression in patients with subthalamic nucleus DBS were within the range of previously reported data from longitudinal imaging studies in PD.

Exclusion criteria for DBS include age greater than 75 years, presence of dementia, significant cognitive abnormalities, or behavioral abnormalities. As DBS has become more common, rare but serious neuropsychiatric adverse events have been increasingly reported. Onset or worsening of depression may occur postoperatively in a small percentage of patients, often in those who were at increased risk before the procedure. Suicide, a well-known risk in depressed patients, has been reported in a handful of patients. Pre-operative neuropsychiatric evaluation and postoperative follow-up is a critical part of patient care.

Non-pharmacological Treatments

A wide variety of problems in PD may respond to non-pharmacological treatments. In all cases, an individualized approach is needed to identify the problems and determine a treatment plan. Multiple members of the treatment team, physical therapists, occupational therapists, speech-language pathologists, gerontologists, neurologists, psychologists, and others, may be involved. Effective treatment may reduce the need for medications and improve quality of life.

Motor, balance, posture, gait, and mobility can respond to physical therapy, occupational therapy, adaptive equipment, and home and workplace modification. For speech, several PD voice-training programs to increase voice volume, use of shorter sentences, breathing exercises, and range-of-motion exercises are useful. Sialorrhea can be reduced by consciously swallowing more often or by small doses of anticholinergics or injection of botulinum toxin into the salivary glands. Management of swallowing difficulties includes the periodic performance of modified barium swallow evaluations with videofluoroscopy to identify the specific disturbances. Dietary changes such as instruction to take smaller bites and to completely empty the mouth before taking the next bite, thickening liquids, and eating softer foods may be indicated at different stages. Constipation can be reduced by a good bowel regimen, increased fluid intake, a diet rich in vegetables and fruits, use of stool softeners, and increased dietary and/or supplemental fiber.

Experimental Therapies

Several experimental therapies are being tried for PD and need further research. They include Coenzyme Q10, anti-inflammatory drugs, glial cell-derived neurotrophic factor (GDNF), gene therapy, and cell transplantation using fetal substantia nigra as well as retinal pigment epithelial cells.

In recent studies stem cells have been shown to be capable of differentiating into dopaminergic neurons that provide benefits following transplantation in animal models of PD. Stem cells offer great promise as a therapy for PD; however, cell survival and behavioral responses are limited and further research is required.

Prevention

Primary prevention of PD includes reduction of identifiable environmental toxins. Genetic counseling in the small proportion of familial PD is helpful.

The regular use of ibuprofen may delay or prevent the onset of PD. A recent study on the use of nonsteroidal anti-inflammatory drugs and PD risk found that individuals who regularly used ibuprofen had about a 35% lower risk of developing PD than nonusers.

Large prospective epidemiological studies have linked the consumption of coffee to a reduced risk of subsequently developing PD. Caffeine consumption is associated with a reduced risk of PD in men but not in women. Caffeine as well as more specific antagonists of the adenosine A(2A) receptor has also been found to attenuate neurotoxicity in a mouse model of PD. The convergence of these epidemiological and laboratory data supports the possibility that caffeine may reduce the risk of developing PD. In addition to possessing neuroprotective potential, caffeine and adenosine A(2A) antagonists are being studied as a symptomatic antiparkinsonian therapy.

Conclusions

The prevalence of PD is likely to increase as the aging population increases in developed and developing countries. The advances in molecular and genetic research indicate that PD is likely to be a heterogeneous disorder with varying genetic predispositions and precipitated by environment, biological factors, and aging. There is an urgent need for more widespread advanced centers for the care of PD patients with trained movement disorder specialists, rehabilitation specialists, and state-of-the-art diagnostic and therapeutic modalities. The use of neuroreceptor imaging should lead to an early (preclinical) diagnosis in familial PD and allow the appraisal of potential neuroprotective therapeutic strategies. The advent and increasing availability of DBS should offer a respite for severely affected PD patients unresponsive to maximal medical therapy. More research into genetic, environmental, and biological factors causing PD may allow preventive and neuroprotective strategies to be devised to reduce the incidence of the disease.

Perception

I E Nagel, M Werkle-Bergner, S-C Li, and U Lindenberger, Max Planck Institute for Human Development, Berlin, Germany

Glossary

Perceptual Span (also called Iconic Memory) – The amount of information that can be captured at a glance and held shortly in a sensory store.

Stimulus Persistence – The afterimage that stays in our mind after having perceived an object.

Introduction

As we know from everyday experience, the use of reading glasses or hearing aids is much more common among older adults than among young adults, adolescents, or children. From early to late adulthood and into advanced old age, sensory functions and perceptual abilities show marked and accelerating decline. Perceptual declines are observed across all modalities, such as vision, hearing, touch, smell, and taste, and they progress in close interaction with age-associated changes in cognition. In light of the steady increase in life expectancy in most developed countries, a thorough understanding of senescent changes in perception is needed in order to prepare for interventions aiming at postponing or at least at attenuating their adverse effects on everyday competence.

Aging is not a unitary process but is systemic and differential in nature. Variations between and within individuals reflect interactions among factors that are biological (e.g., genetic and neuronal), environmental (e.g., support structures), and experiential (e.g., compensatory strategies and expertise). Perceptual processes connect the faculties of the mind with the external world by representing environmental stimulations transmitted through the sensory systems (e.g., bottom-up processes) in the context of higher-order cognitive operations that involve attentional control and working memory (e.g., top-down processes). Thus, the aging of perception is a complex product of age-related negative changes in both sensory and cognitive mechanisms. Accordingly, research on perception in old age requires the empirical and conceptual integration of bottom-up and top-down processes at different levels of analysis (e.g., behavioral and neuronal; sensory, perceptual, and cognitive).

This article begins by summarizing findings on sensory decline, with an emphasis on vision, hearing, and balance control. Next, it reviews the ways in which sensory changes relate to cognitive functioning in the elderly. Finally, it discusses possible mechanisms that contribute to couplings among sensory, perceptual, and cognitive declines.

Perceptual Changes in Adulthood and Old Age: A Summary

Age-related alterations are found for all senses and at all levels of processing, from changes in the retina of the eye or the cochlea of the inner ear to changes in higher cortical sensory processing areas and related perceptual phenomena. This section selectively focuses on two primary modalities – vision and hearing – and modally complex sensorimotor functions (e.g., postural control and gait).

Vision

Various aspects of the visual system deteriorate throughout the adult life span, and numerous factors contribute to this decline. The lenses, for example, become harder, denser, and more opaque, thereby increasing the scattering of light and blurring retinal images. The iris becomes less motile so that the pupil becomes smaller. In addition, the number of receptor cells on the retina also declines. This loss is more pronounced for rods than for cones, contributing to greater age-related decline in peripheral than in central vision.

At a more perceptual level of analysis, aging has negative effects on basically any aspect of visual processing. Close and distant visual acuities, for example, decline with age. After approximately age 30, the ability to resolve images into their smallest details decreases. This loss in acuity is less pronounced for large, bright, and high-contrast stimuli, and it can be corrected, to some extent, by wearing glasses or other corrective lenses. However, even with optimal optical correction, older adults continue to resolve less detail than young adults. Depth perception decreases with age, and cases of stereoblindness increase after age 75. Accommodation and light sensitivity also change with age. Young adults adapt faster to darkness and perceive stimuli much more precisely in situations of little luminance. Young adults can, for example, continue reading a book during dusk, when older adults would need to switch on a light.

Peripheral vision, or the ability to detect objects in the periphery of the visual field, deteriorates with

age, in part reflecting reductions in photoreceptor density. The scotopic rods on the periphery degenerate earlier than the photopic cones in the fovea. The resulting reductions in peripheral vision compromise everyday activities such as driving, for which stimuli in the periphery, such as a car approaching a street crossing, need to be detected in time. Motion discrimination is reduced in old age, especially among women, again with marked consequences for everyday life. For example, one must be able to estimate how long it will take an approaching car to come closer in order to decide whether to cross the street or to let the car drive by first.

Stimulus persistence, which refers to the afterimage that stays in our mind after having perceived an object, is increased in the elderly. Shorter afterimages permit faster perception of new stimuli. Stimulus persistence is assessed by the critical flicker fusion threshold, which refers to the stimulus frequencies above which flickering lights are perceived as a persistent light. This threshold decreases with advancing age, indicating reductions in the temporal resolution of visual processing. Bright and high-contrast stimuli leave a shorter afterimage and result in smaller adult age differences in stimulus persistence than less-bright and low-contrast stimuli.

Perceptual span, or iconic memory, refers to the amount of information that can be captured at a glance and held shortly in a sensory store. Young adults typically capture about nine letters of an array, and this number decreases with age. Relatedly, the area of the visual field that individuals can capture accurately at one glance, the useful field of view (UFOV), is about three times larger in young adults than in older adults. Because older adults perceive smaller chunks of an image than young adults, they also have greater difficulties in recognizing ambiguous figures.

This description of age changes in visual perception is exemplary rather than exhaustive. For instance, color discrimination and the accuracy of eye movements (e.g., saccadic accuracy) also deteriorate with age, whereas color constancy, or the ability to identify colors under different lighting conditions, remains relatively intact (*see* Vision). As a result of all these interacting sensory and perceptual changes, less and noisier information reaches the visual cortex. In conjunction with other neuroanatomical and neurochemical changes, this altered input is associated with marked age differences in brain activation patterns during visual processing. There are two main visual pathways: the ventral pathway follows occipitotemporal connections and codes for object information, whereas the dorsal pathway proceeds via occipitoparietal connections and primarily codes for information about the location or specific nature of objects. Probably in part due to aging losses in sensory and low-level perceptual aspects of vision, the specificity of brain activation in the ventral pathway coding different categories of object stimuli (e.g., faces or objects) is reduced, and task-related differences between ventral and dorsal visual processing pathways are less pronounced.

Age-related changes in visual sensation and perception impinge upon older adults' performance in perceptual and cognitive tasks that depend on processing of visual information. Some of the relevant processes include visual search, feature detection, identification of individual characters (e.g., letters or digits), and object recognition. On the one hand, declines in these basic perceptual-cognitive processes limit higher-order cognition such as perceptual and semantic binding of episodic memory traces, decision making, and response selection. On the other hand, decrements in cognitive mechanisms, such as working memory and selective attention, also influence early stages of visual processing. Perceptual processing in the elderly is particularly compromised when prior knowledge of the task environment is low, be it in everyday life or during experimentally controlled laboratory conditions.

Compromised visual abilities have negative effects on everyday competence. For instance, visual deficits increase the likelihood of risky driving behaviors. Reading and writing abilities can also be affected, which may increase the need for the help of others in filling out forms, reading street signs, and the like. Age-related visual decline also narrows the range of options for entertainment (e.g., watching a movie) and information gathering (e.g., reading a newspaper). To some extent, these negative effects of visual aging can be attenuated by wearing corrective lenses (e.g., glasses) or compensated for by relying more heavily on other senses, such as hearing, and the help of others. Note, however, that very old individuals tend to have multiple sensory impairments, which restricts the opportunity for cross-modal integration.

On the positive side, the ontogeny of the visual system is not just a story of losses, primarily because older individuals have acquired and stored a vast amount of experience with visual perceptual tasks in the course of their lives. This general experience with the visual world, as well as individuals' idiosyncratic, person-specific expertise in processing visual patterns, modulates and sometimes attenuates declines in processing. For instance, young and older adults have been found to be equally proficient in searching for traffic signs in digitized images of real-world traffic scenes, which is remarkable in light of the losses summarized previously. Most likely, everyday

life situations often provide cues such as texture and other contextual information that help older adults identify images that they would find difficult to identify without such context.

In everyday life, then, the behavioral consequences of senescent changes in visual processing at sensory, perceptual, and cognitive levels can be attenuated by the accumulation of task-relevant experience and general visual world knowledge, pointing to the need to consider interactions among top-down experiential factors (e.g., professional expertise), top-down cognitive mechanisms (e.g., selective attention), and bottom-up sensory processes (e.g., contrast sensitivity). It follows that age trends in visual processing observed with decontextualized materials in experimental settings may overestimate the extent of functional decline observed under more naturalistic task conditions. At the same time, careful assessment and possibly control of age differences in visual sensory processing are required to capture and examine the additive and interactive contributions of sensory and cognitive mechanisms to the aging of visual perception. Furthermore, in geriatric assessment, for example, when screening for Alzheimer's disease, one should be aware that decline in visual processing as well as in other sensory systems may affect the specificity and sensitivity of diagnostic procedures.

Hearing

Auditory perception also declines with advancing age. Hearing losses become noticeable at around age 30 for men and age 50 for women, possibly as a result of differential exposure to environmental noise, such as noise associated with the operation of heavy equipment. Losses are most pronounced for high-frequency tones and accelerate with age. Similar to visual perception, age-related changes in the auditory system occur at all levels of processing. In the cochlea, loss of basilar membrane hair cells and reduced neural transmission are observed. Furthermore, the cochlear wall becomes thinner. The number of neurons in the auditory nerve decreases, along with structural, functional, and chemical alterations of early auditory processing pathways. In part as a consequence of these sensory changes, the representation of sounds in the auditory cortex differs markedly by age.

Many aspects of hearing are affected by age. Hearing thresholds show a marked increase with age. Reduced hearing sensitivity at high frequencies is a good predictor for general hearing loss. Hearing loss affects psychoacoustic dimensions such as frequency discrimination (e.g., deciding whether two tones have the same pitch or not), intensity discrimination (e.g., discriminating loudness), and temporal processing. One way to measure temporal aspects of auditory processing is to assess the ability to detect gaps in a stream of auditory stimuli. Similar to critical flicker fusion in the visual modality, older adults are unable to detect short gaps between auditory stimuli that young adults notice easily, especially when the stimuli are complex. Another aspect of temporal auditory processing refers to duration discrimination, or the ability to notice differences between the lengths of two tones. Again, this ability is compromised in old age, especially with complex auditory stimuli. Finally, temporal processing also includes the ability to encode and represent the order of a tone sequence. Older adults show more difficulty than young adults in making such order discriminations. Many other aspects of hearing are also affected by age. One important example is spatial hearing or the sound localization from binaural cues (*see* Hearing).

In concert with other changes in auditory perception, age-based changes in temporal aspects of auditory processing have profound effects on speech comprehension. The increasing inability of elderly people to understand speech is by far the most important everyday implication of age-related auditory decline. Whereas speech perception is at least mildly impaired in half of the 70-to-80-year-olds, two-thirds of 80- to 90-year-olds are moderately to severely impaired, and two-thirds of individuals older than 90 years of age have moderate to severe problems in understanding speech. Difficulties in speech perception are exaggerated when background noise is high, when speech is speeded up, when many people take part in the conversation, or when the topic of conversation is complex. Again, declines in speech perception are best understood as an interaction of sensory changes (e.g., basilar membrane hair cell loss) and cognitive changes (e.g., decreasing working memory capacity). Speech is important for maintaining social contact with others. Hence, problems in understanding speech caused by declines of the auditory system can have far-reaching effects on participation in social life and psychological well-being (*see* Social Cognition). In terms of remediation in applied settings, older people's deficits in speech perception can be attenuated by providing contextual cues (e.g., explicitly naming and introducing the topic to be talked about), lowering the speed of speech production, and using well-adjusted hearing aids.

Posture Control and Gait

As a hybrid, multimodal sensorimotor function, keeping balance while standing or walking requires

online dynamic integrations of the visual, auditory, vestibular, and proprioceptive senses. All of these senses decline with advancing adult age. The standard apparatus used for assessing individuals' postural control ability is the force platform, which measures ground reaction forces and momentums of the displacements of the body's center of balance. In general, older adults sway more than young adults, particularly when the conditions of keeping balance are made more challenging (e.g., standing on a non-stable surface, receiving conflicting visual and proprioceptive sensory information, or performing a difficult concurrent cognitive task). Age-related loss of postural stability also affects gait. Walking requires not only the integration and updating of sensory and proprioceptive information, but also the execution of motor commands that are being sent to the trunk and leg muscles. Aging adversely affects all these stages of the postural control and gait system, which leads to increased demands of cognitive control for gait in the elderly.

In part, aging-related declines in postural and gait control are attributable to declines in vestibular, peripheral sensory, and muscular systems. In addition, senescent changes in several brain areas such as the cerebellum, basal ganglia, sensory motor cortex, and brain stem, as well as the parietal cortex, a brain region involved in the neural representation of the body in space, and preparatory motor attention play a role.

Similar to vision and hearing, declines in balance and gait have profound effects on older adults' everyday competence. Losing balance increases the risk for falls, which often lead to physical injuries (e.g., femur and hip fractures), with long-lasting and often irreversible effects on mobility, health, social participation, and personal well-being. Compromised balance and gait also hinder participation in social activities such as visiting relatives and friends or participating in reading clubs, thereby increasing the risk of feeling lonely and isolated. Also, the fear of falling may foster more generalized feelings of insecurity.

Various strands of research explore ways of attenuating age-related declines in balance and gait. In addition to the use of walking aids, applied bioengineering research has made use of the phenomenon of stochastic resonance, which refers to the improved detection of subthreshold signals through admixture of optimal levels of input noise to the sensory and perceptual systems. For instance, it has been shown that older adults' postural control can be improved by vibrating insoles that provide appropriate levels of subliminal proprioceptive stimulation. Related research aims at strengthening the small muscles of the joints, which are particularly relevant for maintaining balance.

Most research on perceptual aging has examined visual or auditory modalities, but performance in other sensory modalities is known to decline as well. As pointed out earlier, sensorimotor functions such as postural control and gait are among them. Other examples are olfactory and tactile information processing, with noticeable decline in middle adulthood. Furthermore, multivariate research on individual differences in perceptual aging has found that perceptual declines tend to correlate across modalities. For instance, declines in visual processing contribute to difficulties in maintaining an upright stance under challenging conditions. In addition to direct causal relations among declines in different perceptual or sensory functions, available evidence suggests that decline in top-down cognitive functions acts as a third variable that contributes to perceptual and sensory decline across a wide range of modalities.

The Link between Perception and Cognition in Old Age

The aging of perceptual abilities is embedded into sensory and cognitive changes (see **Figure 1**). Even though some aspects of intellectual functioning, such as practical and professional knowledge, are maintained or even show gains throughout adulthood and early old age, other intellectual abilities, especially those related to the fluid mechanics (e.g., processing speed, working memory, episodic memory, and reasoning), start to decline in young or middle adulthood and accelerate their decline in old and very old age.

Converging evidence from correlational and experimental studies points to an increasingly strong connection between sensory and cognitive functioning with advancing adult age. Correlations between measures of sensory functions and measures of intelligence are stronger in samples of older adults than in samples of younger adults. For instance, in one cross-sectional age-comparative study, it was found that the variance in cognitive performance shared with vision, hearing, or both was considerably larger in the older age group (see **Figure 2**). This strengthening of the connection between sensory and cognitive domains of functioning is not restricted to vision and hearing. Posture control and gait, tactile information processing, and indicators of general somatic health also are more strongly associated with measures of intellectual functioning in old age than in adulthood.

Initially, multivariate empirical evidence on cognitive-sensory correlations was based primarily on

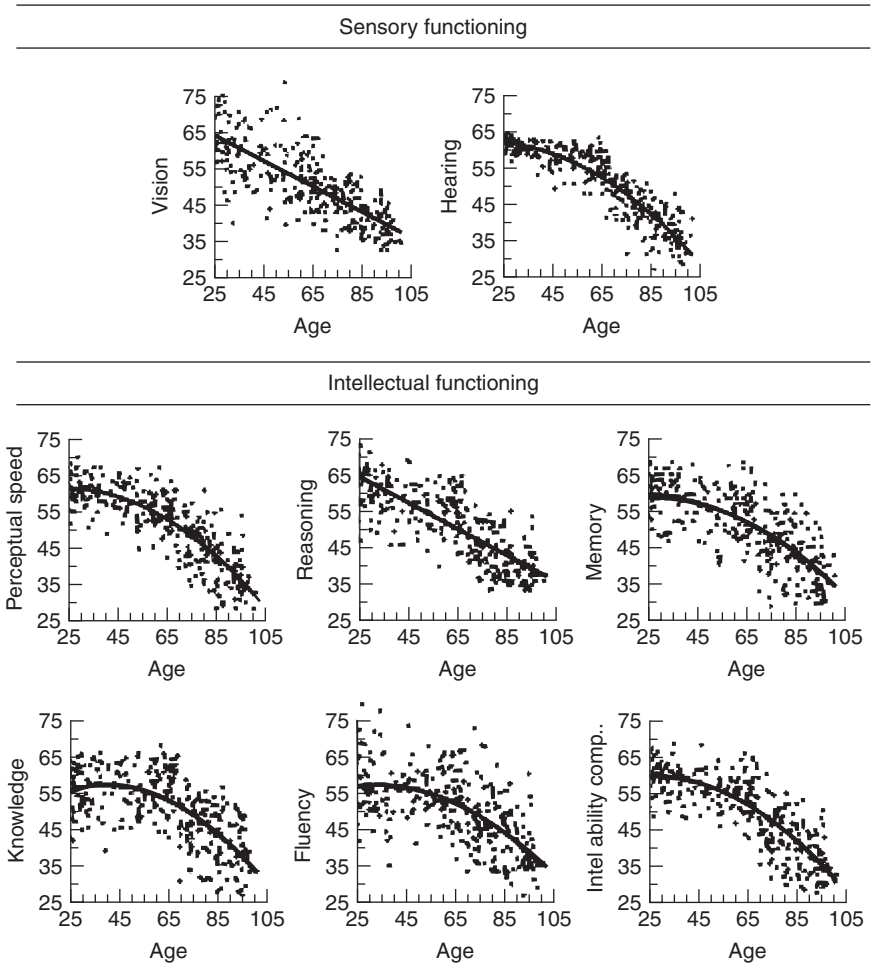

Figure 1 Cross-sectional age gradients for vision, hearing, five intellectual abilities, and the intellectual ability composite ($N = 315$, age range = 25–101 years). With respect to vision and reasoning, quadratic age trends did not differ significantly from zero ($P > 0.01$). Intel. Ability Comp., intellectual ability composite. Reproduced with permission from Baltes PB and Lindenberger U (1997) *Psychology and Aging* 12: 12–21, American Psychological Association.

age-comparative cross-sectional data, which have a number of methodological shortcomings. More recent longitudinal studies report similar, though less extreme, increments in correlations between sensory and intellectual measures. Recent analyses of longitudinal data provide more direct support for dynamic couplings between sensory and cognitive changes in old age. Applying the multivariate dual-change score models (DCSMs) developed by McArdle and colleagues to 8-year, four-occasion longitudinal change data from the Berlin Aging Study, Ghisletta and Lindenberger found that changes in vision and changes in cognition are linked to each other over time by directed effects in either direction. However, other recent analyses of multivariate longitudinal data fail to support dedifferentiation. These discrepancies may be due to measurement issues, the contribution of short-term fluctuations to longitudinal change, and sample heterogeneity. With respect to the latter, sensory/perceptual and cognitive functions may dedifferentiate in some but not all older adults.

Experimental evidence suggests that cognitive involvement in sensory and sensorimotor functions increases with adult age. A common methodological approach is a variant of the dual-task paradigm in which individuals are asked to perform a sensorimotor task (e.g., balancing, walking, or spatial navigation) while performing a cognitive task (memorizing, speech perception or production, or simple decision making) at the same time. Typically, sensorimotor-cognitive dual-task costs increase from early to late adulthood, pointing to greater online interdependence between sensorimotor and cognitive domains of functioning. For instance, in one study, young, middle-aged, and older adults were asked to memorize words while walking on a narrow track. In both task domains, dual-task costs increased with age (for memory performance, see **Figure 3**). Follow-up studies

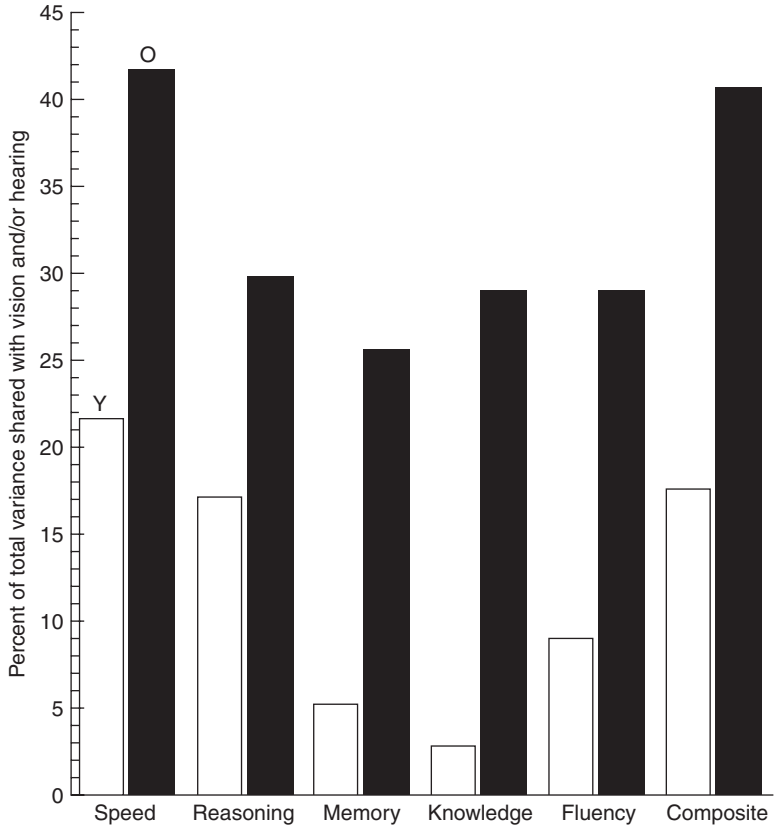

Figure 2 Amount of total variance in intellectual functioning accounted for by vision and hearing in two age groups. Bars represent the amount of total variance predicted by the main effects of vision and hearing. White bars refer to the younger (Y) sample ($N = 171$, age range = 25–69 years), and black bars to the old age (O) sample ($N = 516$, age range = 70–103 years). Except for reasoning, differences in predicted variance were significant at the 0.01 level. Reproduced with permission from Baltes PB and Lindenberger U (1997) *Psychology and Aging* 12: 12–21, American Psychological Association.

found that older individuals tend to prioritize walking as the walking tasks become increasingly difficult, presumably reflecting the adverse consequences of falling.

The finding of increasing couplings between sensory, sensorimotor, and cognitive performance has motivated researchers to design technological support structures such as hearing aids to reduce the cognitive resource load of across-domain multitasking, which is common in daily life (e.g., rehearsing a shopping list while walking on a slippery path).

Perception at the Interface of Sensory and Cognitive Aging: The Search for Systemic Explanations

Three different but not mutually exclusive explanations have been proposed for the increased coupling (dedifferentiation) of sensory and cognitive functions. First, according to the notion of sensory biomarkers, declining sensory abilities represent the first and most valid signs of behavioral and brain aging in general. Second, according to the cognitive permeation hypothesis, sensory and sensorimotor functions are increasingly in need of attentional and related cognitive resources, which themselves are declining, to attenuate the adverse consequences of sensory and sensorimotor losses. Third, according to the common-cause hypothesis, the etiologies of senescent changes overlap across sensory, sensorimotor, and cognitive domains, and this overlap in causal factors imposes increasingly severe and common constraints on sensory, sensorimotor, and cognitive aspects of behavior.

Within the sensory biomarker approach, proponents of the cascade hypothesis state that age-related losses in sensory functions temporally precede and possibly cause age-related losses in cognitive performance. More specifically, the sensory deprivation hypothesis suggests that declining sensory systems result in chronically impoverished sensory inputs, which over time alter the processing interactions between sensory and cognitive processes.

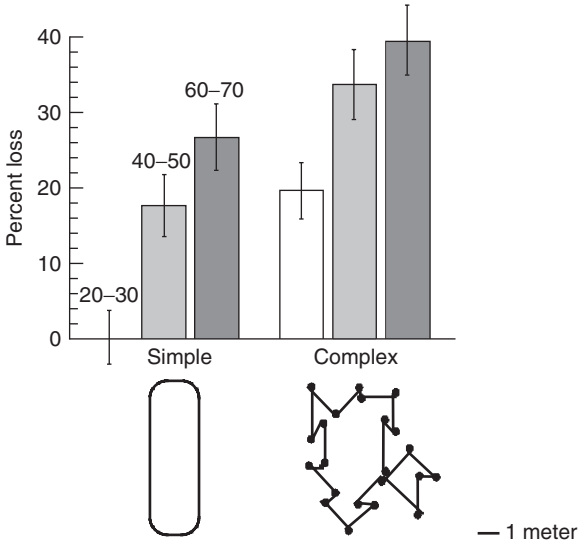

Figure 3 Dual-task costs in memory performance as a function of track and age group. Cost scores refer to the percentage of loss in serial word recall with the method of loci under walking encoding conditions (oval vs. aperiodic track) relative to the average of seated and standing encoding conditions. Middle-aged and old adults showed significantly higher costs than young adults. Error bars represent standard errors of the mean. Schematic drawings of the oval and aperiodic walking tracks are shown underneath. Error bars represent 95% confidence intervals. Adapted from Lindenberger U *et al.* (2000) *Psychology and Aging* 15: 417–436.

According to the cognitive permeation hypothesis, older adults need to invest more attentional resources into sensory and perceptual aspects of stimulus processing and sensorimotor control, which leaves less room for further cognitive processing of the same or some other concurrently executed task. Thus, sensory and sensorimotor tasks or task components that are processed in a largely automatic fashion by specialized sensory and perceptual mechanisms in younger adults are converted into cognitively demanding tasks in their own right with advancing age.

Proponents of the common-cause hypothesis underscore that the aging brain is marked by senescent changes at anatomic, chemical, and functional levels of analysis and that some of these changes have domain-general consequences that transcend the conventional boundaries between sensation, perception, and cognition. The volumes and densities of gray and white matter decline in many brain regions of the brain, though at different rates. For instance, the rate of shrinkage has been found to be larger in the prefrontal cortex and the hippocampus than in other cortical and subcortical regions. Other senescent changes include neuronal loss, loss of dendritic density, and deficient neuromodulation. Sensation, perception, and cognition depend on functional neural circuitries that overlap and interact in space and time. For instance, prefrontal circuitry is involved in attentional control during cognitive tasks and also plays an increasing role in the top-down regulation of seemingly simple sensorimotor tasks. Moreover, certain pathological alterations, such as changes in the basal ganglia and the substantia nigra in Parkinson's disease, are known to affect both cognitive (e.g., working memory) (*see* Intelligence; Memory) and sensorimotor (e.g., tremor) aspects of behavior. Milder forms of these alterations are also present in normal aging. Specifically, decrements in dopamine receptor density result in substantial changes in dopaminergic neuromodulation and related frontostriatal circuitries, with presumably widespread consequences on behavior.

Empirical support for the common-cause hypothesis can be found at different levels of analysis. The majority of findings from cross-sectional as well as longitudinal studies point to a dedifferentiation of ability structures within and across domains of functioning. Similarly, cortical activation patterns become more diffuse with advancing age, and the cortical circuitries activated during performance on different cognitive and perceptual tasks tend to show greater overlap (i.e., less specificity) in older adults than in young adults. These results can be interpreted in terms of age-associated decrements in the signal-to-noise ratio of neural processing. Li, Lindenberger, and colleagues have proposed that aging-related declines in dopaminergic neuromodulation decrease the signal-to-noise ratio of neural information processing, which in turn increases the relative contribution of random processing noise, resulting in less distinctive neurocognitive representations of environmental inputs and dedifferentiated processing pathways.

For instance, neurocomputational modeling suggests that suboptimal dopaminergic neuromodulation in simulated old neural networks reduces the activation intensity and increases stochastic activation variability in response to perceptual stimuli embedded in background sensory noise. More recent simulations of sensory detection demonstrated that both simulated young and simulated old neural networks exhibit the fundamental phenomenon of stochastic resonance, although the magnitude of the effect is smaller in old networks. Moreover, in line with recent empirical evidence, older networks actually needed more external noise to show the stochastic resonance effect.

As for the effect of dedifferentiation, computational results also indicate that suboptimal neuromodulation results in less distinctive neurocognitive representations of different stimuli or stimulus categories, as well as a greater amount of cross-process coactivation

between, for instance, verbal and spatial processes. These computational effects on stimulus dedifferentiation and process coactivation are in line with at least two lines of empirical inquiry. First, with respect to stimulus dedifferentiation, Park and colleagues examined young and older adults' brain activation patterns while perceiving visual stimuli of faces, scenes, objects, and pseudo-words. Previous research with young adults has found that faces activate an area in the temporal cortex (i.e., the fusiform face area), whereas houses and scenes activate an area in the parietal cortex (i.e., the parahippocampal place area). The results of the study by Park *et al.* show that activation patterns were less category specific in older adults than in young adults, which is consistent with the assumption of more diffuse, or less distinct, neuronal representations in the aging brain. According to a rival explanation, the elderly activate more brain areas in order to compensate for age-related losses.

Second, studies on neurocognitive aging have shown that different processes such as verbal versus spatial working memory or memory encoding versus retrieval operations, both of which involve relatively distinct functional cortical regions in young adults, tend to activate more and more similar cortical regions in older adults. Again, it is unclear whether additional activation reflects the inability to suppress competing neuronal groups and to process information in distinct ways (e.g., dedifferentiation), whether additional activation reflects compensatory recruitment of neural circuitry to compensate for aging-related losses (e.g., compensation), or whether it reflects a mixture of both dedifferentiation and compensation.

In summary, normal aging alters perceptual processing through more than one developmental pathway. Some of the causes underlying sensory, perceptual, and cognitive declines are likely to be shared. Also, after critical periods of perceptual development have been completed, reduced sensory input in itself does not seem to exert immediate and widespread negative effects upon cognitive ability. For instance, middle-aged adults whose effective acuity of visual and auditory input was reduced to levels normally observed among older adults did not show generalized decrements in cognitive performance. Also, sensory-cognitive correlations observed in cross-sectional studies are not markedly lowered when individuals with very poor vision or hearing are excluded from the analysis.

Common cause, sensory deprivation, and cognitive permeation are not mutually exclusive explanations of the connections between sensory, perceptual, and cognitive aging. Rather, the mechanisms underlying these explanations may co-evolve and interact during the transition from early to late adulthood and old age. It also is worth noting that some functions such as selective attention remain relatively intact in old age. The various explanatory accounts converge upon the prediction that such functions are less complex, more dependent in acquired knowledge, or both. At a more detailed level of analysis, however, explanations may differ. For instance, according to the common-cause hypothesis, functions are likely to be spared when they are less dependent on the shared common influence. According to the cognitive permeation hypothesis, perceptual functions are more likely to be spared when they show less of an age-related increase in the dependence on top-down processing. Future research needs to discern the ontogenetic dynamics and relative importance of the relevant mechanisms associated with these different explanatory accounts.

Conclusion

Perception involves a multitude of interacting sensory and cognitive mechanisms. Normal aging affects all senses, with marked declines in visual and auditory processing. Multimodal mechanisms of posture control and gait also become less efficient with age. Empirical evidence suggests that sensation and cognition become increasingly intertwined with advancing age. Progress in understanding perceptual aging, with the goal of effectively attenuating its adverse consequences on everyday competence, requires an explicit focus on dynamic interactions between age changes in bottom-up sensory and top-down cognitive processes.

Personality

J-E Ruth, Kuntokallio, Center for Gerontological Training and Research, Helsinki, Finland

Glossary

Neuroticism – The (basic) tendency to react with anxiety, hostility, or obsessive-compulsive behavior in interpersonal relationships or faced with demanding situations in life.

Phenomenology – A method for describing the individual's primary experiences of events. Phenomenology often refers to the perceptual, evaluative, and meaning-giving processes within the individual.

Projective Test – A standardized psychological measurement whereby personality attributes are measured indirectly. Projective tests consist of ambiguous stimuli (persons and situations) onto which the individual projects internal motivations and dispositions.

Psychogerontology – A scientific field of inquiry focused on psychological development and aging. Psychogerontology addresses questions of cognitive aging (intelligence, learning, memory) as well as questions of personality development and mental health.

Self-Concept – Self-awareness, or the way the individual views him- or herself (in relation to others). The self-concept consists of the motivations, attitudes, and behaviors that are relevant to self-definition.

Transactional Processes – Interactive processes between the individual and his or her environment, in which human consciousness (personality) is seen as an ongoing stream and the adapting acts of the individual are in focus.

Introduction

Personality can be defined as the individual characteristics of a person in the way he or she reacts to events. The construct of personality pertains to the internal character as well as the external behavior that differentiates one person from another. Personality psychologists differ remarkably in which aspect of personality they stress. There are those who point to the inner awareness or reflectivity of an individual, called the self, as the core of personality. Others stress outer factors such as learned expectations or the repertoire of learned behaviors. And there are those who are interested in the structure of mind and the profile of personality traits, as well as those who advocate that personality can be observed only from the individual's life as a whole.

Three interrelated themes characterize the field of personality and aging. One theme is the various theoretical and research approaches to the concept of personality. Second is the analysis of whether personality changes over the years, and if so, which aspects show stability and which aspects change. A third theme is the question of how aging individuals can cope with the daily hassles and the major life events that old age brings about. These themes are reflected throughout the sections that follow.

Theoretical and Research Approaches to Personality

The metaphor personality that psychologists have created is a nebulous construct encompassing a multitude of theoretical concepts, research issues, and methods. The three major traditions in personality research – the trait model, the developmental model, and the experiential-contextual model – were created long ago but are all still alive and well. These three models differ widely in their definitions of the concept of personality as well as in their ways of measuring it.

The three traditions also differ in the balance between theory and empiricism. The developmental tradition is characterized by more theorizing, whereas the trait tradition is more empirically oriented. In the experiential-contextual tradition, some models of person-situation interaction have been formulated, and research data in support of these models are gradually emerging.

The Trait Model

The trait model has for some time now been one of the dominant personality research traditions. This model aims at uncovering the basic dimensions of descriptive adjectives of personality found in natural language. There is both a lexical and a questionnaire approach to traits, however. Personality traits are measured by tests and self-report instruments, with the dimensionality of the measures validated by factor analysis.

Personality is inferred in the trait model from the metrical representations of self-reports. It can be argued that the behavior of variables in the metric space is studied in this research tradition, rather than the behavior of persons in real life. The critics of this vigorous research tradition point to its mechanical and abstract way of measuring personality and they question the validity of the sampling of personality constructs used in the instruments. A central question here is how well the tests cover the behavior of the individual in everyday situations. The main issue, thus, is the ecological validity of the tests. Multitrait multimethod (MTMM) analyses linking together self-report measures, peer ratings, and behavioral measures have produced a rather delineated picture of the main personality constructs of the trait tradition and their validity, however.

The Developmental Model

According to the second dominant research tradition, the developmental model, either there are qualitative shifts, such as stages or phases found in the development of personality, or there is a more continuous development around certain themes throughout life. The development model, along with the trait model discussed previously, has generated the majority of empirical research findings within the field of personality.

In the developmental model, the level of development is mapped by measuring instruments (some of which are trait-oriented) or by observation of behavior in social roles or around developmental tasks. In some developmental theories, stages or periods of life are postulated representing qualitative shifts in behavior (such as the development of generativity in middle age and integrity in old age, as in Erik Erikson's theory). In these models, the stages follow each other in fixed succession, advancing from more immature to more mature levels. In other developmental theories, timetables are postulated that are closely linked to chronological age (such as the succession of stable phases and transitions in the life structures, as in Daniel Levinson's model). These theories are mostly based on Freudian reasoning, focusing on the development of the ego and the defense mechanisms the ego uses to protect itself from feelings of distress through life.

In the theories that pertain to a more continuous development, certain developmental themes considered typical for a life period (such as middle age) are investigated. Carl Jung, for instance, focuses on the midlife transition, where the balance of extraversion versus introversion shifts and where an individuation process leads to increased maturity in old age. For the general developmental model, the interesting question is how changes vary in an orderly way, regardless of the direction of change. The general developmental model can depict decline, and decrement with compensation, as well as growth in personality-linked issues.

The stage theories, such as Erikson's, are criticized because they do not seriously take situational and cultural factors into consideration but rather presuppose universal developmental stages for a human being, seemingly irrespective of context. Although the stage and phase theories were conceived long ago, they have not initiated much empirical research that would test their credibility. Daniel Levinson's model can be criticized for making general statements about development for the two genders although his original research sample consisted only of men, and for a rigid chronological time structure that does not take into account sociohistorical change.

The Experiential-Contextual Model

Lately, the experiential-contextual model, which was initiated in the 1960s and constitutes the third tradition in personality research, has grown strong again. In this model the evolving lives of persons and the

meaning people ascribe to life events are in focus. The trajectory of personality change is mapped over extended time intervals, and social and historical factors are considered as important as individual ones.

Within the existential-contextual model, the constructionist approach emphasizes the situations and contexts in which persons create their own selves and those of others. If stability or change are found in personality across the years, this research tradition looks for explanations in the sociocultural and historical context. Accordingly, another characteristic of this approach is to see old age as basically produced and shaped by social factors; there is thus a research interest in uncovering 'the social construction of aging,' for example, in Glen Elder's studies on developmental conditions during the Great Depression.

In the life story approach, another direction within this model that is also based on a life span perspective, personal accounts are studied in order to get a picture of development and aging 'from within' through the stories the self narrates at different points in time. In the life story approach, the phenomenology of the narrator is in focus, and the sociohistorical factors are seen through the interpretations of those factors given by the narrating person. The accounts of lives are collected and analyzed concerning life events, developmental tasks, life projects, turning points, life demands, traumata, life stress, and daily hassles (e.g., the studies by Susan Whitbourne on identity formation and by Dan McAdams on the making of the self, both of which were based on life stories).

Retrospective and prospective data as well as accounts of the present situation are considered useful in this research tradition. The level of analysis can vary from the study of single cases to the study of groups, and from cohorts to subcultures of aging individuals.

The experiential-contextual model seems promising in its ability to combine individual and sociohistorical (internal and external) factors and to study their interrelations in time. In this tradition the management of the self in demanding life situations can be studied, as well as the possibilities of the self proactively creating and changing life circumstances. This method has not yet, however, produced enough data to allow evaluation of its scientific significance within the field of personality.

Findings from Research on Personality and Aging

Results from Research in the Trait Tradition

Traits Costa and McCrae have in several rather extensive studies addressed the question of whether personality 'sets like plaster' at some point during the life span and then remains unchanged, or if change can be found with time. Their studies have been based on a five-factor model of personality traits: neuroticism (N), extraversion (E), openness (O), agreeableness (A), and conscientiousness (C). In some of the studies, a revised N, E, O personality inventory (NEO-PI-R, with full-length measures of the five factors) has been used. The five constructs in a rather systematic way organize hundreds of personality traits proposed by theorists using adjectives that emanate from natural language to describe personality features.

The N scale measures anxiety, hostility, depression, and other variables that refer to maladjustment and psychopathology. N is an important concept because it has been shown that neurotic elderly individuals do not cope as effectively with stressors like severe losses in old age, and that a close relationship exists between low scores for N and subjective well-being. E pertains to external activity, positive emotionality, gregariousness, and assertiveness. O includes intellectual curiosity, active fantasy, and differentiated feelings. A consists of tender-mindedness and compliance. C consists of orderliness, self-discipline, and need for achievement.

Both cross-sectional and longitudinal methods have been employed in the N, E, O, A, and C trait studies. The cross-sectional studies tend to show small declines in N, E, and O and small increases in A and C in older age groups. One of the studies was based on a substantial sample of 10 000 men and women aged 35–84. Similar results have been obtained with smaller samples in other studies. The problematic nature of cross-sectional designs makes the interpretation of these results difficult, however. It can be questioned whether we are seeing in these results the personality features of the different generations under comparison, or if we are really seeing systematic changes in personality with advancing age.

The longitudinal and cohort-sequential studies based on mean levels show another picture: no change or very modest change in personality traits across the years. A 6-year longitudinal study by Costa and McCrae did not show systematic changes in N, E, and O. In overviews of the research on general anxiety, a stability has been reported, but this pertains only to trait anxiety. For more contextual anxieties and fears it is clear that the aged show higher levels of fear, for example, fear of becoming a victim of crime or elder abuse (*see* Abuse and Neglect of Elders).

The picture of no, or little, change in personality traits by age is further strengthened by stability estimates (retest correlations) of individual differences.

The Costa and McCrae research group, as well as other research groups, have in several studies showed considerable stability effects in comparing the rank order of individuals in their personality traits over time. When the studied correlation coefficients are corrected for estimated error of measurement they reach as high as 0.90, which indicate substantial stability. In a study using the Social Introversion Scale of the Minnesota Multiphasic Personality Inventory (MMPI), a stability coefficient of 0.74 has been reported for a follow-up from middle adulthood (30 years) into late middle age.

Correlations across personality components have shown the greatest instability during the formative years, especially in late adolescence to early adulthood. Around age 30, personality presumably takes its final, fully developed form, staying roughly the same over the life span. Stability in personality traits is typical of older adult ages, according to many studies. If correlations among personality components are extended over very long time periods (i.e., over 50 years), a decline in consistency is evident, however, indicating the possibility of some change. But the decline, when it occurs, is generally modest.

In longitudinal studies of persons aged 21–84, based on Cattell's Sixteen Personality Factor Questionnaire (16 PF), Warner Schaie has shown that excitability of emotions is the only trait that increases over the years. Some of the traits in the 16 PF did show age differences in cross-sectional analyses, indicating that they were actually cohort effects.

According to Freudian reasoning, old age should be accompanied by increased rigidity of the ego. In some longitudinal studies by Schaie and his associates this assumption was not confirmed, however. Their studies showed stability both in behavioral and in attitudinal flexibility over the years.

The measuring instruments of personality concepts in the main longitudinal studies within the United States vary widely. This hampers the comparison between projects considerably. On the other hand, generalizability is much enhanced when a robustness in results and resemblances among factors measured in different studies can be found. When the constructs used in the studies are factor analyzed, they do produce factors with reasonable resemblance to Costa and McCrae's N, E, O, A, C model. These results give additional support to the principle of structural invariance in personality over the adult life-span.

Motives Other theorists within the differential psychological research approach have postulated conceptions other than trait as the fundamental unit of personality. According to the Murray tradition, motive is such a unit. Three basic motives – achievement, affiliation, and power, have been studied in depth, within a life-span perspective. Projective tests (such as the Thematic Apperception Test [TAT]) have been used for indirectly assessing motives (defined as dispositions to find a class of incentives attractive). Studies linking the N, E, O, A, and C traits of Costa and McCrae with motivational factors from other types of research have appeared, suggesting that the Murray motives can possibly be conceptualized as motivational traits.

Researchers with a motive approach have challenged the stability claim that has arisen from the N, E, O, A, C studies. Longitudinal studies using the Edwards Personality Preference Schedule (EPPS) have found increases in the achievement and dominance motives and decreases in the abasement and affiliation motives by age, possibly indicating maturational changes in adulthood. Another study has indicated that the need for achievement decreased for employed women who did not get promotion in midlife, and that the power motive was highest for men in midlife.

There are also other longitudinal data implying some personality change from adulthood to middle age. The indication is, therefore, that there are personality constructs that do show changes over time in adult life. It is a challenge to further research to identify these more change-prone aspects of personality.

Control Beliefs Julian Rotter's locus of control idea has initiated some studies that map stability and change in control beliefs over the life span. This research tradition goes back to learning theories that postulate the existence of generalized expectancies concerning behavior possibilities, based on reinforcement. Thus, the individual's feelings of outer control from the caregiving parents would be typical of the childhood years, whereas feelings of increasing inner control in young adulthood will grow out of newly gained independence. Decreased internality of control beliefs is postulated again in old age, when advancing frailty might lead to an increased need for assistance and care.

The research group led by Margy Gatz has generated most of the longitudinal data concerning this issue. In a cross-sequential study with a follow-up of 20 years there seemed to be strong evidence for continuity of internality over the adult years. The mean levels of personal control actually became more internal in all the young, middle-aged, and old-age groups followed in this study, a finding that probably reflects changing contextual factors in the culture. At the same time, the oldest women showed more outer control, most probably a cohort effect. In addition to the gender difference, the researchers point out the

great individual differences found concerning this attribute.

According to some researchers, the inconsistency in some other longitudinal research projects on this issue can be explained by the unidimensional way of defining control (as inner or outer control). Multidimensional approaches might thus be needed. The European researcher Jochen Brandstädter has shown in a cross-sequential study of developmental goals that self-perceptions of autonomous control became more pronounced in middle and late adulthood. This control concerned the domains of health and physical well-being, assertiveness, self-assurance, intellectual efficacy, self-development, mature understanding, and wisdom. Recently, researchers have started to stress the need for studying personality-linked concepts such as control, self-efficacy, or autonomy as transactional processes rather than as personality traits. Where these concepts are studied as processes, the relation between the aging individual and his or her environment will be the focus of the research.

Beliefs Concerning the Future A positive future outlook on life has favorable influences on health-related factors, and the existence of hope has favorable effects on psychological well-being. Future time perspective has been defined as the outcome of cognitive and emotional interactions in the aging person. The European gerontologist Hans Thomae has shown that the existence of a positive future time perspective is related to lifestyle, open-mindedness, emotional responsiveness, active coping, and good adjustment. Those aging individuals who did not attain an inner locus of control, as well as those whose control was lost late in life because of severe illness, exhibit more negative outlooks for the future.

These trends have been confirmed in studies of elderly married women. Women who showed a negative attitude toward the future were socially isolated and devalued by their husband and children, and this detracted not only from their feeling of being needed, but also from their satisfaction with life in general.

A pattern of beliefs in the possibility of changing one's life has also been investigated. The beliefs pertain to the possibility of improving conditions in old age. It has been shown that those with higher income, better subjective health status, and stronger feelings of being needed by others more often show these kinds of beliefs. The stronger the self-perceptions of autonomous control over individual developmental goals are, the more optimistic is the individual's outlook on aging. With a decreasing sense of personal control of life circumstances in old age, symptoms of resignation and depression may emerge (*see* Depression).

Results from Research in the Developmental Research Tradition

General Developmental Conceptualizations

Research on the themes of middle age has produced optimistic as well as pessimistic descriptions. Middle age has been depicted both as a period of increasing maturity and individuation and as a crisis-prone period of life characterized by turbulence and transitions.

According to Jung, a young person will be more extraverted than an old person. After middle age there is a shift in the introversion–extraversion balance. An old person will show increased introversion, and his or her reflectivity on the life he or she has lived will help the individual to develop wisdom. Jung stressed also the process of individuation in midlife, in which the individual becomes increasingly aware of the masculine and feminine features that both men and women show in their personalities. Another aspect of the individuation process is the recognition of both good (moral) and bad (immoral) features of one's personality.

Bernice Neugarten stresses the increased capability of steering one's own life and mastering one's social environment instead of just adapting to it, as in earlier periods of life. The middle-aged cohort has been described as at the top of its capacities and powers. It has also been described as dominating other age cohorts. Studies show that middle-aged men, compared to younger and older men, have the most positive self-concept. Men seem to value career roles highly in this period. At the same time they evaluate their marriages as more satisfying than women do. Women in middle age have been described as possessing a larger and more flexible role repertoire than men. A defense mechanism of rejecting feelings of possible problems and misery seems to add to the feelings of life satisfaction among middle-aged men. The early middle-age period in particular has been seen as a period of active mastery of life themes.

According to Roger Gold, middle age is also a period of reevaluation of earlier assumptions and expectations concerning self and significant others. There are pushes for a reevaluation linked to an arrested career development, the empty-nest issue, and changes in roles. Also, insight on a limited time for life planning as well as insight on the restriction of one's own capacities push for change. Only through a series of transformations will growth toward an increased inner directedness be possible.

Middle age is also a period characterized by an increase in divorce rates, health problems, and psychiatric disorders. Another sign of being middle-aged is that friends and colleagues fall ill and die, perhaps activating thoughts of one's own mortality. The efforts to master these major life events often take the form of personal crises. According to studies, the feelings of loss, reevaluation, and depression are widespread at the peak of a crisis. But when the peak is over, these feelings are gradually replaced by feelings of accepting the realities of life and feelings of the necessity of reorientation.

Large individual differences exist concerning the smoothness versus abruptness of development in middle age. The middle-age transition may pass almost unnoticed by some, whereas individuals who resist change or cannot accept losses or occasional failures seem to be the most crisis prone, according to Levinson.

Earlier it was believed that old age was characterized by increased rigidity and dogmatism. Longitudinal studies show that this usually is not the case. An increased cautiousness (i.e., a lesser willingness to take risks) is still presumed for the aged, however. Studies have suggested that older individuals comply more to social norms and are less aggressive than younger age groups. Neugarten labels the change from active to passive mastery that is typical for the oldest of the old as interiority.

Increased interiority (or even magical mastery) is a male-specific aging phenomenon, however, as David Gutmann found in his comparative anthropological studies. For women, the developmental trend would be the opposite, from passive mastery to an even aggressive mastery. This developmental shift has been seen as a liberation from sex role stereotypes in late old age (*see* Gender Roles).

Levinson's Model of Developmental Periods Levinson's model describes the developmental periods of early adulthood to late adulthood (ages 17–65). The central concept in this model is life structure. The life structure consists of three levels: the sociocultural level (social contexts of class, ethnicity, religion, and political system); the personal level (the self and realization or inhibition of self themes); and the behavioral level (individuals' participation in the world, in significant roles—occupational, familial, and societal). Levinson's own study of 40 men as well as a few other studies seems to affirm his theoretical formulations.

The life structure, according to Levinson, evolves through a relatively orderly sequence during the adult years and this sequence is bound to chronological age (this assumption has been much debated). The developmental task of a life period is crucial for the evolution of the period. (In what follows only the midlife transition will be presented. The other period with significance for aging is the late adult transition, but this period has not been described in detail in Levinson's presentations.)

The developmental tasks of the midlife transition (ages 40–45) are connected with a review and termination of early adulthood, with the initiation of middle adulthood, and with dealing with four polarities in life. There is a need for reevaluation of the relation to the spouse, to the job and one's superiors, to one's mentor, and to one's own values and strivings. Levinson reports that 80% of the men in his study experienced a repeated questioning of and a struggle with these life themes. The need for change will be felt in some areas, and experimentation with new solutions and modification of the life structure will thus start.

The four polarities whose resolutions are considered the principal tasks of midlife individuation are young–old, destruction–creation, masculine–feminine, and attachment–separateness. The most important one is the young–old polarity, which is repeatedly raised throughout life. The middle-aged period of life is experienced as 'in-between,' and the developmental task is to restructure the polarities. Old represents maturity, good judgment, self-knowledge, and getting a perspective on life; young is a symbol for play, initiation, openness, energy, and potential.

In Levinson's theory of developmental periods the concept of life structure is centered on the boundary between self and world. The theory gives equal weight to the self and the world as aspects of life lived. Erikson's theory, which is presented below, is likewise concerned with how the self is engaged with the world, but the focus in this theory is on developmental change within the person.

Erikson's Epigenetic Stage Theory The stage theory of Erikson is the only developmental theory that covers the complete life cycle, but only the last two stages (out of a total of eight) are considered here. The first versions of the theory were created as early as 1950 but they have been elaborated on many times. The most recent presentation is from 1986 and specifically concerns old age.

Three organizational principles constitute the basis for development and change: the biological, psychological, and sociocultural processes. The concept of epigenesis is used for linking the somatic development to the psychological (psychosexual) and social. The concept of ritualization signifies predicted repetitious behavior typical of a certain stage of life. The

development of new life stages arises out of the demands of the biological, psychological, and social areas during critical time periods in life.

The critical time periods in life that induce development of a person's identity are conceived as crises in Erikson's theory. The crises can be solved by finding a balance between two opposite developmental trends. A sign of a successful completion of a developmental crisis is the occurrence of new, age-typical rationalizations.

In middle age, the crises are focused on the polarity of generativity versus self-absorption, and the adaptive strength that can grow out of this crisis is care. Generativity presupposes reproduction, production, and creativity. An adult person cares for children, work-related products, and ideas. By this behavior the adult takes responsibility for the major concerns in his or her life at that time; that is, the adult takes responsibility for self and for the younger generation. The age-typical patterns of behavior, the rationalizations, include the parental and the educational roles, as well as productive and nurturant behavior (*see* Creativity).

In old age the dominant crisis evolves around the opposites integrity versus despair, and the final identity strength that may develop is called wisdom. The last crises of the life cycle accompany the visceral and muscular decrement in the somatic area, the diffusion of the border between past and present and other memory changes in the psychological area, and lost responsibilities in the social area. The major ritualization that grows out of a positive solution of the crisis is a philosophical stance toward one's own life, toward humankind, and toward death.

Wisdom is seen in the development of closeness to persons of earlier times and other cultures, representing other ways of life. But the feeling of integrity is also tied to one's own self with its positive and negative features, and to the life lived with its bright and dark periods. When an acceptance of the self and the life lived is possible, the individual is also ready, without fear, to accept death as the final event of life. The negative developmental path of this stage leads into despair. In this case, the aging individual is unable to accept and finalize his or her life, but rather feels disgust and repulsion toward other human beings, toward life, toward aging, and toward his or her own self.

The generativity typical of the preceding stage may take on an enlarged function in old age and may develop into engagement, if the solution of the crisis is positive. The increasing life expectancy of modern times presupposes new rationalizations based on vital involvement in old age, something not seen before.

Empirical studies of those parts of the theory pertaining to middle age and old age are rather scarce. A test (Erikson Psychosocial Inventory Scale [EPSI]) has been developed, however, to measure resilience to the life crises depicted in the theory. Research based on this test shows that those who have succeeded in solving earlier crises also tend to solve later crises in a positive way. Qualitative studies, by McAdams and other, give delineated accounts of some of the generativity and integrity themes told by the middle-aged and aging self.

Erikson's theory shows rather visible normative underpinnings, based as it is on American norms of development from the period of the 1950s through the 1980s. Thus, it remains to be seen how well the stages cover the development of both men and women today as well as persons from different cultures.

Synthesized Developmental Models Two humanistic, existential models of positive psychological functioning in old age have been proposed: Carol Ryff's successful aging and well-being model and Lars Tornstam's model on gero-transcendence. Both models draw heavily on earlier theorizing in the field (by Gordon Allport, Charlotte Buhler, Carl Jung, Erik Erikson, Bernice Neugarten, Carl Rogers, Abraham Maslow, and many more). The models are creative reconstructions, but seem promising in their own right.

1. Successful aging and well-being: Ryff has criticized research on successful aging for only collecting research data without drawing up models or theories for explaining them. Many researchers routinely use ready-made instruments in research without questioning how well they cover the central constructs in well-being. Some of these measuring instruments are biased against finding evidence of change by including only basic tendencies of personality and by discarding from the scales items sensitive to change. The earlier research on well-being is said to be too focused on illness rather than 'wellness' in old age, and on finding problems rather than resources.

In an effort to integrate mental health, clinical, and life span developmental theories, Ryff proposed a model for multiple positive psychological functioning based on the following dimensions:

- Self-acceptance: A high-scoring individual on self-acceptance shows a positive attitude toward the self, acknowledges and accepts multiple aspects of self (including both good and bad aspects), and evaluates his or her past life positively.
- Positive relations with others: The person has trusting, satisfying, and warm relations with others and cares for them; shows feelings of

empathy, affection, and intimacy; and gives and takes in human relationships.
- Autonomy: The person shows self-determination and independence and is capable of resisting social pressure in ways of thinking and acting. The person regulates behavior from within and evaluates self by personal standards.
- Environmental mastery: The person is competent in managing the environment and has an inner sense of mastery. The person can control a complex array of external activities, makes use of surrounding opportunities, and can choose or create contexts corresponding to personal needs and values.
- Purpose in life: The person has goals in life and a sense of directedness; experiences meaning in past and present life; holds beliefs that give purpose; and has aims and objectives for living.
- Personal growth: The person has a sense of continuous development with a growing and expanding self and increased self-knowledge over time; is open to new experiences; and has a feeling of realizing his or her own potential.

In the preceding presentation, only the positive criteria for well-being were presented. In the self-report scale that Ryff has constructed, characteristics of low scorers on these dimensions can also be found. The model does give a positive outlook on aging, but seems to describe late middle age or early old age better than late old age.

2. Gero-transcendence: A theory suitable for describing the last part of the life span is Tornstam's theory of gero-transcendence. The theory is a reformulation of the disengagement idea, advocating the quest for reaching a metaperspective on life for the oldest of the old. The theory is still tentative, and research to confirm the claims made by this theory has only recently started.

The shift in metaperspective toward gero-transcendence includes the following:

- An increasing feeling of cosmic union with the spirit of the universe.
- A redefinition of the perception of time, space, and objects.
- A redefinition of the perception of life and death and a decrease in the fear of death.
- An increased feeling of affinity with past and coming generations.
- A decrease in interest in superfluous social interaction.
- A decrease in interest in material things.
- A decrease in self-centeredness.
- An increase in the time spent in meditation.

Some evidence for these ideas can be found in the work of Robert Peck who studied the crises faced by aging businessmen. The crises were centered around ego differentiation versus job preoccupation, body transcendence versus job preoccupation, body transcendence versus body preoccupation, and ego transcendence versus ego preoccupation. In an initial study Tornstam found some evidence for the differentiation between gero-transcendence and depression and the differentiation between gero-transcendence and unsuccessful coping. The question of whether gero-transcendence presupposes a religious revival is left unanswered, however, and the theory can be criticized for its metaphysical conceptualizations.

Results from Research in the Experimental-Contextual Tradition

Personality Types, Developmental Trajectories, and Ways of Life In a classic study of adjustment of elderly men to retirement, conducted in the early 1960s by Susanne Reichard, Florine Livson, and Paul Petersen, extensive measurements and self-reports were used in obtaining the data. The researchers found five different personality types that differed in their adjustment. The mature men accepted their own selves and had positive attitudes toward aging. The rocking chair type quietly adapted to aging, enjoying their new freedom from responsibilities. The armored men, however, were not ready for retirement yet; they used overactivity as a defense. The angry men were clearly not well adjusted to retirement; they showed bitterness and blamed others for their predicament. The self-haters turned their aggressiveness inward and were disappointed and depressed.

In another now-classic study, Neugarten and her collaborators, using a multidimensional approach that included an index of life satisfaction, found four types. The integrated and the armored showed high life satisfaction, the unintegrated showed low life satisfaction, and part of the passive-dependent were satisfied and part dissatisfied with their life in old age.

These two studies used many of the traditional personality tests of the trait tradition, but also used some more open measures, such as interviews that are typical of the experiential-contextual tradition. The researchers' efforts to describe personality as a strategy of adaptation or an integrated whole (or type) are features of the experiential-contextual tradition.

It has been suggested that a way of measuring core identity changes would be to focus on the ideas and perceptions the individual has about his or her

life-span development. According to Whitbourne, it is fruitful to focus on two components, the scenario and the life story. The scenario consists of a person's expectations on how his or her life will unfold. The life story will reveal the course of identity formation, and individual values and motives, as well as normative developmental expectations in society for the cohort to which an individual belongs.

Elder has shown that only by describing developmental paths is it possible to reach an ecologically relevant perspective on individual development. The paths, or trajectories, should be examined in the context of time, locality, and social group. Elder, who studied developmental trajectories that took place during the Great Depression, points out that many of the central choices in life, such as career, can be understood only when analyzed along with the individual's personality and social background and the time during which the choices were made.

Ravenna Helson studied lives through time by focusing on normative change (change related to personality patterns and to role sequences). Helson studied a cohort of women attending college in the late 1950s. She found that 'the feminine social clock' (the developmental schedule for this cohort of women) produced self-controlled, tolerant, and responsible women, most of whom were mothers as young adults. But approaching middle age, when those women who followed the 'masculine occupational clock' had gained in independence and dominance, those who followed the feminine social clock had become increasingly overcontrolled. Thus the effect of the homemaker role was to make these women subordinate their own needs to the needs of others. These data give a more delineated pattern of when and why change occurs and the form it takes in different periods of the life-span.

In a recent Finnish study Jan-Erik Ruth and Peter Öberg studied individuals' ways of life and adaptation to old age by using life stories and thematic interviews. Six ways of life were found: the bitter life, life as a trapping pit, life as a hurdle race, the devoted, silenced life, life as a job career, and the sweet life. In these ways of life, earlier life events such as sociohistorical background, marriage, and other human relationships were handled in quite different ways. The sense of locus of control as well as the self-image varied in all of the ways of life. The life lived, clearly, had a substantial impact on the emotional tone of old age.

In the two most negative ways of life, the bitter life and life as a trapping pit, severe losses (such as health problems) and problems in human relationships and career had a negative impact on the respondents' lives and resulted in a dysfunctional old age. There were two gender-specific ways of life; the devoted, silenced life that consisted of caretaking and adherence to the needs of others (typical of daughters at home), and life as a job career where the life story was like a curriculum vitae, with little room for family values (typical of well-educated men). These two ways of life had led up to a satisfactory life or good life in old age. In the sweet life resources like intimate relations with parents, spouse, and children as well as a good education and economy contributed to a healthy lifestyle that resulted in a happy old age.

Coping The coping studies can be classified according to different conceptual frameworks. In some studies personality measures from the trait tradition are used and in some a developmental vantage point is taken. Most coping studies, however, clearly belong in a phenomenological framework, where the perception of stress and the experience of mastering a stressful situation are central. Thus, the results are considered as emanating from an experiential-contextual tradition.

In the work by Lazarus, one of the founders of research on coping, coping consists of the constantly changing cognitive and behavioral efforts to manage specific external or internal demands that the person appraises as taxing or that exceed the resources of the person. The cognitive processes in coping pertain to primary and secondary appraisal. Primary appraisal is the person's assessment of a life situation as stressful or benign and secondary appraisal is the person's perceived ways of mastering the situation.

The ways of coping have been divided into problem-focused or emotion-focused (palliative) coping; active passive coping; and approach-avoidance coping. Research data show that the more active coping strategies lead to a successful mastering of the threat in most situations, resulting in increased life satisfaction. The more passive coping strategies such as minimization of the threat, resignation, or avoidance are considered less successful.

In earlier gerontological studies, old age was depicted as rather stressful, and as a period of multiple losses. The loss of roles, income, health, and even friends and spouse were said to lead to increased distress and to a state of learned helplessness because of an increased inability to master these cumulative losses.

The results from several recent longitudinal studies of the effect of major life events in old age has altered this picture, however. In a US follow-up study of persons aged 40–70, the effects of the empty nest, retirement, retirement of the spouse, medical problems, and widowhood were examined. None of these transition

events from middle age to old age was experienced as overriding the individual's capacity to cope. According to recent data, old age is generally not an unhappy period of life or a period of low morale (*see* Retirement; Widowhood and Widowerhood).

Persons aged 60–70 were followed over a 10-year period in the Bonn Longitudinal Study. It was found that the ways of adaptation differed for persons and situations, but a pattern of constancy, rather than decrement, nevertheless constituted the major finding of the study. In a study in Jerusalem, which spanned about 20 years, this trend was confirmed. No changes in coping patterns (from active to passive) were found across the years. According to this study, coping styles were related to personality dispositions, and a variety of styles were found, from active integrative coping and failing overcoping to dependent passive coping and self-negated undercoping.

The most taxing life events in old age are, according to research findings the death of a close person, one's own illness, the illness of a close person, and giving up activities because of medical problems. But research data also show that only about half of these events occur for the first time in old age. Medical problems, for instance, usually arise in middle age. Small problems and daily hassles may constitute another source of distress in old age, however. Research shows that the coping mechanisms used by the aged are more event specific and more differentiated than was assumed earlier. Seeking social support is, for example, often used in coping with the death of a close person, but seldom in coping with involuntary relocation and giving up activities.

All adults, however, including the aged, have many resources, external and internal, to draw upon in distressing situations. External resources such as high education and high socioeconomic status usually result in coping based on logical choice and flexibility rather than on irrational and rigid solutions. Older individuals with support from the social network, such as family support, are also less likely to use the avoidance coping that is associated with lower levels of well-being (*see* Social Networks, Support, and Integration).

Some studies have suggested that accepting the situation as such, seeking emotional support based on intimacy and friendship ties, and seeking help from religion are used more by women than by men. Men use more information seeking and rely more on instrumental support and camaraderie. These differences between the genders may be cohort specific, and dependent on time-bound and culturally determined behavior expectations.

Internal resources useful in coping are tied to experience or maturation, personality dispositions, and motivation. It has been shown that younger copers rely on denial and projection as a defense mechanism in taxing situations, whereas older copers are more likely to use sublimation, suppression, and humor. An easy-going disposition and optimism are favorable personality dispositions in coping, whereas neuroticism negatively affects perceptions of stress and coping possibilities. Self-efficacious individuals and those with a disposition of commitment, control, and challenge (called hardiness) are more active and successful copers.

The above-mentioned active, and even competitive, ways of coping may be best suited for middle-aged persons and the newly retired, however. Old persons may be better served by accommodating to negative life events, like severe illness, and reassessing the events in a more positive way, or by lowering their own aspiration level. For the frail elderly, the behaviorally oriented coping mechanism may be replaced by more psychological ones, such as relying more on acceptance coping in situations in which they genuinely have little control.

Management of the Self A change can be seen in gerontological research in approaches toward the construct of the self. A more active, creative, and competent self emanates from recent findings. In studies of coping presented previously, there is an increased consideration of resources available for the aging individual. The self is thus no longer seen only as a passive, reactive agent battling life stress induced from outside. In the process-oriented, narrative research tradition there is a possibility of change, in reconsideration and revision of previous history and future plans.

The self-concept is made up of the attitudes, goals, and behavior relevant to self-definition and the meaning of life. This is an enlargement of the former perspective of studying only the actual self, ideal self, and self-esteem, as proposed by Rogers. Now a variety of actual and possible future selves are the focus of research: the good, the bad, the hoped for, the not-me, the ought-to selves (*see* Self Esteem).

Persons of all ages have a tendency to perceive themselves as loving, competent, and good. If they cannot perform a role well, they have a tendency to devalue its importance and put emphasis on other roles that add to their feelings of competency and self-esteem. Another principle of self-concept management is downward social comparison (i.e., a comparison of the self with those even worse off). Other possibilities are attributing failures to external, unyielding causes, and deemphasizing the importance of unattainable goals and emphasizing more

attainable ones. Research data show that in old age the discrepancy between the actual self and the ideal self decreases. Old individuals also stress the need to accept change and lower their expectations in life in order to achieve continued well-being.

Earlier studies showed that elderly women report more health problems and report feeling more lonely than men. Many old men are still living in intact marriages, but even those men who live alone do not report feeling as lonely. Recent data indicate, on the other hand, that a sense of aloneness resulting from multiple bereavements might be compensated for by a feeling of special status as long-term survivors, for both women and men. Data including many age groups also show that deep feelings of loneliness may occur in many phases of the life-span (such as in the teens), rather than only in old age.

The resilience of the self in old age is based on interpretive processes such as reappraisals and social comparisons, but when the self encounters challenges of frailty, a difficulty in identifying possible future selves may occur. It is also more difficult to use selective interaction and feedback from others to formulate new selves. The social interaction is then used for reconfirming the old self and for maintaining hope. Institutionalized elderly often strive to keep their life story intact, and defend against including problems connected to institutionalization in it.

Thomae's Cognitive Theory of Adjustment to Aging Gerontology is data rich but theory poor, according to James Birren. In recognition of that criticism this review ends with some recent theoretical formulations, the first of which was created by Thomae.

Thomae's cognitive theory of aging, which was formulated in 1970, falls under the experiential-contextual framework. In the Bonn Longitudinal Study of Aging (BOLSA), many aspects of the therory have been empirically verified over the years.

In this theory, fixed personality traits are of no interest, but personality is viewed as a process, with the coginitive representations of life situations in focus. According to Thomae, both cognitive maintenance and cognitive restructuring are possible in the individual's adjustment to different situations in life.

Central concepts in this theory are the perceived situation as well as the perceived self. The perception of a life situation, rather than its objective characteristics, is related to behavioral change. The situation, the resources of the individual, and the possibilities for change are perceived according to the needs of the individual at the moment.

Three postulates are basic to this theory:

1. Perception of change rather than objective change is related to behavioral change. This also concerns perception of present, past, and future life and its impact on behavior.
2. Changes and situations are perceived and stored in the memory based on the dominant concerns of the individual. This acknowledges both emotional and motivational factors in the cognitive representations.
3. Adjustment is dependent on achieving a balance between the cognitive and motivational structures or systems of the individual. This postulate focuses on the cognition–motivation interaction in adjustment to problems in old age.

The interrelation between the aging person and his or her enviornment has been stressed in the research based on this theory. Complex competence models including both situation-specific and person-specific areas of social competence have been advanced. In a concept such as social competence both the individual's capacity to meet social (and biological) demands and society's capacity to meet an aging individual's needs have to be considered concomitantly.

Situation–individual interaction patterns have been found in studies on stress and coping in old age, where the specific demands of the situation are met with a specific way of adaptation. The distressing situation can be dealt with cognitively, for example, by accepting what has happened, attaining a distance, or focusing on the bright side of the situation. But adaptation to the situation can also be behavioral, such as adapting to the needs of others or actively establishing new social contact that can provide help. In Thomae's BOLSA studies, the individual has been depicted as an active decision maker, not as just passively adjusting to life stress.

Selectivity Theories Three models based on the selectivity principle have been created within psychogerontology; Laura Carstensen's socioemotional selectivity theory, the selective optimization with compensation model of Paul and Margret Baltes, and Powell Lawton's press-competence model. The conceptualizations differ considerably in their scope, however, and are presented below by moving from the most limited to the most general case.

1. Socioemotional selectivity theory: In Carstensen's socioemotional selectivity theory, the decline with age in initiating new social contacts is explained. It is argued that less social interaction in old age is deliberately chosen by the individual and is not

a sign of social disengagement. According to this theory, social interaction has three basic features: information acquisition; development and the maintenance of identity; and regulation of emotion.

It is argued that in the earlier phases of life increasing social contacts will give access to needed information about life and provide a multitude of developmental models and opportunities. As people age, the need for different kinds of information is reduced and becomes increasingly specialized. Sources other than social contacts (e.g., books and data files) can provide information.

During the life course individuals use a considerable time negotiating their identities with significant others. When the self-conceptions are getting more fixed later in life, only close social partners of long duration can have this self-confirmatory function. Many social partners will not share enough history to verify identity. Close family members and longtime friends, however, provide this function. Thus, these social contacts are selectively chosen and preferred over the overcrowding of social partners in milieus like retirement homes.

The cultivation of a social environment to maximize potential for the experience of positive emotions and minimize negative ones is a deliberate way of regulating affect. In old age, contrary to earlier expectations, no emotional flattening occurs. According to research findings, old age seems to bring an improved understanding of emotional contexts and meanings.

2. The selective optimization with compensation model: Paul and Margaret Baltes's principles for selective optimization with compensation constitutes a general model for successful aging. The model has grown out of the ideas of plasticity and self-resiliency and out of recognition of increasing heterogeneity among individuals in old age.

Persons may be engaged in a process of selective optimization with compensation throughout life, but this process takes on a specific significance in old age, because of lessened biological, mental, and social reserves. By selectively specializing in those areas the individual values highly, the limitations brought on by age can be overcome. This theory resembles Carstensen's socioemotional selection theory, but depicts the psychological adaptation process in aging more generally.

The model is based on three principles:

- The selection principle is seen in a restriction of the individual's world to fewer domains of high priority. The selection process presupposes an adjustment of an aging individual's expectation of satisfaction and control.
- The optimization principle makes it possible for aging individuals to enrich and augment their general reserves and maximize their effectiveness within their chosen life course.
- The compensation principle becomes operative when specific behavioral capacities are reduced or lost and the individual is using a great deal of time or effort to maintain a high level of performance.

A good example of these three principles is provided by Baltes and Baltes, who describe how the aging pianist Artur Rubinstein conquered the weakness in his piano playing in the following way: first, he reduced his repertoire by selective choice of those piano pieces he knew best. Second, he optimized his performance by practicing these pieces more often than when he was younger. Third, he compensated for his increasing slowness by retarding his playing prior to fast passages, which gave an impression of movement in the appropriate passages.

3. The press-competence model: The two previous models based on the principle of selection resemble a third, even more general model: the press-competence model created by Lawton. This model depicts the interaction of persons and environments in producing adaptive or maladaptive aging. The older person is said to construct appropriate environments by selection. An extraverted individual functions best in a stimulus-rich and even stressful environment, whereas an introverted individual functions best in a stimulus-poor and less stressful environment.

Motivation differs by temperament, and neural activation may push an individual toward the external environment (extraversion) or toward internal processes (introversion). In the ideal case, environments match individual competencies. Through the choice or construction of a more suitable environment, the restrictions of old age can, at least partly, be overcome and an optimal fit between person and environment can be achieved.

Conclusions

This article points to the importance of how personality constructs are conceived and measured in psychogerontology. If personality is defined as basic tendencies or traits, as in the N, E, O, C, A five-factor model of personality, the results in longitudinal studies will show stability or only minor change over the years. In the trait tradition, the self is not considered as an active and purposeful agent in a person's life but as an epiphenomenon that passively mirrors the basic tendencies (traits) and the dynamic processes between them and adaptation to life situations.

According to the developmental tradition, personality is defined as motives, commitments, and roles, which represent units more transient than traits; hence, there is possibility for change across the years. In the developmental tradition, the research focus is on the development of the self and its defense mechanisms. The developmental stages or periods depicted in some developmental theories presuppose change in a regular or time-bound order for a positive solution of developmental crises met by the individual throughout life.

In the experiential-contextual tradition, adapting is conceived as a subjective biography, or as mastering based on perception, evaluation, and meaning-giving in the situations encountered by the proactive self; change in personality will not only be possible, but probable throughout the life span. The models and theories within this tradition conceive personality as transactional processes characterized by continuous calibrations in the person–situation interaction.

Pharmacology

W E Fann, Baylor College of Medicine, Houston, TX, USA

Glossary

Enzyme – A biochemical that catalyzes reactions between other biochemicals without itself being consumed.

Ester Linkage – The chemical bond formed in the reaction between organic acids and alcohols uniting them into organic salts called esters.

Glucuronic Acid – A naturally occurring organic acid derivative of glucose used in bodily processes to detoxify drugs and render them excretable.

Hydrolysis – An enzymatic cleavage of an esteric drug. Hydrolysis breaks the ester linkage and returns the compound to its acidic and alcohol constituents.

Introduction

Pharmacology is a discipline concerned with the study of therapeutic medications, their effects on the body, and, conversely, the effects of the body on the medication itself. As a science, it provides the theoretical substrate for the rational prescription of therapeutic agents and is an important element of the physician's training and knowledge base. A cognate discipline, toxicology, the study of the toxic effects of a multiplicity of chemicals, including therapeutic compounds, is sometimes included in pharmacology.

Pharmacology's goals are to pursue an understanding of the mechanisms by which drugs exert their therapeutic effects and adverse consequences and to provide theories for development of safer and more effective agents. The pioneer medicinal chemist Dr. Paul Ehrlich called the ideal drug the silver bullet: it would act rapidly, act only on the targeted disease, organ, or system for which it is administered, and be completely curative. Ehrlich's aphorism remains the unwritten standard for pharmacologists who work today as his successors. Sadly, despite many astounding advances in the discovery and development of therapeutic chemicals, there is no medicinal agent that approaches this ideal. Medications are usually given to achieve one effect on a target disease, but all cause additional effects beyond the one for which they are prescribed. These effects are unwanted, sometimes unanticipated, and can be disabling and even fatal. Despite a host of undesirable non-therapeutic effects, for the majority of patients to whom they are prescribed, drugs continue to help, and even cure. But they remain problematic for many, especially elderly patients and the physicians who prescribe for them.

For a drug to be effective, it must appear at its intended site of action in adequate amounts. The degree and rapidity with which the body is able to absorb, transport, metabolize, and excrete an administered medication may determine that medication's efficacy, therapeutic effects, unwanted side effects, and ultimately the success or failure of the treatment. The ability of the body to perform these functions is, of course, determined by the functional state of the organ systems subserving them, organ systems that may be altered by age and/or disease. The body's ability to handle a drug may be adversely affected by both age and illness, but the relative strength of these two variables is difficult to specify. To help overcome this quandary, an expanding number of studies conducted in groups of healthy older volunteers are contributing important data by which to formulate a general pharmacology of the older patient. Moreover, pre-marketing evaluation of therapeutic compounds, traditionally carried out in relatively small populations of selected younger adults, increasingly includes studies performed on geriatric populations. While the elderly are by no means a homogeneous group, such studies provide the manufacturer, regulatory agencies, and ultimately the practitioner with data reflecting the distinctive requirements of the older patient. With data from tests of such parameters as effective dose, absorption, metabolism, distribution, excretion, onset of action, and side effect profile, predictions can be made of the drug's actions as affected by the altered physiology and special circumstances found in many elderly patients. Health-care professionals have long known, through observation and anecdote, that because of age-related changes in organ physiology and multiple system decompensation, the elderly are likely to show increased sensitivity to medications and are at risk for adverse reactions. The growing body of theoretical and experimental pharmacology from this special population largely substantiates these empirical notions and provides a database to better inform and guide the health-care professionals who care for the elderly patient.

The increasing size and special pharmacological requirements of the geriatric subpopulation energize the thrust for developing a pharmacology for this special group. Not only is the group increasing in absolute size, but the elderly also characteristically visit physicians, are admitted to hospitals, and are prescribed medications at a rate greater than other subpopulation groups. They are more likely to be administered several medications at once (polypharmacy) and for longer periods of time. All of these factors collectively contribute to one of the more vexing pharmacological problems in the elderly, that of non-compliance. More than one-half of elderly outpatients reportedly do not take their medications as prescribed, with underutilization being the predominant deviation. Causes for non-compliance include forgetfulness, misunderstanding of verbal directions, inability to purchase the medication, trouble with side effects, difficulty in swallowing larger capsules and tablets, and, for the frail and arthritic, inability to open some medication containers. For many elderly patients, the sheer numbers of concomitant prescription medications is the problem; it is not unusual to observe an elderly patient arriving at an appointment, carrying his or her medications in paper bags. Many elderly are under the concomitant care of more than one physician and purchase medications from more than one pharmacy; they often accumulate as many as 10 to 15 simultaneous medicaments for themselves. The majority of drugs for elderly outpatients are taken orally, two to four times per day. Such numbers make the patient (or caregiver) responsible for administration of 20 to 30, or more, dosages each day. Under these circumstances, perfect compliance cannot reasonably be expected. Of course, not every alteration in regimens of medication self-administration is necessarily detrimental or contraindicated: in some instances, changes are made because of side effects and toxicity, wherein lowering the dose is the sensible course to follow. Conversely, the dose of a medication may be increased above the prescribed level when the patient correctly perceives an absent or reduced therapeusis.

The patient's adherence to a medication regimen is crucial to the prescribing physician's ability to correctly assess the effect of the medication; any alteration in the regimen should be reported by the patient or caregiver. Such cooperation may be vital to a successful treatment outcome. Unfortunately, the actual effect of incomplete compliance and the magnitude of any deleteriousness to the health of the elderly have not received the research attention they obviously deserve.

This article is intended to outline some basic principles of the discipline of pharmacology and to comment on how these principles apply in the special circumstances of the elderly patient. Emphasis will be given to the important determinants of drug absorption, distribution, metabolism, and excretion. Particular attention will be given to pharmacokinetics, the correlation between a drug's effect and its level in the blood, and to pharmacodynamics, the study of a drug's effects and the bodily mechanisms through which it exerts the effects.

Pharmacokinetics

Pharmacokinetics is concerned with the association between the pharmacological effects of a drug and its concentration in the blood. By studying the drug's blood level, a more accurate estimation can be made of the amount of the drug actually in the body than can be obtained from measuring the oral dose, even if given on a dose per body weight basis. The drug circulating in the blood is one step closer to the target, and its concentration more closely correlates with concentration at the target tissue. The drug's half-life also allows predictions about the time required after multiple doses to reach a steady state level. When considered necessary, information for hepatic and renal clearance and volume of distribution for a drug can be obtained by specialized pharmacological procedures and tests, which may be of utility in severely compromised patients undergoing intensive and prolonged therapy.

Drug Absorption

The most common route for medication administration for all patients is by mouth, with subsequent absorption from the gastrointestinal tract, through the wall of the stomach and/or intestine. In special situations drugs may also be administered by injection intramuscularly or subcutaneously; by intravenous infusion; intrathecally, intraperitoneally, sublingually, rectal suppository, transdermally, inhalation (gases and aerosols through pulmonary membranes), or instillation into the conjunctival sac of the eye; or topically on mucous membranes and the skin. This discussion concentrates on the fate and actions of drugs entering the body through the gastrointestinal tract, with exceptions noted. Absorption from the gastrointestinal tract is mainly by passive diffusion, but certain drugs may be actively transported by cells in the lining of the tract that ordinarily absorb molecules from digested food.

Almost all medications are either weak acids or bases, which may exist in solution in both ionized and un-ionized forms. They can be further divided into two categories on the basis of their solubility. The lipid-soluble (also called non-polar or lipophilic) drugs are not soluble in water and thus, unless specially prepared, cannot be given via routes (e.g., intravenous) that may require an aqueous transport medium for administration. They pass easily through most biological membranes, however, and are thus readily absorbed through the gastrointestinal tract. The more un-ionized the drug, the more lipid soluble (non-polar) it will be. The water-soluble drugs, also called polar or hydrophilic, tend to dissociate into negatively and positively charged ions when dissolved in water. These characteristics may influence how well a drug is absorbed and distributed in the body and, ultimately, how much reaches the target site.

The acid (low pH) environment of the stomach may affect absorption of drugs in several ways. Weak acids will remain mostly in an un-ionized (more lipid-soluble) form and be more readily absorbed through the stomach wall membrane. A weak base, on the other hand, often becomes more highly dissociated into its ionized (more polar and less lipid-soluble) form and hence is not easily absorbed through the gastric wall. Once the drug reaches the basic (higher pH) environment of the small intestine, converse conditions may prevail: weakly acidic drugs often show an increased ionization and become less absorbable, while the weakly basic drugs are frequently less ionized and more absorbable.

While some drug absorption takes place in the stomach, the thickness of its wall, its mucosal lining, small surface area, and strong electrophysiological resistance render it a less-than-optimal organ for absorption of most drugs. It is important, therefore, that the drug pass quickly from the stomach into the small intestine: the more rapid the stomach-emptying time, the more rapid the absorption of the drug. The inner surface area of the intestine is much greater and its wall is thinner, with a lining that promotes passive absorption. The epithelium that lines the intestinal wall also contains cells with mechanisms that actively transport certain drugs out of the intestinal lumen. In any case, the rate of absorption from the

intestine is much more rapid than that from the stomach, even for a drug remaining largely un-ionized in the stomach. Some drugs may be inactivated or destroyed by the stomach's highly acidic juices; the manufacturer may give a particularly susceptible drug a coat that resists decomposition in the stomach, allowing it to pass undissolved until it reaches the intestinal tract. There are also slow-release forms that may be prescribed to prolong the effect of a particular drug or allow it to be given on a once- or twice-daily regimen.

With age, the pH of gastric juice increases (becomes less acidic), the stomach's emptying time is longer, the gastrointestinal wall becomes thinner, and there is some loss of the absorptive and transporting epithelium. All of these conditions may exert an effect on a drug's chemical dissociation phenomena and alter the rate of its absorption. While these age-related changes are of theoretical interest, there is no compelling evidence that they exert a meaningful effect on drug absorption from the gastrointestinal tract or have clinical significance for the elderly patient.

Drug Distribution

Drugs enter the circulating blood by injection or after absorption from the gastrointestinal tract and begin a process of distribution into the fluids within and between cells of body tissue, two of several so-called compartments of the body. The distributed drug goes first to various bodily organs in proportional amounts: the amount of drug an organ receives is determined primarily by the amount of blood it receives. The brain, kidney, liver, heart, and other well-supplied major organs receive most of the first few minutes' dispersion, but within the following minutes to hours, the viscera, muscle, fat, and skin are infused to the same general level. This early phase of drug distribution is a function of cardiac output and blood flow and may be diminished or prolonged by the reduced output of a diseased or aging heart. Another important factor is the drug's solubility. Lipid-soluble drugs that cross biological membranes will easily be more widely distributed than non-lipid-soluble ionized ones. Except for small elemental ions, such as lithium, most biological membranes are impervious to ionized drugs.

During the time they are within the vascular system, many drugs are bound to circulating blood proteins, leaving only the unbound portion of the drug free to diffuse into tissues, other compartments and, ultimately to the target site of its action, the drug's receptor. The binding of drugs to these proteins imposes a limit on the circulating drug's availability for further distribution and the speed with which it reaches its intended site of action. The bound drug is in a dynamic equilibrium with the unbound drug population and is released from binding as the unbound portion is diminished as a result of its leaving the circulation to be further distributed, metabolized, and excreted. The more strongly bound the drug, the less accessible it is for distribution to cells and other body compartments outside the vascular system. In the case of a strongly bound drug, the drug's pharmacological action may be restricted and its metabolism and excretion slowed. There may be an age-related decrease of the blood proteins that bind the drugs, resulting in a smaller bound portion of the circulating drug and a larger portion of it in the unbound state. **Figure 1** demonstrates this phenomenon, comparing the bound:free ratio for a hypothetical drug in a young adult to that in an older patient. Since the unbound portion is that part of the dose that carries out its effects, a small alteration in the amount of unbound drug may cause a large percentage change in the functional dose of the drug, and is one mechanism postulated to underlie an increase in drug sensitivity and adverse effects in the elderly.

Drug distribution is further influenced by the small differences in pH between fluids inside and outside the cells. A drug rendered more lipid soluble by the slightly higher pH of the extracellular fluid might

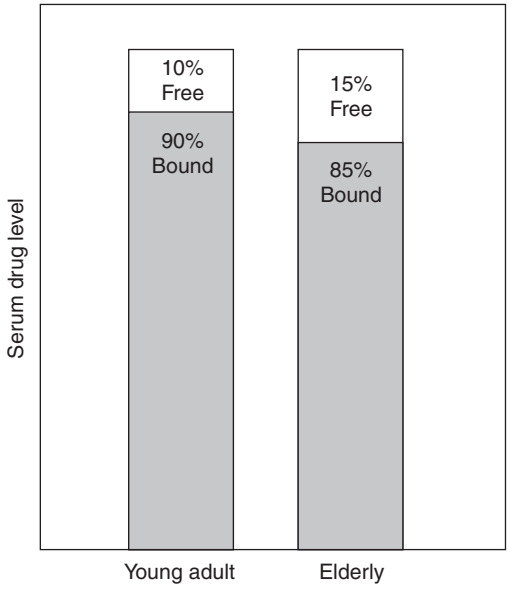

Figure 1 Percentages of a hypothetical drug's molecules circulating free and bound to plasma proteins, comparing a young adult and an elderly patient. In comparison to the young adult, the elderly patient has a lower concentration of blood proteins to bind the drug, leaving a greater percentage of the circulating drug unbound. Note that a 5% increase in the unbound portion represents a 50% increase in this, the functional portion of the circulating drug.

easily traverse the cell membrane but become less lipid soluble in the lower pH of the intracellular fluid and could not then easily diffuse out of the cell. In this manner, the drug could accumulate in a tissue: more would be entering than leaving its cells. Highly lipid-soluble drugs accumulate in fat tissues. Diffusion into tissues where the drug has no pharmacological activity is one of the body's drug inactivation processes, but may also affect drug action in other ways. An accumulation of a drug in a tissue or compartment may become a repository from which the drug, after its administration has been stopped, diffuses back into the general circulation and, in some cases, continues to act pharmacologically. For example, many highly lipid-soluble agents, such as phenothiazines, are stored in fatty tissues, and after chronic dosing can be detected in the patient's serum 6 months after the last dose. One of the highly lipophilic barbiturates given for anesthesia rapidly disperses from serum into the brain, where it acts quickly but transiently if given for only a brief period but becomes longer-acting after repeated or prolonged infusion causes saturation of fatty tissue storage sites. With the storage sites filled, this rapid diffusion/storage mode no longer predominates, and the slower processes of metabolism and excretion become the major mechanisms terminating pharmacological activity. The slower elimination results in continued circulating therapeutic levels and longer pharmacological activity for the barbiturate. This latter instance also illustrates how various pharmacological mechanisms, all of which must be taken into account and understood in the prescription of a medication, contribute to that medication's actions, side effects, and idiosyncrasies.

Only lipophilic drugs are able to diffuse from the blood into the central nervous system (CNS). Ionized compounds, on the other hand, are unable to breach the blood–brain barrier, a factor that must be considered in choosing an agent in particular clinical situations. Many drugs, sold over-the-counter or prescribed to the elderly, possess the ability to block the effects of the neurotransmitter acetylcholine in the CNS and the peripheral nervous system (PNS). Such drugs, commonly called anticholinergics, may in high doses cause delirium, agitation, and hallucinations (CNS symptoms); other effects may include tachycardia, constipation, and urinary retention (PNS symptoms). The elderly, who are particularly sensitive to these effects, may become poisoned by accidentally overdosing on such a drug or drugs and require emergency treatment. The antidote, physostigmine, which easily traverses the blood–brain barrier, will reverse all of the anticholinergic effects. Neostigmine, a strongly ionized congener of physostigmine, which does not enter the CNS, is sometimes mistakenly selected in such cases by the treating physician. In this situation, only the PNS symptoms are reversed. The patient would therefore continue to be delirious, hallucinated, and agitated until the mistake was discovered and physostigmine administered.

Drugs may accumulate in other cells, tissues, and fluids in sufficiently high concentrations to promote a reservoir effect as the plasma level of the drug decreases. For instance, some of the drugs bound to blood proteins may act as a reservoir when displaced from their binding sites by other drugs.

Drug Metabolism

Once a drug has been absorbed and distributed, the body begins processes to inactivate and eliminate it. How thoroughly and rapidly the body eliminates a drug is a strong determinant of that drug's duration of action, efficacy, and toxicity. In any given patient population, there are very large interindividual variations in the rate of these processes. These differences are frequently genetically based and constitute the subject of a rapidly developing subdiscipline called pharmacogenetics. A patient who metabolizes a drug rapidly would maintain a low circulating blood drug level and may require larger-than-usual doses for therapeutic effect. Another who metabolizes slowly, causing a higher-than-expected blood drug level, may become toxic on an average dose of the drug. These elimination processes begin immediately, and variations in their rate must be considered by the prescribing professional when formulating a therapeutic regimen for the individual patient. In most elderly patients these processes are slowed, and unless this fact is recognized and the usual daily adult dose modified to meet the special requirements of the elderly, the blood drug level may reach toxic amounts. For this reason, in order to reduce the incidence of adverse reactions, the dictum 'start low and go slow' is applicable when prescribing for the older patient. The physician must also monitor the patient carefully to ascertain that a therapeutic effect is obtained. After starting low, care must be taken to raise the dose sufficiently; unless therapeutic amounts are given, the drug may not reach adequate blood levels, exposing the patient to risk of adverse effects without providing therapeutic benefit.

Once in circulation, the drug is subjected to the degradative actions of a variety of bodily enzymes. Most of the enzymes that metabolize drugs are found in the liver, but several types are found in the kidney, lung, and gastrointestinal tract as well. Because most of the absorbed drugs are lipid soluble, they must first be converted to water-soluble forms in order to

be excreted by the kidneys. Lipophilic drugs, which diffuse easily out of the kidney and back into circulation, are conjugated with polar molecules provided by the host to make water-soluble products, which are then excreted in the urine. Other types of enzymatic actions result in altered forms, called metabolites, of the drug. These forms may be rendered pharmacologically inactive, but some have as much (occasionally even more) potency as the parent molecule. If the metabolite has pharmacological activity, it will be transformed further to an inactive form, conjugated, and excreted.

After absorption from the gastrointestinal tract, a drug enters the veins of the hepatic portal system and is transported to the liver, through which it must pass before entering the general circulation. Certain drugs are subjected to the combined effects of enzymes in the gastrointestinal wall and the liver, which may prevent a clinically significant amount of the drug from gaining entry to the general circulation. This is called the first-pass effect. While the water-soluble drugs are not well extracted by the liver, highly lipophilic drugs are avidly taken up and transformed. This first-pass process may be so efficient that only 5–10% of the drug dose will pass through into the systemic circulation. The term bioavailable describes that portion of the drug reaching systemic circulation, which then transports it to the site of action. The bioavailability of a drug that is highly extracted by the liver may be markedly increased by a modest reduction in the efficiency of this first-pass effect. Thus, if a drug ordinarily is 95% removed in this process, only 5% of the dose will become bioavailable. If the extraction value were to be reduced to 92%, bioavailability will increase by more than 50%. This would generally have the effect of administering a 50% larger dose of the medication to the patient. If not accounted for, this increase may result in serious side effects normally associated with drugs administered at much higher dosages. Physiological changes, which cause a reduction in this important hepatic function, are reported to occur in otherwise healthy people but are more prevalent, and are prevalent to a greater degree, in those elderly who are frail and with organs decompensated by disease. Many drugs prescribed for the older patient, particularly cardiovascular agents, are affected by these changes. Propranolol is a β-adrenergic blocking agent given for the treatment of cardiac arrhythmias and hypertension. The first oral dose of propranolol is almost completely removed by the extraction activity during its first pass through the liver. It is not until subsequent doses partially or completely saturate the degradative enzymes that sufficient unchanged drug passes through to the general circulation and raises propranolol to clinically effective blood levels. Even so, for propranolol, the average bioavailable amount is only 25% of the administered dose.

Upon extraction from the blood, the drug enters the hepatic cells, where the bulk of drug metabolism occurs in two steps (phase I and phase II). The liver enzymes (and other bodily enzymes as well), many of which are in the microsomal organelles within the hepatic cells, begin transformation of the drug by a variety of enzymatically catalyzed reactions that will determine its fate. The cytochromes P450 are a family of related forms (isoforms) of enzymes found primarily in the liver, with small concentrations in the intestinal wall and other tissues. Their important role (in phase I) is to help rid the body of toxins, including medications, through a process of oxidative metabolism. Other enzymes conjugate the medications in so-called phase II reactions. Both of these processes help convert lipid-soluble drugs to water-soluble ones so that they can be excreted through the kidneys. Not all of these enzymes act on all drugs, but each acts on many. When one enzyme is acting on two or more concomitantly prescribed medications at the same time, unanticipated drug interactions may occur. These include one drug slowing another's excretion, causing it to accumulate until it reaches the clinical equivalent of an overdose, or the first drug can hasten excretion of another, reducing its therapeutic action.

In phase II reactions (conjugation), the drug molecule or its metabolite is combined with another compound, usually a substance found naturally in the body, such as a carbohydrate, amino acid, sulfate, or acetic acid. These conjugations, also called synthetic reactions, commonly utilize the carbohydrate glucuronic acid, but other substances such as the acetyl and methyl molecules, glycine, and sulfate are extensively used. After conjugation, the lipid-soluble drug becomes water soluble and may now be excreted by the kidneys. Part of the dose is converted by a variety of other biochemical actions to inactive (or, for some, pharmacologically active) metabolites. Whether active or inactive, those metabolites that remain lipid soluble will be subsequently conjugated and excreted.

In addition to conjugative metabolism, liver enzymes subject drugs to multifarious other reactions. Oxidative metabolism, an important method for inactivating drugs, is performed by multiple enzyme systems, including heme peroxidases, amine oxidases, alcohol dehydrogenase, and xanthine oxidase. The largest group of oxidases, which are responsible for the breakdown of a multiplicity of drugs, are the cytochromes P450, found in organelles within

the cell. Many therapeutic agents induce or inhibit these enzymes, and a growing body of literature has elucidated important drug–drug interactions at this vector. The frequency with which multiple drugs are concomitantly prescribed to the older patient dictates that drug–drug interactions will inevitably occur.

Imipramine, a tricyclic antidepressant used to treat depression and anxiety states, is initially metabolized by oxidative removal of one of the two methyl groups from its side chain nitrogen, forming the pharmacologically active metabolite desmethylimipramine. This molecule is, in turn, further oxidized to its inactive 2-hydroxy metabolite, glucuronidated, and excreted. Other tricyclics undergo similar side chain demethylations, but with varying sites of oxidation of the ring structure before conjugation. Chlorpromazine, an antipsychotic given in the treatment of such conditions as schizophrenia and manic-depressive disorders, is transformed into as many as 26 different metabolites, some of which may be more toxic than the parent drug. It is possible that a patient whose enzymes idiosyncratically form more of the toxic metabolite would experience more toxic adverse effects than someone whose enzymatic systems transformed chlorpromazine mainly to other less toxic forms. Such variation in underlying enzymatic mechanisms might explain the wide differences in side effect profiles seen in patients treated with chlorpromazine.

Enzymatic chemical reduction of nitrogen atoms within the molecular complex of a drug, through addition of hydrogen to their azo and nitro forms, is another inactivation pathway. Other metabolic enzymes destroy certain drugs by the process of hydrolysis. Physostigmine, which enhances central and peripheral cholinergic action by preventing the breakdown of the neurotransmitter acetylcholine, is itself hydrolyzed at its ester linkage by cholinesterase enzymes. Breaking the ester linkage splits the physostigmine molecule, ending its pharmacological action. This process is rapid: most of an administered dose of physostigmine is inactivated in 2 h.

While activity of drug-metabolizing enzymes is a consistent determinant of drug action, there are a variety of chemicals that enhance or retard their ability to act on particular drugs. Enhancing an enzyme's effect is commonly called induction. Increasing the quantity of a drug-metabolizing enzyme increases its actions and reduces the amount of the circulating drug. Inhibition of an enzyme reduces its degradative activity, resulting in higher blood levels of the drug. Chemicals that inhibit or induce the biochemical activity of the enzymes include other medications, toxins (including nicotine), and ethyl alcohol. Such agents given before or during a drug's administration might cause an acceleration or diminution of that drug's metabolic breakdown, thus raising or lowering the anticipated blood level. Since the broad range of enzyme-inducing and -inhibiting agents includes many commonly prescribed medications, the responsible physician must give cognizance to these interactions when recommending more than one drug at a time for any patient, but especially the more vulnerable older patient. Physiological changes, such as age-related shrinkage of liver mass and reduction in hepatic blood flow, also affect drug metabolism. Reducing hepatic blood flow reduces the amount of circulating drug presented for uptake into the liver cells, whereas loss of liver mass would reduce the amount of that organ's enzymes available for action.

Drug Excretion

The end point of the foregoing operations is the elimination of the administered drug from the body. The final pathway for elimination is the process of excretion, which is conducted mainly by the kidneys, with several other organs and routes playing less significant roles. Orally administered drugs that have not been absorbed or that have been excreted into the intestine in bile are passed out with the feces. Drug metabolites formed in the liver may be excreted into the intestine through the biliary tract and are reabsorbed to be excreted by the kidneys or pass with the feces. Excretion by the lungs is limited almost exclusively to gases and volatile agents. Excretion through tears, sweat, and saliva is relatively insignificant. Salivary drug levels may correlate well with plasma levels (and are sometimes used to measure a drug's concentration when other body fluids are not available); they are generally swallowed and reabsorbed, and only a miniscule amount is excreted.

The excretory function of the kidney involves three intrinsic processes of its nephron: filtration of drugs through the glomeruli, secretion through the tubules, and passive reabsorption into the tubular cells. In the service of maintaining the narrow limits of the body's internal milieu, the kidney is very active in the excretion and reabsorption of a variety of molecular materials, including water and electrolytes, body wastes, and foreign compounds such as drugs and poisons. Once filtered, the fluid containing the drug and/or its metabolites enters the renal tubules, where the metabolites may be reabsorbed or pass into the urine. For a drug to be readily excreted by the kidneys it must be water soluble. This most important variable determines that lipid-soluble drugs must be rendered polar (water soluble) before they will be excreted into the urine. A non-polar (lipid-soluble)

drug, particularly a weak acid or a weak base, in the glomerular filtrate will be almost completely passively reabsorbed through the cells of the proximal and distal tubules of the nephron. The sum total of filtration, reabsorption, and excretion determines the renal clearance of a drug. How tightly bound the drug is to blood proteins also affects its renal excretion, because the bound portion is not readily available for glomerular filtration, and lowers its renal clearance rate. Because tubular cells are not as permeable to ionized drugs as to the un-ionized ones, passive reabsorption of water-soluble drugs becomes dependent in part on the pH of the tubular fluid. In the presence of a more alkaline tubular fluid (higher pH), weakly acidic drugs are more ionized and more rapidly excreted. The opposite occurs when the tubular urine is more acidic (lower pH): a weak acid would remain un-ionized and more readily reabsorbed. For weakly basic drugs, the converse of these conditions would hold true: their excretion would be enhanced in the more acidic tubular fluid but inhibited in the presence of a more alkaline fluid.

Clinicians sometimes take advantage of this renal physiology by manipulating urine pH to accelerate the excretion of a drug that may be present in moderate overdose or causing unwanted effects. Drugs such as ammonium chloride render the urine more basic; ascorbic acid causes a more acid urine. This principle would be salutary in the management of toxic levels of such drugs as a salicylate (i.e., aspirin). Raising urinary pH (rendering it more alkaline) will accelerate elimination of the salicylate in the older patient without having to resort to invasive measures, such as renal dialysis. In order for this treatment to be effective, however, the change in pH must be made to persist until the drug blood level is reduced. An overdose that is very large or life threatening would, of course, be treated by more heroic measures, such as renal dialysis and other appropriate supportive therapy.

An important measurement of a drug's kinetics is its serum half-life (also called half-life and elimination half-life), determined by serial measurements of the drug's blood level after a single dose, and often indicated by the symbol $T_{1/2}$. As illustrated for a hypothetical agent in **Figure 2**, a drug's half-life is defined as the time required to reduce its blood level to one-half of its single-dose peak blood level. The data obtained from the time required for the rise and fall of a drug's blood concentration also reflect rates of its distribution, bioavailability, and clearance. From these data, the pharmacologist can infer how long the drug remains in blood after an acute dose, how much time is required to reach a steady-state level, and how long the drug will remain in the blood after the last dose. The length of time the drug stays in the blood is a function of its clearance, which is a corollary of all the mechanisms previously discussed. Because it is multifactorally determined, the drug's half-life cannot be used alone as the only measure of its disposition or to specify an alteration in any one of the bodily functions that subserve it.

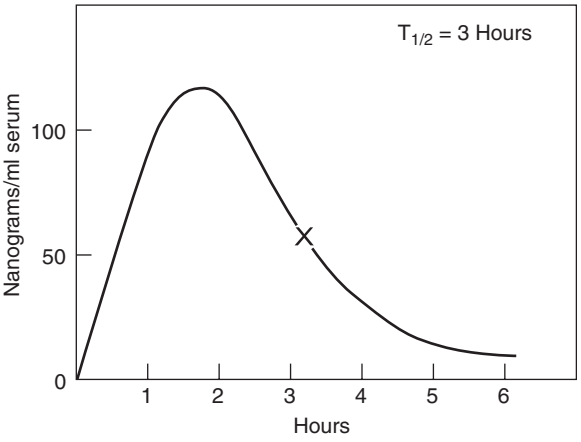

Figure 2 Illustration of the derivation of a drug's serum half-life. In this depiction an oral dose of a hypothetical drug was given at time 0. The drug's blood level rises to a peak of 100 ng/ml of serum. As it is distributed, metabolized, and excreted, its blood level falls. The drug's half-life ($T_{1/2}$) is considered to be the time required for its serum level to reach one-half its peak value. Here, one-half of the peak value (denoted by the X in the downslope) is reached in 3 h.

When a drug's dose is repeated and each subsequent dose is given at an interval approximating its elimination half-life, the drug will accumulate, its blood level will rise, and a steady-state blood level will build. In between each dose, the drug's blood concentration rises and falls, with the steady-state level usually being calculated at a midpoint between the upper and lower blood level values from the individual doses. At the point where the amount of drug entering into the blood equals the amount being eliminated, a steady-state level is attained. Note that **Figure 3** demonstrates that the time required to reach a steady-state level is approximately four of the drug's elimination half-times. When drug blood levels are reported for the usual clinical practice situation, it is the steady-state value that is used. Many drugs have a therapeutic window, by which is meant that there is a steady-state blood level below which it will not be effective, and a level above which it is toxic, with a mid-range wherein it will exert its therapeutic effect with minimal or no toxicity. **Figure 4**, shows the therapeutic window for a hypothetical drug as the shaded area. When a therapeutic window has been established for a particular drug, the physician is able to utilize this information and

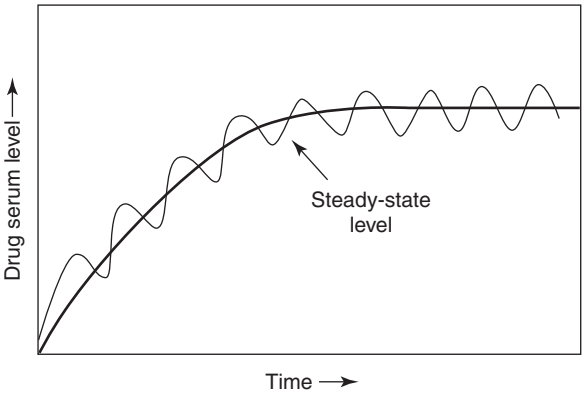

Figure 3 In this illustration repeated oral doses of a hypothetical drug are given beginning at time 0. Subsequent doses are given at approximately the drug's elimination half-life, resulting in a rising drug blood level. In between each oral dose, the drug's blood level rises and falls. At a time between four and five times the drug's half-life, its serum level reaches a steady state. The unwavering line represents the rise of the drug's serum level to steady state during intravenous administration.

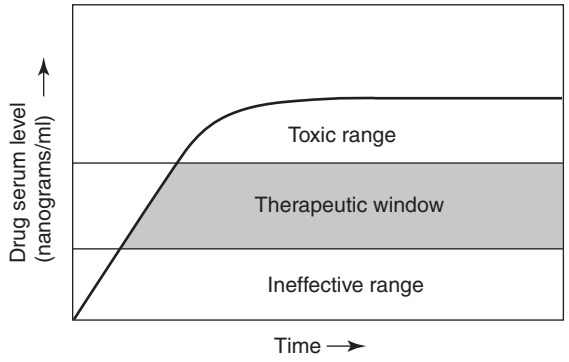

Figure 4 Illustration of a drug's therapeutic window. As a drug's serum level rises, it reaches a value at which it becomes therapeutically effective. As the level continues to rise, it remains effective until it reaches a value above which it begins to exert effects more toxic than therapeutic. The range of the drug's serum level values between the ineffective and the toxic is called the drug's therapeutic window.

determine from one drug blood level value whether or not the patient's blood level is too high or too low before ordering adjustments in the dose. For many drugs, laboratories have established ranges of drug blood level values to assist the physician in adjudging adequacy of the therapy. In elderly patients, many of whom have reduced tolerance to adverse drug effects, it may be difficult to differentiate whether worsening symptoms are due to the primary disease or adverse drug effects. In such cases, drug blood levels may be discriminatory and of definitive clinical value. These same kinetics apply to drugs given intravenously: the blood drug level will rise and reach a steady state at approximately four of its elimination half-times, though the accumulation will be smoother and not show the fluctuations characteristically seen with orally administered doses.

Blood level data and knowledge of a drug's pharmacokinetics may be especially valuable when its therapeutic effects are difficult to judge from observation, its dose must be raised quickly as a treatment necessity, or it has a very narrow dose range (i.e., when there is a small range of values between its therapeutic and toxic levels). Though not foolproof (the patient can go off the medication and restart it shortly before the blood sample is drawn), blood levels offer one of the most reliable methods for ascertaining the patient's compliance with the prescribed medication. Lithium, an important agent in the treatment of affective disorders, has a narrow therapeutic range. In treating a patient with a manic-depressive disorder that has persisted into old age, the physician may order repeated serum lithium levels early in the therapy to establish the oral lithium dose required to maintain the blood level between 0.5 and 1.4 mEq/l serum. Such monitoring is necessary in all patients, but is especially important in the older patient, who may have a reduced renal clearance for lithium. Even if given a lower than usual starting dose, an elderly person can quickly accumulate toxic levels of this ion, making regular blood level determinations mandatory.

Pharmacodynamics

Pharmacodynamics is concerned with drug effects and the body's physiological and biochemical mechanisms through which the drugs exert these effects. Pharmacodynamic data are derived from studies of drug receptor sites, cellular activity, intracellular mechanisms, and structure–activity relationships of the drug itself. Though cellular, molecular, and clinical pharmacology are contributing to a growing body of research in pharmacodynamics, there remains a paucity of data specific for the elderly subpopulation in this area.

Drugs typically begin their pharmacological activity by interacting with a cell at specialized proteins called receptor sites, in its plasma (outer cell wall) membrane, or on channels in the membrane through which ions pass in and out of the cell. They may also act on receptors within the cell or on other proteins or chemical moieties that comprise intracellular mechanisms. The cell wall receptors are typically agonized or antagonized by a variety of endogenous substances (called agonists and antagonists), which transform the receptors, sending a signal into the cell, and stimulation or inhibition of the cell's activity. Drugs are designed to mimic, exaggerate, or interfere in some way with the body's own physiologically

active substances (ions, transmitter substances, enzymes, hormones). Stimulation of a cell's receptor site typically causes a cascade of intracellular events that embrace a multiplicity of mechanisms and lead ultimately to cellular activity (e.g., signaling another cell, contraction, secretion of a substance, or genetic activity).

There is an age-related decrease in some types of receptor sites and a decrease in physiologic cellular and organ activity. These changes may lead to altered sensitivity to medication effects. While there is evidence of an age-related decrease in sensitivity to many medications, some, such as the anticoagulant warfarin, may show an increased effect in the older patient. In general, the elderly are more susceptible than younger patients to the adverse events attendant on drug therapy. Because there is no silver bullet, drugs all act at multiple sites and cause multiple and often unwanted effects, in addition to their action at the target site. Thus, an antidepressant given to treat depression in an elderly patient would cause the downregulation of the β-adrenergic receptor as part of its antidepressant effect. At the same time, it antagonizes the muscarinic cholinergic receptors, producing urinary retention, constipation, dry mouth, blurred vision, and such a degree of discomfort to the patient as to merit stopping the drug, despite its salutary action in lifting the patient's depression.

Drug Interactions and Side Effects

The physician must individualize the elderly patient's therapeutic regimen. Appropriate therapy for the elderly includes careful consideration not only of pharmacokinetics but also of pharmacodynamics. Since the elderly patient is often administered multiple drugs, the physician must note that significant interactions can and will occur. Such interactions can occur during any phase of pharmacokinetic processes, but most of these occur in the process of elimination. The elderly are particularly sensitive to the effects of blocking the body's ubiquitous muscarinic cholinergic receptors. Antimuscarinic actions are therapeutically useful in instances such as relaxing spasmodic smooth muscle (i.e., intestine, urinary bladder) or for parkinsonism, but they are more commonly encountered as unwanted side effects. The US Pharmacopeial Drug Information (USP DI) Review includes a selected list of more than 50 drugs that possess antimuscarinic activity in addition to their primary therapeutic actions. In a regimen of polypharmacy, the side effects of several drugs may be interactive and additive, further slowing an age-related gastrointestinal tract hypomotility, causing severe constipation. Drug-induced urinary retention, even when mild, is problematic for all older patients but can become emergent in the elderly male, who may require prompt catheterization due to a prolonged inability to void. **Table 1** lists several of the more prominent signs and symptoms associated with antimuscarinic effects (often synonymously called atropinic or anticholinergic effects). In addition, the restlessness, delirium, and hallucinations may be misdiagnosed as a psychiatric illness. Prescription of a psychiatric drug, nearly all of which possess inherent antimuscarinic properties, may be contraindicated in such an instance because they may additively aggravate this critical drug-induced situation.

Table 1 Antimuscarinic effects[a]

Blurred (near) vision
Urinary retention
Constipation
Dry mouth
Thirst
Decreased sweating
Tachycardia
Palpitation
Restlessness
Delirium
Hallucinations

[a] A partial list of effects caused by blocking the muscarinic receptors of the various body organ systems. These are also referred to as anticholinergic or atropinic effects. Some of these effects, especially the bottom three, may be misdiagnosed as a psychiatric illness.

Though many drug–drug interactions have been identified by experiential observation and careful clinical pharmacological research, there is a potential for many others among the hundreds of prescription agents and over-the-counter remedies available to the elderly. Some representative examples include the following:

1. The antibiotic neomycin can abolish intestinal bacteria that are responsible for the metabolic transformation of certain drugs. Without these bacteria, the ingested drug in question would not be metabolized at its usual rate and its pharmacological actions may be reduced, or greater than expected. Drugs such as L-dopa, salicylazosulfapyridine, and digoxin are examples of agents affected in this manner.
2. Ion exchange resins (administered to reduce blood cholesterol levels) and gel antacids physically adsorb many concomitantly administered drugs and may thereby reduce or delay their absorption.
3. Guanethidine, an antihypertensive, must be taken up by the adrenergic neuron's norepinephrine

reuptake pump in order to reach its site of action. Drugs that block this pump, such as tricyclic antidepressants and phenothiazines, prevent the uptake of guanethidine and antagonize its antihypertensive actions.

4. Ethyl alcohol is involved in multiple interactions and may variously affect the pharmacology of other drugs through such actions as delaying gastric emptying time, changing gastric pH, delaying drug absorption, or denaturing the drug itself.
5. Probenecid inhibits the renal tubular secretion of penicillin and is often used in a therapeutic interaction to raise the blood level of this antibiotic.
6. Metabolic breakdown of the oral hypoglycemic tolbutamide is inhibited by sulfaphenazole. This interaction raises the blood level of tolbutamide, causing hypoglycemic attacks in patients whose diabetes had been well controlled before the second drug was given.
7. Dicoumarol, an oral anticoagulant requiring careful attention to proper dosing and frequently prescribed to elderly patients, is subject to interactions with a variety of other drugs. Drugs that accelerate its metabolism would lower dicoumarol's blood level and reduce its therapeutic action. A drug that inhibits dicoumarol's metabolism would raise its blood level and increase its therapeutic effects.

The extent of potential problems caused by unwanted effects of prescription drugs may be inferred by reference to the USP DI Review, which lists, in addition to anticholinergically active drugs, an extensive (but not inclusive) compilation of medications that may cause other problems as well. These adverse reactions include such categories as blood dyscrasia, blocking thyroid function, depressing the bone marrow, depressing the central nervous system, stimulating the CNS, inducing hepatic P450 enzymes, inhibiting various hepatic enzymes, extrapyramidal reactions, antagonizing folic acid, hemolysis, hepatotoxicity, hyperkalemia, hypokalemia, hypotension, hypothermia, methemoglobinemia, nephrotoxicity, neurotoxicity, ototoxicity, and blood platelet aggregation. Each of these categories contain from approximately 20 to more than 50 prescription drugs, making it probable that the elderly patient will have some exposure to the potential hazards. Information such as this on prescription medications is regularly disseminated in the USP publications, as well as in continuing medical education forums sponsored by various medical institutions, and is available to professionals and others who care for the elderly.

Physical Therapy and Rehabilitation

A A Guccione, American Physical Therapy Association, Alexandria, VA, USA

Glossary

Disability – Patterns of behavior emerging over long periods of time in which an individual experiences functional limitations that can not be overcome for normal role and task performance.

Disease – An ongoing pathological state that is delineated by a particular cluster of signs and symptoms and is recognized externally by either the individual or a practitioner as abnormal.

Functional Activity – A self-referenced concept dependent on what an individual identifies as essential

to support physical, psychological, and social well-being as well as to create a personal sense of a meaningful life.

Impairment – Evolves as a consequence of disease, and can be defined as alterations in anatomical, physiological, or psychological structures or functions.

Physical Rehabilitation – The practice of promoting changes in an individual, by altering his or her physical or social environments, or by implementing a combination of both strategies to return the individual to as close to the premorbid level of function as possible or to maximize a person's current potential for function and to maintain it for as long as possible.

Introduction

The overarching goal of physical rehabilitation is to return the individual to as close to the premorbid level of function as possible or, alternatively, to maximize a person's current potential for function and maintain it as long as possible. This goal is achieved by promoting changes in the individual, by altering his or her physical or social environments, or by implementing a combination of both strategies. For an otherwise healthy older patient with a simple wrist fracture, rehabilitation may be a reasonably straightforward process. However, considering the necessary steps to return a frail patient following a stroke to a previous, and often tenuous, level of prior function as an example, the rehabilitation program is much more complex because the problems are much more extensive, complicated, and interwoven. Every individual values the ability to function independently and live as he or she chooses. Functional activities, in a gerontological frame of reference, encompass all those actions, tasks, activities, and roles that identify a person as an independent adult.

Although discourse on rehabilitation can often be focused on the extensive and comprehensive efforts necessary to assist an individual who has experienced multisystem impacts and global loss of function from a particular illness, injury, or incapacitation, there are also many active older persons who benefit from less intensive services, including prevention, provided by particular rehabilitation specialists to maintain a desired level of function and quality of life. Thus, rehabilitation services cover multiple dimensions of health service delivery, from simple to complex patient needs, from single provider to comprehensive multidisciplinary teams, and from outpatient private and ambulatory clinics to hospital- or facility-based programs. However, all rehabilitation efforts share the same emphasis on care over cure regardless of complexity or setting and a commitment to mitigating the diminution of function whether it is due to changes associated with the aging process or to some specific disease, disorder, or injury.

Relevance of Rehabilitation to Aging

Functional activity is a self-referenced concept and is dependent on what an individual identifies as essential to support physical, psychological, and social well-being as well as to create a personal sense of a meaningful life. Certain categories of activities are common to everyone: eating, sleeping, dressing, elimination, and hygiene. Locomotion (most typically walking), complex hand activities, and communication are essential underlying components of higher-order tasks and activities, such as cooking, shopping, housecleaning, household chores, and using transportation that can be crucial to living independently in the community. Many older persons also engage in work and volunteer activities as well as recreational activities that require a high degree of functional ability. Loss of function will generally increase with aging and tends to be more prevalent among women at every age, and may also reflect racial disparities in health status. Reported differences in functional status between men and women are a reminder that function is also a sociological phenomenon that depends on what is normal functioning for an adult filtered through social, ethnic, and cultural expectations.

Unique Aspects of Geriatric Rehabilitation

The proportion of elderly at any age without any chronic conditions is small, and disease can trigger a cascade of events resulting in functional deficits and disability. An increase in the number of activities with which an elder has difficulty increases linearly with comorbidity, that is, coexistent medical conditions that further complicate not only the genesis of a functional deficit but also its treatment. For example, rehabilitation for a stroke for an individual who also has painful, degenerative changes in the foot and a low tolerance for stressful activity secondary to angina with exertion would present a particular rehabilitation challenge. Yet, this example encapsulates the rehabilitation specialist's emphasis on care and function, not cure and disease.

Traditionally, geriatric researchers and clinicians have focused on the pathological changes associated

with normal aging, while ignoring a substantial proportion of elders who do not exhibit these changes. Thus, normal aging has been broadly and erroneously equated with pathological aging. Although no one will escape the ultimate eventuality of disease, disability, and death, many older persons are able to decrease their overall morbidity and delay the onset of disability. Moreover, many older persons continue to function with a high degree of independence, even in spite of their chronic conditions, and enjoy an overall positive quality of life. Rehabilitation specialists assist older persons in obtaining an enhanced quality of life by encouraging modification of some lifestyle factors such as diet and exercise in addition to their more traditional concentration on interrupting a vicious cycle of disease, disability, new incident disease, new incident disability among older persons.

Rehabilitation also plays an important role in an emergent subpopulation among aging individuals. Not all disability is acquired in later life. Due to advances in medicine and in rehabilitation throughout the life span, individuals with developmental disabilities as well as people who experience disability from a disease or injury earlier in life are now living well into old age.

The Principles of Rehabilitation

There are two conceptualizations of the relationships among disease and disability that help elucidate rehabilitation practice. The first, sometimes referred to as describing the process of disablement, was first articulated by Nagi and elaborated upon by the Institute of Medicine (IOM), which then later conjoined the concept of disablement with a description of a process of enablement. In this model, health status is parceled out into four distinct components that evolve sequentially as an individual loses well-being: disease or pathology, impairments, functional limitations, and disability. Subsequently, the model identifies the degree to which the physical or social environment contributes to disablement or its opposite, i.e., how these environments enable function. Taken together, these concepts describe the essential elements of an overall framework for examination, diagnosis, and treatment in rehabilitation.

In the Nagi/IOM model, the term disease refers to an ongoing pathological state that is delineated by a particular cluster of signs and symptoms and is recognized externally by either the individual or a practitioner as abnormal. Disease may be the result of infection, trauma, metabolic imbalance, degenerative processes, or other etiologies. The second term, impairment, which evolves as the consequence of disease, can be defined as alterations in anatomical, physiological, or psychological structures or functions. Physical impairments, such as pain and decreased range of motion in the shoulder, may be the overt manifestations (or symptoms and signs) of either temporary or permanent disease or pathological processes. While most individuals anticipate that anatomical and physiological systems will deteriorate with time as they age, an inability to do things for themselves from day to day perhaps most clearly identifies when older persons are losing their health. Nagi proposed that functional limitations were the results of impairments and consisted of an individual's inability to perform the tasks and activities that are typical for that individual, for example, reaching for something on an overhead shelf or being able to dress without assistance. As measures of behaviors at the level of a person, and not anatomical or physiological conditions, limitations in functional status should not be confused with diseases or impairments that encompass aberrations in specific cells, tissues, organs, and systems that present clinically as an individual's signs and symptoms.

Functional limitations occur in distinct categories of tasks and activities: physical, psychological, and social. Physical function covers an individual's sensorimotor performance in the execution of particular actions, tasks, and activities. Rolling, getting out of bed, transferring, walking, climbing, bending, lifting, and carrying are all examples of physical functional activities. These sensorimotor functional abilities underlie the fundamental daily organized patterns of behaviors that are further classified as basic activities of daily living (ADLs), such as feeding, dressing, bathing, grooming, and toileting. The more complex tasks associated with independent community living, for example, using public transportation or grocery shopping, are categorized as instrumental ADLs, often abbreviated as IADLs. Successful performance of complex physical functional activities, such as personal hygiene and housekeeping, typically requires integration of cognitive and affective abilities as well as physical ones.

Psychological function has two components: mental and affective. Mental function covers a range of cognitive activities such as telling the time and performing monetary calculations that are essential to living independently as an adult. Attention, concentration, memory, and judgment are all elements of mental function. An elder's emotional state and effectiveness in coping with the stresses attributable to disease or negative impacts of the aging process are indicators of the patient's affective function. Affective function broadly refers to both the everyday hassles of daily existence that are part of every elder's experience and the more traumatic events such as

death of a spouse. Self-esteem, anxiety, depression, and coping are also represented in the construct of affective functioning.

Social function encompasses an individual's social interactions and activities such as church attendance or family gatherings as well as performance of personally valued social roles and obligations. Many opportunities for social interaction for older persons occur around volunteer and leisure activities. Grandparenting and being employed outside the home are two examples of social role functioning relevant to an older individual.

The term disability denotes patterns of behavior that emerged over long periods of time during which an individual experienced functional limitations to such a degree that they could not be overcome to create some semblance of normal overall role and task performance. Thus, the concept of disability includes deficits in the performance of ADLs and IADLs that are broadly pertinent to many social roles. The person with limited shoulder motion who is fully able to bathe independently by using the range of motion available at other joints to best mechanical advantage and a shower mitt cannot accurately be described as disabled, even though functional performance may be extremely limited without the use of an altered movement pattern and an assistive device. Although each of the terms that have been presented so far involves some consensus about what is normal, the concept of a disability is socially constructed. Disability is characterized by discordance between the actual performance of an individual in a particular role and a set of expectations about what is normal for an adult, i.e., expectations that a task or activity should be accomplished in ways that are typical for an elder's age and sex as well as cultural and social environment.

Unfortunately, identifying a person as being in a particular state of discrepancy between performance and expectation can quickly slip into prejudicially labeling individuals as being disabled as if disability were a merely personal attribute and not the net result of an interactive state between person and environment. Impairment does not always entail functional limitation. One cannot assume that an individual will be unable to perform the tasks and roles of usual daily living solely by virtue of having impairments. For example, an elder with osteoarthritis (disease) may exhibit loss of range of motion and strength (impairments) and experience great difficulty in activities such as bathing (function). Rehabilitation will assist the individual to take a bath without any difficulty, perhaps by increasing strength, using available joint motion to the best advantage, or using assistive devices. The IOM elaboration of the Nagi model, as well as an alternative model, the International Classification of Function (ICF) developed by the World Health Organization, draws attention to the critical interaction between the person and the environment that either disables or enables an individual's function. Disability depends on the capacities of the individual, the suitability of the physical environment, and the expectations that are imposed on the individual by those in the immediate social environment, most often the patient's family and caregivers. The ICF model in particular also calls attention to the critical impact of attitudes and public policy in imposing or eliminating barriers to the full realization of an individual's potential to participate fully in society.

Functional Assessment

The cornerstone of rehabilitation practice is functional assessment. Analysis of function focuses on the identification of pertinent functional activities and measurement of an individual's ability to successfully engage in them. In essence, functional assessment measures how a person does certain tasks or fulfills certain roles in the various dimensions of living described previously. Functional assessment is accomplished through the application of selected tests and measures that yield data that can be used as (1) baseline information for setting function-oriented goals and outcomes of intervention, (2) indicators of a patient's initial abilities and progression toward more complex functional levels, (3) criteria for placement decisions, for example, the need for inpatient rehabilitation, extended care, or community services, (4) manifestations of an individual's level of safety in performing a particular task and the risk of injury with continued performance, and (5) evidence of the effectiveness of a specific intervention (medical, surgical, or rehabilitative) on function. Functional assessment in physical rehabilitation closely examines mobility, basic ADLs, IADLs, work, and recreation.

Mobility

A primary goal for performing a physical functional assessment of an elderly individual is to identify any functional limitations in mobility: ambulation on level surfaces within the home, stair climbing, negotiating uneven terrain, and walking for longer distances in the community.

Basic ADLs

Basic ADLs include all of the fundamental tasks and activities necessary for survival, hygiene, and

self-care within the home. A typical ADL battery, which may be administered by a physical therapist alone or cooperatively with other health professionals, covers eating, bathing, grooming, dressing, bed mobility, and transfers. Incontinence and the ability to use a bathroom are especially important elements in the assessment of physical function in some older individuals. The ability of an elder in three aspects of toileting, to get to the bathroom in an appropriate period of time, to move safely on and off the receptacle, and to perform self-hygiene tasks, may each require exploration.

IADLs

An examination and evaluation of IADLs addresses multiple areas that are essential to living independently as an adult: cooking, shopping, washing, housekeeping, and ability to use public transportation or drive a car. For some individuals, it may also be appropriate to investigate the ability to perform home chores such as shoveling snow or doing yard work.

Work

One measure of adult competence is employment. Older persons who want to, or need to, remain in the work force may do so if they are physically able to perform the tasks of their employment. The ability to work may be investigated in two ways. One approach is to consider the conditions of work itself: whether an individual is working the anticipated number of hours each week, whether the requirements of the job have been modified in any respect to allow the individual to work, and whether the quantity or quality of work done has met the anticipated standard of performance. Another approach to assessing work is to examine the ability to perform particular physical tasks, such as walking long distances; sitting or standing for several hours at a time; stooping, crouching, or kneeling; reaching up overhead; and lifting or carrying various weights.

Recreation

Recreational activities are no less important than work to maintain a sense of well-being. Clearly, older men and women today are maintaining interests in recreational sports that they developed earlier in life. Other elders are just discovering the pleasures of physical exertion. Functional assessment of recreational activities, however, is not limited only to sports. Many elders enjoy dancing and gardening, which require a relatively high degree of balance, flexibility, and strength. Even sedentary activities, such as stamp collecting or playing chess, require a certain degree of physical ability in the hand and upper extremity and therefore may be functional measures of the outcomes of intervention for some patients.

The Process of Rehabilitation

Although rehabilitation may be presented as part of a continuum of health-care services initiated after an acute admission, rehabilitation efforts may actually begin concomitantly with attempts to diagnose and treat the acute condition. While it is logical to assume that rehabilitation should not destabilize the condition of an acutely ill person, efforts to remobilize and promote even very low levels of function may, in fact, assist recuperation and prevent secondary complications. When attention turns toward planning a rehabilitation intervention, a cascade of questions is presented to the rehabilitation team. Of the impairments that are related to the patient's functional limitations, which ones can also be remediated by treatment? Furthermore, if the patient's impairments cannot be remedied, can the patient compensate by using other abilities to accomplish the task, and can the task or environment be adapted so that it can be performed within the restrictions that the patient's condition imposes on the situation? The strings of responses that emerge from this process highlight the process of enablement and encapsulate the rehabilitation specialist's approach to stopping or retarding the process of disablement. Even though many patients will make a full recovery even in the face of substantial functional loss and disability, the emphasis of rehabilitation is turned away from curing the disease that triggered the process of disablement and toward establishing a program of rehabilitative care that enables the highest level of function and quality of life possible.

The Rehabilitation Team

Rehabilitation is a collaborative effort that requires an effective synthesis of the knowledge and skills of multiple medical and health professionals to address the multiplicity and magnitude of problems presented by the patient with complex functional deficits resulting typically from disease or injury as well as the expected complications of aging. Therefore, rehabilitation usually requires a team effort to bring together a substantial division of labor to achieve its comprehensive goals. However, the practice of rehabilitation is perhaps unique in that the patient is regarded as a principal collaborator on the rehabilitation team, as rehabilitation specialists strive to implement their plans of care with the person rather than perform interventions on the patient.

The Core Multidisciplinary Team A physician with specialty training in geriatrics or rehabilitation

medicine often formally heads the rehabilitation team, especially in inpatient settings, and is responsible for all the medical needs of the patient. However, coordination of care is generally managed by nurses, often with advance practice credentials. Physical therapists, occupational therapists, and speech-language pathologists provide the three core rehabilitation benefits established by statute under the Medicare program. Social workers typically round out the team and assist in psychological adjustment to illness, social support issues, financial situations, and continuing care and discharge placement needs.

The Extended Team Depending on the specific needs of the patient, the core team may expand to add the services of additional professionals enlisted to accomplish particular goals, including orthopedic surgeons, neurologists, psychiatrists, psychologists, dentists, podiatrists, dieticians, audiologists, recreation therapists, orthotists and prosthetists, and vocational rehabilitation counselors.

Specific Therapy Services

Beneficiaries of the Medicare program have three rehabilitation-related benefits established by federal statute: physical therapy, occupational therapy, and speech-language therapy. All therapists, who must be graduates of accredited programs, must pass a national examination and be licensed, certified, or registered in their respective professions within the state in which the services are furnished. Medicare covers services that are necessary and likely to result in improvement in a reasonable period of time. Medicare does not currently regard prevention services provided by therapists as falling under therapy benefits and will not cover services intended to maintain a current level of function.

Physical Therapy Physical therapists target their interventions at restoring or maintaining physical function and health, especially as related to movement, and treating or preventing impairments and functional limitations that result from particular diseases or injuries. Impairments of strength, flexibility, and endurance, especially because they limit movement and diminish functional abilities such as gait and locomotion, are specific concerns in the physical therapist's plan of care. The primary forms of intervention used by physical therapists are therapeutic exercise, neuromuscular re-education, manual therapy, and functional training, as well as instruction and training targeted toward prevention. A growing number of physical therapists are credentialed in geriatrics through the American Board of Physical Therapy Specialties.

Physical therapy is sometimes erroneously used interchangeably with physical rehabilitation. Although physical therapy services account for the bulk of rehabilitation provided under the Medicare program (over 70% of all Medicare payments for rehabilitation), physical therapy is a distinct service provided by a particular health professional who is licensed and regulated as a physical therapist under state law. Similarly, physical therapy is often mistakenly regarded as synonymous with an array of interventions that use physical means to achieve a therapeutic goal. There are a number of health-care professionals as well as other kinds of practitioners who use physical agents (e.g., heat, cold, sound, and electricity) and mechanical modalities (e.g., traction) whose services are often incorrectly referred to as physical therapy.

Occupational Therapy Occupational therapists concentrate their attention on a patient's ability to perform all ADLs and IADLs independently, especially in light of perceptual or cognitive deficits, and assisting an individual to re-establish or maintain desired habits and routines that support his or her personal identity and sense of well-being. Primary occupational therapy interventions focus on therapeutic activity and include methods to promote sensory integration, cognitive retraining, and task adaptation to achieve, restore, or maintain a particular level of function, especially one that facilitates independent transition into the community and the resumption of an individual's personal and social roles in a particular environment.

Speech-Language Pathology A speech-language pathologist (also known informally as a speech therapist) helps patients with receptive and expressive components of communication, speech production and quality, and language comprehension as well as difficulties in swallowing that may result following disease, injury, or some surgical interventions. Speech-language pathologists employ a variety of methods to increase or augment skills for communication and use alternative communication methods as well as promote the ability to swallow safely.

Rehabilitation Settings

Rehabilitation describes the practice of professionals to address a range of patient needs and is not limited to any particular setting or organizational structure. Rehabilitation services can be accessed through hospitals, inpatient rehabilitation hospitals, outpatient hospital departments and rehabilitation

facilities, private practices, home health agencies, skilled nursing facilities, and nursing homes. Each of these settings is organized to address a certain range of problems, based on the person's current functional status and ultimate prognosis for improvement, concomitant medical issues, tolerance to participation at varying intensities of treatment, the likely duration of the services, and the necessity for a particular efficiency in coordinating multiple services. Some individuals receive rehabilitation services along a continuum, beginning with admission to an inpatient hospital and then being transferred to other inpatient facilities such as an inpatient rehabilitation hospital or skilled nursing facility. Some of these individuals may complete their rehabilitation programs as outpatients. Other individuals will initiate their rehabilitation on an outpatient basis, perhaps with just a single healthcare professional, without any inpatient admission. A person's own preferences and social situation (e.g., safety issues, caregiver availability, the need for 24-h assistance) also influence decisions regarding setting. Each of these settings has its own rules for both admission and payment that will also affect where, how, and by whom services are provided.

Rehabilitation Outcomes

In general, the literature supports the efficacy of rehabilitation interventions to produce changes in impairments and functional limitations. However, what is far less clear is the appropriate dosage of these interventions and the duration of services to ensure that the most appropriate services are provided to patients to ensure optimal functional recovery without unduly wasting resources. Similarly, the impact of setting on outcome and cost has not been fully addressed. The impact of rehabilitation on long-term disability among older individuals is not as well established in the literature, although the available evidence suggests that rehabilitation, especially when coupled with primary and secondary prevention, mitigates the magnitude of disability associated with aging.

Politics of Aging

C Kelly and V W Marshall, University of North Carolina, Chapel Hill, NC, USA

Glossary

Economic Globalization – The increasing integration of economies around the world, particularly through trade and financial flows, as well as the movement of people and knowledge across international borders.

Electoral Politics – Voting, party affiliation, organized political action, and holding public office.

Politics of Aging – How structured economic interest groups interact in ways that have intended or unintended consequences for resource allocation in relation to the age structure.

Introduction

There are many ways to think about the term politics. First, to many people, politics may mean electoral politics, which includes voting, party affiliation, organized political action, and holding public office. Second, at times individuals collaborate to further perceived or real collective interests through the political process. In this sense, the politics of aging may describe social movements that have coalesced over time, particularly those advocating for the creation and expansion of programs benefiting the aged. Third, politics also refers to other processes through which various actors, primarily economic actors such as corporations and business organizations, act in a political field with governments and voluntary and non-governmental organizations to advance their economic interests and influence public policy and practice. These processes are understood through the political economy perspective (*see* Theories of Aging: Social).

In this context, the politics of aging deals with how structured economic interest groups interact in ways that have intended or unintended consequences for resource allocation in relation to the age structure. The political economy perspective on aging provides an ideal framework for this discussion. This approach can be employed at several levels (national, state and local, international) to bridge electoral politics, social movement politics, and the state–interest group processes shaping public policy that include the role of private actors such as investment companies and health insurers. The bulk of this article is organized by sequentially examining the politics of aging from these three approaches, which in fact are linked. The focus is on these three types of social process as they refer to public policy. Public policy establishes and sets the parameters for age-based programs (such as Social Security and Medicare) that specifically target older persons; but also age-related programs such as Medicaid, as well as education, housing, and transportation programs, that may have differential consequences for different age groups, even though age is not a criterion for eligibility.

The politics of aging are socially constructed. That is, the issues faced by the elderly are created by political actors with their own objectives. It is important to understand not only the policies that affect the aged, but also the people and organizations who set the aging policy agenda by framing what shall be considered an issue, a problem, or even a crisis, requiring policy attention. The location of these agenda setters is continuously evolving. Some decisions that impact older persons (Social Security and Medicare, for example) are made at the national level. Others, such as decisions concerning the use of Medicaid funding for long-term care, are made by state and local officials within parameters set by the federal government. But all decisions occur today within a global context in which the United States is but one player. The lives of elders across the world are inextricably linked, because their social and economic contexts are linked through globalization.

This article focuses on the United States but will also attend to policy developments in other countries that are global or international in scope (for example, age-related policy developments by the United Nations (UN), the World Health Organization, and the World Bank). Many developments relevant to aging politics occur in spheres not typically considered by gerontologists, because the political, social, and economic consequences for the aged are secondary or unintended consequences. The article addresses such issues and suggests that they should be considered when social gerontologists examine the politics of aging. Thus, this article views the politics of aging as multifaceted and multilevel in scope.

Electoral Politics

Throughout the developed world, the growing numbers of older people have been a stimulus to age-related politics. The shape of age-related politics varies considerably by the nature of the polity, for example, whether the country has a one-, two-, or multiparty system, whether a federal system (in which national and subnational governments have spheres of influence) exists, whether the system is parliamentary or presidential, and so forth. In the United States, Republican George W. Bush was elected to a second term as President in 2004, with a plurality of 3 million votes over his challenger, Democratic Senator John Kerry. However, as in 2000, President Bush's margin of victory in the electoral college was thin (286–252) and the election was decided by a single state, with a narrow Bush victory in Ohio deciding the contest. In the aftermath of another closely contested election, political pundits made note of an apparent blue state/red state divide in the electorate. In reality, distinctions between Kerry and Bush voters were more subtle. Senator Kerry garnered much of his support in big cities, while President Bush fared extremely well in the suburbs and rural areas. The President also built upon his conservative base from 2000 with increased support from Latino, Jewish, and Catholic voters, as well as from women.

Older voters have long been viewed as a key battleground in presidential politics. This is largely due to the fact that, beginning in 1976, Americans aged

65 and older have turned out to vote at a rate higher than any other age group. However, the idea that seniors play a decisive role in electing the president deserves closer scrutiny. As Robert Binstock has observed, older Americans had voted in previous elections for different presidential candidates in roughly the same proportion as the general population. In the 2004 election, this pattern was once again in evidence, as the two major candidates received almost the same percentage of votes among voters age 65 and older (52% for Bush; 47% for Kerry) as they did among the overall electorate (51% for Bush; 48% for Kerry). Among all age groups, President Bush fared best among voters age 60–64, with 57% of the vote among this cohort. By contrast, Senator Kerry fared best among the youngest category (age 18–29), with a nine point advantage.

The indication that Senator Kerry failed to garner greater support among older voters may appear surprising, given the unpopularity among seniors of the Medicare prescription drug bill and of Bush's Social Security plan (discussed later). It would seem that seniors supporting the Bush–Cheney ticket had voted against their own self-interests. Nevertheless, as Binstock and others have observed, the self-interests of older people vary, and seniors as a group have rarely voted solely on the basis of programs for the elderly. Postelection polling indicated that Kerry voters across all age groups identified the economy or the war in Iraq as the most important issue in the election, while Bush voters reported that the candidates' moral values mattered the most. However, in closely contested states such as Ohio and Florida, President Bush's advantage over Senator Kerry on the issues of terrorism and national security was considered the most decisive factor.

The 2004 election provided an opportunity to reexamine voting patterns by age and perhaps to reassess assumptions made about age-related patterns in voting behavior. Previous elections revealed little variation among age groups in voting preference, but significant differences in terms of participation. From 1966 to 1996, voting rates among older persons increased while turnout among younger voters declined. However, different age patterns emerged in the 2004 election: significant age-related differences in voting preference, but less variation in terms of participation. Exit poll data revealed an 8% increase in turnout among voters under age 30 from the 2000 election; the ranks of younger voters grew as much as those of older voters in this election. The key question in age-related voting behavior is no longer simply Why are older persons voting in higher numbers? but also Why has voter turnout increased among the young?

To understand the factors that guide electoral decisions among different age groups, we inevitably ask whether age, period, or cohort effects are operating. An age effect would be suggested if people were found to become more conservative as they grew older. A cohort effect would be evidenced if the values of people who are older adults today have been consistent over their lifetimes. A period effect may exist if persons of all ages were inclined toward a specific set of values during one historical era, but a different one in the next.

There are reasons to question whether any of these three types of effects was decisive in the 2004 US election. As previously noted, older citizens rarely vote on the basis of apparent age-related interests. Perhaps other, indirect age-related effects are operative. For example, the elderly have had a lifetime to form political philosophies and allegiances; concerns about their children and grandchildren may lead their attention away from later-life issues; and their age may simply not be a salient aspect of their identity. In the 2004 election, the presence of a cohort effect is undermined by the fact that the age group 65 and older, a generation previously identified as alienated from politics, had the highest voter turnout. Finally, in this election there was little evidence for a period effect cutting across all age groups in respect to issues such as same-sex marriage. With a divided and volatile electorate, it may be years before we can discern what drives voting behavior of Americans.

It is not possible in this space to adequately represent the variations in electoral politics of aging around the world. Suffice it to say that a different dynamic exists when more than two political parties are present. Unlike the United States, where the choices of older persons are limited to two major parties that may or may not prioritize their interests, older persons in many other democracies can turn to a larger number of viable parties more attuned to their interests. For example, in Italy, which has many viable political parties, older voters can communicate their desire to preserve the welfare state status quo through their support of parties opposed to pension reform. As Alan Walker notes, smaller pensioners rights parties have also formed in Germany, Denmark, and the Netherlands.

Social Movements

Another way in which age can be relevant to the political process is through the development of age-based interest groups and the mobilization of these groups in social movements. Prior to the twentieth century, there was little notion of group consciousness among seniors, largely because the number of

older people had not yet reached critical mass. However, with increasing life expectancy came the rise of the older population, the creation of public programs serving the aged, and a growing awareness of the needs of older persons, leading to broad-based movements for aging policy.

In the United States, grass roots movements (for example, Townsend clubs) organized around individual reformers during the 1920s to agitate for the creation of an old age pension (which already existed in several European countries), and years of pressure culminated in the Social Security Act of 1935. While most accounts of its passage attribute the legislation to a policy elite within the administration of President Franklin Roosevelt, Social Security was nonetheless seen as the first triumph of 'gray power.' Individual reformers eventually gave way to organized political interest groups. By 1990, as Christine Day observed, there were more than 1000 aging-based interest groups in the United States functioning at local, state, and national levels and representing a broad ideological and political spectrum. Day also noted that these interest groups vary widely in size and the ways in which they find their support, with many lobbying groups receiving support from private foundations, government agencies, and philanthropists.

The largest aging interest group is AARP (formerly the American Association of Retired Persons), with more than 30 million members (many of whom are attracted by AARP benefits, such as travel discounts). Other more policy-driven organizations include the National Council of Senior Citizens (NCSC), the National Committee to Preserve Social Security and Medicare, and the Gray Panthers. The effectiveness of this 'gray lobby' is the subject of much debate. For example, despite its large membership and public policy division, AARP has historically achieved limited success in expanding public benefits for the aged. One example is the Medicare Catastrophic Coverage Act (MCCA), passed by Congress in 1988 with AARP's support. The MCCA was designed to increase coverage for high-cost care, but it was quickly repealed due to the protest of upper-income elders, who were to be assessed a surtax to finance these new benefits. Recent achievements of the gray lobby have largely been in sustaining existing public programs for the aged in the face of efforts to dismantle them. In 2005 AARP had a major impact in its efforts to derail President Bush's proposal to privatize Social Security.

Social movements centered on aging have been a largely American phenomenon, and aging interest groups have been slow to develop in other countries. However, recent years have seen an upsurge of political activity by organized aging groups in other countries, with gray parties winning seats in the national legislatures of the Netherlands and Czech Republic, and associations forming to prevent cuts in senior services, such as the Gray Panthers in Germany. In contrast to the United States, few other industrialized countries have a single, large mass-membership organization such as AARP that advocates on behalf of the elderly. Canada, for example, does not have a comparable large advocacy-oriented interest group, and an attempt to establish one (One Voice for Seniors) failed. In Italy, pensioners' unions are recognized as the driving force behind that country's elderly oriented welfare state, while in other countries, the most visible aging interest groups represent specific sections of the older population (such as retired civil servants in Great Britain).

Finally, internationally oriented groups pursue advocacy and agenda-setting activities for aging policy on behalf of the aged. One example is HelpAge International, a global NGO with affiliates in 48 countries, which focuses on poverty issues of the aged in the global context. HelpAge International has also influenced European institutions to include intergenerational approaches in their development policies, and it provides direct policy advice to governments in many developing countries. Working with partner organizations, it has advocated for relief of older caregivers of persons with HIV/AIDS in Africa and Asia. Another example is the International Federation on Aging (IFA), which promotes social engagement of and on behalf of older people throughout the world through conferences and publications. IFA can be viewed as an agenda-setting organization, advocating for the well-being of older people through an informal network of Ministers of Aging around the world. The IFA Declaration of Rights and Responsibilities of Older Persons was a foundation for the UN Principles for Older Persons, adopted by the UN General Assembly in 1991.

Political Economy

As scholars such as Carroll Estes have described, the political economy perspective is predicated on the view that old age is socially constructed and that the power struggles between actors such as international capital, the state, and the medical–industrial complex are the forces that shape social policy. This perspective, which emphasizes the broad implications of structural forces and processes such as electoral politics and social movements, provides the framework for discussion of age politics in the income security and health-care policy domains.

Income Security

Across the globe, public pensions have been high on the policy agenda and subject to the politics of age. While some developing countries are struggling to establish state pension plans to accommodate their rapidly aging populations, several developed countries have contemplated, if not implemented, changes to pension systems designed to lower the costs to the state of pension provision and, in many cases, to promote higher employment in the later years or at least counter a trend to early retirement. Almost all of the countries in the developed world have gone through at least one major reform to their old age security systems. The path of this reform largely depends on the nature of the pension program already in place.

In the United States, Social Security reform has risen to a major place in the policy agenda of the Bush administration. The President has proposed a major revamping of the program's current pay-as-you-go funding mechanism, under which benefits for retirees are financed through the earnings of the employed. His proposal would allow workers to divert part of their payroll taxes currently earmarked for the Social Security trust fund into private investment accounts, shifting responsibility for income security in old age from the state to the individual. However, privatizing Social Security is not a new idea. Economists at the University of Chicago and the Cato Institute have proposed private investment as the solution to an eventual Social Security shortfall since the early 1970s. In 1995, Senators John Danforth (R, MO) and Bob Kerrey (D, NE) advanced their own partial privatization proposal, and the idea has been on the policy table ever since. Nor is the United States the first country to consider privatizing a public pension program. Chile, with a push from the World Bank, adopted a fully privatized income security system in 1981, and several other countries in the global south have discussed similar changes.

President Bush's plan to reform Social Security shares with these earlier efforts the conviction that the responsibility for financial security in old age rests with the individual, not with the government. The President has described personal retirement accounts as the centerpiece of an ownership society and has promised that private accounts would provide beneficiaries a higher rate of return in retirement. He has also attempted to garner support for privatization by defining the status quo as a crisis, warning that the Social Security trust fund would run out of money as Baby Boomers began to retire and that the system would be bankrupt by 2041 unless action was taken today. However, the public response to privatization has been generally unfavorable. AARP stated its opposition to carving private accounts out of existing Social Security revenue. Other critics noted that these private accounts would actually harm the long-term solvency of Social Security by diverting money from its trust fund. Instead of privatizing the program, it has been argued, minor corrections to the program such as raising the cap on earnings subject to the payroll tax can ensure the long-term stability of the Social Security program.

Whether public or private provision is more efficient is an empirical question. However, the arguments made in the pension debate tend to be based on ideological grounds. When President Bush described Social Security as a system in crisis, he drew on a rhetoric that had been advanced for many years in the debate over the concept of generational equity, which refers to the principle that different cohorts should be treated equally in terms of resource allocation and should have similar opportunities. Organizations such as Americans for Generational Equity (AGE) and the Concord Coalition have argued that generations currently old have received more government resource allocation (such as for pensions and health care) than the younger generations will receive over their lifetimes, and that older generations have contributed less to the government through taxes and other contributions than will younger cohorts. These groups have recommended reduced transfers to the aged as the solution to generational inequity.

The argument that there is generational inequity has been used as an attack on public pensions and a justification for privatization and the individualization of risk. However, this general form of argument has been severely criticized. For example, the generational equity perspective downplays the diversity in economic conditions and political behavior among the elderly. Further, there is little evidence that current policies toward the elderly adversely affect younger adults. Finally, conclusions that old age policies are unsustainable based on dependency ratios fail to take into account recent demographic trends, such as the many older adults who remain in the labor force. Despite these criticisms, the generational equity perspective remains a concern for the politics of aging. This rhetoric not only persists, but also informs the agenda setting for politics against the welfare state and toward individualism.

Public pension programs in other industrialized nations suggest that there are alternatives to the public pension framework in the United States. Other countries with earnings-related pension programs have successfully avoided the threat of shortfalls. Canada's two-tier program, comprising

work-related and non-work-related income, is one example of a public pension system that is not in crisis. On the other hand, several nations that have more recently created old age pensions (for example, Australia, Ireland, the Netherlands, and New Zealand) have opted for universal or quasi-universal capitalized pension schemes. Public pension reform is on the political agenda of almost all the highly developed countries. However, privatization is not the only option available to fix a national income security system. Japan has scheduled future increases to payroll taxes, while Austria and Finland have adjusted the systems by which earnings are calculated. Incremental measures such as these may prove more feasible than the current Bush proposal to reform Social Security.

The politics of social insurance cannot be separated from the issue of private pensions. Every industrialized country has developed its own mix of public and private provision of income support in the later years, with a growing number of countries moving away from the traditional safety net of public programs and relying more heavily on the private sector. Over the past quarter-century, the predominant structure of employer pension plans (which cover half of private full-time workers in the United States) has changed. In 1980, 83% of private pensions in this country were defined benefit plans, in which the employee receives a guaranteed retirement benefit, usually provided on a monthly basis. The majority of private pensions today are defined contribution plans, in which employees invest a portion of their earnings into their choice of employer-sponsored investment packages. In this way, the responsibility of providing a retirement nest egg for employees has been shifted from the corporation to the individual.

Defined contribution plans were supported by institutions such as AGE and the Concord Coalition that embraced the implicit emphasis on individual responsibility, as well as the idea that the market would eventually solve the problem of a rising ratio of retirees to workers. During the 1990s, a healthy stock market supported this principle. However, the pension system in the United States is currently in disarray. Corporate fraud led to the failure of several defined contribution plans in the early 2000s, including those of Enron, Tyco, and MCI WorldCom. Employee investors in these companies' programs lost their entire pensions, with no hope of reimbursement. The picture for defined benefit plans is also bleak. United Airlines and many other companies have recently terminated their defined benefits pension programs and are unable to meet their obligations to retirees. The Pension Benefit Guaranty Corporation, the federal agency that guarantees defined benefit plans, is now responsible for the pensions of over 130 000 United employees and many other employees and retirees.

In short, the private pension systems in the United States appear vulnerable as American corporations seek to cut costs in order to remain competitive in the face of increasing global competition. This trend poses potentially dire consequences for millions of individuals as they approach old age, as the pension crisis threatens to dismantle one of the traditional sources of retirement income in the United States. The turmoil surrounding private pensions has also had political fallout. Reports of corporate malfeasance have eroded public support for efforts of conservative policymakers to shift the responsibility of income replacement from the government to the individual, as they have reminded Americans of the risks inherent to personal investment. In particular, the private pension crisis has helped to undermine the President's efforts to privatize Social Security; this is one indication that the United States is not yet ready to abandon the welfare state, and embrace the financial market, in order to provide income security for the aged.

The fate of private pension plans in other developed countries is similarly dependent on the vagaries of the global marketplace. This is particularly a concern in countries in which income security in old age is closely tied to private investment (for example, Australia and Ireland). In nations such as these, where an established earnings-based public pension system (as in the United States, Canada, and much of continental Europe) is lacking, the nest egg for aging citizens may consist almost entirely of private pension benefits, leaving these individuals particularly vulnerable in the event of an economic downturn. It may well turn out that a balance between public and private pension benefits is necessary for aging individuals in a global economy.

Health Care

Pensions and health care constitute two major areas of expenditure for modern welfare states. While many national medical care insurance systems are experiencing fiscal strain, the health-care insurance system for older adults in the United States is also reputed to be in financial crisis. Medicare's financial problems are believed to exceed those of Social Security; according to two independent trustees, the Medicare trust fund will be exhausted by 2020. Per capita health-care costs have continued to grow rapidly due to the development of new technology and to the increased use and costliness of medical care.

The cost of the new Medicare prescription drug program, created under the Medicare Modernization Act (MMA) of 2003, is projected to grow to $100 billion per year by 2014, far beyond initial estimates. The rising costs of acute care services under Medicare Parts A and B, coupled with the larger-than-expected price tag of the prescription drug program, fuel fears over the long-term solvency of Medicare, which are only heightened by the anticipated needs of the 70 million Americans who will reach old age by 2030.

However, from the political economy perspective, the concern over the future ability of Medicare to provide affordable health care to older Americans is another socially constructed problem. The Medicare program is not the source of this impending crisis; health-care costs for older Americans have risen because all health care in the United States has become more expensive. National medical expenditures have grown more than 350% since 1980; annual health-care costs in the United States are projected to reach $2.18 trillion by 2008 and to continue to grow at a rate faster than that of the overall economy. Medical costs per capita have actually grown more slowly among older Americans than among the general population, in large part due to the Medicare cost containment strategies of the 1980s and 1990s. In short, as Jon Oberlander warns, the crisis in health care is one facing all Americans, and it is due to the lack of centralized budgetary controls, higher prices, higher administrative costs, and, in some cases, greater use of high-cost medical technology in the American health-care system.

Thus, the challenges facing Medicare must be understood in the larger context of how health care is socially constructed in this country, specifically, why the United States is alone in the developed world in not providing universal national health insurance covering people of all ages. This nation's political institutions are important contributing factors. Contrary to the centralized governments of Great Britain and other European nations, powers are divided in the United States between three separate branches of government (executive, legislative, and judicial). Also, in the federal system of the United States, administrative duties are shared by national and state governments, further increasing the number of veto points at which health-care reform can be blocked. Further, a two-party system characterizes American politics, reducing the potential for the policy innovations that have emerged from reform-minded parties in Canada and elsewhere. The absence of a party representing the labor movement in the United States is a particular hindrance to expansion of the welfare state. Finally, the American political ideology, which tends to emphasize individualism, has limited the growth of public programs based on the principle of collective solidarity.

These factors have created obstacles to national health insurance, which have been exploited by its opponents. In the United States, different stakeholders have derailed previous attempts at major health-care reform. In the early twentieth century, physicians, represented by the American Medical Association (AMA), lobbied against government-financed health care, which they regarded as a potential intrusion to the doctor–patient relationship. In recent decades, the health insurance industry, viewing national health care as a threat to their control of the health-care market, has moved to the forefront. Over time, these different coalitions have employed similar tactics. First, they have defined a possible government takeover of health care (and not the lack of affordable health care for millions of Americans) as the crisis in this policy area. Second, opponents of health-care reform have used the fragmented nature of American politics described previously to full advantage, successfully lobbying Congress to block six different presidential proposals for universal coverage, most recently President Clinton's in 1994. Consequently, health care in the United States has been largely ceded to the private sector.

As Jacob Hacker has chronicled, national health insurance has long been a fixture in other industrialized nations, beginning with Germany in 1883. In 1948, Great Britain became the first Western democracy to provide free and universal medical care; in Canada, universal health-care coverage (through provincial governments) was initiated in 1971. Programs such as these are alike in their provision of health care that is more extensive and less expensive than that which is available in the United States. However, each country's path to universal coverage has been unique. National health insurance has arisen not as the result of widespread demand, but through the efforts of policy elites in these respective nations, acting in different historical periods in response to specific health conditions, interest group configurations, governmental constraints, and political windows of opportunity. Further, the United States is an exception in the developed world in restricting universal health-care coverage to those aged 65 and older; the politics of age are less salient in the health-care politics of other countries.

Long-term care (LTC) is a related health-care issue that is particularly salient for the aged and disabled. The system of long-term care in the United States has developed in piecemeal fashion. Medicare, based on the private health insurance plans of its time, contained no provision for long-term care. However,

Medicaid, which allows states to enroll persons who became medically needy due to high medical costs, has become the largest purchaser of long-term services in the United States. An institutional bias has long existed in Medicaid's payment of long-term care; nursing homes are the most prevalent destinations for these services, and the nursing home industry has lobbied successfully at the national and state levels to preserve this dominant position. While several states have experimented with using Medicaid funds to support alternatives to nursing home care, such as in-home nursing assistance and community-based respite care, these programs are vulnerable to Medicaid cuts recently proposed by the Bush administration. At the national level, the focus on LTC is recent and relatively minor compared with the attention paid to medical care.

In contrast to physician and hospital care, provision of LTC in the United States is fairly typical of rich democracies. While some countries, such as Germany and Japan, have created some form of social insurance for LTC, and Canada is likely to implement such a system, most have relied on an ad hoc mixture of national and subnational funding and administration, many (like the United States and some provinces of Canada) with a means test and requirement to spend down assets. In other words, LTC throughout the developed world has evolved in piecemeal fashion, separate from national health-care plans. Like the United States, most countries are approaching the demand for LTC services in the future without a comprehensive plan in place.

In summary, any understanding of the politics underlying either income security or health-care policies must recognize that the public–private distinction is fuzzy at best. As Hacker has illustrated, national policies have sustained the growth of private insurance markets, either directly through tax subsidization or indirectly through public coverage of high-cost populations. At the same time, however, private insurers have constrained government efforts to expand public insurance or regulation.

Globalization

As is evident from this discussion of current aging policy issues, gerontology has become aware of and concerned about globalization. More importantly for the politics of aging, major actors concerned with globalization have become concerned with aging. These developments move gerontology to a new, international focus and place local and national issues in the context of global social and economic forces. The social and economic processes of globalization generate tremendous controversy and conflict, with some praising its benefits and others decrying what they see as the exploitation of underdeveloped countries by first-world countries. Walker (2005:817) maintains that "it is not globalization per se that is problematic but its dominant neo-liberal economic form."

In 2000, the International Monetary Fund (IMF) defined economic globalization as the increasing integration of economies around the world, particularly through trade and financial flows. Economic globalization also refers to the movement of people and knowledge across international borders. The term global aging depicts the world as a holistic system, addressing international demographic changes in areas such as health and family support. However, its focus is mostly in the economic realm, specifically, the impact of global aging on the economies of countries at various levels of economic development, and whether the global economic system can afford to support the needs of a growing older population. Because population aging varies across nations, it is possible that differential aging will have an impact on market economies, affecting the social situation of older people differently in have and have-not countries, as well as special groups of the aged such as migrant workers and immigrants.

Concerns about global aging take on an even more dramatic tone when it is asserted that economic conditions affect international stability. Two initiatives in particular illuminate the forces driving the international politics of aging. The first is the release of a policy paper by the US Central Intelligence Agency under the title *Long-term Global Demographic Trends: Reshaping the Geopolitical Landscape*. The report asserts that global demographic trends will have far-reaching economic, military, and political consequences. By 2050, the size of the age 65+ population will have tripled, to about 1.5 billion people, or 16% of the total. Many developing countries (the report specifically names Pakistan, Afghanistan, Saudi Arabia, Yemen, and Iraq) will see significant youth bulges. Countries such as these face great economic challenges creating productive work for large youth and young adult populations. However, countries that are currently the economic engines of the world face a far different problem, the report alleges, because of population aging. While the young countries may see great unrest due to continuing poverty and the challenge of meeting the needs of rapid population growth, the old countries, struggling economically because of their aging population, may be less able to deal with geopolitical flashpoints.

The second significant initiative is the Global Aging Initiative program undertaken in 1997 by the Center for Strategic and International Studies (CSIS) in Washington, DC, and backed by high-level

government leaders, top executives of major global-reach corporations (including international insurance and venture capital companies), academics, and think-tank representatives. According to their report, Japan, Western Europe, and the United States will undergo unprecedented demographic transitions over the next 30 years characterized by a "dangerous combination" of rising elderly populations and negative labor force growth. CSIS asserts that the fact that this transformation is limited to the world's leading economies has far-reaching consequences for global security and economic stabilization. As with the CIA report, the CSIS Global Aging Initiative is concerned not only with economic issues, but also global security issues, communicating a vision of apocalyptic demography.

These two examples illustrate the point that the politics of aging, in a global context, involves major parties and interest groups, including governments and corporations seeking to set the agenda through which national and international policies will be put in place. Powerful voices from sectors other than the field of gerontology argue that there is a crisis of global aging and make a number of proposals to ameliorate the problem. The general tone of such recommendations parallels those of AGE and the Concord Coalition that had been framed at the national level in the United States, for a shift of responsibility for Social Security and health care from the state to the individual and for steps to be taken to retain people in the workforce to more advanced ages, as a means to both meet labor force needs and reduce fiscal strains on both the pension and health-care systems. Many academics and some interest group organizations, such as AARP, oppose the crisis rhetoric, as well as the focus on the economic aspects of globalization (as opposed to its social costs). As Walker argues, globalization makes increasing inequality inevitable, particularly by raising questions about the sustainability of pension and social protection systems that mainly benefit the older population. The use of crisis rhetoric by these organizations serves to legitimize neo-liberal attacks on the welfare state, which as we have noted, is very relevant to the lives and life chances of older people.

Finally, there has been a decided shift of focus toward developing and transitional countries, as international organizations have begun to pay more attention to the social consequences of globalization for older people. These include the efforts of the UN, which issued the Vienna International Plan of Action on Ageing in 1982 and the Madrid International Plan of Action in Ageing in 2002, adopted a resolution containing the United Nations Principles for Older Persons in 1991, and declared an International Year of Older Persons in 1999. In addition, the World Health Organization (WHO), a constituent agency of the UN, issues similar statements in the global aging and health area. The UN and the WHO have very few resources to advance their own agenda, but statements these agencies issue become material that can be used to legitimate policy positions of UN member states.

Conclusion

This article began by noting the complexity of the field of politics of aging and that its scope would be broad, going beyond electoral politics to include social movement politics and to frame this discussion in a political economy perspective that recognizes the importance of actors such as political parties, interest groups, corporations, and non-government organizations. Political decisions at many levels affect the aged, even if the decisions are not made with the aging in mind, and instead concern issues such as international economic competitiveness. It is likely that certain actors have more resources to bring to the process of agenda setting, and are thus likely to strongly influence the policies that affect the well-being of older people, whether these are aging policies, economic policies, health policies, or other kinds of policies. In addition to familiar domestic players such as AARP and the Concord Coalition, international organizations are also helping to shape the politics of aging at home and abroad. Our major goal has been to broaden the scope of interest in the politics of aging. Another major goal has been to stress that the so-called problems of aging are socially constructed. In this sense, electoral politics, social movements, and the political economy of aging are interrelated.

Premature Aging

G M Martin, University of Washington, Seattle, WA, USA

Glossary

Progeroid Syndromes – Premature aging syndromes.

Introduction

Professor Mitchell Turker's excellent article on this subject in the first edition of the *Encyclopedia of Gerontology* covered fundamental mechanisms of aging as well as syndromes that were thought to lead to premature aging. There has since been substantial progress in both areas, precluding any systematic coverage of both topics. Moreover, despite numerous publications, there is still no consensus on the number and types of fundamental mechanisms of aging. Even the venerable free radical theory or oxidative damage theory has been recently challenged (but not falsified) by an analysis of mice that are prone to undergo mutations in their mitochondria. Surprisingly, there is also a paucity of information on the detailed phenotypes of aging in model organisms such as round worms, fruit flies, and even laboratory mice. The term progeroid syndromes, therefore, is used here in order to emphasize the uncertainty in deciding the degree to which premature aging syndromes in fact match mechanisms and phenotypes of aging as they usually unfold. Given the paucity of information on the phenotypes of aging in model organisms, most of this article deals with humans, for which there is indeed a great deal of information on how aging changes structure and function. But it also gives two examples of progeroid syndromes in mice, as the genetic analysis of mice is now well developed, providing the potential to elucidate basic mechanisms of mammalian aging. The genetic basis of progeroid syndromes is emphasized because genetics has great power to reveal primary mechanisms. It is important to keep in mind that discoveries of variations in genes that appear to accelerate aging raise the possibility that there also exist variants that contribute to enhanced structure and function during the life course. The article also considers, however, some examples of environmental agents that have the potential to accelerate features of aging.

Differentiating Premature Onsets of Aging and Accelerated Rates of Aging

Very few publications attempt to differentiate conditions in which aging begins at a prematurely early

age and conditions in which aging begins at a usual age, but proceeds at an accelerated pace. It is also apparent that both phenomena may occur as a result of genetic mutations or environmental factors. A formal mathematical analysis of rates of change in age-specific mortality rates is helpful in differentiating these two types of premature aging.

Gene Variants Associated with Progeroid Syndromes

Segmental Progeroid Syndromes

There are no known agents, environmental or genetic, either in humans or in mice, that move forward in time all aspects of aging. The term segmental progeroid syndromes was therefore introduced to emphasize that only a subset of features of aging are affected in any given condition. There are a great many such genetic syndromes in humans. They appear to reproduce, with variable fidelities, aging as it usually occurs. A subset of the most informative examples, those for which a responsible genetic mutation has been discovered, is reviewed here. A number of such reports have appeared since the publication of the first edition of this encyclopedia. With the exception of older literature on the effects of ionizing radiation, there has been much less research on the potential roles of environmental agents capable of accelerating features of aging. Perhaps the best candidate of an environmental segmental gerontogen is cigarette smoking, which not only causes certain forms of cancer in mid-life, but also has progeroid effects in the reproductive, cardiovascular, pulmonary, musculoskeletal, and integumentary systems.

Werner Syndrome Werner syndrome (WS) (**Figure 1**) is the prototypical segmental progeroid syndrome of humans. It is sometimes referred to as progeria of the adult in order to differentiate it from progeria of childhood (see following section). WS results from a deficiency of a member of a family of proteins (helicases) that function to unwind double-stranded DNA. In order to do business with DNA, e.g., replication, recombination, repair, and transcription, the duplex DNA has to be unwinded so that specialized protein machinery can gain access. The Werner protein (WRN) is unusual in that it also functions as an exonuclease (i.e., it can digest base pairs from the ends of DNA). Precisely how WRN works is a subject of intense research, but a consensus is emerging that it is required for DNA transactions with unusual substrates, such as those that are found at the ends of chromosomes (telomeres) or as intermediates during the recombination of the genetic material (Holliday junctions). At the cellular level, elevated frequencies of both large-scale somatic chromosomal mutations and point mutations are observed, as are striking limitations of the replicative potentials of somatic cells.

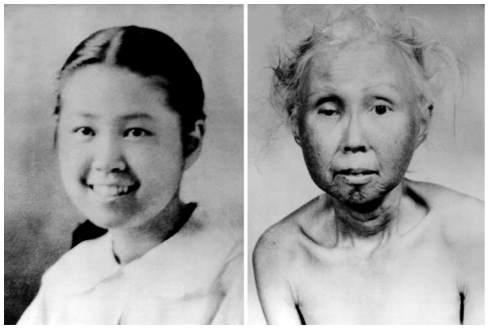

Figure 1 Photographs of a patient with Werner syndrome. (A) Age 15 years. (B) Age 48 years. See Epstein CJ *et al.* (1966) *Medicine* 45: 177–221 for information on this patient (Case 1-M8a) and her pedigree. The syndrome is caused by a double dose of a mutation in the *WRN* gene, the product of which unwinds double-stranded DNA. Reproduced with permission from the University of Washington.

WS patients exhibit a striking array of progeroid features, typically beginning at the time of puberty, when they do not enjoy the usual adolescent growth spurt. This is followed by premature thinning and loss of hair, loss of subcutaneous fat, bilateral ocular cataracts, gonadal atrophy, osteoporosis, type 2 diabetes mellitus (although not in all patients), several forms of arteriosclerosis and, in many patients, cancer. The cancers tend to be sarcomas rather than carcinomas, just the opposite of the situation in normative aging. The distribution of the osteoporosis is also unusual; there is less impact upon the vertebrae than upon the long bones of the limbs. Death usually results from cancer or from a myocardial infarction at a median age of around 47 or 48.

Hutchinson-Gilford Progeria Syndrome Hutchinson-Gilford Progeria syndrome (HGPS) (**Figure 2**) is also known as progeria or progeria of childhood. Unlike WS, which has an autosomal recessive mode of inheritance, it is caused by a dominant mutation of a type known as a gain of function or a dominant negative. The affected gene is known as *Lamin A/C*. It codes for a protein that coats the inner lining of the nuclei of cells. There is evidence that defective forms of the protein result in two broad classes of abnormalities – a mechanical weakness of nuclei, with herniations of nuclear material, and defects in the regulation of gene expression. There is also evidence of accelerated replicative senescence of cultured somatic cells, but this is not as striking as in WS.

Figure 2 Photographs of Rachel, a patient with Hutchinson-Gilford syndrome (progeria). (A) Age 13 months. (B) Age 9 years. The syndrome is caused by a dominant mutation in the *Lamin A/C* gene, the product of which forms part of the inner lining of nuclei. Reproduced with permission, courtesy of The Progeria Research Foundation.

Symptoms appear within the first few years of life. There is marked loss of subcutaneous fat, growth failure, severe abnormalities of cartilage and bone, including osteoporosis, and a severe form of arteriosclerosis. The latter is the usual cause of death, typically at about the age of 13. There is controversy concerning the extent to which this mimics atherosclerosis, the most common form of arteriosclerosis. An unusual aspect is the severe degree of loss of arterial smooth muscle cells. Cataracts and insulin resistance have been occasionally reported, and there is at least one case report of a malignancy (a sarcoma of the chest wall). Many other features of normative aging are not apparent, however. HGPS is extraordinarily rare (about one in four million births). It has been associated with advanced paternal age, consistent with the notion that sperm from older fathers are more likely to harbor mutations, most of which would be expected to have deleterious effects on the fetus.

Cockayne Syndrome Cockayne syndrome (CS) (**Figure 3**) is caused by the inheritance of genes that are thought to be of special importance in the repair of DNA within genes that are active in transcribing their information from DNA to RNA. The clinical syndrome has been associated with at least two such genes, one on chromosome 5 and the other on chromosome 10. Other genes that are important for transcription-coupled repair cause different progeroid syndromes, one of which (a form of xeroderma pigmentosum) is discussed later.

Figure 3 Photographs of a patient with features of both Cockayne syndrome and a form of xeroderma pigmentosum at ages 18 months and 6 years. The syndrome is caused by a deficiency in the repair of the DNA of genes that are active during transcription. Reprinted from J. O. Andressoo and J. H. J. Hoeijmakers (2005) Transcription-coupled repair and premature ageing. *Mutation Research* 577: 179–194, with permission from Elsevier and J. H. J. Hoeijmakers.

Like HGPS, CS causes a major impact upon development. It is therefore difficult to determine the extent to which the complex phenotypic features result from failures in development or postdevelopmental biological aging. There is profound growth failure and severe developmental/degenerative changes in the central and peripheral nervous systems. There is regional loss of subcutaneous fat, a common theme for many progeroid syndromes, contributing to prematurely aged, wizened facies. Other features include

retinal degeneration, optic atrophy, ocular cataracts, corneal opacities, sensorineural hearing loss, hypertension, cardiac arrhythmias, skin atrophy, kyphosis, and proteinuria.

Ataxia-Telangiectasia Ataxia-telangiectasia (AT) is yet another example of a progeroid syndrome caused by a deficiency of a gene product of central importance to the maintenance of genomic stability. Others could also be cited, permitting a generalization of what would seem to be intuitively obvious – namely, that an organism that has lost proficiency in maintaining the structure and function of its DNA will develop a pleiotropic set of signs and symptoms that only get worse during aging. These observations support the hypothesis that increasing genomic stability pays a major role in normative aging.

AT, like CS and WS, exhibits an autosomal recessive mode of inheritance. The mutant gene product, ATM, is an enzyme (a serine kinase) that regulates the response to certain forms of DNA damage, including ionizing radiation. When it is functioning normally, it signals a key molecule (p53) to assist in arresting progression of the cycle until the damage can be repaired. The checkpoint for arresting progress of the cell cycle is just before the beginning of another round of DNA synthesis. If repair is not successful, the pathway signals the cell to undergo apoptosis – a form of cell suicide.

AT patients develop degeneration of the Purkinje cells of the cerebellar cortex, resulting in a debilitating ataxia. Other progeroid features involve hair, skin, and the immune system. The immune deficiency results in an increased susceptibility to infections, particularly pulmonary infections. AT patients are also susceptible to certain forms of cancer, especially to lymphomas and leukemias.

Dyskeratosis Congenita, Autosomal Dominant Form Dyskeratosis congenita (DS) is of special interest to gerontologists because it is caused by a mutation in the gene coding for the RNA component of telomerase, an enzyme that is essential for maintenance of the ends of chromosomes. The absence of telomerase should have particularly significant consequences for stem cells, certain differentiated somatic cells, and the germline, as there are normally high levels of this enzyme activity in such cell types. In the absence of telomerase, repeat units at the ends of chromosomes are lost, leading to chromosomal abnormalities and exit from the cell cycle. The absence of the enzyme in most forms of replicating somatic cells is thought to be the major factor in replicative senescence. DS can be classified as a segmental progeroid syndrome, as patients have scanty hair, dystrophic nails, abnormalities in skin that partially overlap with normative skin aging, osteoporosis, immune deficiency, anemia, somatic cytogenetic abnormalities, and premalignant changes in mucosa. There is likely to be germline maldevelopment and/or atrophy, but this is not well studied. Like a number of progeroid syndromes, there is always concern that the phenotype may be largely due to impacts upon development rather than impacts upon aging. That said, it is of interest that there is evidence of increased rates of loss of telomere repeats in several segmental progeroid syndromes, including WS and HGPS.

Down Syndrome Most forms of Down syndrome (DS) are caused by an extra copy of chromosome 21 (trisomy 21), but it can sometimes be caused by chromosomal lesions that result in an extra copy of a critical portion of chromosome 21. Progeroid features include graying of the hair, ocular cataracts, hearing loss, early ovarian failure, diminished bone density, and certain leukemias. The most striking and relevant feature, however, is the development of all of the neuropathological features of Alzheimer's disease by middle age in essentially 100% of patients. This may be attributable to the extra copy of the gene for the β-amyloid precursor protein. DS is the most common chromosomal abnormality in newborns. Its frequency rises dramatically with advancing maternal age, probably reflecting aging processes within oocytes.

Mitochondrial Mutator Mice Two independent research groups have genetically engineered mice that have lost the ability to proofread errors in the enzyme (DNA polymerase gamma) that replicates mitochondrial DNA (**Figure 4**). This model is of special interest because the progeroid features have no obvious association with elevated levels of free radicals or of oxidative damage to macromolecules. The results thus pose a challenge to the free radical theory of aging. It may be, however, that the mitochondrial dysfunction that occurs during normative aging does indeed involve oxidative stress, as there are a number of lines of evidence supporting that proposition. The genetically engineered lesion in this animal may represent another pathway toward mitochondrial dysfunction. The progeroid features include a dramatically shortened life span despite apparently normal development, graying and loss of hair, loss of bone mass, kyphosis, loss of muscle mass (sarcopenia), testicular atrophy, loss of intestinal crypts, anemia, and hearing loss. It is of interest that this collection of phenotypes is more characteristic of human aging than of normative mouse aging. The same statement can be made about other mouse

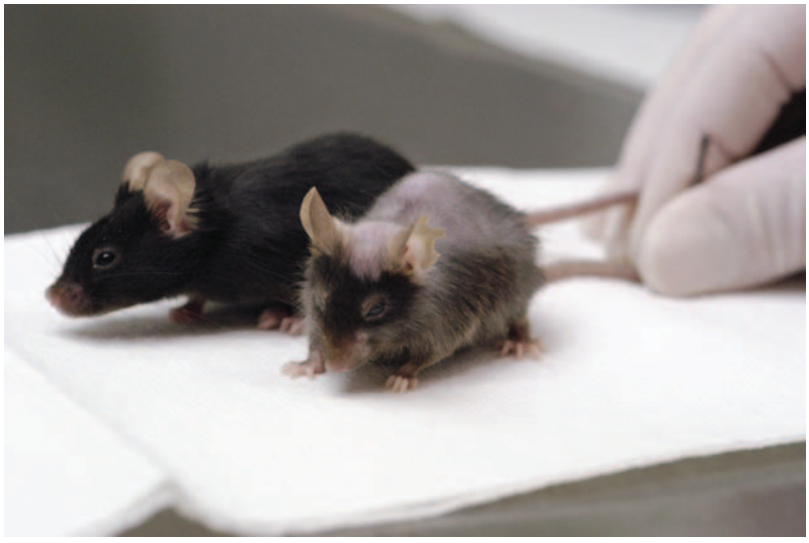

Figure 4 A normal 13-month-old male mouse (left) and a 13-month-old male mouse with a mutation in a gene (DNA polymerase gamma) that replicates mitochondrial DNA (right); the part of the gene that has been mutated is responsible for proofreading the replicated DNA. models of premature aging, including the following example.

The Klotho Mouse The term Klotho is derived from the name of the Greek goddess who 'spins the thread of life.' This mutant mouse model of premature human aging was discovered by accident – a gene that was introduced into the genome of the mouse happened to land in and therefore mutate the gene now known as Klotho. This model is of special interest because subsequent research has shown that overexpression of the Klotho gene leads to increased life span, a much more valuable phenotype from the point of view of our understanding of fundamental mechanisms of aging. Klotho appears to code for an enzyme with features of a β-glucuronidase. Although it is expressed mainly in the distal convoluted tubules of the kidneys and in the choroid plexus of the brain, a portion of the gene product circulates and acts as a hormone. It may also act as a paracrine hormone, affecting nearby cells, especially in the kidney. The major impact of the gene is thought to be on the metabolism of calcium and phosphate. Precise details of mechanisms are currently being pursued. Some of its progeroid features may result from developmental abnormalities and others from postmaturational degenerations. The overall features include a short life span, growth retardation, testicular atrophy (or maldevelopment), pulmonary emphysema, loss of Purkinje cells of the cerebellar cortex, premature involution of the thymus, calcific forms of arterioslcerosis and ectopic deposits of calcium in other tissues, osteoporosis, skin atrophy, and lipodystrophy.

Unimodal Progeroid Syndromes

Some genetic mutations appear to accelerate certain features of aging only within a single tissue. There are a very large number of these conditions, which might be referred to as unimodal progeroid syndromes. Here only three examples are considered: one that has a major impact on sun-exposed skin, one that results in an early onset of the most common form of dementia, Alzheimer's disease, and another that results in early-onset Parkinson's disease.

Xeroderma pigmentosum While AT patients are hypersensitive to ionizing radiation, xeroderma pigmentosum (XP) patients are hypersensitive to forms of ultraviolet light (UV). Since, in the real world, some degree of exposure to sunlight is virtually inevitable, old people develop varying degrees of sun-mediated degenerative and proliferative changes in sun-exposed skin. These changes include degeneration of collagen and elastin in the dermis. What is life threatening, however, is the premalignant and, eventually, malignant changes in the epidermis. Ocular involvement can also occur, including ocular neoplasms. There are a number of genetic variants of XP; all impair the ability of cells to repair DNA.

Familial Alzheimer's Disease (FAD) Some studies have suggested that almost half of all community-dwelling US residents over the age of 85 years have the signs and symptoms of probable Alzheimer's disease. It is thus by far the most common disorder of the aging central nervous system. Three groups of families have been discovered in which a single

dominant mutation segregates with an early onset of the disease – usually defined as presenting before the age of 60, sometimes presenting as early as the late 20s. The three affected genes are *APP* (coding for the β amyloid precursor protein, the same gene suspected of being responsible for the dementia of DS subjects), *PS1* (presenilin 1), and a closely related gene called *PS2* (presenilin 2). While these families are quite rare, biochemical genetic studies resulting from these discoveries have led to a leading hypothesis for how common, so-called sporadic forms of the disease develop. This hypothesis implicates a key role for a small peptide derivative of the *APP* gene product known as A-beta 42. It is thought to develop as a minor product of metabolism, eventually forming an oligomeric molecule that is toxic to neuronal synapses. With normal genes for this metabolism, it takes many decades for the neurotoxic effects of this peptide to reach some phenotypic level of expression, thus escaping the force of natural selection. The process is accelerated, however, in DS and in FAD.

Familial Parkinson's Disease (FPD) During normative aging there is a gradual loss of dopaminergic neurons from a small, pigmented pair of structures in the midbrain. The rates of loss vary among individuals so that, for some, the masked facies and movement disorders that characterize Parkinson's disease emerge late in the life span. In the past few years there has been unprecedented progress in defining a series of rare gene mutations that lead to early-onset forms of this common disorder of aging, thus opening the door to a detailed understanding of mechanisms. There are currently 11 genetic loci implicated in its pathogenesis (*PARK* 1–11). This research has implicated potential roles for such processes as oxidative and nitrosative stress, dysfunctional mitochondria, the accumulation of altered proteins and a malfunctioning system for ridding cells of altered proteins. Environmental factors are clearly of importance, as evidenced by the emergence of a variant of the disease among large numbers of individuals affected by the 1918 influenza pandemic and the more recent discovery that a chemical by-product of an illicit street drug can cause the disease to appear almost overnight. Experiments have shown that an agent that damages mitochondria, rotenone, can also lead to marked loss of dopaminergic neurons.

Productivity and Age

S J Czaja, University of Miami Miller School of Medicine, Miami, FL, USA

Glossary

Workforce Demographics – The proportion of the labor force represented by different ages and abilities.

Introduction

A number of demographic and social trends – including the aging of the population, changes in the labor force participation of younger workers, the aging of the Baby Boom cohort, and changes in retirement policies, programs, and behavior – are contributing to a renewed interest in older workers and the topic of aging and work. According to data reported by the US Administration on Aging in 2002, in the year

2000 the number of persons aged 55 and older in the US population was about 56 million – a 50% increase since 1900. By 2020, there will be about 120 million people in the United States in this age group, representing almost 40% of the population.

Data from the US General Accounting Office also indicates that in the near future, older people will also represent a significant proportion of the labor force. By 2010 the number of workers age 55 and older will be about 26 million, a 46% increase since 2000, and by 2025 this number will increase to approximately 33 million (**Figure 1**). Although labor force participation rates are projected to be slightly greater for older women than for older men, in contrast to previous decades the labor force participation rate for older males is increasing. For example, in 1995, about 66% of males age 65 were out of the labor force as compared to 61% in 2001. Importantly, there will also be an increase in the number of workers over the age of 65.

This change in workforce demographics is largely due to the aging of the Baby Boomers, changes in Social Security and retirement policies, and a more recent trend toward longer labor force participation – including postretirement jobs – among older people. Retirement from one's full-time, primary career job can no longer be assumed to occur at the time of workers' eligibility for Social Security benefits or to mean the total cessation of paid employment. Most older workers, according to a variety of studies, say that they would prefer to continue to be engaged in some kind of work following their retirement, and a significant number of full-time retirees say they would like to be employed. Furthermore, as the Baby Boomers start reaching retirement age, because of lower birth rates at the end of the twentieth century certain industries and occupations will find the available labor pool inadequate. Thus, many companies will be looking to older adults to fill employment needs. In addition, the retirement of the Baby Boomers is putting corporate knowledge at risk. Because of an increasingly knowledge-based economy, knowledge is considered to be a critical organizational asset. To help preserve this asset many countries around the world, such as the UK, are developing programs to encourage the retention of older workers.

Clearly the issue of aging and work is highly significant, and there is a need to develop strategies to prepare for and accommodate an aging workforce. This requires understanding (1) the characteristics of the older workforce and the growing older nonworkers, (2) the potential implications of aging for work performance, and (3) the technological and social characteristics of existing jobs and work environments. This article discusses what is currently known about older workers and productivity. An emphasis is placed on technology, given the proliferation of technology in today's work environments. Initially, a brief profile of today's elderly is provided.

Characteristics of Older Workers

In general, older Americans today are healthier, more diverse, and better educated than previous generations. The percentage of adults aged 65 and older who have completed high school has substantially increased, as has the number of older adults who have at least a bachelor's degree. Increased levels of education should prove to be beneficial to older workers, as higher levels of education are generally

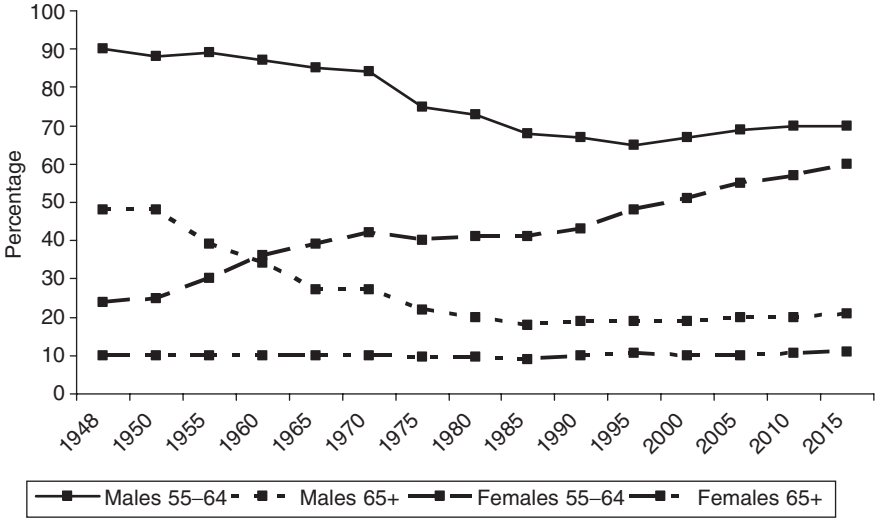

Figure 1 Labor force participation rates for older workers, by sex, 1948–2015. From US Department of Labor Bureau of Labor Statistics using the Current Population Survey (2001).

linked to increased employment opportunities, especially in today's work environments. The influx of technology into the workplace and the transition to a knowledge-based economy are creating a need for workers who are highly skilled. For example, the expansion of information technologies implies a need for workers with technical skills to operate, program, and repair technical systems. Even workers in non-technical jobs are expected to have some experience with computer applications. Thus, in addition to formal education, knowledge of technical applications is also important to employment opportunities. In addition, technology has led to an explosion in information and has enabled more data to become available at faster rates than ever before. This is turn has increased demand for workers with high-level cognitive skills, such as problem solving, analytic reasoning, and communication skills. To this end, the term knowledge worker has evolved.

On some indices, today's older adults are also healthier than previous generations. The number of people 65 and older reporting very good health and improvements in physical functioning, such as ability to walk a mile or climb stairs, has increased in recent years. Disability rates among older people are also declining. However, the likelihood of developing a disability increases with age, and many older people have at least one chronic condition (the most common being arthritis, hypertension, hearing impairments, chronic joint symptoms, heart disease, and cancer) (**Figure 2**). Cognitive and memory impairments also increase with age. Disability rates among older adults have important implications for workplace and job design. Employers may need to adapt workplaces or provide adaptive equipment or technology (such as low vision aids) to workers who have functional limitations. Generally, labor force participation rates are lower and retirement rates are higher for people with chronic conditions.

Consistent with demographic changes in the US population as a whole, the older population is also becoming more ethnically diverse. The greatest growth will be seen among Hispanic persons, followed by non-Hispanic Blacks. Work policies, programs, and services will require greater flexibility to accommodate this diverse population.

Finally, there are more older women than men, and the proportion of the population that is female increases with age. The higher percentage of older females may have implications for employment, since in recent years older women have been more likely to continue working or return to work than older men. Women are also more likely than men to be involved in caregiving responsibilities. According to recent data from the Family Caregiver Alliance, about 25 to 35% of all workers report that they are currently providing, or have recently provided, care to someone 65 or older and the majority of these workers are females. Working caregivers often suffer many work-related difficulties due to their caregiving roles. For example, many caregivers report the need to re-arrange their work schedule, decrease their hours, or take an unpaid leave in order to meet their caregiving responsibilities. Thus, employers need to provide more flexible work arrangements to accommodate this growing proportion of the workforce.

There are a number of changes in abilities associated with normal aging that have implications for work productivity. Currently, about 14 million people in the United States suffer from some type of

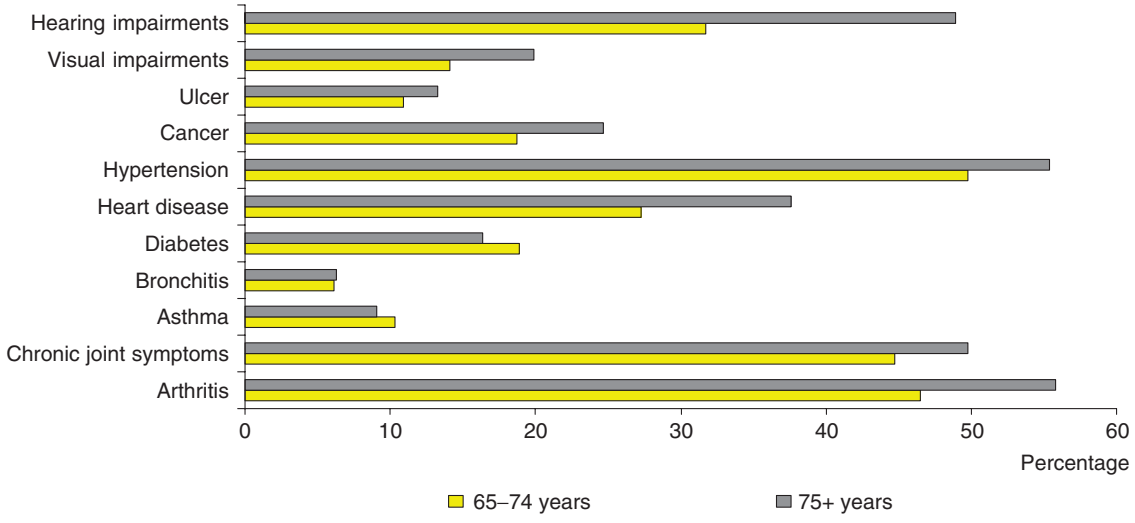

Figure 2 Selected diseases and conditions in the US population by age 2004. Data form Summary Health Statistics for the US Adults. National Health Interview Survey 2004. Vital and Health Statistics Series 10 (228), 2006.

visual impairment, and the incidence of visual impairment increases with age. Although most older adults do not experience severe visual impairment, they may experience declines in vision that affect their ability to perceive and comprehend visual information. This has vast implications for today's computer-oriented workplace, given that interaction with computer systems is primarily based on visually presented information. Age-related changes in vision also have implications for the design of written instructions and manuals and lighting requirements.

Many older adults also experience some decline in audition that has relevance to work settings. For example, older people may find it difficult to understand synthetic speech, as this type of speech is typically characterized by some degree of distortion. High-frequency alerting sounds such as beeps may also be difficult for older adults to detect. Changes in audition may also make it more difficult for older people to communicate in noisy work environments.

Aging is also associated with changes in motor skills, including slower response times, declines in ability to maintain continuous movements, disruptions in coordination, loss of flexibility, and greater variability in movement. As previously noted, the incidence of chronic conditions such as arthritis also increases with age. These changes in motor skills may make it difficult for older people to perform tasks, such as assembly work that requires small manipulation, or to use current input devices, such as a mouse or keyboard. For example, older people have more difficulty performing mouse control tasks (pointing, clicking, double-clicking, and dragging) than younger people, and age-related changes in psychomotor abilities such as manual dexterity are related to performance differences.

Older adults also tend to have reduced strength and endurance. These are population mean differences, and there is a great deal of variability in muscle groups, in types of muscular performance, and between individuals. However, in general older adults are less able to perform physically demanding jobs.

Age-related changes in cognition also have relevance to work activities, especially in tasks that involve the use of technology. Declines in working memory may make it difficult for older people to learn new concepts or skills or recall complex operational procedures. Declines in attentional capacity may make it difficult for an older person to perform concurrent activities or switch their attention between competing displays of information. They may also have problems attending to or selecting task targets on complex displays. Also, because of changes in processing speed, highly paced work may be unsuitable for older workers.

However, the picture is not all one of decline. There is clear evidence that general knowledge and domain-specific knowledge (e.g., occupational knowledge) increases well into middle-age and beyond, and this knowledge may compensate for age-related declines in other cognitive abilities such as working memory. In fact, the literature suggests that there is a relationship between standard measures of component cognitive abilities and job performance. Thus, one would expect to find age-related declines in work performance. However, as discussed later, there is little evidence that older workers are less productive than younger workers. One explanation for this is that the ability measures are not assessing the abilities needed for particular jobs. Another explanation is that the measures fail to capture the complexity of work situations. For many types of work tasks, older people are able to use their expertise and contextual support to compensate for age-related declines in abilities. Use of compensatory strategies is not possible when performing psychometric tests that are relatively novel and place a heavy emphasis on test taking and academic skills as opposed to acquired knowledge. As previously noted, knowledge is an extremely important commodity in today's work environment, and a knowledge preservation problem is plaguing many industries.

In summary, although there is a great deal of information about aging as a process, there are limited data on the practical implications of age-related changes in abilities for work activities. The majority of studies regarding the impact of age-related changes in abilities are based on laboratory tasks. Laboratory tasks do not capture the contextual elements that are present in work environments and may not allow older people to evoke compensatory strategies that are used in real-world settings. It is also important to recognize that aging is associated with substantial variability and that older adults as a group are very heterogeneous. For many indices of performance there are greater differences within the older population than between older and younger age groups. Thus, although we can discuss age-related trends in abilities, predictions about an individual's ability to learn a new skill or perform a particular job should be based on that individual's functional capacity relative to the demands of the job or skill as opposed to chronological age.

Aging and Work Productivity

Common beliefs about older workers include beliefs that they are physically unable to do their job; have a high rate of absenteeism; have a high rate of

accidents; are less productive, less motivated, and less receptive to innovations than younger people; and are unable to learn. While these are rather commonly held beliefs, there are few actual data to support these assumptions; in fact, most research studies indicate that these stereotypes are inaccurate.

The available data concerning age and productivity are limited, especially for technology-based jobs. Several extensive reviews of aging and work productivity for both blue collar and white collar jobs have been conducted. The general conclusion of these reviews is that there is little evidence to suggest that productivity declines with age. Instead, it appears that the relationship between age and work productivity is quite complex and is dependent on the type of performance measure, the nature of the job, and other factors such as experience. Furthermore, many jobs do not require performance at full capacity, and there is tremendous variability in performance for both younger and older people. In terms of creative work, the relationship between age and productivity (the quantity of creative work), for both the artistic and scientific fields, is generally one in which productivity increases until around age 40 and then declines slowly with age. However, there are three important caveats to this trend: (1) the exact age location of the peak of productivity and rate of change in productive performance depends somewhat on the field of endeavor; (2) there are numerous examples of creative work by people in the later decades; and (3) there are large individual differences in the change in productivity with age.

With respect to other measures of job behavior, the findings, while limited, are more conclusive. Older workers tend to have lower accident rates than younger workers; however, older workers tend to remain off the job longer if they are injured. Absenteeism and turnover rates are also lower for older adults.

Overall, the relationship between age and work productivity is complex and far from understood. Many studies examining this issue involve small samples or restricted age ranges or are cross-sectional, which may result in age effects being confounded with factors such as experience, education, or exposure to technology. Studies that rely on supervisory ratings of performance may be biased if the rater has negative attitudes about older workers. The results also vary according to the type of task and type of performance. Finally, the number of recent studies conducted in actual employment settings has been limited. It is reasonable to conclude that chronological age is associated with a host of age-related changes in processes and lifestyle patterns that have diverse and indirect effects on work outcomes. It is also important to recognize that many older adults engage in other forms of productive activities outside of the workplace, such as mentoring, volunteerism, or continuing education.

Another important factor to consider when addressing the topic of age and productivity is worker motivation. A number of authors have recently concluded that age-related changes in motivational variables play a key role in work outcomes for middle-aged and older people. Yet there are few empirical studies that have examined the impact of the effects of aging and adult development. A recent review of the literature suggests that work motivation in the later years generally follows the same pattern as work motivation for younger adults, such that the allocation of resources will be given to work behaviors that build on competencies, promote self-efficacy, and result in desired outcomes. The major age-related differences in motivation may relate to differences in competencies, and as such motivation of older workers may be enhanced by employing organizational practices that take into account normative changes in adult development – e.g., practices that capitalize on the domain knowledge and expertise of the older worker.

The Implications of Technology for Older Workers

A discussion on age and productivity would be remiss if it did not consider the impact of technology on work and employment opportunities. Today, technology is pervasive in the workplace, and most workers need to interact with some type of technology in the day-to-day performance of their job.

Given the widespread use of technology in most occupations, one important issue concerns how the influx of technology will affect employment opportunities and the productivity of older workers. This issue is particularly important for today's cohort of older workers, as they have not had the same exposure to technology that younger people have had. However, despite cohort differences, technology will continue to be a pertinent issue for future generations of older adults, as technology is dynamic and continuing to develop at an unprecedented rate.

In essence, technology influences the types of jobs that are available, creating new jobs and opportunities for employment for some and eliminating jobs and creating conditions of unemployment for others. Technology also changes the way in which jobs are performed and alters job content and job demands. Often, existing job skills and knowledge become obsolete and new knowledge and skills are required. As

previously noted, there is a greater emphasis on cognitive skills such as information integration, problem solving, and communication. Workers also need to learn to operate technical systems and new ways of performing jobs. This will hold true for future generations of older adults, as technology by its nature is dynamic. For example, there have been dramatic changes in the design of cell phones, portable computers, input devices, and personal organizers over the past several years.

The issues of skill obsolescence and worker retraining are highly significant for older workers, as they are often bypassed for training or retraining opportunities and may also be less willing to invest in retraining, as they may have a decreased expectancy of obtaining valued outcomes (such as promotion) or the value of these outcomes may diminish with age. A commonly held belief is that older people are resistant to change and have negative attitudes toward the use of technology. However, the available data dispute this stereotype and indicate that in general older people are receptive to using technology if they perceive the technology as useful, the technology is easy to use, and they are provided with adequate training and support. While they may experience more anxiety and less technology efficacy, older people's attitudes toward technology and comfort using technology are largely influenced by experience and the nature of their interactions with these systems.

Experience with computers generally increases user comfort and confidence. Although there are a number of settings, such as the workplace, the home, health-care settings, and service settings, where older people are likely to encounter technology, such as computers, use of technology among people over the age of 55 is still low compared to other age groups. Furthermore, although the use of the Internet is increasing among older people, it is still significantly lower than usage among other age groups (**Figure 3**). The Pew Internet and American Life Project reported that in 2004 about 22% of Americans aged 65 or older reported having access to the Internet, in contrast to 58% of Americans age 50–64 and 75% of those aged 30–49. In addition, use of the Internet within the older age cohorts is still predominantly restricted to white, highly educated seniors who live in households with higher incomes.

Problems with usability may also make it difficult for older workers to successfully interact with technology. Unfortunately, to date designers of most systems have not considered older adults as active users of technology, and thus many interfaces are designed without accommodating the needs of this population. Usability problems include poor screen design, poor input device design, complex commands and operating procedures, and inadequate training and instructional support. Although the usability of systems has improved substantially, current interfaces still exclude many people, such as those who are older or those with disabilities, from effective interaction with technology.

A number of studies have examined the ability of older adults to learn to use technology such as computers. These studies span a variety of computer applications and also vary with respect to training strategies such as conceptual versus procedural training. The influence of other variables, such as attitude toward computers and computer anxiety, on learning has also been examined. Overall, the results of these studies indicate that older adults are, in fact, able to use technology such as computers for a variety of tasks. However, they are typically slower to acquire

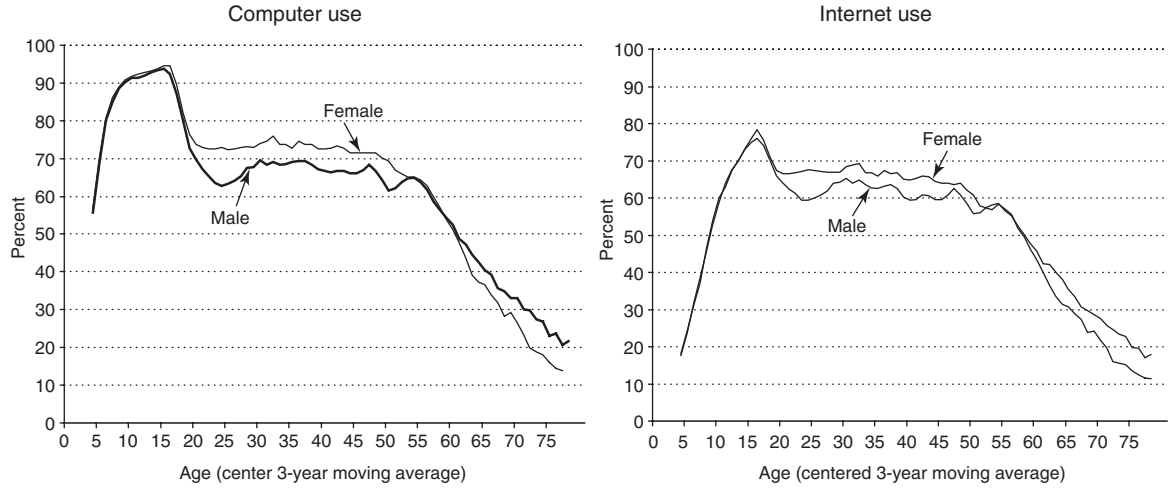

Figure 3 Computer and Internet use distribution by age and gender. From NTIA and ESA, US Department of Commerce, using US Census Bureau Current Population Survey Supplements.

new skills than younger adults and generally require more help and hands-on practice. Also, when compared to younger adults on performance measures, older adults often achieve lower levels of performance. However, the literature indicates that training interventions can be successful in terms of improving performance and points to the importance of matching training strategies with the characteristics of the learner. Clearly, greater attention needs to be given to the design of training and instructional materials for older learners. The potential use of technology as a training aid also needs to be examined. For example, older people may benefit from multimedia systems or interactive online training programs that allow for self-paced learning. However, careful attention needs to be given to the design of such packages. The current cohort of older adults might also need training on basic concepts such as mouse and windows management, in addition to training on the application area of interest. Finally, employers need to ensure that older adults are provided with access to retraining programs and incentives to invest in learning new skills and abilities. Consideration also needs to be given to the scheduling and location of training programs and potential for industry and community partnerships.

There have only been a handful of studies that have examined the ability of older people to perform computer-based tasks that are common in work settings. Generally, these data suggest that overall older adults are willing and able to perform these types of tasks. However, there may be age differences in the performance of some tasks such as data entry that emphasize speed and accuracy of performance. Importantly, the data also indicated that similar to other age groups, there is considerable variability in performance of older people and that with task experience performance improves for people of all ages. In addition, the data clearly show that usability issues have an impact on performance and that design interventions such as redesigning the interface, providing on-screen aids, and reconfiguring the timing of the computer mouse can result in performance improvements. Finally, the data indicate that it is important to provide people (especially those with limited technology experience) with training on the use of the technology as well as the task.

Summary

The topic of aging and work is increasingly important given current demographic trends, but the empirical data regarding the impact of aging on work performance are limited, especially for present day jobs and those likely to exist in the public sector in the future. There is a critical need for further research in this area.

Overall, we need more information on the relationship between age-related changes in functioning and the specific skill requirements of jobs. Although there are age-related declines in some functions, changes are gradual and most jobs do not demand constant performance at the level of maximum capacity. The majority of the population of older adults remains healthy and functionally able until very late in life. One important area of needed research is developing a knowledge base that links age-related changes in skills and abilities to specific skill requirements of jobs. For example, currently, the relationships among aging, cognition, and work productivity are unclear. A more complete understanding of these relationships would help direct the development of intervention strategies for older workers. This underscores the need to investigate differences in health, abilities, workplace performance, and technology use by cohort and by finer age categories, as well as to follow particular subgroups over time.

We also need sound, research-based information about the impact of technology on an aging workforce and how technology might be used to promote employment opportunities for older people. In addition, we need knowledge about how technology can be used to facilitate career and employment transitions. It is also important to understand how to design technology so that it is useful and usable for older adult populations, especially those with some type of impairment. All too often designers restrict their vision of user groups to young, able-bodied populations. Research also needs to be directed toward examining the cost-effectiveness of technological interventions.

In general, research attention directed toward those aspects of work that could become more difficult, less productive, or less satisfying with age could make a worthwhile contribution to improving the work life of older adults. Such research would also help to assure the availability of appropriate employment opportunities for older people and broaden the pool of potential employees for public agencies competing for increasingly scarce labor.

Prostate

W J Aronson and J B deKernion, University of California, Los Angeles, School of Medicine, Los Angeles, CA, USA

This article is reproduced from the previous edition, volume 2, pp 355–364, © 1996, Elsevier Inc.

Glossary

Autocrine – Pathway in which a cell responds to the same peptide growth factor that it simultaneously produced.

Exocrine Gland – A gland that releases a secretion external to the surface of an organ by means of a canal or duct.

Paracrine – Pathway in which a peptide growth factor is elaborated by one cell type but affects a different neighboring cell type.

Introduction

The prostate functions as a reproductive exocrine organ and functions to prevent urinary tract infections. However, the prostate is most noted for the frequency with which it is the origin of benign and malignant neoplasms and infectious diseases in aging men. The most important of these diseases are prostatitis, benign prostatic hyperplasia, and prostate cancer. This article will review the prostate in health and disease with an emphasis, where possible, on the gerontological aspects of prostate disease. (*See* Renal and Urinary Tract Function.)

Anatomy

The adult prostate gland weighs an average of 20 g, is approximately the size of a walnut, and surrounds the urethra just below the bladder neck as shown in **Figure 1**. The posterior surface of the prostate can be palpated by a digital rectal exam. The prostate is composed of tubuloalveolar glands and stroma. The fluid produced by the prostate glands drains into 20 to 30 ducts that enter the urethra at or distal to a bulge in the distal prostatic urethra called the verumontanum. On each side of the verumontanum are the ejaculatory ducts, which are the conduits for sperm from the testicles and seminal fluid from the seminal vesicles. The prostate stroma surrounds the prostate glands and is made up of smooth muscle and fibroblasts.

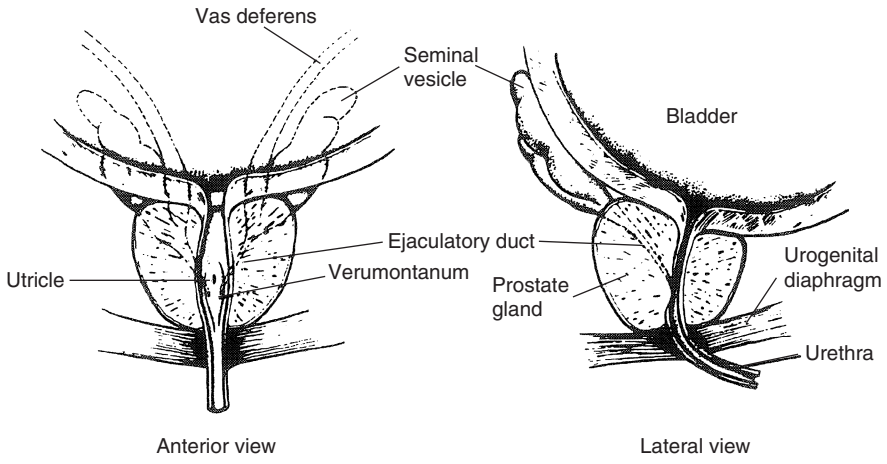

Figure 1 The prostate surrounds the urethra just below the level of the bladder neck. Fluid from the vas deferens and seminal vesicles drains into the ejaculatory ducts that enter the urethra just lateral to the verumontanum. The verumontanum is a midline bulge at the distal prostatic urethra. From Goluboff ET, Stifelman MD, and Fisch H (1995) Ejaculatory duct obstruction in the infertile male. *Urology 45*(6): 925. Used by permission of Elsevier.

Physiology

Reproduction

The prostate is an exocrine gland (excretes fluid) and has no known endocrine (hormonal) function. The exocrine secretions make up 15% of the ejaculate volume, but this fluid in itself is not necessary for fertility. The prostate along with the bladder neck and prostatic urethra play a critical role in coordinated antegrade sperm delivery during ejaculation. At the time of ejaculation, sympathetic nerve fibers innervating the $\alpha 1$ receptors in the smooth muscle in the prostate, bladder neck, and vas deferens cause emission of seminal fluid and sperm into the prostatic urethra, and closure of the bladder neck and prostatic urethra. This closure prevents the sperm and seminal fluid from going into the bladder during ejaculation and is necessary for normal ejaculation.

Infection – Host Resistance

The prostate glands produce numerous substances that are continuously released into the urethra. These include zinc, citric acid, calcium, phosphoryl choline, prostatic acid phosphatase, and prostate-specific antigen (PSA). The prostatic fluid has the highest concentration of zinc in the body, and zinc is known to be an antibacterial factor. Ongoing release of zinc by the prostate may play a role in preventing urinary tract infections. There is a great deal of popular literature purporting that intake of zinc is beneficial in preventing urinary infections and prostate disease, but this is unsubstantiated.

Prostatitis

Prostatitis, or inflammation of the prostate, is a term used to describe infectious and non-infectious inflammatory conditions of the prostate. Prostatitis may occur in men from puberty through adulthood. Patients may present with a variety of symptoms, including pain in the perineum, low back, and suprapubic area, painful ejaculation and urination, and a decrease in the force of the urinary stream. There are four different types of prostatitis that are described herein.

Etiology

A variety of theories have been proposed to explain the cause of prostatitis. These include urinary reflux into prostatic ducts, alterations in the secretory products of the prostate, and the presence of infected prostatic calculi. Unfortunately, we do not understand why men develop prostatitis, and as a result, physicians are frequently unsuccessful and frustrated in their attempts to treat patients. Not surprisingly, patients also have a poor understanding of their disease and are frequently unhappy with treatment results.

Bacterial Prostatitis

The most common organism causing bacterial prostatitis is *Escherichia coli,* which is also the most common pathogen causing urinary tract infections. Indeed, bacterial prostatitis is the most common cause of urinary tract infections in older men. Other organisms causing bacterial prostatitis include

Proteus, Klebsiella, Enterobacter, Pseudomonas, Serratia, and less frequently, *Enterococcus*.

Acute Bacterial Prostatitis

Acute prostatitis is an acute febrile illness associated with constitutional symptoms as well as the prostatitis symptoms previously described. On examination, patients are acutely ill and the prostate is exquisitely tender and should not be palpated with any force. Pathologically the prostate is infiltrated with neutrophils. These patients require admission to the hospital and intravenous antibiotics. If patients have urinary retention or severe obstructive voiding symptoms, a suprapubic tube is placed into the bladder to drain the urine to avoid traumatizing the prostate with a urethral catheter. If the infection fails to resolve then studies are performed to rule out a prostatic abscess, which may require drainage. Treatment for acute prostatitis is quite successful, and subsequent urologic studies are directed towards identifying a source for the infection.

Chronic Bacterial Prostatitis

A diagnosis of chronic bacterial prostatitis is based on positive cultures of prostatic fluid obtained by digitally massaging the prostate and culturing the expressed fluid that exits the meatus. Microscopy on this fluid shows >10–20 white blood cells per high-power field. A small volume of urine is voided after the prostate massage, and the bacterial count of this culture exceeds that of the urine voided prior to the prostate massage. Treatment consists of 1 month of oral antibiotics based on bacterial sensitivity testing. The ideal antibiotic must have good coverage of Gram-negative bacteria and must be lipid soluble to penetrate the prostate tissue. The quinolone antibiotics have these characteristics and are effective in the majority of cases of bacterial prostatitis. For reasons that are unknown, some infections persist and do not respond to treatment.

Chronic Non-bacterial Prostatitis

The diagnosis of chronic non-bacterial prostatitis is based on the expressed prostate fluid showing >10–20 white blood cells per high-power field but no documentation of any bacterial infection. These patients present with symptoms of prostatitis, but the etiology of the inflammation is unknown. Physicians explain to these patients that there is inflammation of the prostate the causes of which are not understood. In general, physicians will try a course of empiric oral antibiotics, usually the quinolones, for 1 month. If symptoms do not resolve then treatment becomes difficult because the etiology of the disease is not understood. Treatment options include frequent hot sitz baths, anti-inflammatory agents, and in some patients, diet alteration, if they find that their symptoms are exacerbated by spicy foods, caffeine, or alcohol.

Prostatodynia

Prostatodynia, literally prostate pain, is a diagnosis given to patients with prostatitis symptoms but no evidence of infection or inflammation in the prostate fluid. Typically these patients are young to middle-aged and suffer a great deal from their symptoms. Empiric antibiotics and supportive treatment as described in the chronic non-bacterial prostatitis section are prescribed with varying results. In some of these patients, non-relaxation of the pelvic floor muscles and hyperplasia of the bladder neck has been documented. Urodynamic studies to measure the pressure generated in the bladder during voiding may be indicated in patients with prostatodynia, and if bladder outlet obstruction from bladder neck hyperplasia is documented, these patients may benefit from incision of the bladder neck. Thermotherapy of the prostate is also being studied for patients with non-bacterial prostatitis and prostatodynia, and uncontrolled trials have shown some success with this treatment. Unfortunately, the etiology of prostatodynia remains quite speculative.

Benign Prostatic Hyperplasia

Benign prostatic hyperplasia (BPH) is the most common benign tumor of adult men and is a major factor affecting the health of older men. BPH is a pathologic term referring to growth of the glandular and stromal elements in the prostate. With this growth of the prostate, men can develop bothersome urinary symptoms and complications resulting from bladder outlet obstruction. This section will review the etiology, physiology, and clinical aspects of BPH.

Incidence

Men begin to develop BPH in their 30s, and the incidence increases with age, as shown in **Figure 2**. Over 50% of men older than age 50 have BPH, and 75% of men in their eighth decade have BPH. The urinary symptoms caused by bladder outlet obstruction, termed prostatism, occur in 25% of men 55 years of age and occur in 55% of men aged 75.

Etiology

The two conditions necessary for BPH to develop are the aging process and testosterone production from the testicles. Men who receive an orchiectomy before

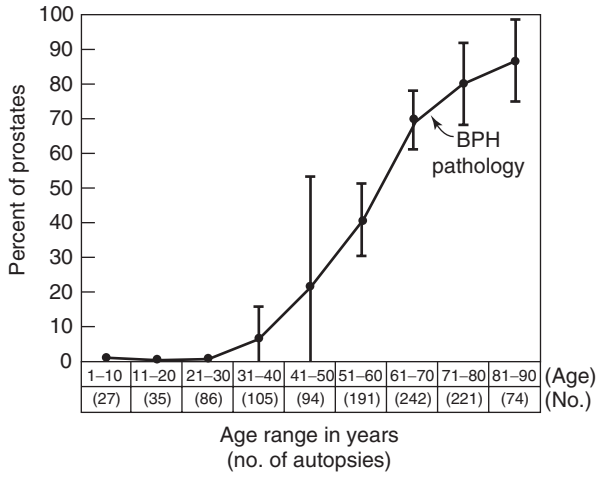

Figure 2 The prevalence of benign prostatic hyperplasia (BPH) as assessed in autopsy specimens. As men get older the prevalence of BPH increases. From Berry SJ, Coffee DS, Walsh PC, *et al.* (1984) The development of human benign prostatic hyperplasia with age. *Journal of Urology* 132: 474. Used by permission of the American Urological Association.

puberty do not develop BPH. Testosterone produced by the testicles is converted to dihydrotestosterone in the cytoplasm of the prostate stromal and epithelial cells. Dihydrotestosterone then binds to an androgen receptor, and this complex binds to specific DNA sites in the nucleus and causes protein synthesis and cell growth. As further evidence of the role of testosterone in the development of BPH, 5-α reductase inhibitors, androgen receptor blockers, and orchiectomy all cause a decrease in prostate size.

As men age, their testosterone levels decrease. The ongoing growth of the prostate can be explained in part by an increase in number of androgen receptors in the prostate with age. More recent experiments support the role of stromal and glandular interactions via growth factors in causing BPH. Basic fibroblast growth factor (FGF) and transforming growth factor (TGF) beta have been shown in tissue culture to act as autocrine and paracrine factors leading to BPH. Researchers are just beginning to understand the causes of BPH in aging men.

Physiology

Benign prostatic hyperplasia occurs in both the glandular and stromal elements of the prostate. The enlarging prostate can cause bladder outlet obstruction by physically blocking the prostatic urethra, termed *static obstruction*. In addition, contraction of the smooth muscle in the prostate stroma and capsule causes dynamic bladder outlet obstruction. This contraction is under the influence of sympathetic nerve fibers innervating the α1 receptors in the smooth muscle. Pharmacologic therapy that blocks the α1 receptors is extremely effective in alleviating symptoms of BPH and will be discussed later.

Table 1 Prostatism symptoms

Obstructive	*Irritative*
Difficulty initiating stream	Frequency
Slow force of stream	Urgency
Hesitancy (stream starts and stops)	Urgency incontinence
Straining to urinate	Dysuria
Feeling of incomplete bladder emptying	Nocturia

With bladder outlet obstruction from BPH, men may develop obstructive voiding symptoms including a decreased force of their urinary stream and difficulty emptying their bladder. In response to the bladder outlet obstruction, the smooth muscle in the bladder wall hypertrophies and the bladder wall thickens. This causes a decreased functional capacity of the bladder, and men develop the so-called irritative voiding symptoms that include urinary frequency, urgency, and nocturia. These irritative symptoms are usually more bothersome to patients than their obstructive symptoms, and can interfere with their daily activities and their sleeping.

A small percentage of patients will develop complications from their BPH, including recurrent urinary tract infections, gross hematuria, urinary retention, and obstructive uropathy. These patients usually require surgical rather than medical management of their BPH.

Diagnosis

The diagnosis of benign prostatic hyperplasia is based on clinical assessment and does not require a biopsy of the prostate tissue. The history begins with assessment of the presence and severity of the obstructive and irritative voiding symptoms shown in **Table 1**. To this end, the American Urologic Association (AUA) developed the AUA Symptom Score shown in **Figure 3**, a scientifically valid and reproducible questionnaire to assess the severity of prostatism symptoms and to assess the efficacy of treatment. The AUA Symptom Score can be quite helpful in managing patients with BPH. The symptom score also has limitations in that it does not diagnose prostatism, and any number of causes of voiding dysfunction can cause an elevated AUA Symptom Score. In addition, the AUA Symptom Score does not assess the degree of bother that patients have as a result of their symptoms, and some patients have a high AUA score but are not troubled by their symptoms and do not want any type of treatment.

The history of patients with suspected BPH is also directed at elucidating any other etiologies for the

The AUA symptom index

Question	Not at all	Less than 1 time in 5	Less than half the time	About half the time	More than half the time	Almost always
1. During the last month or so, how often have you had a sensation of not emptying your bladder completely after you finished urinating?	0	1	2	3	4	5
2. During the last month or so, how often have you had to urinate again less than 2 hours after you finished urinating?	0	1	2	3	4	5
3. During the last month or so, how often have you found you stopped and started again several times when you urinated?	0	1	2	3	4	5
4. During the last month or so, how often have you found it difficult to postpone urination?	0	1	2	3	4	5
5. During the last month or so, how often have you had a weak urinary stream?	0	1	2	3	4	5
6. During the last month or so, how often have you had to push or strain to begin urination?	0	1	2	3	4	5
7. During the last month, how many times did you most typically get up to urinate from the time you went to bed at night until the time you got up in the morning?	None	1 time	2 times	3 times	4 times	5 or more times*
	0	1	2	3	4	5

AUA symptom score = sum of questions 1 to 7.

Figure 3 The American Urological Association Symptom Score is a standardized questionnaire that gives a numeric value to the severity of voiding symptoms. Voiding symptoms are considered mild if the score is 0–7, moderate if the score is 8–19, and severe if the score is 20–35. From Barry MJ, Fowler Jr. FJ, O'Leary MP, *et al.* (1992) The American Urological Association symptom index for benign prostatic hyperplasia. *Journal of Urology* 148(5): 1549. Used by permission of the American Urological Association.

patient's voiding dysfunction. The differential diagnosis for voiding dysfunction is extensive and includes malignancy, infection, neurologic diseases, other causes of bladder outlet obstruction, such as urethral stricture disease, and side effects of various medications on the bladder and bladder outlet.

Physical examination includes a careful digital rectal exam of the prostate to assess for any nodules suggestive of malignancy and to rule out prostatitis. A common misconception is that the size of the prostate correlates with urinary symptoms or with the need for some type of intervention. In fact, the size of the prostate does not correlate with the incidence or severity of prostatism symptoms and in no way correlates with the risk of malignancy. The physical exam also includes palpation for a distended bladder, examination of the meatus to rule out meatal stenosis as a cause of bladder outlet obstruction, and a thorough neurologic exam.

All patients with prostatism symptoms should have a urinalysis to rule out infection and microscopic hematuria, and a serum creatinine to rule out renal failure. There is ongoing debate concerning whether a PSA is necessary in all patients with suspected BPH. In general, we obtain a PSA in all of our patients with prostatism symptoms because the PSA appears to be more sensitive than the digital prostate exam in detecting prostate cancer. Moreover, if prostate cancer is present it would greatly change our management.

Medical Treatment

Once we establish the diagnosis of BPH, we explain to our patients about their condition and reassure them that there is no evidence of malignancy. We also explain that, unfortunately, symptomatic BPH appears to be a normal part of aging. Usually, patients are reassured to hear that there is no evidence of prostate cancer, and if their voiding symptoms are not bothersome, they will frequently elect watchful waiting and periodic checkups. If the prostatism symptoms are bothersome to the patient, we usually first offer pharmacologic treatment consisting of either $\alpha 1$ blocking agents or 5-α reductase inhibitors.

The selective $\alpha 1$ blocking agents (doxazosin, terazosin) exert their effects by relaxing the smooth muscle in the prostate stroma, capsule, and bladder neck, and thus decrease the dynamic component of the bladder outlet obstruction. In prospective randomized double-blind trials, these agents have been shown to give patients symptomatic improvement and to increase the urinary flow rate. Whereas placebo is effective at improving symptoms in about 40% of patients with BPH, $\alpha 1$ blockers are effective in about 75% of patients. Patients can notice improvement within several weeks of beginning therapy, and they must continue to take these drugs on a daily basis or else their symptoms will recur. Because $\alpha 1$ blocking agents are also effective for treating

hypertension, in some patients this one medication can treat two problems at once. These agents are tolerated well by normotensive as well as hypertensive patients, and side effects include dizziness, fatigue, and hypotension.

The other medical therapy available to treat prostatism is finasteride, a 5-α reductase inhibitor that blocks the conversion of testosterone to dihydrotestosterone. This drug causes the prostate to decrease in volume by 25% and causes a 50% reduction in the PSA at 6 months. Prospective randomized blinded trials have demonstrated that finasteride gives symptomatic improvement and causes a modest increase in urinary flow rate after at least 6 months of treatment. Side effects include impotence, decreased libido, and decreased ejaculatory volume in less than 5% of patients.

Surgical Treatment

Surgery is indicated for BPH when there is documented obstructive uropathy (kidney failure), urinary retention, recurrent urinary tract infections secondary to high postvoid residuals, or gross hematuria secondary to BPH. Surgery is also indicated for symptomatic improvement especially if pharmacologic treatment is insufficient. The gold standard technique that gives the best improvement in urinary flow rate and the best symptomatic improvement is the transurethral resection of the prostate (TURP). In this procedure the obstructing prostate tissue is resected using a cautery-wire loop through a cystoscope in the urethra. This procedure requires an anesthetic and several days of hospitalization after the procedure with an indwelling foley catheter in the bladder. The catheter is removed prior to discharge from the hospital. Several weeks of convalescence are required to allow the surgical site to heal. Most patients have retrograde ejaculation following a TURP in which the ejaculate goes into the bladder instead of out the penis during the sexual act. Other side effects are rare and include incontinence, impotence, stricture, and bleeding requiring a blood transfusion. In patients who require surgery and have extremely large prostates in excess of 100 g, an open prostatectomy is performed. In this procedure the benign obstructing prostate tissue is removed through a lower abdominal incision, while the peripheral prostate tissue and capsule are left behind.

There is a great deal of ongoing research investigating other surgical procedures to remove obstructing prostate tissue. The most promising of these techniques involves use of laser energy to either coagulate or vaporize the obstructive tissue. Laser surgery offers advantages over TURP, including less hospitalization time and less bleeding complications as well as a decreased incidence of retrograde ejaculation. TURP, on the other hand, continues to give better improvement in the urinary flow rate compared to the laser. Until more data are available concerning the type of laser energy used, the power level, and the duration of laser exposure, we continue to use the TURP for patients requiring surgical treatment of BPH.

Another technique that is actively being investigated is transurethral vaporization of the prostate, which uses a steel rollerball device to transmit high-power electrical cutting current to the prostate. This technique is purported to require less hospitalization, cause less bleeding, and be technically easier than a TURP, but controlled studies are not yet available.

Prostate Cancer

Incidence

Adenocarcinoma of the prostate is the most common internal cancer of males in the United States and is the second most common cause of cancer deaths, second only to lung cancer. The incidence of prostate cancer continues to rise each decade. Overall, men in the United States have a 9.5% lifetime risk of developing prostate cancer and a 2.8% lifetime risk of dying of prostate cancer. Clearly, prostate cancer is a major health problem in aging males. (*See* Cancer and Age.)

Etiology

As men age, the incidence of prostate cancer increases. There is a great disparity between the incidence of clinical carcinoma of the prostate (CAP) and the incidence of prostate cancer found at autopsy (occult cancer) in men who die of other causes. Autopsy studies reveal that 30% of men in their seventh decade, 40% of men in their eighth decade, and 50% of men in their ninth decade have subclinical prostate cancer. Of great interest is that only a small percentage of these men go on to develop clinical prostate cancer. The factors that cause subclinical prostate cancer to progress to clinical prostate cancer are presently under intense investigation.

Although the autopsy incidence of prostate cancer is equal in Japanese and American men, clinical prostate cancer is uncommon in Japanese men. However, when Japanese men move to the United States, the incidence of clinical CAP approaches that of Whites in one to two generations. The reason for this is not known, but research is focusing on the difference in dietary habits of Japanese and Americans. In Japan, unlike America, the usual diet is low

in fat and high in soybean. Studies in tissue culture and in mice have shown that low fat and high soybean confers protection from growth of established prostate cancer. Other environmental factors may also play a role in converting latent prostate cancer to clinical prostate cancer. (*See* Diet and Nutrition.)

Race also plays a significant role in the development of clinical CAP. Whereas the autopsy incidence of CAP in Blacks equals that of Whites in the United States, Black men have a higher incidence of clinical prostate cancer than Whites, and these cancers present at more advanced stages and have a higher mortality in Blacks. These statistics hold even when controlling for age, socioeconomic status, and the geographic area. Access to medical care, diet, and genetic factors may all play a role, and research in this area is ongoing.

In a subset of men, genetics also plays an important role in the development of prostate cancer. Men with first-degree relatives with prostate cancer have a two- to three-fold increased incidence of developing prostate cancer, and this risk increases with the number of family members affected. Therefore, inquiry into a family history of prostate cancer should be made in every man undergoing a routine history and physical examination, and patients with a positive family history need more careful follow-up.

Prostate-Specific Antigen

PSA is presently the most unique marker in cancer biology, and its discovery has revolutionized the detection, diagnosis, and treatment of prostate cancer. PSA is a glycoprotein normally produced by prostate epithelial cells and it functions to hydrolyze the coagulum of the ejaculate. Prostate cancer as well as inflammation, BPH, and prostate trauma can cause increased amounts of PSA to be released into the bloodstream. An abnormally elevated serum PSA has been shown to be more sensitive than the digital prostate exam in detecting prostate cancer. With the discovery of PSA, physicians are now detecting many more prostate cancers, and there is now a sensitive marker to measure the effectiveness of treatments. However, up to 20% of men with clinical prostate cancer have a normal PSA level, thus emphasizing the importance of the digital prostate exam.

Screening

With the discovery of PSA, numerous screening programs have been set up with the hope of detecting prostate cancer earlier. Although physicians are now detecting more early and advanced stage prostate cancers, to date there is still no evidence that prostate cancer screening has decreased the mortality from prostate cancer. This may be partly because many prostate cancers appear to be slow growing, and patients often die of other causes than their prostate cancer. Conclusions on the effectiveness of screening for CAP are forthcoming, but at this time the American Cancer Society and the AUA are recommending yearly PSA measurements and prostate exams in men beginning at age 50, and beginning at age 40 in patients with risk factors for prostate cancer.

Diagnosis and Staging

Patients suspected of having prostate cancer from an abnormal digital prostate exam or an elevated serum PSA undergo biopsy of the prostate. This is accomplished by advancing a biopsy needle transrectally into the prostate with either ultrasound or finger guidance and obtaining cores of tissue from the prostate. Transrectal ultrasound allows accurate sizing of the prostate and helps in directing the biopsy needle to specific areas in the prostate. Volumetric measurement of the prostate with ultrasound is especially important because a large volume of BPH can sometimes explain an increase in the PSA.

Once the diagnosis of CAP is made, the tissue is graded pathologically by the Geason scale, with grade 5 being the most poorly differentiated and grade 1 being well differentiated. Staging is based on the size and extent of the palpable cancer and on the metastatic workup, which includes a chest X-ray, bone scan, blood count, and liver function tests. The prostatic acid phosphatase blood test is also frequently used; elevation of the enzymatic acid phosphatase usually means the prostate cancer is advanced and cannot be cured by surgery or radiation therapy.

Treatment

The appropriate treatment depends on a broad range of factors including tumor grade and stage, the patient's 10- to 15-year life expectancy and general health, and most importantly, the patient's preference. A great deal of controversy exists regarding the best treatment for prostate cancer, and numerous ongoing studies are attempting to address this issue.

Expectant Management

Expectant management for prostate cancer consists of regular clinic visits, monitoring for the complications of prostate cancer, and treating patients for symptoms if they arise. This is the primary management used for prostate cancer in some parts of Europe and Scandinavia. Several prospective studies show that the majority of patients treated

by expectant management die of causes other than their prostate cancer, and the cancer does not impact on their life expectancy. This is because many prostate cancers grow slowly and may take decades to spread or cause symptoms. Expectant management has come under harsh criticism because a significant percentage of patients in expectant management studies go on to develop locally advanced or metastatic disease. Also, many of the patients in these studies have lower-grade, less aggressive tumors to begin with.

Radical Prostatectomy

Radical prostatectomy consists of removing the entire prostate and seminal vesicles. After the prostate is removed, the bladder neck is sutured to the urethra over a urethral catheter. Patients are hospitalized for about 3–4 days and are required to wear the urethral catheter for 2 weeks at home. Radical prostatectomy cures 60–80% of patients and is a good option in patients with a 10- to 15-year life expectancy. The cure rate of radical prostatectomy approaches 90% if the cancer is confined to the prostate gland on pathological examination. Potency can be preserved in a select group of younger patients with small tumors by sparing the nerves that run along each side of the prostate. A significant number of patients suffer from impotence and periodic urinary incontinence after the surgery, and this can impact negatively on their quality of life. On the other hand, radical prostatectomy offers the possibility of a cure of a potentially deadly cancer. If impotence and incontinence develop, various treatments are available that deal successfully with these complications.

Radiation Therapy

Radiation therapy either by external beam or by interstitial seed implantation also offers the chance for cure in patients with localized prostate cancer. Although retrospective studies suggest that surgery may offer a better chance for cure than radiation therapy, there still has not been a good prospective randomized study comparing these two treatments. It may be that many patients receiving radiation therapy in these studies are poor surgical risk patients and have more advanced disease than the patients in the retrospective surgery series, thus making these studies invalid for comparison. Although patients who receive radiation therapy suffer less impotence and urinary incontinence than patients who receive surgery, these as well as other side effects, including bowel and bladder irritation, can occur from radiation treatment.

Hormonal Therapy

The growth of prostate cancer is partly dependent on androgens produced by the testicles and adrenal glands. By either removing the testicles (orchiectomy), or giving drugs that inhibit the production of or action of androgens, prostate cancer can be put into a remission for up to several years. Unfortunately, this effect is only temporary and eventually the prostate cancer becomes independent of androgens and continues to grow.

Patients with advanced prostate cancer usually receive some form of hormonal treatment. This consists of either bilateral orchiectomy or medical therapy. The leutinizing hormone (LH)-releasing agonists leuprolide and goserelin act by preventing the release of LH from the anterior pituitary. These medications ultimately stop the production of testosterone by the testicles and are as effective as orchiectomy. Another agent, flutamide, blocks androgen receptors and prevents the binding of androgens produced by the adrenal glands and the testicles. These hormonal treatments are extremely effective in putting advanced prostate cancer into a remission for a variable period of time. Side effects of these agents include hot flushes and, most notably, impotence.

Cryotherapy

More recently, numerous medical centers are attempting to cure clinically localized prostate cancer by freezing the prostate via special probes placed in the perineum under ultrasound guidance. Patients go home the same or next day. Although many patients develop an undetectable PSA after cryotherapy, the side effects can be significant. Long-term results of cryotherapy are needed before we can recommend this treatment.

Recent Advances in Prostate Cancer

A number of recent discoveries concerning PSA deserve mentioning here. Age-specific reference ranges are now being established for PSA. As men age, the upper limit of normal for PSA increases. Whereas a PSA of 4 ng/ml was previously the upper limit of normal for the Hybritech PSA test, now for men in their 70s, a PSA of 5 or 6 ng/ml is probably within normal limits. Hopefully, this will help relieve the great anxiety these older men experience when they are told that their PSA is elevated and will prevent some unnecessary prostate biopsies from being performed.

Further technology in PSA measurement may help us better predict which patients with an elevated PSA require a prostate needle biopsy. Many men with a PSA between 4 and 10 ng/ml (normal Hybritech range 0–4 ng/ml) have a PSA elevation secondary to

their BPH and undergo needless prostate biopsies. PSA can now be measured in both a free and bound form, and it appears that the fraction of the bound PSA to the total PSA may help distinguish which of these men may have a higher likelihood of having prostate cancer and require a biopsy.

Another recent advance is in the area of molecular staging of prostate cancer. With gene amplification techniques, physicians can now detect a single PSA-producing prostate cancer cell in the bloodstream. This technology may help physicians to better detect or stage prostate cancer, and may help them evaluate better the effectiveness of various treatments of prostate cancer.

Conclusion

A number of prostate diseases including prostatitis, BPH, and prostate cancer are having a major impact on the health of aging men. For reasons that are not understood, these diseases develop as men get older. In fact, BPH and prostate cancer seem to be a normal part of aging, and many men live with mild symptoms or occult cancer and die before these diseases have a significant impact on their quality of life. Part of the art of medicine is determining when to treat patients and subject them to the side effects of medications and surgeries, and when to observe patients without any active interventions.

Psychological Well-Being

C L M Keyes, Emory University, Atlanta, GA, USA

Glossary

Emotional Well-Being (also called Hedonia) – The balance of feelings (positive and negative) experienced in life.

Positive Functioning – Encompasses six dimensions of psychological well-being: self-acceptance, positive relations with others, personal growth, purpose in life, environmental mastery, and autonomy.

Subjective Well-Being – Emotional well-being and positive functioning.

Introduction

Social and psychological scientists have created a variety of self-report measures to tap people's subjective sense of the quality of their lives. Although research shows that people use multiple criteria to evaluate their subjective experiences, there are two general lines of research that have evolved. According to one line of well-being research, evaluations of the degree of positive feelings (e.g., happiness) experienced and perceptions (e.g., satisfaction) toward one's life overall constitute subjective well-being. A second stream of well-being research specifies dimensions of positive functioning in terms of psychological well-being and social well-being. Overall, subjective well-being consists of two broad domains – emotional well-being (hedonia) and positive functioning (eudaimonia). These domains, their conceptions and measurement, and their levels throughout the adult life span are reviewed in this article.

Varieties of Subjective, Psychological Well-Being

Hedonia: Emotional Well-Being

The emotional well-being cluster of symptoms reflects the presence and absence of positive feelings about life operationalized as evaluations of happiness and satisfaction with life and the balance of positive to negative affect experiences over a time period. Thus, emotional well-being can be conceptualized as the balance of feelings (positive and negative) experienced in life and the perceived feelings (happiness and satisfaction). Most single-item measures of life satisfaction are adaptations of Cantril's Self-Anchoring Scale, which asks respondents to "rate their life overall these days" on a scale from 0 to 10, where 0 meant the worst possible life overall and 10 meant the best possible life overall. Variants of Cantril's measure have been used extensively in numerous studies worldwide and have been applied to the measurement of avowed happiness with life. Single-item indicators and multi-item scales of life satisfaction and happiness have also been developed and employed extensively.

Most measures of positive and negative affect investigate the frequency or the duration of time that a respondent reports the experience of symptoms of positive and negative affect. For example, individuals are often asked to indicate how much of the time during the past 30 days they have felt six types of negative and six types of positive indicators of affect. Response choices for the negative affect and positive affect items shown in **Table 1** are all, most, some, a little, or none of the time. Estimates of internal reliability of the multi-item scales of satisfaction and happiness and positive and negative affect usually exceed 0.80. Studies also support a proposed factor structure of emotional well-being with a cognitive domain of avowed life satisfaction and an affective domain of happiness.

Eudaimonia: Positive Functioning

Psychological Well-Being Subjective well-being is more than the presence and absence of affective states; it also includes the perceived presence and absence of positive functioning in life. Positive functioning encompasses six dimensions of psychological well-being: self-acceptance, positive relations with others, personal growth, purpose in life, environmental mastery, and autonomy. Conceptual definitions and representative items of each dimension of psychological well-being are shown in **Table 1**.

Self-acceptance requires the maintenance of esteem for one's self, while facing complex and sometimes unpleasant personal aspects of the self. In addition, individuals accumulate a past and have the capacity to recall and remember themselves through time. Healthy individuals perceive themselves positively across the life course and accept all parts of themselves. Positive relations with others consist of the ability to cultivate warm, intimate relationships with others. It also includes the presence of satisfying social contacts and relations. Autonomy measures the degree to which people seek self-determination and personal authority, in a society that at times requires obedience and compliance. However, healthy individuals seek to understand their own values and ideals. In addition, healthy individuals see themselves guiding their own behavior and conduct from internalized standards and values.

Environmental mastery is the active engagement of the environment in order to mold it to meet one's needs and wants. Healthy individuals recognize personal needs and desires and also feel capable of taking, and feel permitted to take, an active role in getting what they need from their environments. Purpose in life captures the adult's perception of having direction in life, even when the world offers none or provides unsatisfactory alternatives. Healthy individuals see their daily lives as fulfilling a direction and purpose, and, therefore, they view their personal lives as meaningful. Last, personal growth is the ability and desire to enhance existing skills and talents and to seek opportunities for further personal development. In addition, healthy individuals are open to experience and have the capacity to identify challenges in a variety of circumstances.

Table 1 Subjective well-being traditions, dimensions, operational definitions, and representative items

Hedonia *Emotional well-being*	*Eudaimonia* *Psychological well-being*	*Eudaimonia* *Social well-being*
Affect balance: the balance of the amount of positive to negative affect experienced over a time period.	**Self-acceptance**: possess positive attitude toward the self; acknowledge and accept multiple aspects of self; feel positive about past life.	**Social acceptance**: have positive attitudes toward people; acknowledge others and generally accept people, despite others' sometimes complex and perplexing behavior.
Positive affect: symptoms suggesting the presence of pleasant feelings.		
• During the last 30 days, how much of the time did you feel cheerful; in good spirits; extremely happy; calm and peaceful; satisfied; and full of life?	• I like most parts of my personality. • When I look at the story of my life, I am pleased with how things have turned out so far. • In many ways, I feel disappointed about my achievements in life (–)	• People who do a favor expect nothing in return. • People do not care about other people's problems. (–) • I believe that people are kind.
Negative affect: symptoms suggesting the absence of unpleasant feelings.		
• During the last 30 days, how much of the time did you feel nervous; worthless; everything was an effort; hopeless; restless or fidgety; so sad nothing could cheer you up?		
Life satisfaction: a sense of contentment, peace, and satisfaction from small discrepancies between wants and needs with accomplishments and attainments.	**Personal growth**: have feelings of continued development and potential and am open to new experience; feel increasingly knowledgeable and effective.	**Social actualization**: care about and believe society is evolving positively; think society has potential to grow positively; think self-society is realizing potential.
• During the past 30 days, how much of the time did you feel satisfied; full of life? • Overall these days, how satisfied are you with your life? (0–10, where 0 = terrible and 10 = delighted) • Satisfaction may be measured in life domains such as work, home, neighborhood, health, intimacy, finances, parenting.	• For me, life has been a continuous process of learning, changing, and growth. • I think it is important to have new experiences that challenge how I think about myself and the world. • I gave up trying to make big improvements/changes in my life a long time ago. (–)	• The world is becoming a better place for everyone. • Society has stopped making progress. (–) • Society hasn't improved for people like me. (–)
Happiness: having a general feeling and experience of pleasure, contentment, and joy.	**Purpose in life**: have goals and a sense of direction in life; past life is meaningful; hold beliefs that give purpose to life.	**Social contribution**: feel I have something valuable to give to society; think daily activities are valued by the community.
• Overall these days how happy are you with your life? • How frequently have you felt (joy, pleasure, happiness) in the past week, month, or year?	• Some people wander aimlessly through life, but I am not one of them. • I live life one day at a time and don't really think about the future. (–) • I sometimes feel as if I've done all there is to do in life. (–)	• I have something valuable to give to the world. • My daily activities do not create anything worthwhile for my community. (–) • I have nothing important to contribute to society. (–)
	Environmental Mastery: feel competent and able to manage a complex environment; choose or create personally suitable community.	**Social Coherence**: see a social world that is intelligible, logical, and predictable; care about and am interested in society and contexts.
	• The demands of everyday life often get me down. (–) • In general, I feel I am in charge of the situation in which I live. • I am good at managing the responsibilities of daily life.	• The world is too complex for me. (–) • I cannot make sense of what's going on in the world. (–) • I find it easy to predict what will happen next in society.

Table 1 Continued

Hedonia *Emotional well-being*	*Eudaimonia* *Psychological well-being*	*Eudaimonia* *Social well-being*
	Autonomy: am self-determining, independent, and regulate internally; resist social pressures to think and act in certain ways; evaluate self by personal standards.	**Social integration**: feel part of community; think I belong, feel supported, and share commonalities with community.
	• I tend to be influenced by people with strong opinions. (−) • I have confidence in my own opinions, even if they are different from the way most other people think. • I judge myself by what I think is important, not by the values of what others think is important.	• I don't feel I belong to anything I'd call a community. (−) • I feel close to other people in my community. • My community is a source of comfort.
	Positive relations with others: have warm, satisfying, trusting relationships; am concerned about others' welfare; capable of strong empathy, affection, and intimacy; understand give and take of human relationships.	
	• Maintaining close relationships has been difficult and frustrating for me. (−) • People would describe me as a giving person, willing to share my time with others. • I have not experienced many warm and trusting relationships with others. (−)	

A negative sign in parenthesis indicates that the item is reverse scored. Response options range from strongly disagree (1), moderately disagree (2), or slightly disagree (3) to neither agree nor disagree (4), slightly agree (5), moderately agree (6), to strongly agree (7).

Social Well-Being Still, there is more to subjective well-being than emotional and psychological well-being. Keyes has asserted that positive functioning includes social challenges and tasks and proposed five dimensions of social well-being. Whereas psychological well-being (and its component, positive relations with others) represents more private and personal criteria for evaluation of one's functioning, social well-being epitomizes the more public and societal criteria whereby people evaluate their functioning in life. These societal dimensions consist of social coherence, social actualization, social integration, social acceptance, and social contribution. Conceptual definitions and representative items are shown in **Table 1**.

Social integration is the evaluation of the quality of one's relationship to society and community. Integration is therefore the extent to which people feel they have something in common with others who constitute their social reality (e.g., their neighborhood), as well as the degree to which they feel that they belong to their communities and society. Social contribution is the evaluation of one's value to society. It includes the belief that one is a vital member of society, with something of value to give to the world. Social coherence is the perception of the quality, organization, and machinations of society, and it includes a concern for knowing about the world. Social coherence is the obverse of a sense of meaninglessness and involves appraisals that society is discernable, sensible, and predictable.

Social actualization is the evaluation of the potential and the trajectory of society. This is the belief in the positive evolution of society and the sense that society has potential that is being realized through its institutions and citizens. Social acceptance is the construal of society through the character and qualities of other people in general. Individuals must function in a public arena that consists primarily of strangers. Individuals who illustrate social acceptance trust others, think that others are capable of kindness, and believe that people can be industrious. Socially accepting people hold favorable views of human nature and feel comfortable with others.

The Structure of Subjective Well-Being

Studies using community and nationally representative samples have supported the theory that social and psychological well-being belong to distinct, but correlated, latent factors. Confirmatory factor models have revealed that the proposed five-factor theory of social well-being provides the best fit, and the proposed six-factor theory of psychological well-being is the best-fitting model. Moreover, the factors of social and psychological well-being are mutually distinct. The scales of social and psychological well-being correlate as high as 0.44, and exploratory factor analysis revealed two correlated ($r = 0.34$) factors with the scales of social well-being loading on a separate factor from the items measuring happiness, satisfaction, and the overall scale of psychological well-being.

Factor analysis also reveals that measures of social well-being are distinct from, but correlated with, measures of emotional well-being. Measures of emotional well-being (positive and negative affect, life satisfaction) are factorially distinct from the measures of psychological well-being. In a national sample of youth between the ages of 12 and 18, measures of emotional well-being, psychological well-being, and social well-being were factorially distinct, suggesting that the structure of the varieties of subjective well-being are continuous from youth to old age.

Age and Subjective, Psychological Well-Being

Since the 1950s, gerontological studies employed subjective well-being as a central construct with the aim of characterizing normative and successful modes of aging. This direction was facilitated by Erikson, who provided the first comprehensive theory of development throughout the entire life span. Erikson proposed stages of adult development, characterized by unique life challenges that provide opportunities for growth as well as decline. The study of subjective well-being in gerontology was facilitated by two main instruments: the Life Satisfaction Index (LSI) and the Philadelphia Geriatric Center Morale Scale (PGCMS). Each of these scales was subjected to factor analysis, which revealed positive as well as negative aspects of aging. Overall, this first generation of research on subjective well-being and aging sparked the conceptualization and study of successful aging.

Early theories and models of aging portrayed it as a process of disengagement and decline in cognitive, social, and emotional functioning. Such portrayals of growing old in America reflected the social reality of aging during about the first two-thirds of the twentieth century, during which time many older adults lived in poverty. Up to 1967, about 30% of adults aged 65 or older lived at or below the government's standard of poverty and reported an average of 30 to 40 days of restricted activity due to their health annually. However, contrary to the models of aging as uniform decline, large national studies have shown that advanced age is often associated with the maintenance or the increase in subjective well-being.

A host of theories that build on the paradigm of successful aging have emerged to explain how individuals adapt or compensate for loss at the same time that they resolve new challenges and optimize extant skills. Moreover, the study of life transitions now reveals that many individuals actively shape the meaning of stressful experience, resolve those stressors to their satisfaction, and thereby learn new coping skills and information about their own strengths and abilities.

Cross-Sectional Age Trajectories

Literally all studies that have investigated age differences in psychological, subjective well-being in adulthood employ cross-sectional data. As such, all observed age differences must be interpreted with caution, since cross-sectional age differences are as likely to reflect generational, cohort differences as they are to reflect developmental changes that reflect the process of aging. This is true of the MIDlife in the United States (MIDUS) national study of adults between the ages of 25 and 74, which was conducted in 1995. This cross-sectional study was the first study of its kind to include all measures of subjective well-being so that one could make comparisons of age differences in emotional, psychological, and social well-being.

Research using the MIDUS data has shown a complex pattern of age increments and age decrements in specific facets of each dimension of subjective well-being. **Figures 1A** and **1B** represent the typical pattern observed for the two main components of emotional well-being, i.e., positive affect and negative affect (items for each scale were shown in **Table 1**). The frequency with which individuals experience positive affect is higher among the oldest adults than among the middle-aged or the younger adults. Moreover, the frequency of negative affect decreases with age. Middle-aged adults report less negative affect than the younger adults, while the older adults report less negative affect than the middle-aged adults.

Unlike emotional well-being, the age differences of facets of psychological well-being reveal a mixed

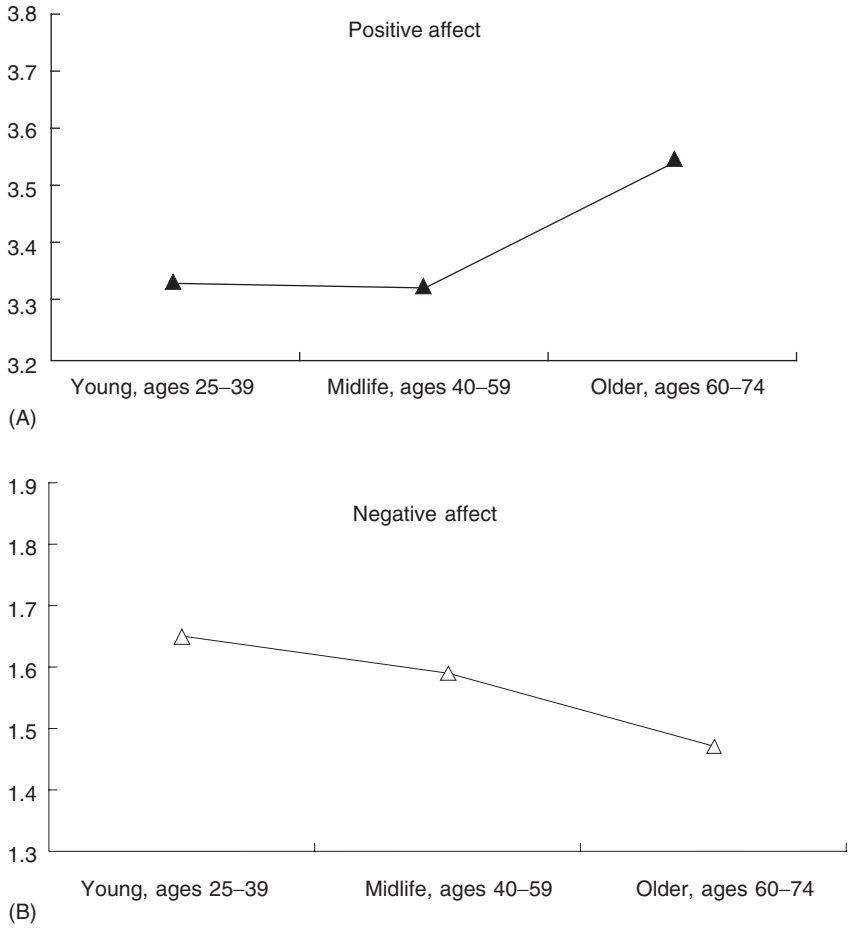

Figure 1 Mean level of positive affect and negative affect scales by age group in the MIDUS national study ($n = 3032$, sample weighted).

pattern of improvement and decline. Using age as a continuous variable, Ryff et al. found age decrements in purpose in life and personal growth. This same pattern is revealed in **Figure 2**, in which age is broken down into age groups of young, midlife, and older adulthood. On the other hand, Ryff et al. found age increments in self acceptance, positive relations with others, environmental mastery, and autonomy. These increments by age are less apparent but still visible in **Figure 2**. These findings coincide, in large part, with three prior studies of psychological well-being summarized by Keyes and Ryff that varied in depth of measurement (i.e., from 20- to 3-item scales), mode of administration (i.e., self-administered and telephone interviews), and sampling technique (i.e., purposive and random national samples). In these prior studies, personal growth and purpose in life declined with age as in the MIDUS study. In the prior studies, environmental mastery and autonomy (autonomy increased in two of the three prior studies) increased with age as in the MIDUS study. In the prior three studies, levels of self-acceptance and positive relations with others remained the same with age, which contrasts with the age increments found in the MIDUS study.

Age variation in social well-being has been studied in two samples – a random sample of adults aged 18 or older residing in Dane County, Wisconsin, and the sample in the MIDUS study. Findings reported in Keyes showed comparable age trajectories in both samples; age was treated as a continuous variable. Social coherence decreased linearly with age. On the other hand, social integration and social acceptance increased linearly with age. Although social actualization and contribution increase with age, the increase decelerates with each added year of life in both studies. That is, the relationship between age and social actualization and social contribution was non-linear, increasing from younger adulthood through middle age, and decreasing from middle age to older adulthood. Findings reported in Keyes coincide with the level of each dimension of social well-being by age group in **Figure 3**. That is, there is a consistent decline in social contribution and social

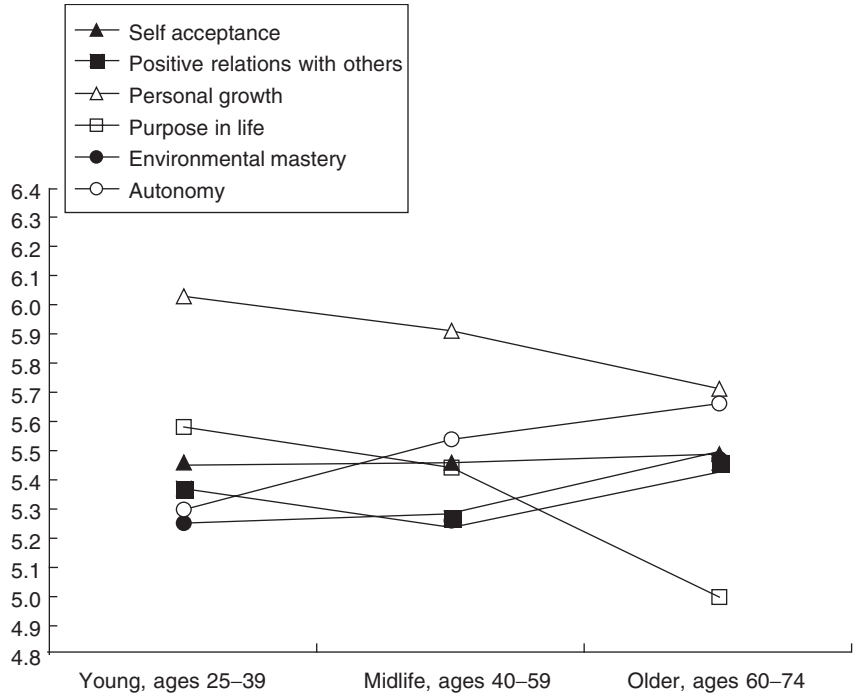

Figure 2 Mean level of Ryff's (1989) three-item psychological well-being scales by age group in the MIDUS national study ($n = 3032$, sampled weighted).

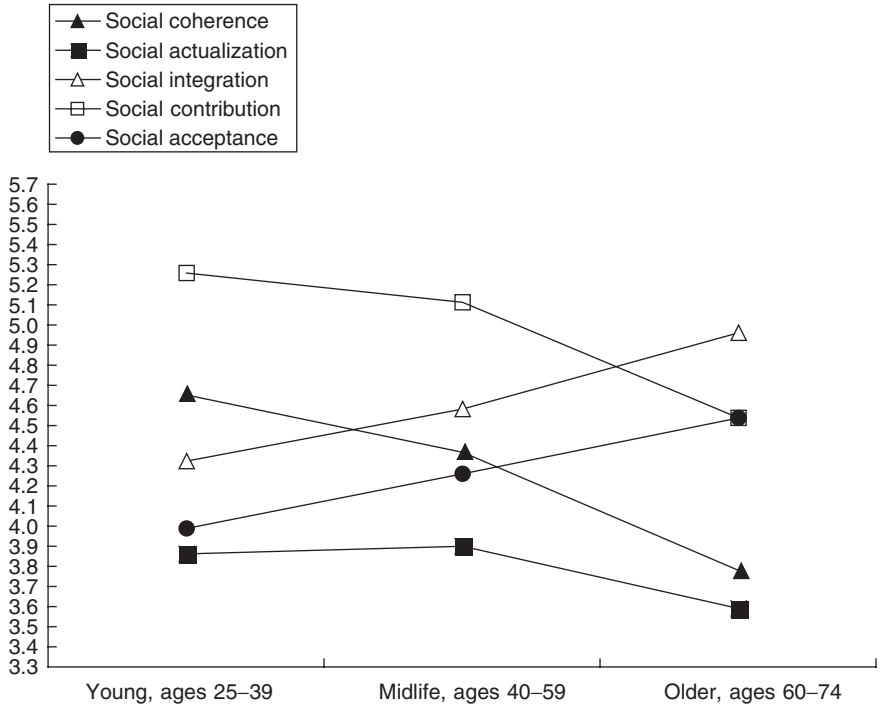

Figure 3 Mean level of Keyes' (1998) three-item social well-being scales by age group in the MIDUS national study ($n = 3032$, sample weighted).

coherence, while there is some suggestion that social actualization increases slightly between young and middle-aged adulthood and then decreases again among older adults. **Figure 3** also reveals consistent age increments in social integration and social acceptance.

Conclusion

In conclusion, psychological well-being is a term used synonymously with subjective well-being and sometimes specifically to refer to a specific kind of subjective well-being. The most inclusive term, subjective well-being, refers to the evaluations and judgments individuals make about the quality of their lives. This domain of gerontological research, sometimes called successful aging because of its focus on positive measures of mental health by age, reveals a diversity of kinds of subjective well-being. A host of studies reveal that subjective well-being consists of two broad traditions that reflect hedonic well-being and eudaimonic well-being. Measures of emotional well-being reflect the hedonic tradition, in which quality of life improves as individuals perceived their lives as more emotionally satisfying. Measures of psychological well-being and social well-being reflect the eudaimonic tradition, in which quality of life improves as individuals see themselves functioning more fully to their potential and capacities.

Overall, research (based primarily on the MIDUS study) suggests that subjective well-being improves between the ages of 25 and 74. Overall, positive affect tends to increase while negative affect tends to decrease with age. Overall, psychological well-being tends to improve with age. Four of the six dimensions of psychological well-being increase with age in the MIDUS study, while personal growth and purpose in life show age decrements. Social well-being, on the other hand, reveals a more balanced profile of age increments (i.e., in social integration and social acceptance) and age decrements (i.e., in social contribution and social coherence), while social actualization is lowest among the young and oldest adults (i.e., it peaks in middle-age).

Reaction Time

T A Salthouse, Georgia Institute of Technology, Atlanta, GA, USA

This article is reproduced from the previous edition, volume 2, pp 377–380, © 1996, Elsevier Inc.

Glossary

Choice Reaction Time – The time between the presentation of one of several stimuli and the occurrence of one of several responses. It is termed choice reaction time because a discrimination has to be made between two or more stimuli and a different response made depending on which stimulus was presented.

Cognition – Mental or intellectual abilities, typically assessed with special psychometric or experimental tests.

Neurological Status – The level of one's health with respect to the central nervous system.

Perceptual Speed – A cognitive ability usually assessed with simple paper-and-pencil tasks requiring search or discrimination tasks.

Slowing – The decrease in speed in many reaction time and perceptual speed tasks associated with increased age.

Speed – The rate at which an individual can carry out many processes. Typically assessed with choice reaction time and perceptual speed tasks.

Introduction

Reaction time is typically measured in terms of the time elapsing between the presentation of a stimulus, which is often a brief visual or auditory signal, and a discrete response such as the press or release of a response key, the initiation of a movement, or the emission of a vocal response.

Historical Background

The first systematic assessment of the relations between adult age and reaction time (RT) was performed by Galton in the late 1800s, although analyses of his data were not published until much later. There were sporadic investigations of the relations between age and RT until about 1950, when interest in this topic increased because of an assumption that an individual's RT might be informative about the status of his or her neurological system. A number of studies then appeared in which RT was the focus of the research.

Beginning in the 1960s, there was an increase in the use of RT as a primary dependent variable because it was assumed to reflect the duration of interesting mental processes. RT measurement in the context of mental chronometry has been a valuable tool in the information-processing perspective on cognition, and a very large number of studies have been reported within this tradition. In recent years a major issue in RT research has been the extent to which RT measures reflect general or specific age-related influences.

Importance

There are three major reasons why RT is an important topic in gerontology. First, the speed with which a simple response can be produced is a very elementary behavioral measure, and therefore may function as a relatively direct indicator of an individual's neurological status. Second, studies of RT have revealed moderately large age relations, and these relations are among the most consistent and robust in all of the behavioral sciences. And third, RT measures have been found to be related to measures of higher cognitive functioning. In fact, measures of speed are actually included in several intelligence test batteries. These three points are elaborated in the following sections.

Indicator of Neurological Status

RT has been considered a reflection of neurological status because a rapid response to an external stimulus not only requires intact sensory and motor processes, but also an efficient system of communication between input and output processes. There are clearly many neurological conditions that could exist

with little effect on RT, but at least at a very gross level it seems reasonable to assume that factors related to intactness of neural connections contribute to the efficiency of responding to environmental stimuli.

Unfortunately, although RT has been assumed to have sensitivity to certain neurological conditions, its specificity is unknown. That is, because all the factors responsible for slowed RT have not yet been identified, slow RT is not necessarily informative about the specific types of neurological impairment that might exist. Among the neurophysiology factors that have been mentioned as possible contributors to age-related slowing are loss of neurons due to vascular complications, reductions in degree of myelination, extent of dendritic branching, or in the quantity of certain neurotransmitters. Until these alternatives can be discriminated, RT may have limited value as an indicator of particular types of neurological impairment.

There is some evidence that age-related slowing is not simply mediated by poorer health because slower RTs with increased age are still evident in samples of adults who report themselves to be in good to excellent health. However, it has been reported that the age-related slowing was greater for individuals reporting incidents of head trauma or general anesthesia, and thus this conclusion should probably be considered tentative until more data are available.

Robustness of Age Relations

In an earlier review of adult age differences in speeded performance, it was found that the median of over 50 correlations between age and a variety of speed measures was 0.45. The magnitude of the relations between age and measures of RT can also be illustrated with results of several recent studies. For example, in a study similar to that of Galton, RTs were obtained from visitors to a public exhibition. In a sample of 2190 adults age 20 and older, simple RT to a single stimulus increased approximately 0.7 ms per year.

Comparisons of simple RT and choice RT are also interesting because the difference between the two times can be interpreted as the time to discriminate between stimuli. That is, choice RT involves a different response for each stimulus, and simple RT consists of the same response to all stimuli, and thus the additional time needed for the choice RT response can be assumed to reflect the duration of the added process. In another study, both simple and choice RT tasks were administered to 1265 adults (833 males, 432 females) between 20 and 90 years of age. The regression equations in this sample indicated an increase of about 0.5 ms per year for simple RT and an increase of about 1.7 ms per year for choice RT. Because the age trends are greater in the measure requiring stimulus discrimination, results such as these suggest that age-related effects on RT are not simply attributable to slower sensorimotor processes.

Age relations have also been investigated in more complex RT tasks. For example, a wide range of tasks can be created in which one response (depression of one key) is made when two stimuli are the same in some dimension, and another response (depression of a different key) is made when the two stimuli are different. To illustrate, in one version of the task the stimuli can be pairs of digits, with the decision based on physical identity, and in another version of the task the stimuli can be pairs of digits and symbols, with the decision based on whether the digit–symbol pair was equivalent according to a code table displayed simultaneously with the stimuli.

Figure 1 illustrates means by decade for these two measures in a sample of 583 males and 776 females, with between 70 and 152 individuals in each decade. Notice that the age trends are monotonic and nearly continuous and that the patterns are nearly identical for males and females. However, the average RTs are greater, and the age-related effects are larger for decisions based on associational equivalence (i.e., digit–symbol) compared to those based on physical identity (i.e., digit–digit). Regression analyses for the physical identity RT measure revealed an increase of approximately 6.4 ms per year, whereas those for the association RT measure had an increase of about 15 ms per year.

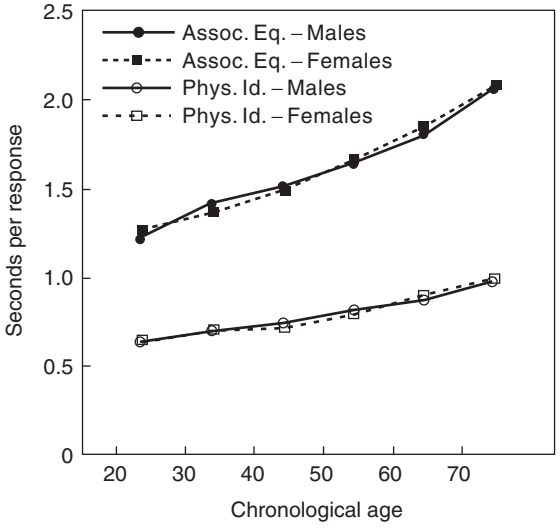

Figure 1 Mean reaction time for physical identity and associational equivalence decisions as a function of age.

The pattern of larger age-related effects on measures in which greater amounts of cognitive processing seem to be required is consistent with a large amount of data in the gerontological literature. That is, when the task is merely to make a predetermined response to a single stimulus the age effects are rather slight (e.g., less than 1 ms per year); when the task requires a choice between different stimuli with a different response to each stimulus, the age effects are somewhat larger (e.g., about 1.5 to 2 ms per year); when the task requires two stimuli to be compared the age effects are larger (e.g., about 6 ms per year); and when stimuli are to be compared on the basis of an association then the age effects are even larger (e.g., about 15 ms year).

Because similar patterns of age relations have been found with other speed measures, such as paper-and-pencil tests merely requiring simple motoric responses (e.g., connecting lines, copying digits) or also requiring cognitive operations (e.g., comparison or substitution), RT measures have been interpreted as reflections or indicators of a more general processing speed construct. Age relations on four paper-and-pencil tests hypothesized to reflect sensorimotor speed (i.e., connecting lines: boxes, or copying digits: digit copying), and perceptual comparison speed (i.e., comparing letters: letter comparison, or comparing patterns: pattern comparison) are illustrated in **Figure 2**. Notice that the age trends are relatively slight (i.e., about 5 ms per year) for the two sensorimotor tasks, but larger (i.e., approximately 20 and 56 ms per year) for the two perceptual comparison tasks.

In addition to similar patterns of age relations, speed measures from paper-and-pencil tasks have also been found to have moderate correlations with RT measures. For example, in two samples of 372 adults, the correlations between the paper-and-pencil Pattern Comparison measure and the digit symbol RT measure were 0.60 and 0.61.

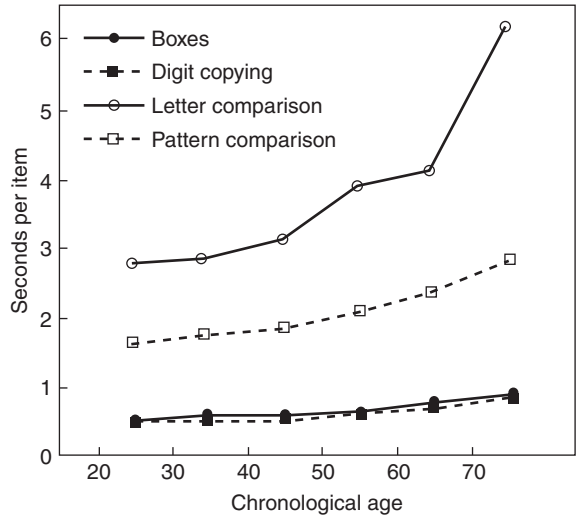

Figure 2 Mean levels of performance in four speeded paper-and-pencil tasks as a function of age.

Relation to Cognition

As noted earlier, speed measures have been incorporated into several widely used cognitive test batteries. The fact that paper-and-pencil speed measures have been found to be moderately correlated with more traditional measures of cognitive functioning indicates that some relation exists between speed and cognition. Moderate relations between RT and paper-and-pencil speed measures and a variety of cognitive measures have also been found in several experimental studies, including some in which the cognitive tests were administered under self-paced conditions with no external time limits.

In several of these studies statistical control analyses have been conducted in which statistical procedures were used to equate people of different ages on an index of speed before examining the relation between age and measures of cognitive functioning. The typical outcome from these analyses has been that the age relations on cognitive functioning are greatly reduced after statistical control of speed. Moreover, with certain combinations of speed and cognitive measures the statistical control procedure has resulted in the complete elimination of the age-related variance in the measure.

Results such as these imply that RT and other speed measures reflect something that is important for the age differences in cognitive functioning. What is not yet obvious is the exact nature of the processes or factors assessed by speed measures that contribute to the age-related variations in cognitive functioning.

Religion and Spirituality

S H McFadden, University of Wisconsin, Oshkosh, WI, USA

Glossary

Extrinsic Religiosity – An instrumental, utilitarian orientation toward religion adopted to provide personal and social well-being; religion used as a means to an end.

Intrinsic Religiosity – An internalized religious orientation in which faith is integrated into beliefs, behaviors, and feelings; religion lived as an end in itself.

Spirituality – A motivational-emotional phenomenon associated with a sense of meaningful integration within the self, with other persons and the world, and with the divine.

Introduction

Once relegated to the margins of gerontology, the study of religion and spirituality now attracts attention from researchers and practitioners representing disciplines that include psychology, sociology, medicine, theology and religious studies, social work, history, literature, the arts, and public policy. The article on religion and spirituality in the first edition of the *Encyclopedia of Gerontology* observed that 'religious gerontology' was emerging in the mid-1990s as a legitimate focus of study for these disciplines, although it also noted that from the 1950s to the 1980s, only a few researchers – primarily sociologists – conducted research on religion and aging. This article begins by examining the current context for thinking about religion, spirituality, and aging, and then reviews major points from the earlier entry in light of recent developments in the field. The article concludes with reflections on themes for scholars and researchers to consider as the baby boom cohort moves into late life.

Contexts for the Study of Religion, Spirituality, and Aging

The life span perspective embraced by most people who study aging processes and older adults emphasizes the ecology of development. This means that gerontologists pay close attention to contextual issues that affect the people they study, the way they formulate their research questions, the methods they employ to gather data, and the conclusions they reach from analyzing the results of the research. The ages of research participants, the shaping events of cohorts' development, and the historical period in which the research is conducted influence the information added to the knowledge stream in gerontology. This is no less true for the study of religion and spirituality than for other topics addressed in this encyclopedia. Therefore, it is important to examine some of the contextual issues that have affected the study of religion and spirituality since the early 1990s. These contexts affect both researchers and the persons who participate in their research.

Some gerontologists, particularly those who conduct qualitative research from a feminist, postmodern perspective (a good example is the work of Janet Ramsey and Rosemary Blieszner), believe it is important to be aware of how the personal perspectives of researchers affect the research enterprise. As author of this article, as well as the previous one, I come to the study of religion and spirituality from the discipline of psychology, particularly the psychology of religion. Psychologists have studied religion

for over a century, although their work has not received wide recognition in the field. Recently, however, this has begun to change, and many of the contextual forces driving increased interest in religion and spirituality among gerontologists are also affecting psychologists. Research on religion and spirituality has become more scientifically rigorous and thus more acceptable in mainstream scholarly journals. The emerging area of 'positive psychology,' which has received widespread attention in the discipline, has created a supportive climate for research on religion and spirituality by emphasizing human strengths, self-transcendence, forgiveness, awe, wonder, gratitude, and hope.

Another influence on the topics reviewed here comes from the fact that my work has been conducted in an environment in which religion, spirituality, and aging are studied primarily from Christian and Jewish perspectives. Although there are some excellent publications on Buddhist, Hindu, and Muslim older persons and the ways their religious beliefs affect various outcomes such as satisfaction with life, the majority of current research publications focuses on participants from either Christian or Jewish denominations, or participants who identify with no religious groups. With the rapid increase in ethnic and religious diversity in the United States, as well as the growth of research on aging in other parts of the world, this situation will undoubtedly soon change, and gerontologists who study religion and spirituality will need to include other world religions in their studies.

Several streams of religious thought and action have converged in the early period of the twenty-first century and have shaped the general intellectual climate, sometimes referred to as the *Zeitgeist*. These include worldwide attention to terrorist groups that claim their actions spring from devotion to religion. Since September 11, 2001, the word 'terrorist' has often been connected with two other words: 'fundamentalist' and 'Muslim.' This has resulted in stereotypes that foster prejudice about all persons who might be called fundamentalists or who embrace the Abrahamic faith tradition of Islam. Another influence on the public's thinking about religion, particularly in the United States, comes from tensions between religion and science, and between religion and politics. This has prompted considerable discussion in academic circles of a wide variety of issues related to how religious faith affects individuals and social groups. However, gaps still exist in scholars' knowledge of religious diversity – gaps sometimes reinforced by social attitudes. For example, the noisy debate about the relation between religion and politics in the United States has solidified stereotypes of evangelicalism and fundamentalism by connecting them with the political category of the 'religious right.' Like all stereotypes, these fail to recognize the diversity and complexity of evangelical and fundamentalist forms of Christianity.

Some of the increased attention to religious topics has resulted from observations of the rapid growth of certain religious groups. Evangelical Christian congregations (often not denominationally affiliated), along with Roman Catholic parishes serving racial and ethnic minority populations, are expanding rapidly, while traditional, 'mainline,' White Protestant congregations are shrinking. Faith communities that are growing often emphasize programs designed to attract families and meet the spiritual needs of children and young adults. In contrast, many religious older people have roots in congregations that are not experiencing this kind of growth. The emphasis on promoting congregational growth by serving younger people can lead to the conclusion that faith communities with high median ages (e.g., those serving mainline Protestants or Jews) are 'dying' and thus a poor 'investment' of religious groups' resources. In other words, ageism can be just as prevalent in religious organizations as in secular settings.

With some exceptions, Christian and Jewish seminaries that educate the next generation of congregational leaders have tended to focus on ways to nurture young families rather than on ministry with aging persons. This situation may be slowly changing, however. With greater recognition of aging demographics, some recent publications have received attention because of their thoughtful treatment of theological and pastoral care issues related to older persons. For example, Stanley Hauerwas – a theologian once described as 'America's leading theologian' by a popular news magazine – has collaborated with several colleagues to edit a book that addresses the theological and ethical challenges to aging Christians in the twenty-first century. Some examples are the tension between secular and religious views of sources of late-life well-being, moral obligations of aging persons, conflicts between capitalist and religious assumptions about dying and death, intergenerational continuity in religious communities, memorial and funeral practices, Christian meanings of suffering, and responses to calls for physician-assisted suicide. A book on Jewish pastoral care edited by Rabbi Dayle Friedman, a leader in seminary training for rabbis working with elders, contains many chapters relevant to work with older persons, including those with dementia. Authors of these chapters wrestle with the nature of healing relationships, pastoral responses to suffering, Jewish understandings of prayer and presence, and Jewish

pastoral care for people who are very ill, dying, or grieving losses.

Prompted in part by greater awareness of the number of people with dementing diseases and the need to provide holistic care that values the personhood of all who suffer from Alzheimer's disease and related dementias, practitioners and researchers are paying attention to their spiritual needs and potential for spiritual growth. Evidence of this can be seen in the second volume of *Aging, Spirituality, and Religion: A Handbook,* which has four chapters entirely devoted to dementia; the first volume had none. The journal *Dementia* devoted an entire issue in 2003 to the subject of spirituality and dementia. Topics covered included effects of personal spirituality on the quality of life of persons in early-stage dementia, experiences of Christian, Jewish, and non-religious spousal caregivers, and approaches to spiritual care of persons with dementia. In addition, Elizabeth MacKinlay, Director of the Centre for Ageing and Pastoral Studies in Australia, has edited several books that address dementia.

MacKinlay's work highlights numerous creative ways of applying the scholarship and research of theologians, ethicists, and social scientists to the design of supportive interactions with older adults. Long interested in late-life depression and the possibility that hope can arise from despair, MacKinlay argues that some persons can be helped by being encouraged to explore their need for ultimate meaning in life. Pastoral caregivers and other practitioners attuned to spiritual needs can assist people in finding ways to experience transcendence of disability and loss. Out of this kind of nurturing relationship, older persons may discover a renewed sense of intimacy with God and other persons. In addition, MacKinlay's research has documented how spiritual reminiscence in small groups can help even those with dementia to discover a deeper sense of life meaning.

Another example of the convergence of research and practice comes from work on caregiving. This has been a topic of great interest to gerontologists for many years and has been the object of considerable research. A number of studies have identified religion as an important variable that buffers caregiver stress, particularly among African Americans who perceive greater rewards from caregiving, in all likelihood because of the comfort they experience in religious practices, including prayer. This research supports the important work of faith communities in providing various forms of help to caregivers such as respite care, support groups, and education about caregiving and the needs of frail elders.

Conducting research on issues related to religion and spirituality has always been challenging because of the complex, multidimensional nature of the subject. The current intellectual climate has added to the challenge, while paradoxically also making it possible for more of this work to be done with scientifically sound methods. For example, having adequate funding and institutional support for their work has meant that researchers can conduct large, national probability studies of diverse samples of older persons. In the United States, numerous private foundations as well as federal agencies like the National Institute on Aging have supported this work, and scholarly journals now publish articles on religion that never would have appeared 20 years ago. On the other hand, some researchers worry that some funding sources may promote religious or political agendas that are incompatible with the pursuit of science. Nevertheless, there have been many important developments in the study of religion, spirituality, and aging in the last decade.

A Decade of Research on Religion, Spirituality, and Aging

Definitions and Measures

The article on religion and spirituality that appeared in 1996 included a lengthy discussion of definitions of religion and spirituality. At the time, scholars and researchers were debating the need to define 'religion' and 'spirituality' as discrete phenomena. The context for this was the commonly noted observation in the 1990s that many people claimed to be spiritual but not religious. Researchers were concerned that standard measures of religious behaviors (such as prayer, reading sacred literature, and worship attendance) and beliefs (in a deity, an afterlife, etc.) would exclude those persons who had preserved a sense of the sacred while rejecting so-called 'organized religion.'

Many writers identified religion with institutions that promoted rigid, dogmatic perspectives on human life, whereas spirituality was viewed as more amenable to individual desires to select beliefs and practices from many faith traditions, or to invent new ones. Debates about definitions permeated the literature for several years, although interestingly, these issues were probably more salient to the young and middle-aged researchers than to their older adult research participants. Several studies found that older people described themselves as religious because of their institutional connections, long-held beliefs, and in some cases ethnic identities; unlike many researchers, they tended to equate being religious with being spiritual.

In 1997, Brian Zinnbauer and his colleagues presented research findings that persuasively showed that these two constructs overlap but are distinct. Titled 'Unfuzzing the fuzzy,' their paper argued that both religiousness and spirituality involve beliefs, feelings, and behaviors associated with a search for the sacred – the human conceptualization of ultimacy that transcends material existence. However, religions go further by defining the sacred realm for communities of believers and providing shared methods of approaching, experiencing, and responding to the sacred.

A year later, Robert Wuthnow reported on his studies of the changing landscape of spirituality and religion in the United States and concluded that some people focus on 'dwelling' within patterned, communal, traditional ways of approaching the sacred, while others emphasize 'seeking' the sacred outside of the boundaries of religious institutions. Wuthnow argued that arguments about the merits of dwelling (religiousness) versus seeking (spirituality) missed the point; he stated that a third focus – practice-oriented spirituality – was needed. This refers to practices that originate within religious institutions and are strengthened as people engage in them privately. This view of spiritual disciplines nurtured within a faith community may turn out to be important for how the baby boom cohort attends to religious and spiritual matters as it moves into later adulthood.

Among the current cohorts of older adults, researchers continue to find high levels of professed religiousness, although it is important to note the many ways this can be measured. The multidimensional nature of being religious is now more widely recognized, and researchers are employing a number of scales to assess various aspects of religiousness. Using more than one scale is necessary because, for example, a scale that assesses aspects of an older person's prayer life would not address that individual's involvement with service activities sponsored by religious organizations. For a long time, it has been recognized that older adults' rates of religious attendance may not necessarily reflect their inner feelings of being religious since physical incapacity might prevent them from getting to worship services. Nevertheless, there continues to be a need for measures of religiousness and spirituality that reflect the life worlds of frail persons and those with dementing illnesses.

Diversity

Women of all ages score significantly higher than men in measures of religiousness. Researchers are now attempting to understand the reasons for this difference, which has been repeatedly observed across many cultures. One study showed that gender alone may not be the significant influence. Rather, norms of masculinity may reduce older men's willingness to engage in private religious devotions. Those with a more feminine outlook on life (e.g., with less emphasis on 'toughness') show more intrinsic religiousness. On the other hand, men with low scores on feminine gender orientation (measured by the well-known Bem Sex Role Inventory) are more likely to take leadership roles within their faith communities when they participate in them.

The question of religious diversity is growing increasingly important, although as stated previously, most of the research on religion, spirituality, and aging has involved participants from Christian and Jewish traditions. Even within those groups, however, it is important to recognize diverse theological and social perspectives. Just separating Protestants from Catholics in the Christian tradition ignores Christians from Eastern Orthodox traditions and overlooks vast differences in theology, polity, and practice both within and between denominations. Among Jewish congregations, variability among practitioners of Orthodox, Conservative, Reformed, and Reconstructionist Judaism is rarely acknowledged. Even within religious groups, older and younger persons may have divergent views on worship, private prayer, sacred literature, and rituals like weddings and funerals. Thus, it is important to understand how historical changes within religious traditions may have affected different cohorts' religious faith and identity. For example, the researcher whose knowledge of Catholicism rests upon assumptions formed post-Vatican II may fail to appreciate the spiritual world occupied by those socialized into the faith before Vatican II.

Diversity in race and ethnicity also affects how religiousness and spirituality are experienced and expressed by older people. Neal Krause, a prolific researcher on this issue, has concluded that people of different races experience the same religion (e.g., Christianity) in very different ways. Compared to White Christians, older African American Christians score higher on various religiosity measures, including worship attendance, service sponsored by the congregation, and prayer. Some research with older Blacks shows that they receive greater health benefits from their religious involvement than Whites. Similarly, a longitudinal follow-up of research on older Mexican American Christians found an association between church attendance and reduced risk of mortality; those who attended church once a week had a 32% reduction compared to those who never attended services. Now researchers need to determine

the reasons for variability in the salutary effect of religious attendance in different racial and ethnic groups. One source of promising suggestions comes from work in the areas of positive psychology and health psychology on cardiovascular health. Some studies suggest that people who attend religious services have less hostility and anger and more optimism and hope. Linda Chatters, another prominent researcher on race and religion, has suggested that for African Americans, religious communities reinforce strong social ties and shared beliefs that promote feelings of hope and optimism. She also notes the prophetic function of religion and the way it has functioned within minority communities to mobilize people's critiques of social oppression.

Sexual orientation represents a category of diversity that was rarely noted in the literature on religion, spirituality, and aging a decade ago. Here is another example of contextual forces influencing research and practice. The twenty-first century opened with considerable ferment within religious groups over homosexuality. The community of lesbian, gay, bisexual, and transgendered (LGBT) persons has been welcomed in some religious communities but has been the object of scorn and rejection from others. In 2003, *Aging and Spirituality*, the newsletter of the Forum on Religion, Spirituality and Aging (a constituent group in the American Society on Aging), was devoted to the theme of 'meeting the spiritual needs of LGBT elders.' The authors urged chaplains to recognize that LGBT elders living in long-term care facilities often fear rejection should their sexual orientation be identified. They also described how long-time members of faith traditions that actively campaign against homosexuality experience abandonment by clergy and fellow congregants. The effects of supportive versus rejecting religious communities on the physical and mental well-being of LGBT elders have not yet received attention from researchers.

Religion and Well-being

In the last 10 years, research on religiousness, spirituality, and health accumulated rapidly. One influence on this growth was the collaboration between the Fetzer Institute, a private philanthropic organization, and the National Institute of Aging to bring together a group of researchers who had been studying religion and aging since the 1980s. In 1999, they defined 12 domains of religiousness and spirituality that are important to health, and they published a collection of instruments to measure these domains: daily spiritual experiences, meaning, values, beliefs, forgiveness, private religious practices, religious/spiritual coping, religious support, religious/spiritual history, commitment, organizational religiousness, and religious preference. This work has been widely acknowledged to have advanced the field by defining the multidimensionality of religiousness and spirituality and by providing researchers with reliable and value instruments to use in studies of health.

Two years later, the *Handbook of Religion and Health* appeared. This comprehensive review of the research literature categorized and reviewed an enormous body of research on religion, mental health, and physical disorders. Although not all of this work specifically addressed issues related to older adults, much of the work cited was from the gerontology literature, and the lead author (Harold Koenig) is widely credited as being one of the first persons to conduct large, well-controlled studies of aging, religion, and health.

In regard to mental health, the handbook showed that across the adult life span, religious beliefs and practices are associated with greater well-being, hope, optimism, purpose and meaning, self-esteem, adaptation to bereavement, and social support, and less loneliness, depression, suicidal behavior, anxiety, and alcohol and drug abuse. Marital satisfaction and stability also appear to be higher among more religious persons. Reasons for these associations include the health behaviors favored in some religious traditions, the coping resources offered by religious practices, the social support of faith communities, and the way that religious world views shape the appraisal of stressful life events. The authors took care to note that religion can also have deleterious effects upon people's attempts to cope with life's stressors, and they also reported on studies that showed no associations between religiousness and various mental health measures. However, in general, the message was that religion does have a positive effect on mental health.

The *Handbook of Religion and Health* also reviewed research on many of the serious physical illnesses that afflict older people, including heart disease, hypertension, cardiovascular disease, and cancer. Religious beliefs and practices appear to have a salutary effect on physical health through a multifactorial combination of influences that include encouraging healthy behaviors and discouraging risky behaviors, providing social support systems, and eliciting positive emotional experiences.

Neal Krause has identified six dimensions of religion that may affect health in older persons. As shown in the work on Mexican Americans mentioned earlier, religious attendance is important but very complex to study, as it involves so many different experiences, such as communal singing, silent

prayer, listening to sermons, and having a cup of coffee after worship while chatting with fellow congregants. Prayer has been identified as contributing to health and well-being, although again the picture is complicated by different forms of prayer, beliefs about prayer, physiological responses to prayer, and experiences of connections to others and to God. Prayer represents one form of religious coping, another factor in the relation between religion and health in older people. Encouragement and support for forgiveness by religious communities may alleviate stress and produce positive health outcomes in older adults. Faith communities offer older adults considerable social support that can take many forms, such as public prayers for the sick, inquiries about well-being after a worship service, or a casserole delivered when a person returns from a hospitalization. Finally, Krause notes that religion provides a sense of meaning, which involves not merely an intellectual assessment but also a positive emotional affirmation of life in spite of the suffering and loss of old age.

Across the life course, these dimensions of religiousness can change in significant ways, with some becoming more important and central to a person's life, and others fading in significance. For example, a homebound elder may no longer experience the salutary effects of religious attendance, but may instead develop a more meaningful prayer life. Or prayer may become challenging for the person experiencing dementia, but that individual can still benefit from the loving care and attention of members of the faith community.

Religious and Spiritual Development

The earlier article on religion, spirituality, and aging described a paucity of research on religious and spiritual development in adulthood and a lack of clear answers to the question of whether people become more religious as they grow older. This situation has significantly changed in the last decade with the publication of research using data from longitudinal studies, the development of a validated measure of spiritual life history, investigations of spiritual turning points, and widespread use in congregational and long-term care settings of various approaches to spiritual autobiography.

Paul Wink and Michele Dillon have published a number of papers reporting on their analyses of longitudinal studies of a group of men and women born in the 1920s. This rich source of information about aging and development through the twentieth century has produced several important insights about religious and spiritual development. Wink and Dillon employ Wuthnow's metaphors of 'dwelling' and 'seeking' to describe either people who emphasize traditional religious beliefs as nurtured and supported by religious institutions, or people who focus more on individual quests for connections with the sacred. The participants in this longitudinal study have been interviewed periodically from childhood and adolescence through adulthood, and they have completed numerous psychometric instruments. Wink and Dillon found that the religious lives of the dwellers have been relatively stable, although after midlife, interest in spirituality increased, especially among women. Religious dwellers experienced well-being as a function of their meaningful social interactions and involvements in their communities. People who emphasized seeking also experienced well-being, though this feeling was derived more from individual creative pursuits, acquisition of knowledge, and attention to personal growth.

Another line of research on religious and spiritual development has examined religious trajectories and transitions across the life course. This work employed interviews with older people reflecting on the role of religion in their lives. The authors identified several dimensions of religion that may change as people age: their religious affiliations, the nature and extent of their religious participation, their tolerance for different religious beliefs, their prayer lives, and the salience of religion (experienced in terms of relationship with God, and the balance between certainty and doubt). This research also revealed four different trajectories of religiosity: an increase through adulthood, stability, a decrease, and an ebbing and flowing pattern with religion having greater or lesser significance and influence at different points in adulthood. Finally, the authors identified what they called 'forces' that either increased or decreased religiosity in their participants' lives. Growth in religiosity results from joining a faith community, raising children, having more time for reflection, and experiencing adversity. Reductions in religiosity were associated with children leaving home, disillusionments with religious leaders and institutions, and again, adversity.

Another study on spiritual turning points offers some help in understanding why some people experience an increase in religiosity with adversity and others fall away from their former religious convictions. Interviews with older adults about these turning points found that nearly half occurred during midlife. Most were triggered by loss of some kind. These negative experiences were associated with feeling a loss of control. Some persons had a sense of external control, believing that God was completely in charge of their fates. Others displayed what the authors called 'God-mediated control,' in which

they saw God as a friend or guide with whom they could communicate and from whom they could derive strength and courage. Use of coping strategies that employed this God-mediated sense of control in times of adversity enabled these persons to overcome feelings of helplessness and recover their own sense of personal control.

The data on spiritual turning points were collected as part of a larger study aimed at developing a valid and reliable scale to assess dimensions of an older person's spiritual life history. The research identified four important factors reflecting religious and spiritual experience across a lifetime: lifelong experiences of asking for and receiving help from God, a family history of religiousness, religious social support experienced through adulthood, and the 'cost of religiousness' (problems experienced in religious life such as conflicts within religious organizations). These factors were then examined to see how well they added to explanations of health outcomes based on religious attendance. Only the family history factor failed to be associated with health status (though it significantly predicted consistency in religious affiliation through the years). This study is an excellent example of how examination of factors affecting religious and spiritual development through life can provide insights into the reasons why religion seems to be so strongly associated with late-life physical and mental well-being.

In addition to research on older adults' religious and spiritual development, programs have appeared in recent years to encourage older people to conduct their own spiritual life reviews (sometimes called spiritual autobiographies). Several 'how-to' books have been published for use by individuals and by groups, usually within the setting of a faith community or long-term care facility. David Moberg, a major figure in twentieth-century studies of religion and aging, has suggested that engaging in spiritual life review can help older people to identify their spiritual needs and to evaluate how well they are being met. These needs include meaning and purpose, love and relatedness, forgiveness, spiritual integration, coping with loss, freedom to question, flexibility, preparation for dying and death, being useful, and expressing gratitude. Moberg details several activities that he believes are important for a spiritual life review: listing major turning points in life and reflecting on their spiritual impact, describing religious doubts and fears, identifying blessings, discerning the spiritual meaning of life experiences, rating periods of life in terms of spiritual growth or stasis, and determining a spiritual legacy to be left to others. Moberg urges elders to share their spiritual life reviews with other persons. He believes that through this process, people can discover the possibility of spiritual growth even at a time in life when they feel more like they are shrinking than growing.

Definitive answers to the question of whether adults increase in religiousness and spirituality as they grow older still elude researchers. However, longitudinal studies of religious trajectories, cross-sectional comparisons of religiousness, and retrospective accounts of spiritual life histories all point to the conclusion that most aging persons do experience increased engagement with the search for the sacred, and many call upon the beliefs, rituals, and sacred texts of established religions to support that search.

Researchers now can anticipate working in a kind of natural laboratory as they observe the aging of the baby boom cohort. Many important questions about religion and spirituality have already been posed to members of current cohorts of older people; in 2025, when the oldest members of the baby boom cohort are approaching age 80, we will undoubtedly have a clearer picture of their late-life religious and spiritual development that can be compared with data collected from earlier cohorts and interpreted in the context of well-developed theories of adult development and aging.

Looking Ahead

A number of important new topics have emerged in the literature on religion, spirituality, and aging, and they will undoubtedly be addressed in the next edition of this encyclopedia. These topics include forgiveness, gratitude, prayer, and service to others. In addition, new areas of research and scholarship are just over the horizon, with the merest hints of their existence beginning to seep into some published work. For example, in another decade or so, we may better understand some older adults' desire to become more involved with mystical traditions associated with their religions. Also, discussion about the arts and late-life spirituality is just beginning and will undoubtedly grow in the coming years. The role of faith communities in nurturing religious and spiritual development through involvement with the arts and the practice of meditative disciplines will need to be carefully examined. This work cannot be done solely by social scientists and health researchers; greater participation by scholars with roots in the humanities will be imperative.

A number of behaviors associated with being religious such as forgiving others, expressing gratitude, praying, and offering help should be examined in light of theories about how older adults adapt to

the vicissitudes of aging, regulate emotions, and maintain good social relationships. Instead of merely documenting that older people are more willing than younger adults to forgive others, express more gratitude about the blessings in their lives, pray more often, or show more caring concern for others, researchers in the future will increasingly base hypothesis testing on well-supported psychosocial theories of adult development and aging.

Along the journey of life, many older adults discover that holding grudges, extracting acts of contrition, being bitter, and refusing to forgive or help other people create more stress. Focusing on the positive aspects of life and being grateful for them is an important way in which older adults regulate their emotions. Religious beliefs and acts, supported by participation in faith communities, can offer considerable support and encouragement for living this way. Moreover, when life's 'shipwrecks' come along, older adults are most likely to turn to religious coping, as amply documented in the work of Kenneth Pargament and his colleagues. A major challenge for future researchers will be to assess how the next cohort of elders employs religious resources to cope with the losses and narcissistic insults of aging.

Increasingly, we are viewing older persons as individuals who are actively managing their lives by making choices to optimize well-being and compensate for deficits and losses. Even those with dementia are now being seen in this light despite their very real cognitive challenges. These are robust observations in gerontology and will likely hold up for the next cohort of elders. However, the forms these optimizations and compensations take will likely evolve and change. Aging baby boomers will create their own adaptations to aging; the work reviewed here allows us to predict that many will ground these adaptations in religious beliefs and practices that are supported by participation in faith communities.

Research on older people's religious and spiritual lives in the late twentieth century largely focused on various metrics of well-being, both physical and mental. We now have the well-being question pretty well answered. Good diet, regular exercise, avoidance of harmful substances, maintenance of positive social relationships, control of stress, and experiences of joy and happiness all have been conclusively shown to contribute to late-life well-being. Along the way, researchers showed how all these factors can be connected to certain religious beliefs and practices, although it is also clear that people can experience well-being without being religious.

Perhaps the questions that occupy researchers and scholars in the twenty-first century will not be so concerned with well-being, but, rather, with meaning. Although people will live longer, healthier lives, they will still experience suffering and mortality. Traditionally, people have turned to religious beliefs and faith communities for support and guidance in their efforts to make sense of the contingencies of human life. In the future, practitioners (including clergy), researchers from the behavioral and social sciences, and scholars working in the humanities may take what has already been accomplished in the study of religion, spirituality, and aging and produce a new form of gerontology focused not on well-being, but on meaning. We might call this existential gerontology.

Reminiscence

B K Haight, Medical University of South Carolina, Charleston, SC, USA
B S Haight, Sullivan's Island, SC, USA

Glossary

Guided Autobiography – Facilitated meetings for individuals to produce a record of their lives while exploring the journey with others in a group.

Reminiscence – The process of recalling the past.

Simple Reminiscence – Remembering the past for enjoyment or socializing.

Structured Life Review – A process of reviewing, reorganizing, and reevaluating the overall picture of one's life until it is acceptable to the self.

Introduction

Reminiscence is the process of recalling the past. The memories produce a product: a biography, a story, or a narrative. The product is accessed and reconstructed throughout one's life, and current events continue to color and influence the memory. The topic of remembering the past has captured the imagination of writers for years, but only since the 1960s has the process of reminiscing been seen as a helpful method, rather than as a wandering of the mind.

Since the early 1960s, when a seminal article was written by Butler describing the presence of reminiscing and life review in older people, there has been a proliferation and confusion in the literature regarding reminiscing approaches. Presently there are several approaches falling under the reminiscence paradigm. This article focuses on comparing and contrasting three specific and well-defined approaches to reminiscing: simple reminiscence, guided autobiography, and structured life review. Thus, this article clarifies more than philosophizes.

Three Common Approaches

The following is a general description of each of the three most common reminiscence approaches: simple reminiscing, described by Burnside, Gibson, and Merriam; guided autobiography, based on work published by Birren and Deutchman; and structured life review, according to Haight and Bahr. Though each of these processes uses long-term episodic memories, each approach is a unique and defined method for accessing memory. To clarify and simplify, **Table 1** compares the differences and similarities among the three approaches and presents the separate elements of the three processes under the headings of initial

purpose, components, procedure, and outcomes. Understanding the comparative elements of these three approaches is particularly important for lucid and coherent research. The discussion of each approach follows the differential analysis set out in **Table 1**.

Simple Reminiscing

Simple reminiscing is a broad term, within which all types of recall can occur, but here it is simply remembering the past. Gibson described memory as much more than recall of past stimuli. It involves emotion, will, and creativity in the reconstruction of the past to serve present needs. Burnside described reminiscence as spontaneous and free flowing, occurring in a group or occurring individually when instigated by an event. Simple reminiscence can perhaps be defined as using the past to serve the present.

Initial Purpose The basic purposes of simple reminiscing are usually for enjoying and for socializing. Additional purposes include encouraging informal conversation, promoting emotional and social stimulation, using reminiscence in the assessment process, and creating group cohesion. Bender stressed the importance of defining a purpose before starting any intervention, because in fact the purpose will color the way the intervention is implemented and thus influence the outcomes.

Components The goals for simple reminiscence are simply to get the participants to talk about the past. Common topics that all participants can relate to, such as school years, are chosen to begin the process of reminiscing.

Simple reminiscing can occur individually with one or more persons, but therapeutically simple reminiscing is often conducted in specific groups. Burnside used reminiscing repeatedly as a nursing intervention and noted its acceptance by varied groups of older people. She had great success using reminiscence with groups who had dementia, and she often followed stringent guidelines to implement the intervention she had chosen. There is probably little structure to simple reminiscence, but when occurring in a group the leader ascertains that all participants get a chance to speak and participate. Leaders of reminiscence groups are facilitators, but the inherent expertise in the group lies with the people recounting their personal memories.

Parameters of group work must be respected when conducting a reminiscence group. Because the presence of people recalling memories often stimulates new memories in others, group work lends itself well to reminiscence. As in all groups, the leader should meet individually with potential members to ascertain that they are comfortable participating in such a group and to present the first group topic for their approval. Before the meetings start, the leader must be sure that she or he has located a physical place appropriate for group dynamics, where chairs can be placed in a circle in a relatively quiet atmosphere with few distractions such as loud music or a blaring television. Though the leader chooses the first topic for discussion, the group should pick the future topics. The group can decide on the topics, using props and pictures to stimulate memories. If the group is mixed gender, there should be a division of topics of interest, for example, cars for men and fashions for women. Often it is easier to run a reminiscence group with people who have similar backgrounds and interests. Participants may or may not be literate and educated; all can enjoy the process.

Procedure Simple reminiscence involves certain procedures for implementation. There may be only one reminiscence session, or there can be a series of them.

The act of reminiscing is spontaneous, not methodological work, so there are few rules for participants. Taking part in a reminiscing group is a pleasurable event and requires minimal work from participants. Any cue can instigate the process in one's mind, and when the thoughts are shared there is a transmission of memories to another person who may become excited to divulge similar and spontaneous ideas. The cues may be about past events or specific occasions, not necessarily about the self and the inner self. Sharing memories can create a dialogue and a connection between people.

Memories often involve emotions, and the effective leader of reminiscence must validate the emotional content of the memory as well as the memory itself. The simplest of events can contain hidden trauma in someone's memory. For instance, in a reminiscence/life review workshop, volunteers were invited to share their memories to demonstrate the reminiscence process in groups. A very safe topic was selected: memories of Thanksgiving. Participants spontaneously offered their accounts, except for one young lady not participating even though she had volunteered. When called on, she began to cry as she recounted her husband's early and unexpected death on Thanksgiving day. Her story put an end to the spontaneity and gaiety that had been taking place; the remainder of the time was directed toward putting her back together and continuing the workshop. The mistake was not sharing the topic beforehand. If she

had known the topic, she probably would have refused to engage in the demonstration.

Often memories are triggered by stimuli. A trigger is anything that causes a memory to resurface; it can be a physical prop, a picture, a book, or even an activity such as singing or music. Most triggers are harmless and helpful, especially triggers that are objects that can be touched, smelled, or eaten. Often smell will evoke a long-forgotten memory. Rooms with old-fashioned objects can act as triggers, or an activity from the past, such as cooking, can cause memories to surface. Actually, most fruitful activities with older people in nursing homes are accompanied by reminiscence in some way, even though reminiscence is not the intent. The memories are always present in the subconscious, waiting to surface. When a group of women making bread is kneading dough together, they are generally sharing past experiences from their own kitchens and families.

The time necessary to run a reminiscence group is another part of the process to consider. The reminiscence group can be a one-time affair or can continue each week. It should last for no more than an hour; however, thought must be given to the time involved in getting the participants to and from the group, especially when in a nursing home with participants in wheelchairs. One hour may cover the actual running of the group, but the time commitment on the part of the leader can be much longer.

Six participants who are homogeneous in most ways will make a most successful group. People with hearing and speech difficulties may participate, but getting prostheses, such as the earphones in movie theaters for the hearing impaired, should be planned in advance. The leader must remember that all memories are partial reconstructions, and the veracity of the memory is not as important as the joy found in the telling. For the leader, there is a continuous reward in learning from these living history books.

Outcomes There are numerous outcomes from reminiscing reported in the literature, but most importantly, reminiscence is therapeutic. Many research projects have investigated the effects of reminiscing. Rural-dwelling institutionalized women reported a positive effect on depression. This outcome was particularly important in this community, where there was no available mental health service. In a review of psychological treatments, Kasl-Godley and Gatz found that reminiscence provided people with dementia with interpersonal connections while optimizing their remaining abilities. Puentes used reminiscence with staff to teach therapeutic communication skills.

Guided Autobiography

Guided autobiography offers yet another way to reminisce. Guided autobiography creates an environment that provides the social support and mental stimulation for older adults to review their life stories and share them with others. Writing about one's life is a very powerful form of self-expression while one searches for evidence that his or her life has mattered and has made an impact on the world.

Initial Purpose The initial purpose of a guided autobiography group is to produce a record of one's life while exploring the journey with others in a group. Birren and Deutchman designed guided autobiography to promote successful adaptation to old age and to assist persons in life transitions.

Components Several of the components necessary for writing an autobiography are different from the basic reminiscing components. For example, those who participate in autobiography groups must be literate and able to read and write. They must also be educated enough to enjoy putting their words on paper. The goal of a guided autobiography group is not only self-exploration, but also to produce a book, and there is a structured format in place that helps the writer to achieve this goal. Though this is a systematic group effort, what a participant ends up writing and sharing in class has been edited continuously by the participant her- or himself, between group classes. This process of recalling past events and writing them down provides personal, private thinking time to review the past so that participants can be more thoughtful about what they share in a group.

In guided autobiography, there are specific topics or themes to be addressed at each weekly meeting. Well-designed themes are wonderful bait designed to catch elusive memories and to provide a structure to the whole process of autobiography. There are nine themes presented systematically. Birren described the nine themes as nine prisms reflecting the life story differently, depending on the theme. For example, the first theme is the major branching points in life. The assignment includes probing explanations and questions to help writers gain clarification of their own branching points. A branching point is a life choice; for example, choosing college, getting married, and having children are all significant branching points. Questions that help to clarify the themes such as "What were the events and experiences that had a major impact on the way your life flowed?" help participants to address the themes. The themes themselves prime the pump and spill forth other related

stories, or at least lead to internal thinking about specific events in the past. The themes often cause forgotten emotions to surface as people remember the past. A different theme is addressed at each meeting for nine or ten meetings, sometimes held a week apart or sometimes, in a more intense format, held every other day. Additional themes address family, work, money, health, loves and hates, sexuality, death, and the meaning of life. The autobiographical process is very systematic.

Procedure The procedure for writing an autobiography, while enjoyable, is also work and requires a great deal of effort. The process itself is planned in advance, and anyone who participates must make a personal commitment beforehand because of the time and effort involved. There is a 10-week commitment to recall and examine the participant's life through the themes that serve as the triggers and address multiple life occasions.

Rules govern the way the weekly meeting is run. At the start of each meeting the facilitator presents the theme for the next meeting. At least 30 min is set aside for discussion and clarification of the next theme. After this, refreshments may be served, allowing writers a few minutes to refocus on the theme for the present week. Then the facilitator asks the group for a volunteer to read what they had written during the past week on last week's theme. Each writer can read for 15 min with an additional 5 min set aside for the group to comment and ask questions. The facilitator guides this interchange, particularly at the start of the group's life, when participants are reticent with one another. Over time the group becomes more open and more willing to share personal issues, and often the group will lead itself. By definition, the content is about the self during multiple occasions throughout life.

The autobiography group consists of five to six writers and one facilitator, with each meeting lasting 2 h. This method of recall is systematic and open while being private and spontaneous. When people begin their homework, they are alone at home, giving them private thinking time. By the time they come to a meeting, they have had time to mentally edit their thoughts and can choose to share what they wish, instead of being caught unaware in the presence of others. Though participants write their autobiography, they can choose to read only those parts that they want to share with the group. Once they are within the group, different emotions and thoughts may surface, but if the group has been meeting and sharing for a given amount of time, the group becomes a safe place in which to share troubling thoughts. There is a group effect that occurs in this process. The group can provide immediate and supportive feedback. Individuals in the group can see that their behavior was acceptable because others in the group may describe worse behaviors, thus allowing social acceptance by the group. There is something healing about not being alone, or being not the only one who has had a particularly bad experience. The group process is effective in erasing guilt and shame, which are often the result of harboring secrets over time.

Outcomes Guided autobiography groups apparently are therapeutic, but this is known only from anecdotal evaluations of the groups by the participants and descriptive papers written by the facilitators. There are minimal research projects reporting measured outcomes, yet when people talk about their participation, it is evident that they feel better about themselves and their achievements. The addition of a quantitative evaluation of this group process would support the use of this process more widely.

Structured Life Review

Butler was the first to describe life review as a spontaneous and universal process in which life events were surveyed and reintegrated. He said that as reintegration takes place, people gain new strengths and begin to live life more purposefully. Life review is a process of reviewing, reorganizing, and revaluating the overall picture of one's life until it is acceptable to the self. The structured life review is a time-limited psychosocial intervention specifically designed for older people and readily accepted by them. This process was first established out of a need to structure the life review for research. Over time and through research, the variables that make the process unique and therapeutic were confirmed.

Initial Purpose The initial purpose of the life review is to help the participant reach integrity: a stage of wisdom and peace in which the individual accepts the way his or her life has been lived. Erikson saw integrity as the positive achievement of the eighth stage of life and defined it as accepting the way one's life was lived with no substitutions. The opposite or failure of integrity is depression and despair, a condition common to older people. The past-scanning function of the life review allows people to regain their past while sharing their memories and to view life as a whole.

Components The components of a structured life review are systematic, discrete, and different from other ways of reminiscing. Butler's definition and

Erikson's model form a blueprint for the process and dictate the purpose and goals of a structured life review. For instance, the goal of the life review is to help older people achieve high levels of integrity; this goal is accomplished through a systematic and organized developmental process of reminiscing that covers birth and childhood to the present.

By definition, the life review is structured. The structure of the life span is an integral part of the life review. Structure sometimes feels forced, as the therapeutic listener makes certain the reviewers cover all phases of their lives; however, it is very important to the process. If the intervention was not structured developmentally, reviewers might ignore childhood as unimportant because those memories are so far away. Yet childhood underlies the basis for the rest of the life and may be responsible for issues later in life. Talking about one's childhood often provides great insight. For instance, Haight and Hendrix performed a qualitative analysis of the life reviews of women who were suicidal, comparing them to women who exhibited high life satisfaction. The suicidal women often had lonely, isolated, and unhappy childhoods, resulting in lonely and unhappy girls, who married at a young age to escape from homes where they felt unloved. They then experienced loveless marriages and, since they had never learned to love, did not feel love for their own children. At age 82, while participating in the life review, one woman said, "I was born lonely"; sadly, she would die lonely as well. Structure ensures a complete story, the essence of a life review. People who have not thought of their childhood for years can relive it again. Hence, the structure helps return a sense of self and completeness to the individual.

Structured life review also helps the cognitive process that creates more orderly thinking when problem solving. In many respects, structure serves as retraining; people begin to process their thoughts more clearly. For example, in a project in nursing homes in Northern Ireland, the Mini Mental State Exam (MMSE) was given to a group of women diagnosed with dementia as a way of evaluating the group for baseline cognition. After the structured life review, the MMSE was given again at posttest, resulting in very different and significant gain scores between the group's pretest and posttest ($p < .005$), with the group receiving life review making immense gains. Because it is impossible to change the course of dementia, it was concluded that the structured remembering caused group members to think more efficiently.

The life review is performed on an individual basis. There are only two active people: the reviewer and the therapeutic listener. The therapeutic listener is the person who is conducting the life review and the reviewer is the one recalling the past. A one-to-one interaction is essential for the valuable commitment that occurs during a life review and the therapeutic catharsis that happens. This individual approach results in an intimacy, a significant other for the reviewer, but not a dependency. By doing life reviews on a one-to-one basis, the therapeutic listener provides privacy and acts as a sounding board to reflect the individual's story. Because the listener must be trained in life reviews, he or she can accept the story as it is told, and this in itself builds self-esteem in the reviewer. The reviewer shares innermost thoughts and dark secrets, while the therapeutic listener listens, accepts, and approves so that in the storytelling the reviewer begins to accept him- or herself. With that realization comes a strength that builds self-esteem and independence. The congruence and caring experienced by the reviewer creates a sense of self-worth and makes the therapeutic listener a very significant person to the reviewer. For some reviewers, it may be the first time ever that they have connected with another human being, and that connection is powerful.

People who participate in a life review need not be literate or educated because the questions are asked of them by a trained therapeutic listener. Life reviewers can be healthy and robust, but they may also be frail, ill, at the end of life, and dying. As opposed to both autobiography and reminiscing, life review is performed in private and on an individual basis and thus lends itself to being used with less healthy populations and at the bedside or in a participant's home.

Procedure The procedure that directs a life review is systematically planned. Six to eight 1-h sessions cover the review unless the participant is very old or sick and cannot talk for an hour. If that is the case, the sessions are spread out, but the total amount of time spent reviewing is about 6 to 8 h. The hours are allocated so that the first 2 h are devoted to childhood, family, and home. The second two are devoted to adulthood, and the last two are spent summarizing and evaluating the reviewer's life. When the life review is initially negotiated, the person who is reviewing is given the life review questions and told how the process will be conducted; thus, she or he has full disclosure before agreeing to participate.

The structured life review is guided by questions in a form known as the Life Review and Experiencing Form (LREF), derived from Butler's definition of the life review. These questions are similar to the themes in autobiography in that these questions provide structure, instigate thought, and serve as bait when the participant is fishing for memories. The questions

do not demand an answer but rather serve as probes to help the reviewers explore their lives and perhaps think about things they have not recalled for some time. For example, regarding childhood, the listener might ask whether the reviewer ever felt lonely, who they admired most, if they were ever afraid, or whether they had had enough to eat. When addressing adulthood, the focus is more on jobs, relationships, sexuality, and achievements. Finally, what is called the summary is reached. The summary actually causes an evaluation to take place and includes provocative questions such as "On the whole, what kind of life do you think you've had?" "What was the hardest thing you had to face in your life?" and "What would you change and do over?"

Although these questions are simplistic, what they reveal is often amazing. For example, a Japanese gentleman who had survived the war in Japan and now had dementia was initially totally focused on food. During his life review, he discussed living in the woods, stealing food, and always being hungry. In his dementia, he was continually worried about being hungry, and he began stealing and hoarding food in his daughter's home. During his fourth session, he started to laugh and said it was no wonder he cared about food so much. Surprisingly, he had gained insight into his hoarding behavior, and he became less focused on food and able to enjoy life more.

The amount of time spent in a life review seems essential. The life review process cannot happen in 1 h or in a one-time visit. The relationship between listener and reviewer must build and trust must develop for the therapy to happen. A 6- to 8-week intervention is optimal. In the third week, something happens: people realize what they are doing, and most eagerly embrace the opportunity to continue to disclose, or they may decide against the intervention and ask to drop out. In addition to the time commitment, the life review is work and requires a great effort on the part of the reviewer because it can be so emotional.

The structured life review is of course about the self, and the evaluation of the way a person has lived his or her life is the most important therapeutic factor. The review, reevaluation, and reintegration that take place in a life review allows a person to accept life as it has been lived, resulting in integrity. When a life issue is successfully addressed, the person can put it away and move on with greater energy because the energy is no longer used up in indecisiveness, brooding, or unfinished business. For instance, a review with a 55-year-old depressed woman finally revealed that she thought that the death of her son was her husband's fault. As she talked it through, she determined that he was responsible in one particular way but that there were other factors that contributed to her son's death over which neither she nor her husband had had any control. In the reevaluation, she was able to forgive her husband and move on. The life review helps people finish their business through evaluation. Also, a general freeing of the reviewer's energies allows the reviewer to deal more efficiently with the problems of the present.

Outcomes Life review is therapeutic, as substantiated by outcomes research. Several researchers have noted that the structured life review decreases depression and increases positive psychological outcomes. But research in this area is still minimal because the manualization of the intervention has not reached the sophistication found in other behavioral and psychodynamic approaches, making independent replication difficult. Additionally, much of the research is conducted with small non-randomized samples with no identifiable criteria or diagnoses.

Summary

Simple reminiscence, guided autobiography, and structured life review, three approaches to reminiscence work, offer health providers unique opportunities to serve the general aging population. Defining the purposes before choosing an approach is key to successful reminiscence. An analysis of procedures and components of the processes will clarify the best approach for achieving the desired outcomes.

Renal and Urinary Tract Function

R D Lindeman, University of New Mexico School of Medicine, Albuquerque, NM, USA

Glossary

Effective Renal Plasma Flow (ERPF) (Para-aminohippuric Acid [PAH] Clearance) – A measure (in ml or cc per minute) of the volume of plasma flowing through the kidney. This can be measured by the para-aminohippuric acid (PAH) or diodrast clearance as low concentrations of these substances are cleared completely by tubular secretion each pass through the kidney. Approximately 92% of plasma perfusing the kidney secretes its PAH into the tubular system so it can be excreted. Renal blood flow (RBF) can be calculated as

$$\mathrm{RBF} = \frac{\mathrm{ERPF} \times \dfrac{100}{92}}{1 - \dfrac{\text{hematocrit}}{100}}$$

The PAH clearance is normally four to five times the glomerular filtration rate.

Glomerular Filtration Rate (GFR) (Inulin or Creatinine Clearance) – A measure (in ml or cc per minute) often corrected to body surface area (meters^2), of the volume of filtrate formed by the kidney glomeruli. The most accurate measure is the inulin clearance, but this requires a constant infusion. Endogenous creatinine clearance provides a much simpler, clinical measure that approximates inulin clearance. The normal value is 100–120 ml per minute; blood urea nitrogen and serum creatinine concentrations begin to increase above normal when this clearance falls below 30 ml per minute.

Urine Osmolality (mOsm/l) (Concentrating and Diluting Ability) – The serum and urine osmolality per kilogram or liter of water is a measure of all solute particles per unit of volume and can be used to measure ability to concentrate urine when water is restricted and to dilute urine when water loaded.

Introduction

Cross-sectional studies of healthy populations show a decrease in kidney function that approximates 1% per year after the age of 40 years, as measured by glomerular filtration rates (inulin or creatinine clearances) and other measures of kidney function that parallel this measure. However, longitudinal studies show there are some elderly individuals who, when followed for periods of up to 20 years, show no decrease. This suggests that loss of renal function is not an inevitable involutional process, but may be the result of pathologic processes in selected individuals. Studies of structural changes with age, on the other hand, demonstrate an increasing prevalence of ischemic obsolescence of glomeruli and glomerulo-sclerosis with age. The ability of the kidney to conserve sodium (salt) and water and an impaired thirst mechanism increases the susceptibility of older individuals to dehydration (hypernatremia). An increased sensitivity to osmotic stimuli with release of antidiuretic hormone increases the

susceptibility to hyponatremia. Kidney and urinary tract diseases are not different in the elderly compared to the young, but frequency and prognosis are altered. Finally, urinary tract dysfunction with age is generally not life-threatening, but does affect quality of life.

Studies in rats have shown the development of proteinuria and impaired renal function during the course of aging associated with significant structural changes in the kidney. The most striking anatomic features are focal and segmental glomerulosclerosis, increases in mesangial matrix, and glomerular and tubular basement membrane thickening. Whether the proteinuria is the cause or an effect of those structural lesions remains unclear; immunological and/or environmental factors may play a prominent role.

In otherwise healthy individuals, the aging kidney also is associated with structural and functional changes. In both cross-sectional and longitudinal studies, mean values of kidney function decrease with age. Results from the Baltimore Longitudinal Study on Aging, however, suggest that the loss of renal function with age is not inevitable and that decreases in mean values may be primarily the result of superimposed pathology (e.g., undetected glomerulonephritis or interstitial nephritis secondary to infections, immunologic insults, drugs, or other toxic exposures; atherosclerotic vascular occlusions with resultant ischemic injury; and urinary tract infections or obstruction). The terms successful and usual aging have been used to distinguish between individuals who age without loss of organ function and the usual cross-section of any aging population where mean values are tabulated. The latter must include individuals with asymptomatic, or at least undocumented, pathology.

A variety of lesions can be observed by the pathologist in patients with impaired renal function. These can be divided into glomerular, tubulointerstitial, and vascular pathologies. For clinical purposes, in this article we have divided the renal disorders into acute renal failure (ARF), nephrotic syndrome, chronic renal failure, and urinary tract infections (UTIs).

Lower urinary tract dysfunction in the elderly, although responsible for a number of medical concerns, is rarely life-threatening with the exception of malignant disease and unrelieved obstruction. These dysfunctions affect quality of life and many require medical management. Urinary incontinence, for example, is one of the most frequent reasons elderly persons are placed in nursing homes. It occurs in more than 50% of nursing home residents. The involuntary loss of urine severe enough to cause social and hygienic problems is seen in 15–30% of community-living elders, especially women. Benign prostatic hypertrophy is another example of a medical concern that develops in virtually all men if they live long enough.

Age-Related Changes in Kidney Structure and Function

Changes in Renal Morphology with Age

Both kidney mass and function decrease after the third or fourth decade of life at the rate of approximately 1% per year so that there is a reduction in renal mass up to 30% by the eighth decade. There is a 30–50% reduction in the number of glomeruli, with a substantial number of the rest developing focal glomerulosclerosis. The number of mesangial cells increases, thereby decreasing the filtering surface while the percentage of epithelial cells decreases, and the mesangium increases from 8 to 12% of the total glomerular volume. Although the number of glomerular tufts per unit area decreases, as does the number of glomerular and tubular cells, the size of surviving cells increases with age. There also is a significant increase in connective tissue in the medulla. Thickening of the glomerular and tubular basement membranes becomes apparent. Finally, diverticula of the distal nephron begin to appear and may be the cause of the cysts frequently seen in the elderly, but not in the young.

The loss of renal mass is principally from the cortex and is primarily vascular in origin, with the most significant changes occurring at the capillary level. Normal aging is associated with sclerotic changes in the walls of the larger renal arteries, but these lesions generally do not encroach on the lumen sufficiently to produce functional changes. Smaller vessels are relatively spared in non-hypertensive elderly subjects with only a small percentage of senescent kidneys showing arteriolar changes. The incidence of sclerotic glomeruli increases with advancing age, from less than 5% of the total glomeruli at 40 years to 10–30% of the total by the eighth decade. One study reported a strong direct correlation between the number of sclerotic glomeruli and the severity of atherosclerotic disease. Furthermore, when the percentage of sclerosed glomeruli was less than 5%, the distribution between cortex and medulla was relatively uniform, but as the percentage increased, the distribution became predominantly cortical.

Several investigators have compared ischemic obsolescence in cortical and juxtamedullary glomeruli. Initially, in both, there is a progressive collapse of the glomerular tuft with wrinkling of the basement membranes, followed by simplification and reduction

in the vascular channels. Hyaline is deposited within both the residual glomerular tuft and the space of Bowman's capsule. Identifiable structures rapidly disappear so that the obsolete glomerulus may be reabsorbed and disappear completely. Reabsorption is suggested by the scantiness of the cellular response and the residual scar. In the cortical glomeruli, there is obliteration of the afferent arterioles with complete atrophy of the glomerular tuft; in the juxtamedullary glomeruli, there is spiraling of the arterioles with subsequent shunting of blood from the afferent to the efferent arterioles. This produces a redistribution of blood flow from the cortical to the juxtamedullary portions of the kidney with age.

Changes in Renal Function with Age

Most data on changes in renal function with age come from cross-sectional studies, because they are easier to perform and can be accomplished over relatively short periods of time. Potential misinterpretations can be introduced by cohort differences and selective mortality, problems that can be avoided only by much more costly, time-consuming, longitudinal studies.

Glomerular Filtration Rate Cross-sectional studies have shown an age-related decrease in renal function after age 30–40 years. Four decades ago, researchers observed a 50% reduction in inulin clearances between 30 and 90 years of age. Data were subsequently collected from 38 studies where individual inulin clearances and ages were recorded and found an accelerating decrease in glomerular filtration rate (GFR) with increasing age in both men (**Figure 1**) and women. The rate of decline was more rapid in men. Rowe and co-investigators, reporting on results from the Baltimore Longitudinal Study on Aging, showed a similar rate of decline in mean creatinine clearances in normal male subjects followed over a 10-year period with clearances obtained every 12 to 18 months.

Although mean true creatinine clearances fell from 140 ml/min/1.73 m^2 between 25 and 34 years of age to 97 ml/min/1.73 m^2 between 75 and 84 years of age, mean serum creatinine concentrations rose insignificantly from 0.81 to 0.84 mg/ml. This shows that mean creatinine production falls at essentially the same rate as mean creatinine clearance, paralleling the decrease in body muscle mass with age. Serum creatinine concentrations in older individuals must be interpreted with this observation in mind when used to determine or modify dosages of drugs cleared totally (e.g., aminoglycoside antibiotics) or partially (e.g., digoxin) by the kidney.

A subsequent report from this study showed that the mean decrease in this volunteer cohort followed over a 23-year period was 0.87 ml/min/year in all subjects and 0.75 ml/min/year in the individuals free of renal and urinary tract disease and not under treatment for hypertension. This is very close to that observed in the above-mentioned cross-sectional analyses. One-third of these subjects, however, had no decline in creatinine clearance, as illustrated by six subjects followed for 15–21 years (**Figure 2**). These observations suggest that the decline in renal function seen with age in cross-sectional analyses is not the result of a universal chronic involutional change, but more likely is a result of intervening pathology in a portion of each population: for example, (1) undetected glomerulonephritis or interstitial nephritis secondary to immunological insults, infections, drugs, and other toxic exposures; (2) vascular occlusions with resultant ischemic injury; and (3) UTIs or obstruction. One of the variables that affects the rate of decline in renal function is blood pressure, as hypertensive individuals exhibit a more rapid decline in renal function when compared to normotensive subjects.

Renal Blood and Plasma Flow The effective renal plasma flow (ERPF), as measured by quantifying para-aminohippuric acid (PAH) clearance, decreases from a mean of 649 ml per min during the fourth

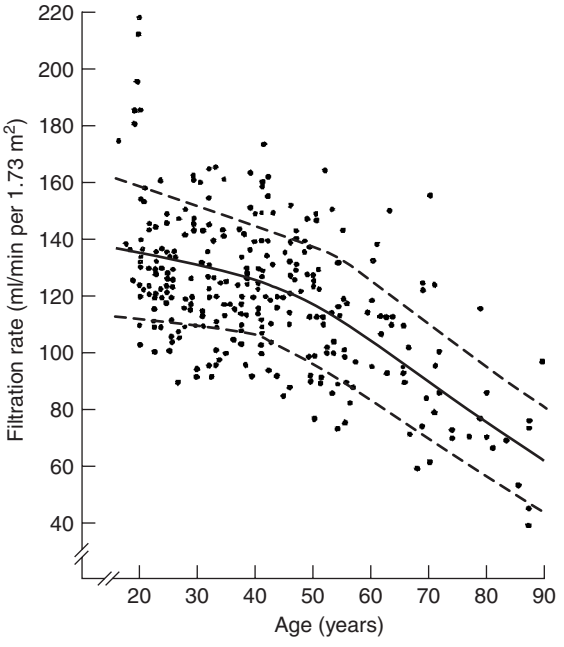

Figure 1 Glomerular filtration rate (inulin clearances) per 1.73 m^2 in normal male volunteers plotted against age from 38 studies. Solid and broken lines represent mean $\pm$ one standard deviation. New York: Grune and Stratton.)

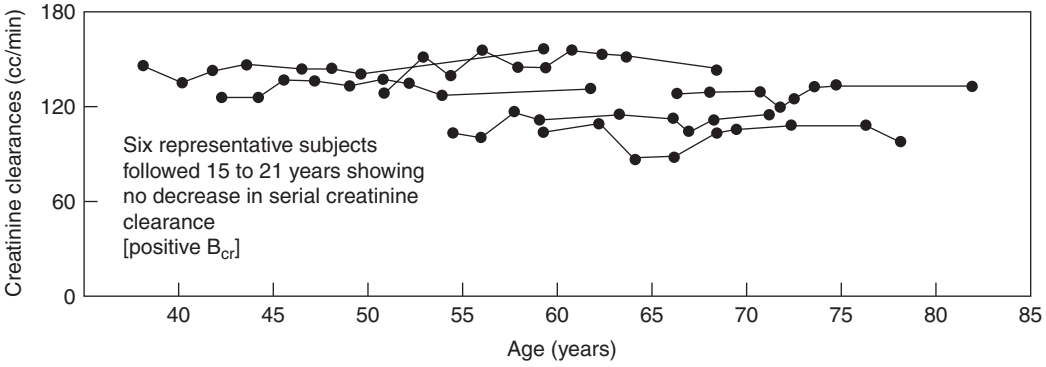

Figure 2 Individual displays of serial creatinine clearances plotted against age in years for six representative subjects from the Baltimore Longitudinal Study of Aging. These six subjects were followed from 15–21 years and showed no decrease in creatinine clearances over this period of time (positive slope of creatinine clearance plotted against time in years). This was representative of the one-third of the 254 normal subjects followed who showed no decline in renal function over the 23 years the study was being conducted. (Reprinted by permission of Lindeman RD, Tobin J, and Shock NW (1985) Longitudinal studies on the rate of decline in renal function with age. *Journal of the American Geriatric Society* 23: 278–285.)

decade to a mean of 289 ml per min during the ninth decade. Since the extraction ratio (ERPF/RPF) at low arterial PAH concentrations is not affected by age (92% in young and old subjects), PAH clearance can be used to reflect changes in renal blood flow with age. The ERPF decreases more rapidly than the GFR, resulting in an increase in the filtration fraction.

The decrease in renal blood flow with age without a parallel decrease in blood pressure could be explained by either the presence of intraluminal vascular pathology (e.g., atheromata or sclerosis) or by increased renal vascular resistance caused by arteriolar vasoconstriction. Two studies have examined this issue, one suggesting that there is a greater resting vasoconstriction in older subjects, and the other suggesting there is a greater resting vasodilation in older subjects. The latter study, using xenon washout techniques, also reported that perfusion of the outer cortical nephrons fell more with age than perfusion of corticomedullary nephrons.

Maximum Tubular Transport Capacity The tubular maximum for PAH secretory transport decreases with age at a rate paralleling the decrease in inulin clearance. The tubular maximum for glucose reabsorption decreases similarly with age. Although reductions in the secretory and reabsorptive tubular maxima with age could be explained by a progressive loss of functioning nephrons, animal studies suggest that tubular cells in old compared to young kidneys have fewer energy-producing mitochondria, lower enzyme concentrations, lower concentrations of total or sodium-potassium-activated adenosine triphosphatase (ATPase), decreased sodium extrusion and oxygen consumption, and decreased tubular transport capacity. Because these studies were performed on tissue slices, it is difficult to be sure that these decreases are not attributable to a higher proportion of non-tubular mass in old compared to young kidneys.

Concentrating and Diluting Abilities A decrease in urine concentrating ability with age is well documented. In the Baltimore Longitudinal Study on Aging, 12 h of water deprivation increased mean urine osmolality to 1109 mOsm/l in young subjects (mean age 33 years), 1051 mOsm/l in middle-aged subjects (mean age 49 years), and 882 mOsm/l in older subjects (mean age 68 years). The decrease in concentrating ability could not be related to an increase in solute load in surviving functioning nephrons, but most likely appears explainable by an increase in medullary blood flow that reduces medullary tonicity due to washout of solute that occurs with age.

Maximum urine osmolality following infusions of large doses of pitressin is decreased in older subjects first undergoing a water diuresis. Elderly subjects, however, respond normally to infusions of pitressin insufficient to maximally concentrate the urine, further supporting the hypothesis that the decrease in concentrating ability observed in older individuals is the result of a decrease in medullary tonicity rather than any defect in the ability of the tubule to respond to antidiuretic hormone.

Maximum diluting ability, as measured by minimum urine osmolality achieved with water loading, also decreases with age. When one compares maximum free water clearance per unit of nephron mass (GFR), there is little difference between young and old individuals, suggesting no basic defect exists in the ability to produce a diluted urine.

Excretion of Acid To maintain systemic acid–base balance, the kidney must excrete a quantity of hydrogen ion equal to that generated by metabolism. Under basal conditions, the blood pH, pCO_2, and bicarbonate of older persons without significant renal disease do not differ from the values observed in young subjects. However, the decreases in blood pH and bicarbonate concentrations following ingestion of an acid load (e.g., 8 g of ammonium chloride) persist longer in elderly persons. The minimum urine pH achieved after an acid load is comparable in young and old individuals. A much larger percentage of the ingested acid load, as measured by total acid excretion (ammonium plus titratable acid minus bicarbonate) is excreted over an 8-h period by the young subjects; however, if total acid excretion is factored by GFR, similar rates of excretion are observed. Young subjects excrete a higher percentage of total acid as ammonium, whereas older subjects have a higher percentage as titratable acid, presumably because they have an increase in urinary buffers per unit of GFR. This limitation in the kidney's ability to excrete acid in older individuals may predispose them to the development of metabolic acidosis and delay their recovery from it.

Glomerular Permeability Functional studies of glomerular permeability show no change with age. Although the incidence of clinical proteinuria increases with age, glomerular permeability to free hemoglobin and a spectrum of different molecular weight dextrans does not differ between young and old subjects. Glomerular basement membrane does thicken with age.

Pathophysiology of the Decrease in Renal Function with Age

Whether the decrease in renal function with age is the result of a progressive involutional process with loss of nephron units and a loss of cellular function similar to the glomerulosclerosis observed in rodents, or is the result of a variety of pathological processes, often undetected, producing acute or chronic damage, or both, remains unresolved. Although results from the Baltimore Longitudinal Study on Aging showed that one-third of the male volunteers (some followed for over 20 years) failed to show any decrease in renal function over the period studied, anatomic studies show a progressive increase in the number of sclerotic glomeruli with advancing age. The former data suggest that there is no inevitable progressive involutional change with age, at least not in all individuals, and support the concept that the decrease in renal function with age observed in cross-sectional studies is the result of superimposed pathology in a portion of the population under study. Anatomic studies, however, suggest there is a sequence of events that results in sclerosis and loss of function in glomeruli that parallels the severity of atherosclerosis elsewhere in the body. An alternative possibility is that as glomeruli become sclerotic, there is a hyperplasia and hypertrophy of cells in remaining glomeruli, perhaps stimulated by circulating growth factors, that compensates and maintains renal function much as observed after unilateral nephrectomy and in diabetes mellitus and hypertension.

A number of examples of undetected pathology causing reduced renal function in the elderly can be cited. For example, one study utilizing scanning techniques to localize defects in kidney function in elderly patients (mean age 75 years) without a history of renal disease found abnormal scans in 25 of 35 (71%) subjects with a mean creatinine clearance of 53 ml/min. Sixteen (46%) showed focal areas of diminished uptake, which were felt to represent ischemic or infarcted areas. Significant pyuria was present in 37% of the patients, and intravenous pyelograms were interpreted as normal in all cases. These findings suggest that vascular occlusions, interstitial infection (pyelonephritis), or both contribute to the decrease in renal function observed in any aging population.

Once a critical level of renal functional deterioration is reached in individuals with kidney injury from any cause, progression of the damage occurs, even if the initiating event or condition is resolved. This is due to a progressive glomerulosclerosis. A vast literature has been generated on the role of hyperperfusion and hyperfiltration in the progression of declining renal function as it has been observed in rodents. It has been hypothesized that high glomerular pressures and plasma flow rates created by high protein intakes contribute to the development of glomerulosclerosis, resulting in a progressive decline in renal function with age alone, as with primary renal disease, renal ablation, diabetes mellitus, and hypertension.

Age-Related Changes in Renal Control of Fluid and Electrolyte Homeostasis

Under normal circumstances, age has little or no effect on serum sodium and potassium concentrations or the ability to maintain normal extracellular fluid volumes. The extrarenal mechanisms responsible for maintaining volume and composition of the extracellular fluids, however, often become impaired in the elderly, especially when stressed by acute and/or chronic illness.

Control of Sodium Balance

Older subjects fail to conserve sodium as efficiently as young subjects when subjected to rigid salt restriction. They have consistently lower plasma renin concentrations and urinary aldosterone excretions on both restricted and unrestricted salt diets and in both supine and upright positions. These decreased plasma renin concentrations and urinary aldosterone excretions in the elderly may be related to the impaired responsiveness to β-adrenergic stimulation observed in the elderly because one of the effects of β-adrenergic stimulation is to increase levels of circulating renin and aldosterone. The decrease in aldosterone at least partially explains the decreased ability of the elderly to conserve sodium when challenged with a low-salt diet.

Two other factors may affect the ability of the elderly to conserve sodium. Circulating atrial natriuretic factor (ANF) levels, although very variable, are increased in the elderly, increasing the salt-losing tendency of the kidney, both directly by its natriuretic effect and indirectly by suppressing renin and aldosterone synthesis and release. Also, as renal function decreases with age, assuming food and salt intake are maintained, the solute load in each residual functional nephron increases, thereby producing a relative osmotic diuresis and a decreased ability to conserve sodium and water.

Control of Potassium Balance

The low renin and aldosterone levels described earlier also could account for the greater tendency of older individuals to develop hyperkalemia when challenged with an increased exogenous (potassium supplements, potassium-containing medications) or endogenous (tissue catabolism, blood in the intestine) load of potassium. Because the distal nephron has such a large capacity for secreting potassium, even in patients with markedly reduced renal function, hyperkalemia generally develops only with one or more additional factors (e.g., excess endogenous or exogenous potassium) or introduction of a drug or disease that affects distal tubular secretion of potassium. Drugs that interfere with this aldosterone-dependent tubular secretion of potassium include the potassium-sparing diuretics (spironolactone, triamterene, amiloride), the β-adrenergic blockers, the angiotensin-converting enzyme (ACE) inhibitors, and the non-steroidal anti-inflammatory drugs (NSAIDs). Elderly persons with a chronic interstitial nephritis, especially diabetics, develop a more pronounced hyporeninemic hypoaldosteronism (type IV renal tubular acidosis) with hyperkalemia.

Susceptibility of Older Individuals to Dehydration (Hypernatremia)

The increased tendency of the older individual to lose both sodium (salt) and water (concentrating defect) contribute to the more rapid development of dehydration and hypernatremia. Another factor that might accelerate the development of dehydration is an impaired secretion of antidiuretic hormone (arginine vasopressin, AVP) associated with the hypoangio-tensinemia (decreased renin-angiotensin-aldosterone) commonly seen in the elderly. This would result in an inability to concentrate the urine and thereby conserve water.

More important, however, is the impairment in the thirst mechanism that develops with age. In one study reported, older subjects following 24 h of water deprivation had increased serum osmolalities and plasma AVP levels and decreased urine osmolalities (concentrations) compared to younger subjects. The younger subjects, however, reported much more thirst, and at the end of the study rapidly drank water to restore plasma osmolality to normal. The older individuals, in contrast, drank little water and still had not corrected the hyperosmolality after 2 h. If older persons had a normal thirst response to water deprivation, the inability to conserve salt and water would be compensated for by an increased fluid intake.

Susceptibility of Older Individuals to the Development of Hyponatremia

Surveys of older individuals in both acute and chronic care facilities show a high incidence of hyponatremia. Chronically hyponatremic individuals show an impaired ability to increase urine volume and decrease urine osmolality when challenged with a water load. The most frequent etiology is a normo-volemic hyponatremia consistent with the syndrome of inappropriate antidiuretic hormone (SIADH) release. Other etiologies included primary salt depletion (hypovolemia), dilutional hyponatremia (hypervolemia, as seen in congestive heart failure (CHF), cirrhosis, nephrotic syndrome) hyperglycemia, and renal failure. In one study of elderly, hospital-acquired hyponatremics, non-osmotic (baroreceptor) stimulation of vasopressin release was a major factor in the development of this electrolyte disorder, regardless of cause. Elderly patients, under a variety of stressors, are much more likely to develop hyponatremia than younger subjects (e.g., postoperatively and following diuretic and sulfonylurea [chlorpropamide] therapy).

Antidiuretic hormone activity in the serum or plasma tends to be higher in older persons when compared to younger persons under comparable

conditions. Following infusions of a standardized hypertonic saline infusion designed to raise serum osmolality to 306 mOsm/l, older subjects had more than a twofold greater rise in serum AVP concentrations. In contrast, ethanol infusions, known to inhibit AVP secretion, produces a more prolonged decrease in serum AVP concentrations in young than in old subjects. These two observations suggest an increasing osmoreceptor sensitivity with age with a greater release of AVP and thus more water retention in response to any given osmotic stimulus. Subsequent studies designed to determine if this was a consistent, age-related increase in vasopressin responsiveness or was specific only for osmotic stimuli showed that older subjects, following periods of quiet standing, failed to increase serum AVP concentrations as much or as consistently as younger subjects. Because these subjects had an intact norepinephrine response to orthostasis, the age-related defect was felt to be distal to the vasomotor center in the afferent limb of the baroreceptor reflex arc. Furthermore, it was suggested that the contrasting influence of age on the vasopressin response to osmolar and volume-pressure stimuli, in at least some elderly, might be related to impaired baroreceptor input to the supraoptic nucleus, which in turn might remove constraints on the response to osmotic stimuli.

Aging and Kidney-Urinary Tract Disease

The inability of the kidney to excrete, through the process of formation of a glomerular filtrate and selective reabsorption and secretion in the tubular system, the normal load of metabolites produced by the body can be separated into ARF or chronic renal failure. When one discusses ARF, and, to a lesser extent chronic renal failure, a further distinction needs to be made between prerenal, renal, and postrenal azotemia. Useful in categorizing these broad groups is calculation of the blood urea nitrogen (BUN)/serum creatinine ratio. With prerenal azotemia, there is either a decrease in renal perfusion (dehydration, hypotension, CHF) or an increase in nitrogen production (bleeding into the gastrointestinal tract) so that the BUN/serum creatinine ratio increases to over 20 to 1. The decreased perfusion associated with prerenal azotemia enhances tubular urea reabsorption disproportionately, raising BUN to serum creatinine concentrations. In one study of ARF in the elderly (>70 years of age), nearly one-half was prerenal in origin (over half of these due to dehydration). The increased hydrostatic pressure transmitted to the tubular fluid in postrenal (obstructive) azotemia also creates a disproportionate reabsorption of urea compared to creatinine increasing the BUN/serum creatinine ratio. These changes are in contrast to azotemia resulting from intrinsic renal disease, where the BUN/serum creatinine ratio ranges between 10 and 14 to 1.

Acute Renal Failure

Of the renal causes of ARF in the elderly, glomerular, tubulointerstitial, or vascular pathology may be causative. The tubulointerstitial nephropathies (acute tubular necrosis [ATN], acute interstitial nephritis [AIN]) are the most common etiologies; the ATN can either be ischemic or nephrotoxic in origin. Most of the acute tubular necrosis of ischemic origin in the elderly is associated with surgical procedures and problems, including pre- and postoperative sepsis. Medical illness such as pneumonia, sepsis, and ischemic heart disease, especially those that produce hypotension, can cause ischemic ATN. Causes of nephrotoxic ATN include the aminoglycoside antibiotics (gentamicin) and intravenous contrast agents used in pyelography, angiography, and computerized tomography (CT). Beside age, factors that increase risk of ATN include diabetes mellitus, preexisting renal insufficiency, multiple myeloma, renal hypoperfusion (dehydration), hypertension, and hepatic disease. A review of prognosis in older patients with this type of ARF suggests age does not appreciably affect survival rates, but older patients need more time to recover renal function and recovered less fully.

Drug-induced AIN has become an increasingly common cause of ARF in the elderly; AIN can also be seen as a complication of infections or systemic disease. Over 40 drugs have been implicated as potential etiologic agents with the penicillins, most commonly methicillin, and NSAIDs being the most frequently incriminated. Patients commonly develop fever, rash, and eosinophilia–eosinophiluria along with non-oliguric, progressive azotemia (*see* Pharmacology).

Acute glomerulonephritis, generally regarded as a cause of ARF in children and young adults, also is more common in the elderly than generally believed. The essential clinical features of hematuria, proteinuria, sodium and fluid retention, decreased renal function, and hypertension are not different in the elderly but are obscured by the presence of preexisting cardiovascular disease and a low index of suspicion. It may be difficult clinically to distinguish patients with poststreptococcal or postinfectious glomerulonephritis from patients with rapidly progressive (crescentic) glomerulonephritis or glomerulonephritis related to systemic disease (lupus erythematosus, vasculitis, subacute bacterial endocarditis, etc.)

Glomerular Disease (Nephrotic Syndrome)

The nephrotic syndrome is defined by the urinary excretion of protein in excess of 3 g per day and other features that are the consequence of this protein loss (e.g., hypoalbuminemia, hyperlipidemia, edema, and a hypercoagulable state). Hypertension and renal insufficiency may or may not be present. The nephrotic syndrome can result from primary glomerular disease, neoplastic disease, or multisystem disease. Studies of nephrotic syndrome in the elderly suggest it is at least as common as it is in younger persons. Several reviews of histologic diagnoses indicate that over one-third of the biopsied patients have a membranous nephropathy with the next most common diagnoses being minimal change disease, primary amyloidosis, mesangial proliferative glomeulonephritis, and focal/segmental glomerulosclerosis. The incidence of membranous nephropathy and amyloidosis was higher than in younger adults, proliferative glomerulonephritis was much lower, whereas minimal change disease was comparable but lower than in children. The incidence of IgA nephropathy and rapidly progressive (crescentic) glomerulonephritis appears to be low in the elderly. Several authors have reported on the increased incidence of underlying malignancies (5–10%) in patients found to have membranous glomerulopathies on biopsy.

Glomerulopathies resulting from systemic disease are more common in the elderly because of the increased incidence of such underlying diseases as diabetes mellitus, amyloidosis (dysproteinemias), vasculitis, and scleroderma. In one review, a secondary cause was found in one-third of the cases. Diabetic nephropathy is the most frequent cause of glomerular disease associated with systemic illness in the elderly (diabetic glomerulosclerosis); however, because many of these patients have an obvious etiology for their nephrotic syndrome, documentation in biopsy series tends to be low and to underestimate the prevalence of this lesion, especially in the elderly. All elderly nephrotics should have urine and serum electrophoreses performed as amyloidosis is the most frequent cause of nephrotic syndrome secondary to systemic disease in biopsied patients.

Chronic Renal Failure

Chronic renal failure results from irreversible damage to both kidneys from a wide variety of glomerular, tubulointerstitial, and vascular causes. Up to 90% of kidney function may be lost without significant morbidity. Progression of the renal lesions can be delayed by managing hypertension, infection, obstructive uropathy, heart failure, and dehydration.

Occlusive arterial disease can cause either acute or chronic renal failure. Bilateral renal artery stenosis due to atherosclerosis may cause, in addition, accelerated hypertension. Renal cholesterol embolization is a geriatric disorder that may occur spontaneously or in association with aortic surgery or angiography in patients with diffuse atherosclerosis. Hypertensives may develop benign or malignant nephrosclerosis. Systemic vasculitis, polycystic renal disease, and scleroderma are other diseases that can cause chronic renal failure without sufficient glomerular disease to cause nephrotic syndrome (*see* Atherosclerosis).

The high frequency of arthritis and arthralgia in the elderly increases the risk of long-term use and abuse of NSAIDs and analgesics. The NSAIDs, because they inhibit vasodilatory prostaglandins, reduce medullary blood flow and inhibit the hexose mono-phosphate shunt that leads to oxidative injury of medullary cells and frequently cause chronic interstitial nephritis and ultimately papillary necrosis. Phenacetin is the most frequently incriminated analgesic, but salicylates and acetaminophen also may be implicated.

Urinary Tract Infections

Pyelonephritis is a serious infection, being the most common cause of Gram-negative bacteremia in elderly hospitalized patients. *Escherichia coli* causes approximately two-thirds of the episodes of infection, with *Klebsiella, Enterobacter, Citrobacter, Enterococcus, Proteus*, and *Pseudomonas* accounting for most of the rest.

Acute symptomatic pyelonephritis often offers a greater diagnostic challenge in elderly than in younger patients, where the classic irritative voiding symptoms make diagnosis readily apparent. Patients with neurological disease (dementia, cerebral vascular disease, parkinsonism) especially have an increased incidence of infection and often present only with altered mental status (somnolence, confusion), tachypnea, loss of appetite, and vague abdominal pains that may suggest pneumonia, diverticulitis, or intestinal obstruction as alternative diagnoses. Fever and leukocytosis may be absent. Pyuria and bacteriuria are seen with both pyelonephritis or infections limited to the lower urinary tract (cystitis) which are common in the elderly, especially women. It is often difficult to determine whether or not infections are limited to the bladder and urethra alone or extend up to involve the kidney. High fever and back (costovertebral angle) pain and tenderness suggest the latter.

Asymptomatic bacteriuria (pyuria and bacteria in the urine greater than 10^5 organisms per milliliter on clean voided examination) is increasingly prevalent

with advancing age, being present in one-third of patients in long-term care facilities. Although these patients with asymptomatic bacteriuria have an increased mortality rate, it remains unclear whether this is an independent risk factor for shortened survival or merely a marker for severe underlying disease. It does not appear that antibiotic therapy has been useful in prolonging survival or preventing recurrent bacteriuria or symptomatic infection, so the prevailing philosophy seems to be to leave asymptomatic bacteriuria untreated until it becomes symptomatic. This also may prevent emergence of resistant organisms.

Lower Urinary Tract Dysfunction with Aging

Effect of Age on the Lower Urinary Tract

Aging affects the lower urinary tract in a number of ways, but incontinence is not a normal consequence. Bladder capacity, the ability to postpone voiding, bladder compliance, and urinary flow rate appear to decline in both sexes, and maximum urethral closure pressure and urethral length appear to decline in women. The number of uninhibited contractions of the detrusor (bladder) probably increases with age, and postvoiding residual volume may increase but probably to no more than 25–50 ml. Although none of these age-related changes causes incontinence, each can predispose one to incontinence, especially because older persons are prone to additional problems that increase the likelihood of this dysfunction.

Transient Incontinence

A number of medical, functional, and cognitive problems superimposed on an elderly person can lead to the development of incontinence. Resnick has used the mnemonic DIAPPERS (with a double P) (**Table 1**) to describe these problems.

Delirium is an acute confusional state, often precipitated by an acute medical problem such as pneumonia or heart failure, that affects one's ability to react appropriately when the bladder becomes distended. UTIs promote a sense of urgency that precipitates voiding. Atrophic vaginitis (urethritis) in elderly women, due to estrogen deficiency, presents with dysuria, dyspareunia, urgency, and incontinence. A number of medications are capable of causing incontinence, most notably those with anticholinergic properties that can impair emptying, especially in those individuals with partial obstruction (e.g., men with benign prostatic hypertrophy). Psychological disturbances, most notably depression, can lead to incontinence. The endocrine causes listed all can cause polyuria, and reduced mobility and stool impaction also can contribute to the development of incontinence. Many times in the elderly, the cause of incontinence is multifactorial, with confusion, medications, and mobility all playing roles (*see* Endocrine Function and Dysfunction).

Table 1 Common causes of transient incontinence

Mnemonic designation	*Cause*
D	Delirium or confusional state
I	Infection, urinary tract
A	Atrophic urethritis or vaginitis
P	Pharmaceuticals (sedative hypnotics, loop diuretics, anticholinergics [antipsychotics, antiarrythmics, antiparkinsonism medications], α-adrenergic agonists and antagonists, calcium channel blockers)
P	Psychological disorders (depression)
E	Endocrine disorders (hypercalcemia, hypokalemia, hyperglycemia)
R	Restricted mobility
S	Stool impaction

Established Incontinence

There are essentially four ways that the lower urinary tract can malfunction to produce incontinence. The detrusor (bladder) muscle either contracts when it should not (detrusor overactivity), leading to urge incontinence, or fails to contract as well as it should (detrusor underactivity), leading to overflow incontinence. Also, outlet resistance can be either persistently high, as seen with obstructive lesions such as prostatism, leading to overflow incontinence, or persistently low, as in the outlet incompetence seen with stress incontinence, usually in women with a history of multiple or difficult deliveries, or men following transurethral resection of the prostate (TURP).

Detrusor overactivity is a condition in which the bladder contracts precipitously with little warning and often empties itself completely. This can occur with normal or impaired contractile function and can result from damage to the central nervous system inhibitory centers (e.g., cerebrovascular accident, Parkinsonism, or Alzheimer's dementia), or it can result from local irritative pathology (e.g., cystitis, bladder carcinoma, or bladder stone) which impairs the ability of the normal brain to inhibit bladder contraction. Both outlet obstruction and outlet incompetence can predispose to detrusor hyperactivity.

Detrusor underactivity can result from damage to the nerves supplying the bladder (disk compression, tumors) or from an autonomic neuropathy (diabetes, alcoholism, pernicious anemia, tabes dorsalis). It can also result from replacement of bladder muscle by

fibrosis and connective tissue, as seen with chronic obstruction (prostatism), whereby the bladder is no longer able to empty normally.

Glossary

Design – The plan for carrying out a research study. This plan specifies every detail of the study including (but not limited to) what are the variables to be studied and how they are defined and measured; who are the individuals who will be participating in the study; what treatment will be administered to which participants, and how it will be decided which participants receive which treatment; and what statistical analyses are to be used.

Measurement – The procedure by which variables in a study are quantified so that they will be amenable to statistical analysis and in order to form a basis for comparison of results across scientific studies.

Statistical Analysis – A set of procedures by which a researcher uses information gathered from a sample in order to draw more general conclusions applicable to a larger group or population.

Introduction

Science is about studying causes and effects through research design and methods in order to draw conclusions and thereby provide knowledge about the world. When researchers carry out gerontological research, they are trying to establish the causes of certain phenomena that have been observed to be associated with aging. Much of the time it is difficult to determine the independent causes of these phenomena. Possible causal factors such as biological changes, preprogrammed genetic influences, environmental insults including drug and alcohol abuse and workplace exposure, education, and cultural and historical influences not only coexist, but influence each other as well as the aging process.

Disentangling which factors cause the phenomena observed and which merely accompany aging is a difficult task. Sometimes, the factors cannot be disentangled completely. But if the issues surrounding causation are carefully thought out, a researcher can usually carry out a study so as to narrow the list of

alternative possible causes dramatically. This is done by paying careful attention to the design of the study, statistical analysis, and measurement.

Fundamentals of Design for Research on Aging

The Role of Theory

Every scientific study starts with a hypothesis, which is a specific statement about what the scientist expects to find out by conducting the study. In the social sciences in general and in aging research in particular, it is very important that the hypotheses stem directly from a clearly and thoroughly specified theory. The theory must incorporate prior research relevant to the topic of interest, and must make predictions that can be tested in an empirical study.

The Concept of Causation

A great deal has been written about the meaning of causation, what constitutes evidence of causation, and how to infer causation in social science research. Covering this literature thoroughly is well outside the scope of this article. Here we will simply mention several aspects of causation that are important to keep in mind, without claiming to have done justice to this important topic. First, a cause always precedes an effect, even if only instantaneously. An effect never precedes a cause. Second, an effect may have several causes. These causes may each be sufficient but not necessary, as when any one of several causes operating alone can trigger an effect; or they may each be necessary, but each alone is not sufficient, as when several causes occurring together are needed to trigger an effect. Third, manipulation of a cause results in manipulation of the effect. This property of causation is the basis of scientific experimentation.

Subject Sampling

A population is the entire universe of individuals to which a research question or finding pertains. The theory upon which a study's hypotheses are based specifies the population. The population may be the entire human race, or all individuals over the age of 50, or all individuals over the age of 50 with at least a high school education, or any group of people of interest to the researchers. Except for the rare instances where resources and subject availability permit collection of data on the entire population, it is necessary to select a manageably sized subset of individuals from the population who will participate in a study. Sampling is the method by which these individuals are selected.

Once the population has been identified, the next step is to identify a sampling frame. The sampling frame specifies the exact pool from which a study's sample is to be drawn. Although in an ideal study the sampling frame would be identical to the population, in practice this is rare. For example, a sampling frame may be confined to a particular geographic area, or to those who have telephones, or to those who will not be moving during the time period the study is to be conducted. It is important to make every effort to identify a sampling frame that is as close as possible to the population of interest, and to be specific about the differences between the sampling frame and the population so that the implications of these differences for the study's results can be carefully considered. The third step in sampling is to draw a random sample of study participants from the individuals in the sampling frame.

In much research in the social sciences 'convenience' sampling is used. In other words, rather than starting with a defined population, identifying a sampling frame, and then drawing a random sample, researchers use samples of individuals who are available for study participation but are not drawn from a population defined *a priori*. There are many reasons why circumstances force researchers into this less than optimal way of collecting data. In general, although drawing a random sample is unarguably the most scientifically sound approach, it is difficult and expensive, particularly if the study involves much more participation than answering a few questions over the telephone. For these reasons and others, researchers are much more apt to draw a sample from a group made up of individuals who are likely to agree to participate (alumni of the university sponsoring the study, for example) even if the group is not completely representative of the population of interest. This non-random sampling procedure has important implications for the external validity of research, which is discussed below.

Variables

As the name implies, variables are quantities that can vary across the individuals in a study. For example, one variable that appears frequently in aging research is age itself, when the individuals taking part in the study are of different ages. Often the variables in a study can be categorized as independent and dependent variables. In traditional laboratory experimentation, the independent variable is the putatively causal variable manipulated by the experimenter, and it has an effect on the dependent variable. With the

advent of field experimentation and quasi- and nonexperimental designs (see below), variables are often referred to as independent even if their relationship with the dependent variable is only predictive rather than causal *per se*. Sometimes the terms *exogenous* and *endogenous* are used in place of independent and dependent, respectively. These are relative terms; a variable may be independent in one context and dependent in another.

Operational Definitions

An operational definition is an exact description of how a variable is to be defined and measured for the purposes of a study. For example, if a study is to compare middle-aged and older adults, it is necessary to have an operational definition of what range of ages constitutes middle age and what range of ages constitutes older. Whenever a standardized instrument, such as an IQ test, is used, the test score serves as an operational definition of the variable of interest. In the case of IQ tests, the test score is an operational definition of intelligence.

Laboratory Experiments and Control

Causal factors can be isolated most convincingly by means of an experiment. An experiment is distinguished from other types of scientific studies by the use of random assignment to treatment. The logic behind an experiment is to establish groups that on average are identical, and then to expose one or more of the groups to a treatment. Usually one of the groups is left untreated so that it can serve as a baseline or *control* group. If *the groups start out identical* and then a treatment is administered *under carefully controlled conditions,* any differences between the groups that are observed can be attributed to the treatment.

There are two parts of the previous sentence that should be elaborated on. First, how does the researcher ensure that the groups start out identical? This is where random assignment, the distinguishing feature of an experiment, comes in. If a scientist decides randomly which group a participant will be in, then on the average (across many studies) the groups will be comparable. Random assignment can be carried out by tossing a fair coin, rolling a fair die, or using a computer program to generate random numbers for use in assignment. It should be noted that the use of random assignment does not guarantee that comparability has been achieved in any particular study. If it is known that balance on certain subject characteristics is desirable, it is wise to stratify the random assignment accordingly. For example, if gender balance across groups is necessary, the experimenter can conduct random assignment separately for males and females.

Second, what is meant by carefully controlled conditions? This means that when the independent variable is manipulated, *only* the independent variable accounts for differences across groups, rather than any other aspect of the study. For example, suppose a scientist wishes to conduct an experiment to study the effects of a particular drug on cognitive performance in the elderly. In this case the independent variable is drug dosage. Participants are randomly assigned either to a group receiving the drug or to a control group receiving a placebo (inert substance). Thus the independent variable can take on two values, either some prespecified dosage of a drug or no exposure to the drug. The dependent variable is cognitive performance. It is operationally defined as performance on a set of several cognitive tasks.

After the drug dose is administered, the participants are given the cognitive tasks to perform. Now suppose all those who receive the drug are tested in the morning hours and all those who receive the placebo are tested in the late afternoon. Thus the time of day that testing takes place differs substantially between the group receiving the drug and the group receiving the placebo. If the group that receives the drug performs better on the cognitive task, it may be because these subjects were fresher and more energetic than the placebo group rather than because of the effects of the drug. A better approach would be to bring all of the subjects into the laboratory at the same time of day, or to make sure that drug and placebo condition subjects are equally likely to participate in a morning or afternoon session.

Field Research and Quasi-Experiments

Although excellent control can be achieved in the laboratory, it is not a very realistic setting. Sometimes the behavior people exhibit in the laboratory does not generalize very well to the world outside the laboratory. In addition, there are many interesting and important questions that cannot be investigated by means of a laboratory study. Questions about such topics as workplace performance and ability to carry out activities of daily living, as well as many others, can often be addressed most directly by venturing outside the laboratory and observing behavior in its natural setting.

Ideally, field research is experimental, that is, it uses random assignment. These are the conditions under which the strongest conclusions can be drawn from a field study. However, in practice, random assignment often cannot be used in field settings.

More often questions must be addressed by means of a quasi-experiment. The term *quasi-experiment* refers to a study where there are treatment and control groups, but random assignment is not used. There are many problems associated with drawing causal inferences from quasi-experimental studies, all of which stem from the initial non-equivalence of groups. If random assignment is not used, the groups are usually not comparable at the outset. Often the existing differences between the groups provide alternative explanations for any results that are observed. For example, suppose a researcher desires to examine the effects of retirement on health. The independent variable is thus retirement, and it can take on two values: retired or still in the workforce. The dependent variable is health, in this case operationally defined as score on a self-report health questionnaire. The researcher takes a sample of people of retirement age, records who is retired and who is not, and has them complete the self-report questionnaire. Suppose it is found that the retired respondents report, on average, poorer health than the respondents who are still in the workforce. Can it be concluded that retirement causes poorer health? No, there is an important alternative explanation. There may be a tendency for the individuals who are in poorer health to choose to retire, while the healthier individuals stay on the job longer. In other words, retirement does not cause poor health; instead, poor health causes retirement. A more definitive study could be done if individuals would agree to be randomly assigned to retire or to stay in the workforce. This is impractical for obvious reasons. Another, more practical approach would be to start with a group of older adults who are still in the workforce but nearing standard retirement age, and observe them over a period of several years. In this way an important question can be addressed: Is declining health followed by retirement, or is retirement followed by declining health? The answer to this question is necessary but not sufficient to allow an inference about which variable, if either, is causal.

The term *non-experiment* refers to a study where there are not treatment and control groups *per se*; instead, the relations among two or, usually, more variables are passively observed with no direct manipulation of an independent variable. The difference between a quasi-experiment and a non-experiment is a matter of degree rather than kind. The main difference between the two approaches is that a quasi-experiment involves a comparison between clearly defined groups. But in neither case does the experimenter use random assignment, so neither design provides inherently stronger causal inference than the other.

Age, Cohort, and Time

Most behavioral research investigates interindividual differences, or differences between people. In research on aging, as well as in all developmental research, researchers are also interested in investigating intraindividual differences, or change within an individual across time; and interindividual differences in intraindividual differences, or differences between people in the nature and amount of individual change over time. There are three broad classes of predictors of intraindividual change over time: age, cohort, and time. Age refers to each individual's chronological age at each observation; cohort refers to the birth cohort or generation, in a sociological sense, to which an individual belongs; and time refers to the time that an observation is made on an individual. These are not independent, because any two of them determine the third. For example, if the time of measurement and an individual's age are known, that individual's cohort can be determined. (*See* Generational Differences: Age-Period-Cohort.)

For many years there were two primary approaches to studying aging: the cross-sectional design and the longitudinal design. In a cross-sectional design, data are collected on individuals of different ages at a single time. Comparisons are then made across ages. The cross-sectional approach has the advantage of being relatively inexpensive and fast. However, the conclusions about aging that can be drawn from a cross-sectional study are limited. First, the existence of differences across groups defined by age does not necessarily imply that individuals undergo corresponding change as they age. Second, the cross-sectional approach confounds age and cohort. In a cross-sectional study, all of the individuals who are a particular age belong to a particular cohort. It can be argued that any observed age differences are in reality due to cohort membership, and that if individuals from different cohorts were involved the results would be different.

In the longitudinal approach, data are collected on individuals repeatedly across time. Longitudinal studies are more expensive and time-consuming, but this design offers the ability to observe intraindividual growth over time. However, with traditional longitudinal designs only a single cohort is studied. Thus it is impossible to determine whether the results will hold for another cohort.

Somewhat more elaborate versions of these designs have been devised in order to address these concerns. In the cross-sequential design, cross-sectional data are collected in two different years. The first year is a traditional cross-sectional study, where people of several different ages are included in

the sample. In a second year, data are collected on independent samples from the same cohorts (who are now older) and on individuals who are the same age as the participants were in the first year, but are members of different cohorts. This permits the comparison of age differences with several different pairs of cohorts involved. In the cohort-sequential design, a longitudinal study involves several cohorts simultaneously. The data collection is arranged so that data are collected on the same ages in each cohort. This allows the comparison of results across cohorts.

Internal Validity

The internal validity of a study is the confidence with which causation can be attributed to the independent variable and not to some other uncontrolled aspect of the study. A few of the possible threats to the internal validity of aging studies are listed below. This is by no means an exhaustive list.

Testing This can be a problem in longitudinal research if participants are given the same tests or asked to complete the same questionnaires frequently. Scores on tests can go up because of increased familiarity with the test rather than because of any real growth in skill or ability, or participants may become bored or irritated and stop paying attention, leading to a decline in test scores.

Instrumentation If a test or questionnaire has different meanings at different points in time in a longitudinal study, this can pose a threat to internal validity. A frequently occurring example of this is floor and ceiling effects. A floor effect is when a test is not sensitive at the low end of the range, usually because it is too difficult and many individuals in a sample score zero on it. Correspondingly, a ceiling effect is when a test is not sensitive at the high end of the range because it is too easy. In aging studies where decline over time may be of interest, floor effects can create a problem.

Differential Subject Attrition It is almost inevitable in longitudinal studies for some participant dropout to occur. Of course, the investigators should do everything possible to keep this to a minimum. Subject attrition becomes a threat to the internal validity of a study when treatment-group dropouts are a different kind of person than control-group dropouts. For example, suppose a study has taken a random sample of older individuals for a study on the effects of cognitive exercises on memory. Participants are randomly assigned to a treatment group that is taught the exercises or a control group that is not taught any exercises. Suppose the individuals most in need of the memory exercises drop out of the control group, because they know they need help and decide to seek it elsewhere. This would leave only the least impaired individuals in the control group. This pattern of subject dropout can make a treatment look less effective than it really is or even ineffective. Other patterns of subject dropout can make a treatment look more effective than it is in reality.

External Validity

External validity is the extent to which the results of a study can be generalized to a clearly defined and theoretically interesting population. Internal validity is a logical prerequisite for external validity, because if a study has poor internal validity it makes little difference whether or not it is generalizable.

The results obtained from a sample can be generalized to a population with a high degree of confidence when the sample was drawn randomly from the population. Thus studies that use careful subject sampling procedures and enjoy good participant retention have the best external validity. However, many studies in the social sciences use convenience sampling, as described above. When a convenience sample is used, the investigator is in a considerably weaker position with respect to generalizability, because the convenience sample is not a random sample. Non-random subject attrition also has a deleterious effect on external validity, even in the rare cases where it does not affect internal validity. Those who choose to drop out of a study are nearly always different from those who choose to continue. They may be involved in more competing activities, less patient, more transient, lower or higher in socioeconomic status, or different in a wide variety of other ways. When the individuals who drop out of a study are different from those who remain, the remaining sample is no longer a random sample, and the results of the study may not be generalizable to the population from which the researchers originally sampled. Severe non-random subject attrition can even transform a random sample into essentially a convenience sample, with a corresponding reduction in external validity.

A Brief Introduction to Statistics

Descriptive Statistics

Descriptive statistics are numbers used to describe a sample or population. Usually descriptive statistics computed on samples are intended as estimates of the corresponding population quantities, called parameters. One type of descriptive statistic is the

measure of central tendency. There are three measures of central tendency in widespread use: the mean, median, and mode. The mean is what is commonly called the average, computed by summing up all the values of a variable and dividing by the number of individuals. The median is the 50th percentile of the distribution, in other words, the point at which half the distribution is above and half is below. The mode is the most frequently occurring score. Although all three measures of central tendency are used to describe distributions, statistical inference (see below) makes much more extensive use of the mean than either the median or the mode.

Another type of descriptive statistic is the measure of dispersion, which conveys a sense of how much variability there is in a sample or population. The simplest and most intuitively obvious measure of dispersion is the range, commonly computed by subtracting the smallest value occurring in a sample or population from the largest. However, the largest and smallest values in a sample tend to be among the least stable, so the range is itself an unstable measure of dispersion. Statisticians prefer the variance, which for populations is defined as the average squared deviation about the mean. The sample-based estimate of variance is computed slightly differently.

Statistical Inference

Research is conducted on samples so that conclusions can be drawn about populations. In fact, researchers are interested in a sample only as a means to an end. The end is drawing conclusions about the population, which contains all the individuals that are ultimately of interest. If it were possible, researchers would study the entire population. However, constraints imposed by time, money, and subject availability preclude this in most cases, except where resources are extensive or the population is small. The purpose of statistical inference is to provide guidelines to the researcher for drawing inferences about a population based on information gathered from a sample.

For purposes of illustration, suppose researchers are interested in whether 40-year-olds differ from 60-year-olds in performance on a cognitive task. In classical statistical inference, one begins with a null hypothesis and an alternative hypothesis. These hypotheses refer to the population, not to any particular sample. The null hypothesis is a statistical straw man, stating that the mean performance on the cognitive tasks is the same in the two populations. The alternative hypothesis is simply that the null hypothesis is not true, in other words, the two populations have different mean performance on the cognitive task. (When the direction of the difference between groups is not specified, as in this example, the hypothesis is *two-tailed*. When the direction of the difference is specified, the hypothesis is *one-tailed*.)

Suppose data on performance on the cognitive task have been collected on a suitable sample of 40-year-olds and a suitable sample of 60-year-olds. Sample means and the difference between the sample means have been computed. Because sample means are usually not exactly equal to population means, even in a case where the population means are identical, there usually will be a difference between the 40-year-old sample mean and the 60-year-old sample mean, due to chance. Over repeated sampling, relatively small differences will occur frequently, whereas larger differences occur less frequently. The logic of hypothesis testing is as follows.

Assume for the moment that the null hypothesis is true, that is, the means are identical in the 40-year-old and 60-year-old populations. Then ask the question: If the null hypothesis is true, what is the probability of observing a difference between sample means of a magnitude at least as extreme as the one obtained in this study? If a difference between sample means at least as large in absolute magnitude as the one observed in this study occurs very commonly when the null hypothesis is true, then the researcher concludes that there is no basis for rejecting the null hypothesis. However, if results at least as extreme as these are very rare when the null hypothesis is true, then the researcher concludes that the null hypothesis is probably incorrect in this case.

The decision about whether or not to reject the null hypothesis hinges on the answer to the question about the probability of obtaining results at least as extreme as those observed, conditional on the null hypothesis being true. The answer is found by referring to one of the many tabled distributions found in statistics books. Depending on the statistical analysis done, the researcher refers to a *t*, *F*, chi-square, or some other distribution. If the statistical analysis is done by computer, the researcher instead refers to the computed probability conveniently appearing on the output.

It is important to understand that statistical hypothesis testing is a decision accompanied by the risk of making an incorrect decision. When the null hypothesis is in reality true, in a certain proportion of cases extreme results will occur by chance, and the researcher will mistakenly conclude that the null hypothesis is false. Concluding that the null hypothesis

is false when it is in fact true is known as a type I error. On the other hand, when the null hypothesis is in reality false, in a certain proportion of cases results will occur by chance that will lead to the conclusion that the null hypothesis should not be rejected. Concluding that the null hypothesis is true when it is in fact false is known as a type II error.

The type I error rate, designated by the Greek letter α, can be controlled very easily simply by defining what is meant by extreme results. For example, if it is decided ahead of time that the null hypothesis will be rejected only if the probability of results at least as extreme as those obtained is 0.01 or less, then the type I error rate is 0.01. However, all else being equal, any measures taken to reduce the type I error rate will increase the type II error rate, sometimes to unacceptable levels.

Statistical power is an important aspect of research that is often not given sufficient consideration. Statistical power refers to the probability of rejecting the null hypothesis given that it is in fact false. It is 1 minus the type II error rate. Statistical power is a function of three aspects of a study: the type I error rate chosen, the true effect size, and the sample size. All else being equal, larger values of any of these quantities result in an increase in statistical power. In practice, a type I error rate of no larger than 0.05 is considered acceptable in scientific research, and in many cases (although by no means all) the effect size cannot be influenced by the researcher. Thus, in most situations the researcher tries to obtain the largest sample size possible in order to maximize statistical power. Whenever a study concludes that the null hypothesis cannot be rejected, a careful look should be taken at the study's statistical power. If the statistical power is low (i.e., the type II error rate is high), this means that the study was not an adequate test of the hypothesis.

Statistical Procedures

There are many statistical procedures that are used extensively in research on aging, including the following:

1. Independent groups *t*-test: compares means from two independent samples to infer whether the corresponding population means are different.
2. Related groups *t*-test: examines the difference between means from two related samples to infer whether in the population this difference is zero.
3. Analysis of variance (ANOVA): compares means from two or more independent samples to infer whether at least one of the corresponding population means is different from the others. Usually accompanied by further examination of differences between means, by means of either *a priori* or *post hoc* procedures. A factorial ANOVA may involve more than one independent variable, which allows the examination of interactions. An interaction occurs when the effect of one independent variable depends on the level of the other.
4. Analysis of covariance (ANCOVA): an extension of ANOVA that allows a statistical elimination or partialling out of the effects of a variable under certain circumstances.
5. Correlation: estimates the extent of linear relation between two variables.
6. Regression: closely related to correlation. Uses one or more independent or predictor variables to build a linear prediction model for a dependent variable.
7. Contingency table analysis: a broad class of procedures involving categorical variables. These procedures are roughly analogous to *t*-tests, correlation, regression, and ANOVA, but they involve all categorical variables. In this category are procedures such as the chi-square test for independence and log-linear models.
8. Multivariate analysis of variance (MANOVA): An extension of ANOVA for situations where there are many related dependent variables. The procedure finds one or more linear combinations of dependent variables that provide maximum differentiation among groups, subject to the provision that the linear combinations are uncorrelated.
9. Discriminant analysis: Exactly the same as MANOVA, but often treated as if it is different. In discriminant analysis the emphasis is placed on using the dependent variables to predict the category of the independent variable.
10. Canonical correlation: the most general multivariate procedure. Canonical correlation starts with two batteries of variables, and then finds the linear combinations of the variables that produce the largest correlation, subject to the provision that the linear combinations are uncorrelated.
11. Growth curve modeling: A relatively new approach that is likely to become widely used in aging research. In growth curve modeling an individual growth trajectory is fit for each participant in a longitudinal study, allowing examination of individual and group differences in growth.
12. Factor analysis: A general set of procedures for empirically determining whether a large set of manifest variables can be represented by a smaller number of latent variables.
13. Covariance structure modeling: A procedure by which models involving latent variables, including regressions between latent variables, can be estimated and tested.

A Brief Introduction to Measurement

Measurement is a set of rules by which numbers are assigned to objects. In research, the objects are usually research participants, often called subjects. Measurement is something commonly done in everyday life. When one measures his or her height with a yardstick, the yardstick is the set of rules by which a number is assigned to height. In much the same way, an IQ test provides a set of rules for assigning a number to an individual's intelligence, a grade point average provides a set of rules for assigning a number to a person's scholastic achievement, and a questionnaire provides a set of rules for assigning a number to an individual's attitude.

Measurement is one of the most significant challenges facing social science researchers. Unlike research in the natural sciences, where quantities can usually be measured directly with a caliper, scale, and so on, research in the behavioral sciences is faced with measurement of quantities that cannot be seen directly. These quantities are called *constructs*. Constructs such as intelligence, temperament, opinions, cooperativeness, and ability to perform a task must be measured by means of subject self-report, subject test performance, or observations by others. Because of this, extensive work on measurement theory has been done in the behavioral sciences. Measurement theory provides guidelines for evaluating the quality of an approach to measurement, and for how to develop a high-quality measurement instrument.

Measurement Validity

Validity is the most important goal in measurement. It is the extent to which an instrument measures the construct it is intended to measure. This is a broad concept, and there is not one single widely accepted method for determining measurement validity. Instead, there are several aspects of validity that should be addressed. In any particular situation, some aspects of validity will be more relevant than others.

Criterion Validity This is the extent to which an instrument can be demonstrated to be related to a variable that serves as a criterion. There are two types of criterion validity, concurrent and predictive. Concurrent validity is established by demonstrating a relationship with a variable measured at about the same time as the measurement instrument being evaluated. For example, a researcher may wish to establish the validity of a shorter self-administered measure intended to replace a lengthy interview. Concurrent validity can be established by collecting data using the self-administered measure along with the interview data, and then computing the correlation between the two measures. A large correlation is evidence for concurrent validity. Predictive validity is established by demonstrating that the instrument in question is a useful prospective predictor in a longitudinal design.

Content Validity Content validity is the extent to which the items or questions making up a measurement instrument are representative of the construct being measured. Good content validity does not require that the items exhaust every aspect of the construct, but it does require that no important aspect is left out.

Construct Validity This has to do with the extent to which the measure is theoretically meaningful. There are many ways to demonstrate this, with the most appropriate way depending on the research questions of interest. One widely used way of demonstrating construct validity is by means of the multitrait multimethod (MTMM) matrix. This framework involves multiple constructs, or traits, all of which are amenable to measurement by a set of several different methods. For example, sociability, extroversion, and altruism might all be measured by means of a self-report questionnaire, reports of friends, and behavioral observation. Data are collected measuring each of the traits by means of each of the methods, and all possible correlations are computed. If there is good construct validity, it is expected that the correlations between different methods measuring the same trait will be large (this is referred to as *convergent validity*) and that correlations between the same method measuring different traits will be low (this is referred to as *discriminant validity*). Today the MTMM matrix is often analyzed by means of covariance structure modeling.

Measurement Precision

Another very important aspect of measurement is its precision. The various measurement theories in the behavioral sciences offer somewhat different definitions of measurement precision. One of the most widely used measurement theories is classical test theory. It offers a definition of measurement precision known as reliability. A new approach to assessing measurement precision, known as generalizability theory, is beginning to be widely used.

Classical Test Theory and Reliability According to classical test theory, every observed score on a test or measure, denoted X, can be divided up into two

components: a true score, T, and an error component, E.

$$X = T + E \quad [1]$$

There are several important assumptions made. First, this relationship is additive; in other words, X is the sum of $T + E$, it is never the product. Second, T and E are independent of each other. Third, the error component, E, is random, so it is independent of any other measure, any other true score, or any other error component. Fourth, if an individual is measured repeatedly, the true score T is unchanging, but the error component E may change. It follows from these assumptions that the variance of X can be divided into two components: the variance of the true score and the error variance.

$$\sigma_X^2 = \sigma_T^2 + \sigma_E^2 \quad [2]$$

It is important to note that the true score variance can be further divided into valid and invalid variance. Valid variance is variance due to the underlying trait the instrument is intended to measure. Invalid variance is true score variance that is not due to the underlying trait the instrument is intended to measure. Instead, it is due to some other trait or quantity. Thus it is a type of error variance, but it is systematic rather than random error. In some ways the term *true score* is a misnomer, because true scores are not necessarily a true reflection of the construct being measured.

Measurement reliability is defined as the proportion of observed score variance that is made up of true score variance:

$$\frac{\sigma_T^2}{\sigma_X^2} \quad [3]$$

All else being equal, a large reliability is desirable in a measurement instrument. When reliability is large, it means that a relatively small proportion of the observed score variance in an instrument is made up of random error. However, a large reliability does not imply that the instrument is valid. In fact, it is possible for an instrument to have a large, even perfect reliability but zero validity, if the true score variance is made up exclusively of invalid variance. Validity, the proportion of observed score variance made up of *valid* true score variance, cannot exceed reliability.

Methods for Assessing Reliability In most measurement situations only the observed score is known. The true score and the error score are unknown. Thus one cannot directly determine reliability. However, there are several methods for approximating reliability.

Test–retest reliability Test–retest reliability of an instrument is computed by measuring subjects at two distinct occasions on the instrument and then computing the correlation. If the correlation is large, this is considered evidence for good test–retest reliability. However, the test–retest procedure makes the assumption that the construct being measured does not change over time. In life span developmental research, this assumption is usually unwarranted. If the subjects in a study undergo change on the construct at different rates between the first and second occasions, the correlation between the two occasions can be low even if the measurement instrument is highly precise.

Split-half reliability Split-half reliability is computed by administering an instrument at a single occasion, randomly dividing the items into two subsets, and correlating the two subtests. The idea is that if the instrument is highly precise, any two halves should be highly correlated. A problem with the split-half approach is that the assessment of reliability can differ considerably depending on which of the many possible divisions of the items is used.

Cronbach's alpha Cronbach's alpha is a way of assessing reliability by comparing the amount of shared variance, or covariance, among the items making up an instrument to the amount of overall variance. The idea is that if the instrument is reliable, there should be a great deal of covariance among the items relative to the variance. Cronbach's alpha is equivalent to taking the average of all possible split-half reliabilities. Most computer packages for statistics in wide use today can compute Cronbach's alpha. Often it is helpful to examine what the Cronbach's alpha becomes after a particular item is deleted. If Cronbach's alpha goes up considerably upon deletion of an item, the item may not belong in the measure.

Generalizability Theory Generalizability theory focuses on identifying and assessing the effects of various possible sources of error in measurement. According to this approach, each measurement situation involves one or more facets. One facet is usually test or questionnaire items. Other facets may be raters, times, or any of a number of possible aspects of a measurement design. (Although times may be a facet, it is important to note that generalizability theory assumes that the quantity being measured is unchanging.) Usually the items, raters, or times are

sampled from the larger population. For example, a test contains a sample of items, not an exhaustive list of all possible items. Generalizability theory poses the question. How generalizable is the score on the instrument to other samples of items, raters, times, and so on? In order to perform a generalizability study, it is necessary to collect data on the instrument in question. Then ANOVA is used to partition the variance in the instrument into components. Some of the variance is attributable to individual differences among the subjects, whereas other variance is attributable to differences within a facet, such as differences between raters. All else being equal, good generalizability is reflected in a larger proportion of variance due to individual differences between subjects and a smaller proportion due to a facet.

A generalizability analysis can provide a great deal of useful information. Because it partitions error variance, it allows the researcher to study the sources of error in a study. The results of a generalizability study give the researcher the information necessary to decide what to do to reduce error. Often increasing the number of elements of a facet, such as increasing the number of raters or the number of items, can reduce the amount of error. Furthermore, the analysis can help the researcher to assess the costs of reducing the length of an instrument or using fewer raters.

Behavioral Observation

Sometimes asking individuals to report on their own behavior is not desirable or even feasible. For example, very young children are not capable of completing self-report questionnaires or responding to in-depth interview questions. Or, it may be desired to measure certain aspects of interpersonal interactions, such as grandparent–parent discussions about child rearing, as they are taking place so that a sequence of conversational statements and responses can be determined. In these situations and many others data are collected by behavioral observation. Trained observers watch behavior, either as it occurs or recorded on videotape, make judgments about what is going on, and record the instances of whatever behavior is of interest. There are several important procedures to follow when collecting behavioral observations. First, a detailed and explicit system for coding the observed behaviors must be developed and pilot tested before data collection begins. Second, the observers should be thoroughly trained in the behavioral rating system. Third, it is critical to have more than one observer rating behaviors simultaneously. Fourth, where possible the observers should be kept uninformed about the study hypotheses or any expectations the experimenter has about the outcome, so that this information will not bias their interpretation of what they see. (They can be briefed about the study after data collection has been concluded.)

There are several methods used to establish measurement precision of behavioral observation. Often the correlation between raters is called interrater reliability. Technically this quantity is not a reliability, although it may be useful information. When the rating involves choosing among qualitatively different categories, Cohen's kappa is an informative measure of interrater agreement and is recommended over the more commonly used percent agreement. For most research the method of choice for assessing measurement precision of behavioral observations is generalizability theory, because it allows the investigator to distinguish among, and ultimately act upon, different sources of measurement error.

Respiratory System

N S Cherniack, University of Medicine and Dentistry of New Jersey, Newark, NJ, USA
E P Cherniack, Miami VA Medical Center, Miami, FL, USA

Glossary

Alveolar Capillary Membrane – The alveolar epithelium, interstitial tissue, and capillary endothelium separating gas in the alveoli from the blood in lung capillaries.

Carbon Dioxide Response Slope – The change in ventilation per minute produced by a change in arterial partial pressure of CO_2.

Functional Residual Capacity (FRC) – The volume of air in the lungs at the end of a normal expiration with the respiratory muscles at rest.

Mucociliary Blanket – Hairy cells with covering mucus that lines the airways of the lungs.

Oxygen Response Slope – The change in ventilation per minute produced by a change in arterial partial pressure of O_2.

Oxygen Saturation – The amount of oxygen combined with hemoglobin as a percent of the maximal amount that can be so combined.

Partial Pressure – The escaping tendencies of dissolved gas in the blood (e.g., pO_2, partial pressure of O_2; pCO_2, partial pressure of CO_2).

Residual Volume (RV) – The volume of air remaining in the lung after a maximal expiration.

Vital Capacity (VC) – The maximal volume of air that can be expired after a maximal inspiration.

Introduction

The function of the respiratory system is gas exchange. It supplies oxygen to the body and removes carbon dioxide by propelling air into and out of the lungs in a controlled manner, keeping the levels of the two gases in the blood within narrow limits. This operation is complicated in humans by the sleep/waking cycle, which alters the activity of the muscles of the chest wall and upper airways; by speech, which involves the use of the respiratory muscles; by eating, because the airways must be protected from the entrance of food particles; and by exercise, because the increased demand for oxygen must be met by muscles, such as the diaphragm and intercostals, which are perched on a platform that moves with the contraction of the arm and leg muscles. All this requires the coordinated activity of many elements so that it is not surprising that there are many causes of respiratory failure, as shown in **Table 1**. Although respiratory failure is increasingly frequent in the elderly, aging per se produces only small changes in respiratory system function. However, the continuous exposure to microorganisms and other noxious elements in the air places the airways and lungs in danger and requires elaborate humoral and cellular mechanisms to defend gas exchange. Decreases in immune function do occur with age. In some cases, in part depending on lifestyle, repeated inflammation and repair of the lungs and the airways lead to remodeling, resulting, depending on the balance of repair and destruction, in the loss or fibrosis of lung tissue. This results in hypoxia with its consequent adverse actions on the neurological and cardiovascular systems.

Normal Operation of the Respiratory System

Breathing is an involuntary act controlled by respiratory neurons in the lower brain stem, primarily the medulla and pons. These neurons are interconnected

Table 1 Causes of respiratory system failure

Functional element	*Disease example*
Central nervous system	
Mind	Severe depression
Brain	Stroke
Spinal cord	Amyotrophic lateral sclerosis
Peripheral nerves	Multiple sclerosis
Chemoreceptors	Congenital hypoventilation syndrome
Electrolyte/acid–base balance	Vomiting
Chest wall	Kyphoscoliosis
Respiratory muscles	
Diaphragm and intercostals	Myopathy
Laryngeal and pharyngeal	Enlarged tonsils
Circulation	
Systemic circulation	Heart failure, pulmonary edema
Pulmonary circulation	Pulmonary hypertension
Lungs	
Upper airways	Laryngeal paralysis
Bronchial tree	Asthma
Alveoli	Emphysema
Extracellular matrix	Idiopathic pulmonary fibrosis

in networks and probably also contain pacemaker neurons. They direct the muscles of the thorax and abdomen to contract and relax, altering the pressure around the lung so that air enters the tracheobronchial tree during inspiration and is expelled during expiration. The incoming air is brought to body temperature and humidified, and particulate matters ($>5\,\mu m$) are removed as air travels down through the nasal and oral cavities and the larynx (the upper airways) and then through the trachea, bronchi, and bronchioles (the lower airways). The lower airways are lined by a mucous layer and cilia (mucociliary blanket), which help to remove particulate matter.

Air makes contact with the blood in microscopic air sacs of the lung called alveoli, where O_2 enters and CO_2 leaves the blood by diffusion. The pumping action of the right ventricle propels blood returning from body organs and tissues through the pulmonary artery and its branches to the capillary bed. The pulmonary veins bring blood enriched in O_2 and with lower levels of CO_2 back to the left side of the heart, where the left ventricle pumps the now arterialized blood to the tissues. Oxygen is carried in the blood mainly in combination with hemoglobin but also as dissolved O_2. Carbon dioxide is carried in the blood mainly in the form of bicarbonate but also as CO_2 in solution.

Sensors in the arterial blood (peripheral chemoreceptors) and in the brain (central chemoreceptors) monitor CO_2 and O_2 levels and send signals to the respiratory neurons in the brain, which activate the respiratory muscles. A decrease in the partial pressure of oxygen (pO_2) or a rise in the partial pressure of carbon dioxide (pCO_2) excites these sensors and in turn increases the activity of brain stem respiratory neurons. Contraction of the respiratory muscles becomes more vigorous and more frequent, thereby increasing ventilation (the volume of air entering and leaving the lung). Neurons in the brain stem also help coordinate the operation of the respiratory and cardiovascular systems so that tissue metabolic requirements are met. Increased metabolism, for example, results in increased ventilation and increased blood flow to the tissues where metabolism is arising. When the respiratory system is healthy, the oxygen supplied at the gas–blood interface in the lung (the alveolar–capillary membrane) maintains pO_2 in the arterial blood at sufficiently high levels (>90 mmHg) so that the hemoglobin is nearly saturated with oxygen. Enough CO_2 is removed so that pCO_2 is kept near 40 mmHg to maintain acid–base balance near normal (as measured by arterial pH, about 7.40).

The deterioration of respiratory function as a result of aging itself, although measurable, is relatively small.

In large part, respiratory function is preserved by a special system that includes reflexes that prevent aspiration of foreign material into the lungs. These include the mucocilary blanket lining the airways, which clears particulate matter from the tracheobronchial tree. In addition, immune cells in the alveoli and lymphatic system of the lung remove microbes and other harmful inhaled matter and help neutralize toxic chemicals released in the lung with age.

Effects of Aging on Lung Function

With aging, there is a significant decrease in the elasticity of the lung. Alveoli widen and the alveolar surface area per unit of lung volume decreases. These structural changes are a consequence of biochemical alterations in the extracellular matrix of connective tissues that surrounds the alveoli and bronchi.

Changes in lung elasticity with age affect lung volumes. When the respiratory muscles are inactive, lung volume is determined by the balance between the tendency of the lung to collapse due to its elasticity and the opposing tendency of the thoracic cage to expand. The resting lung volume, the volume at the end of a normal quiet exhalation, is termed the functional residual capacity (FRC). Because the elasticity of the lung decreases with age more than that of the chest wall, FRC is larger in the elderly than in the young.

Peripheral airways are essentially tethered to the lung parenchyma. Lung tissue pulls outward on the airway walls, and the airways are kept open by the elastic recoil of the attached alveolar walls. The loss of lung elastic recoil with age decreases this tethering effect, resulting in a narrowing of peripheral airways. With narrowing, the resistance of the airways to the flow of air becomes greater. The resistive properties of the airways are commonly assessed from measurements of airflow rates out of the lungs during rapid, forceful expiratory maneuvers. Following a maximum inspiration, the volume exhaled during the first second of a subsequent forced expiratory maneuver is termed the FEV1 (forced expiratory volume in 1 second). The reduction in airway caliber that accompanies the loss of lung elastic recoil with advancing age results in a decline in FEV1 that averages about 30 ml/year from age 25 to 65. FEV1 continues to fall after age 65 but at a somewhat reduced rate of 20 ml/year. The annual rate of decline in FEV1 is considerably accelerated in cigarette smokers.

As lung volume decreases from total lung capacity (TLC) (i.e., the volume of air contained in the lungs at the end of a maximum inspiration) to residual

volume (RV) (i.e., the volume of air remaining in the lungs after a maximum expiratory effort), the airways normally shorten and narrow. Near RV, some airways, particularly those at the lung bases, actually close. With reductions in elastic recoil of the lung with advancing age, airways tend to close at higher and higher lung volumes, trapping alveolar gas behind them and raising residual volume. Also, the vital capacity (VC), the difference between TLC and RV, decreases with age.

Changes in lung elastic properties with advancing age do not occur uniformly in alveoli throughout the lung. This lack of uniformity results in unevenness in the distribution of ventilation, usually without adequate compensatory readjustments in the distribution of pulmonary blood flow. As a result, there is a mismatch in the ratio of ventilation to perfusion in some gas-exchanging areas of the lung, and blood leaving those alveoli may not be fully oxygenated, increasing the gradient between the partial pressure of oxygen in the alveolar air and the arterial blood. Some, but not all, investigations suggest impaired diffusion of gas across the alveolar–capillary membrane with aging, but abnormalities in diffusion probably do not contribute significantly to changes in oxygenation with age. The alveolar–arterial oxygen gradient increases by about 1 mm/year from ages 60 to 75 and then remains virtually constant. Overall, arterial O_2 saturation falls only slightly with age, and there are no significant changes in arterial pCO_2 that can be ascribed to aging alone.

The decrease in the ability of the elderly to achieve levels of exercise as high as those of younger people is largely due to changes in the cardiovascular system and in the fiber composition of skeletal muscles rather than to changes in the elasticity of the respiratory system. Both the maximal heart rate and maximal cardiac output that can be achieved during exercise fall with advancing age. The kinetics of changes in cardiovascular variables and oxygen consumption decline as well. However, the elderly may be able to perform for longer periods of time at a higher percent of maximal oxygen consumption than the young.

Effects of Aging on Respiratory Muscle Function

Changes with age in the respiratory muscles contri bute to decrements in respiratory function. Respiratory muscle strength is weaker in the elderly, reducing the maximal pressures that can be exerted during inspiration and expiration. Maximal inspiratory pressure decreases progressively after age 20, whereas the loss in maximal expiratory pressure accelerates past age 50. These reductions in maximal respiratory pressures correlate with age-related reductions in the strength of other muscles, such as the trunk flexor and the handgrip muscles. Moreover, there is evidence suggesting that the respiratory muscles may be more liable to fatigue in the elderly than in the young.

The diaphragm in mammals is the main inspiratory muscle. Studies in hamsters show that there are decreases in the rate of both contraction and relaxation of the diaphragm with age. Tensions per cross-sectional area of the diaphragm are reduced, and the velocity of its shortening is slowed. These functional changes may reflect less activated actinomycin cross-links in older animals, decreases in rates of cross-bridge cycling, and reduced actinomycin ATPase activity.

Effects of Aging on the Regulation of Respiration

Ventilation is controlled reflexly through the mediation of chemo- and mechanoreceptors but can also be controlled deliberately and can be modified via the action of suprapontine brain centers, which can alter breathing as emotional conditions and states of alertness change. In the awake state, the behavioral and reflex controls interact to shape ventilation patterns and allow impediments to breathing to be detected. During sleep, breathing is mostly controlled reflexly, but sleep is interrupted by an arousal mechanism when breathing difficulties occur.

Chemoreceptors in the carotid and aortic bodies are responsible for the changes in ventilation that accompany alterations in the partial pressure of oxygen in the arterial blood. Central chemoreceptors located at multiple sites in the medulla primarily mediate the ventilatory responses that occur with changes in pCO_2. These chemoreceptors are critical for the maintenance of normal body oxygenation and acid–base balance. The sensitivity of the chemoreceptors is assessed from measurements of the ratio of changes in ventilation to changes in blood gas when breathing or rebreathing various gas mixtures containing oxygen and carbon dioxide. The effects of age on respiratory chemoresponses remain uncertain. Several published reports describe age-related decreases in respiratory responses to chemical stimuli. Other studies, however, have failed to note any significant differences in the responses of young and elderly people. On average, the ventilatory responses to hypercapnia are usually lower in older subjects as compared to young subjects. However, the interindividual variability in

responses is so great that group differences are usually not statistically significant.

Similarly, the results of studies of the effects of aging on hypoxic ventilatory responses vary. Some studies have reported attenuated ventilatory responses to hypoxia in elderly adults. A decrease in type I cells, the O_2-sensitive cells in the carotid body, has been reported in the elderly. In contrast, other investigations indicate that hypoxic ventilatory responses, particularly when measured at normal resting pCO_2 levels, are actually higher in the elderly as compared to young people.

There is an important synergistic interaction between the responses to hypercapnia and hypoxia, and the strength of the interaction may vary with age. Whereas in the young there is a multiplicative interaction between hypoxia and hypercapnia (i.e., hypercapnic ventilatory response slopes are steeper during hypoxia than during hyperoxia), in the elderly hypoxia has only an additive effect on hypercapnic responses, with no change in CO_2 response slopes.

This alteration in respiratory regulation in the elderly is probably due to age-related changes in central respiratory neuronal activity. Changes in ventilatory system mechanical properties and respiratory muscle strength found in the elderly are not sufficiently severe to account for changes in ventilatory chemoresponses.

In addition to chemoreceptors, there are other systems that provide information to the central respiratory controller about the state of the lungs and the respiratory muscles. Vagal receptors, including stretch receptors, irritant receptors, and J-receptors, report volume, flow, and pressures within and around the airways and lungs. Respiratory muscle receptors, including muscle spindles, and tendon organs monitor muscle length and tension. Reflexes involving these mechanoreceptor inputs help control the pattern of breathing and mediate adjustments in breathing when the mechanical properties of the lung are rendered abnormal by disease. For example, some diseases may increase the fibrous tissue in the lung (e.g., many occupational lung diseases), making the lungs stiffer. Other diseases (e.g., asthma) narrow the airways and increase the resistance to airflow. In both instances, greater muscular force is required for ventilation, and the activity of respiratory muscle receptors may be altered.

Emotions such as anxiety tend to accelerate breathing rates, lowering expiratory time. In addition, a wakefulness drive prevents the lowering of CO_2 partial pressures (hypocapnia) from producing apnea. A period of voluntary hyperventilation in awake individuals is rarely followed by a period of apnea, but apnea does occur in persons who have cerebrovascular disease, indicating an abnormality in wakefulness drives. The effect of voluntary hyperventilation in the elderly has not been studied.

Changes in the elastic and resistive properties of the lung can be perceived consciously and can be simulated with externally applied devices. Respiratory mechanoreceptor afferents transmitted to higher brain centers may subserve some of the sensations associated with the act of breathing. Psychophysical studies of respiratory sensations have shown that the perceived magnitude of externally applied elastic and resistive ventilatory loads is reduced in the elderly. This impairment of ventilatory load sensation is consistent with other age-related changes in perceptual sensitivity. Advancing age is associated with a reduced ability to detect changes in joint motion, vibration, and heaviness of lifted weights. This suggests that blunted respiratory sensation in the elderly is due to a generalized loss of kinesthetic sensibility.

Breathing During Sleep in the Elderly

Breathing during sleep becomes more variable with aging. Sometimes breathing during sleep ceases momentarily but repeatedly during the night. These episodes of sleep apnea occur more frequently in older than in younger individuals. Apneas are of two types: central, in which respiratory effort stops, and obstructive, in which respiratory efforts continue but no air enters the lungs because of blockage in the upper airway. Both types of apnea occur more often in the elderly. Periodic breathing, a waxing and waning of respiration during sleep, is also more common in the elderly and contributes to the occurrence of both central and obstructive apneas.

Why sleep apneas occur more often in the elderly is still uncertain. A number of different mechanisms may be involved, including the sensitivity of the chest wall and upper airway muscles to chemical and mechanical stimulation and the strength of wakefulness drives.

Sleep consists of two distinct stages: rapid eye movement (REM) sleep, which is generally associated with dreaming and rapid movements of the eyes, and non-REM sleep (NREM). Responses to hypoxia and hypercapnia diminish during NREM sleep and diminish even more so during REM sleep. A study in animals demonstrated no changes in the ventilation response to CO_2 during sleep with age, but the response to hypoxia was not studied. Responses to mechanical stimulation of the upper airways are generally diminished during sleep, but the effect of aging on these responses is not known.

The patency of the upper airway during sleep depends on the activity of the upper airway muscles. Many of the laryngeal and pharyngeal muscles, in addition to their protective function, display a respiratory rhythm that during inspiration serves to stiffen and dilate the airways. With inspiration the pressure in the airways becomes subatmospheric. The upper airways tend to collapse with the negative pressure produced in the pharynx and larynx during inspiration if these muscles are not appropriately activated. Like the diaphragm and the intercostal muscles that move the ribs, the activity of the upper airway muscles increases with hypoxia and hypercapnia. The tongue muscles, which widen the pharynx, and the laryngeal abductor muscles, which widen the laryngeal aperture, contract more forcefully when CO_2 is raised or when O_2 levels are decreased. Sleep has a much greater depressant effect on the activity of these upper airway muscles than on the thoracic muscles. Thus, airway obstruction is more likely to occur during sleep than it is during wakefulness. Snoring is a result of partial obstruction of the upper airways.

Cyclic changes in the activity of upper airway muscles and the diaphragm have been observed during periodic breathing. Poor coordination of the activities of the upper airway muscles and the inspiratory chest wall muscles such as the diaphragm, particularly during periodic breathing, may be an important cause of both central and obstructive apneas in the elderly.

Although there have been very few studies of the upper airways in the elderly, in younger individuals differences in the ability of the upper airway muscles to respond to chemical or reflex stimulation have not yet been found. No anatomical differences in upper airway diameters between young and old were found in one study in humans that used computerized axial tomography (CAT) scanning to assess upper airway cross-section. However, in edentulous individuals the upper airway is narrowed and obstructive sleep apneas are more common.

The intermittent hypoxia that occurs with sleep apnea and the surges in sympathetic activity that accompany arousals from apnea have adverse health effects that predispose the individual to pulmonary and systemic hypertension and that have been implicated in epidemiological studies in causing diabetes, strokes, and heart attacks.

The Effect of Aging on the Defenses of the Lungs

Table 2 lists the mechanisms that protect the lungs. Aging affects both the innate and adaptive arms of the immune system. The elderly are at greater risk for viral and bacterial infections of the lung, conditions that suggest deficiencies in immune response.

Table 2 Respiratory defense mechanisms

Chemokines
Antiproteases
Anti-oxidants
Multisystem warning signals
Fever
Dyspnea
Leukocytosis

The gag reflex is diminished in the elderly so that aspiration of material from the pharynx into the lungs is more likely, as are pneumonias. The airways of the elderly respond normally to challenges by bronchoconstrictors such as methacholine. The lower airways also contain receptors that allow them to constrict or dilate when stimulated via the autonomic nervous system. Generally, the response to such stimulation is smaller in the elderly, which may help limit particle access to the alveoli.

The clearance of particles in the airways of the lung occurs by movement of cilia in the airway that are embedded in a lining layer of mucus. This mucociliary clearance is diminished with aging. Ultrastructural changes have been observed in the tracheal glands, and the composition of the mucous blanket is changed so that its viscosity is increased with age.

Inflammation in the lungs caused by inhaled injurious elements leads to the release of enzymes that cause tissue breakdown. Destruction of the extracellular matrix of the lung, a complex structure composed of long-chain proteins such as collagen, elastin, laminin, and gelatin, is central in the pathogenesis of emphysema. Proteolytic enzymes found in the lungs are of three types, serine proteases, cysteine proteases, and matrix metalloproteinases. They are produced in the respiratory tract by macrophages and bronchial epithelial cells but mainly by the influx of neutrophils that occurs during inflammation. Neutrophil elastase, an important serine protease, is inactivated by antiproteases such as α1-antitrypsin.

Oxygen radicals released during inflammation also promote lung injury. Extracellular oxidants such as glutathione peroxidase are upregulated in conditions of oxidative stress, such as during cigarette smoking.

A number of growth factors are involved in repair processes following tissue damage. One important factor in the lung is TGF-β, which is formed by many different cells in the lung, including epithelial cells and macrophages, and is induced by tissue injury. TGF-β plays a central role in limiting inflammation and in tissue remodeling and repair. However, overexpression of TGF-β and its receptors leads to pulmonary fibrosis.

Neutrophil function is reduced by aging and leads to decreased ability to phagocytize and to release superoxides and proteases. There is some decrease in chemotactic ability in those over 80.

Alveolar macrophages are of major importance in lung defenses. Alveolar macrophages are a unique type of cell that differs from other macrophages in types of receptors, antigen presenting capacity, and eicosanoid production. They are involved in the clearance of foreign proteins and inflammatory cells. Alveolar macrophages also have a regulatory function and initiate signaling cascades during inflammation and in repair processes. They secrete diverse substances, such as leukotrienes, cytokines, proteases, and antiproteases. Macrophages may help modify lung fibrosis. Macrophage function does not seem to change appreciably with age.

However, there are substantial deficiencies in the activity of T and B lymphocytes with age. B lymphocytes are able to produce less immunoglobulin, but the ability to produce autoantibodies has been reported to be greater. This may lead to poorer immune regulation by suppression in the elderly. T cells show less proliferative response to antigens or to mitogens such as plant lectins. The production of cytokines (chemicals important in the immune response) by T lymphocytes is also lower, with decreases in both interleukin-1 and -2 formation. Tumor cell lysis is less, as is natural killer cell activity.

There is an age-related expansion of undifferentiated lymphocytes. These T cell changes appear to be related to reduced secretions of thymic hormones.

Other changes in immune function occur with the aging process. Responses to skin antigens are decreased in the elderly, but reactivity to most antigens in the inspired air is not. Immune responses to tuberculosis as measured by tuberculin test responsivity are reduced.

Decreases in lung defenses probably contribute to bronchitis, pneumonia, and chronic obstructive lung disease, which are common illnesses in the elderly. But an additional problem is the absence of the usual systemic signs and symptoms of lung infection. The elderly frequently fail to become febrile with an acute infection or to mount an appreciable increase in white cell count. Many times confusion is the main symptom of a serious infection. In addition, sensations of breathless are sometimes blunted in the elderly. This increases the difficulty of diagnosing community-acquired pneumonia and pulmonary emboli, which are frequent life-ending events, and may delay appropriate treatment. While some elderly develop significant impairment of respiratory function, others, perhaps by adopting appropriate lifestyles, are able to maintain nearly normal respiratory capacity.

Retirement

R C Atchley, Lafayette, CO, USA

Glossary

Retired Person – Someone with a lengthy work history who has experienced a substantial reduction in employment, accompanied by retirement pension income.

Retirement – (1) The institutional arrangements that provide retirement pensions and rules of eligibility for retirement. (2) The transition between a lifestyle that includes a substantial amount of employment and a lifestyle focused mainly on retirement. (3) The life stage following retirement from the labor force.

Retirement Pension – A periodic payment, usually linked to past earnings and years of service, provided to those who meet retirement eligibility rules, usually age and/or years of service.

Introduction

To society, retirement is a social institution consisting of rules of permissible and required exit from the labor force based on age or length of service and the financial arrangements for creating and delivering retirement pensions. To individual workers, retirement is the transition to a life stage that does not require employment. As an individual attribute, retirement is characterized by withdrawal from the labor force and support from one or more retirement pensions.

The Importance of Retirement to Society

Industrial societies today have well-developed financial and social arrangements for the orderly withdrawal of aging and older people from the labor force. Although the specifics of retirement policies and financing differ considerably across countries, more than 90% of the population age 65 or older is retired in a large majority of industrial nations. In addition, non-industrial nations have adopted features of the retirement institution in selected areas of their economies, especially in civil service and in the military.

Although retirement is quite similar from one industrial society to another in terms of the proportion of elders who are retired, eligibility rules and financing mechanisms vary considerably, and forces influencing retirement policies are often culture specific. Exploring international variations in retirement is beyond the scope of this discussion. Instead, the development of retirement in the United States is used as a case study to illustrate various concepts and theories concerning retirement's origins, functions, and development.

As a social institution, retirement revolves around two important sets of social policies: (1) rules establishing eligibility for retirement pensions, and (2) policies that gather the financial resources to pay retirement pensions. As a result of the develop ment of retirement, industrial societies allocate about 10% of gross domestic product to public Social Security-type retirement pensions alone. In addition, 20–30% of all stocks, bonds, and government securities in the United States are held by employee pension programs.

Individuals usually see retirement as an emancipatory life stage, one in which the individual is free

to decide for him- or herself what goals to pursue. At retirement, individuals see themselves as shifting from working for someone else to working for themselves. Employers see retirement as an effective labor management device that allows them to reduce their labor force or replace less desirable (older) workers with more desirable (younger) workers. Legislators and administration policy makers, however, tend to be ambivalent about retirement. On the one hand, they see it as an appropriate individual reward for lengthy employment service and as a significant social achievement. On the other hand, they view retirement as a social problem that 'wastes' potentially productive human resources and places an economic 'burden' on society.

Few in this cast of characters understand a basic underlying function of retirement: controlling unemployment in high-energy industrial societies. In industrial and postindustrial societies, most physical work is done by machines, which continue to displace people in the economy at a breathtaking pace, especially in the production sectors of the economy. For example, in the United States in 1930, electric power delivered to commerce and industry provided energy equivalent to the effort of 365 million people. By 1980, the use of electric power by industry was equivalent to the work of 6.9 billion human beings. Today, computerized 'expert systems' displace professional and technical employees as well as clerical workers and industrial wage laborers.

High unemployment has historically been a major source of political instability in industrial democracies, and various social policies evolved that on the surface addressed the public welfare but also had the important function of reducing the size of the labor pool competing for available jobs. Child labor and compulsory education laws removed children from labor competition, and retirement removed older people. Enormous public expenditures go to provide the educational institutions that keep young people occupied. Likewise, public revenues are usually a major source of retirement income in all industrial democracies. Industrial societies need well-educated workers, and elders certainly benefit from having a period of retirement following a lengthy employment history, but the important relation between retirement and the need to control unemployment is a mostly invisible engine that drives the need for retirement. Accordingly, retirement policies have become more liberal in times of high unemployment and more stringent in times of labor shortage. For example, the minimum retirement age tends to drop in response to high unemployment, whereas retirement incentive plans tend to disappear during labor shortages. The benefits of industrial production are many, but there are also costs, and retirement is an important and usual cost of living in industrial societies (*see* Work and Employment: Individual; Work and Employment: Society).

Concepts

Retirement pensions provide the means for carrying out retirement. Without pensions, retirement is possible only for the economic elite. Pensions come in many varieties: public social insurance retirement pensions such as Social Security; employer pensions that provide a defined benefit amount per month, usually based on a formula tied to years of service and earnings; employee pensions based on defined contributions by the employer, the employee, or both, which can often be taken as a lump sum or as a monthly annuity; and self-initiated retirement annuities, many of which are encouraged by tax shelters.

In essence, 'retired person' is an individual status earned by many years of service in the workforce. It is morally approved and economically supported as a legitimate earned right. At the same time, the status of the retired person is presumed to be voluntary. Operationally, a retired person can be defined as someone with a lengthy work history who has experienced at least partial withdrawal from the labor force, accompanied by retirement income earned through prior employment. Retired person can also be a subjectively assigned personal attribute, and in addition is sometimes used as a euphemism for an older person. However, as a legitimate status attribute, retired person is an achieved status, not an ascribed status based solely on age.

Determining retirement status is relatively easy for people who work continuously for 40 years or more and then retire completely, but other categories are more ambiguous. For example, people who 'retire' from one job only to take another full-time job may consider themselves retired and may receive a retirement pension, but are they really retired? What about people who worked only sporadically and thus do not qualify for a retirement pension but who see their means-tested welfare benefit as a retirement pension and label themselves as retired? As the idealized pattern of a long work career followed by abrupt and complete retirement becomes less and less common, defining who is retired becomes more complex and more difficult.

Retirement is also a life transition during which a person moves from full-time employment to no employment. Retirement pensions usually begin when employment is substantially reduced. For some, this transition is abrupt, but an increasing

number of people experience 'bridge' employment, which often involves fewer hours or weeks of employment, sometimes at reduced pay or occupational status, for some period of time before they withdraw completely from the labor force. A broader definition of the retirement transition includes a period of preparation for retirement and a period of adjustment to retirement. By either definition, retirement transitions vary greatly in length and may span a considerable period of time. However, by age 75 all but a very small proportion of adults in industrial societies have withdrawn completely from the labor force.

Retirement is also a life stage that follows a lengthy period of reasonably continuous employment during adulthood. It emphasizes a lifestyle that includes an array of social roles appropriate to a person who is no longer required to be part of the labor force. Retirement is literally a 'do-it-yourself' life stage in that the only cultural expectation of retired people is that they avoid competing for full-time jobs, and even this norm is only half-heartedly applied. Retirement lifestyles can be built around a wide variety of activities such as sports, travel, community service, religious activities, maintaining a home, landscape or vegetable gardening, spiritual contemplation, or taking care of grandchildren. However, the 'busy ethic' requires that retired people remain productively engaged in some way (*see* Leisure).

Retirement is also a social institution made up of a cultural rationale for retirement and a complex array of social policies that establish rules under which people are allowed or encouraged to retire and that provide mechanisms for financing retirement. Ageism – prejudice against aging or older people – is at the heart of the cultural rationale for retirement as a social institution. All industrial societies espouse a widespread cultural belief that aging has profound cognitive and physical effects that interfere with an aging person's capability to engage in productive employment. This often erroneous belief legitimates employment policies that discriminate against middle-aged and older people seeking jobs and that encourage retirement long before the onset of old age, if old age is defined symptomatically as significant physical or mental incapacity.

However, industrial cultures also contain a long-standing norm of caring for elders, which means that simply discharging middle-aged and older workers is not a morally acceptable option. In order to discriminate against older workers and at the same time preserve the illusion that no harm comes to them from this practice, retirement pensions were developed to prevent elders who were displaced from employment from becoming destitute. The extent to which pension systems are designed to provide pensions that will support preretirement lifestyles depends in large measure on the robustness of the economy, the proportion of elders in the population, and organized political advocacy on behalf of, or in opposition to, retirement pensions.

The underlying rationale for retirement may be cultural, but specific retirement policies are managerial and political. In most cases, employer policies are designed to move workers into retirement at the earliest age possible given the level of funding of the employer pension program. By not allowing pensions to increase with years of service beyond the minimum retirement age and/or years of service requirements, employer pensions often contain strong economic incentives to retire. Employers use pensions as bargaining tools in negotiations with employees, even in the absence of unions, particularly as a way of deferring wages into the future.

Public retirement programs are governed by policies developed through a political process. Elements of public retirement policies include the proportion of the population covered, funding mechanisms, minimum retirement age, length of service requirements, relation of eligibility and/or benefit amounts to age, retirement tests, links between benefit amounts and career earnings, special provisions for unhealthy occupations, pension supplements for dependents or retirees, indexing of benefits to offset inflation, and the extent to which benefits are expected to replace preretirement earnings from employment. This large complex of interrelated policies is manipulated legislatively to maintain the functioning of the retirement institution within an area bounded by unemployment rates, levels of poverty in old age, adequate pension replacement rates, and public willingness to finance retirement (*see* Economics: Society).

Each of these elements is in turn influenced by a wide array of factors, chiefly, the robustness of the economy, the proportion of elders in the population, and the extent to which the political process is open to influence by class and/or interest group organizations. The goals of public retirement policies are (1) to keep unemployment down by manipulating retirement levels, (2) to minimize the proportion of older people in poverty, (3) to replace at least 60% of preretirement earnings, particularly for low-income workers, in order to minimize the individual financial hardship connected with retirement, and (4) not to exceed the public's willingness to pay. These goals rise and fall in national value systems in parallel with changes in overall political philosophies. In times of concern for societal safety nets, retirement rises on the public priority list. In

times of concern for individual or family wealth accumulation or minimizing government, retirement assumes less importance. To balance constantly changing factors, most retirement systems are continually under adjustment in response to feedback, especially from business cycles. When the complex of factors that influence employer and self-initiated retirement income programs are included alongside issues shaping Social Security-type public retirement systems, retirement can be a very complex social institution indeed.

History of Retirement

Retirement is a creature of modernization, the sociocultural shift that began in the late 1700s and brought new ways of thinking about how to pursue material progress, particularly in the form of more and better goods and a higher general level of living. Key aspects of modernization included the rise of science as a way of knowing, technology as a means of production, hierarchical bureaucracy as a form of organization, universalistic law as a means of social control, individualism as a moral philosophy, communication as a means of generating agreement, and geographic and social mobility as means of matching people with jobs in an increasingly complex division of labor. As an ideal, a modern society is typified by techno-scientific rationality, universal education, mass organization and communications, cosmopolitan urban populations, and political democracy.

But what is it about modernization that caused older people to be singled out for exclusion from the labor force through the development of retirement? The rise of science as a way of knowing, technology as a way of production, and impersonal bureaucratic rule as a way of deciding are all aspects of modernization that played key roles in excluding elders from the pool of workers defined as desirable and in the development of retirement as a method of ensuring society against widespread personal hardship and political instability that could be expected to accompany the wholesale exclusion of elders from the workforce in the absence of retirement pensions (*see* Modernization and Aging).

Early science was crude in both measurement and research design. The first studies of physical and mental aging focused on mean age differences and paid almost no attention to dispersion around the mean. Thus, early medical texts stressed the sharp declines observed in mean level of functioning for various bodily organs and systems. Early psychology texts stressed mean age differences in cognitive functioning. Little or no attention was paid to the enormous variation in functional capacity within age groups, and no studies were based on longitudinal research designs that looked at actual changes over time. In addition, differences in functioning were compared only across age categories, not against a benchmark level of functioning necessary to sustain a normal level of adult activity. As a result, outrageous generalizations were made and believed about the scientific 'evidence' concerning the negative effects of aging. For example, William Osler, physician-in-chief of Johns Hopkins University Hospital, gave a widely reported address in 1905 in which he contended that aging had such profound effects on human creativity and productivity that men older than 40 could be considered benign but relatively useless workers, and men around age 60 were so useless that they represented a drain on an organization and absolutely had to be retired. Although Osler's view was extreme, it was endorsed in milder forms by influential industrial leaders. This erroneous belief in the relative worthlessness of older people as workers remains strong today, and it forms an important part of the belief system that sustains retirement.

Technology increased productivity enormously, but at a tremendous cost in terms of a net loss of jobs. For example, mechanization of agriculture began to displace farmers and farm workers from the land in large numbers after the American Civil War in the late 1860s. Rapid cycles of technological change led to wide short-term fluctuations in urban industrial employment. Unrest and mob violence associated with cycles of very high unemployment led employers, labor leaders, and politicians to search for ways to moderate the unemployment effects of business cycles.

Retirement was a potential solution to the problems of excess workers, but as long as work organizations were small and proprietary and the relatively few older workers who had to be assigned to lighter work could be paid lower wages, personal relationships insulated older workers from ageism to a great extent. Older workers tended to be dealt with as individuals rather than as members of an age category. However, with the growth of corporate management forms and impersonal, bureaucratic organizational policies, it became possible to justify and implement universalistic policies based on assumed characteristics of age categories. Individual characteristics no longer mattered, nor did variations within age categories.

But as long as retirement was not accompanied by pensions, employers were reluctant to simply throw out older workers. In the United States, the spread of employer pensions in the 1920s and passage of

Social Security legislation in 1935 provided basic models for retirement financing. In the 1950s, changes in labor and tax laws allowed collective bargaining to rapidly expand employer pension coverage. These changes combined to provide a financial foundation for the adoption of retirement as a universal social expectation. Similar systems developed throughout the industrial nations.

In summary, ageism in science, displacement of older workers by technology, and bureaucratic impersonality all combined to devalue older workers and to justify their exclusion from the labor force. The development of public and employer pensions provided the stimulus that attracted workers to retirement.

Current Retirement Trends

In society, levels of retirement gradually increase in response to maturing retirement pension systems. In the United States, the average age of first retirement began to decline in the 1950s. The decline accelerated in the 1970s, leveled off in the 1980s, and then began to increased in the mid-1990s. In 1950, most American workers felt that retirement was justified only if the individual was physically unable to continue working, but by 1960 most said that retirement was legitimate if the individual wanted to retire and had a pension to support it. By 1975, a large majority of American workers had very positive attitudes toward their own retirement. By 2000, a large majority still had a favorable attitude toward retirement, but had much less faith in the capacity of pensions and Social Security to provide the promised retirement income.

Retirement decisions are sensitive to both the lure of pension generosity and the opportunity for continued employment. After 2000, the uncertainty of pensions and retiree health benefits caused more prospective retirees to have second thoughts. This factor is related to fluctuating faith in the governmental systems that ensure pension systems and health-care benefits for retirees. In recent years, both have become more problematic throughout the industrial world. Public discussions of these trends often invoke a demographic argument that retirement is not sustainable in an aging society, but close examination reveals that the most important factor is political willingness to use economic resources to support retirement. In the United States, polls continually show very high public support for programs that ensure adequate pensions and health care for retirees, but political policy makers seem more responsive to voices coming from leaders of commerce and industry, who want to minimize their labor costs.

Early first retirements are not necessarily complete retirements. In the 1980s, labor force data in the United States began to reveal a pattern of 'bridge employment,' a period of continued employment, often full-time, that bridged the point at which the individual began to draw a private pension and the point at which the person could receive Social Security benefits. By 1990, more than half of men who retired completely were retiring from bridge jobs.

Retirement is becoming an increasingly diverse set of patterns: (1) continuation into retirement of occupational inequalities in income and health-care insurance, (2) different age patterns of retirement, and (3) divergent meanings of retirement. Although public Social Security-type pensions provide nearly universal access to retirement in all industrial societies, various rules concerning years of service and benefit computation formulas tend to be a disadvantage for those who have spent significant amounts of time as adults outside the labor force. Sporadic work histories are most common among women, particularly those who drop out of the labor force for childrearing or other types of caregiving.

Industrial societies all have social class and minority group inequalities in opportunities to generate adequate retirement income, but these inequalities range from substantial to trivial. Nations with strong welfare states tend to have strong safety nets and small inequalities in access to retirement income and health care, whereas nations with relatively weak welfare states tend to have much greater inequalities in access to retirement income and health care. But most retirement institutions recapitulate the wage inequalities of the occupational system. Nevertheless, in the latter half of the twentieth century, the maturation of retirement in industrial societies was a major factor in the reduction of poverty associated with old age.

Retirement lifestyles have become increasingly diverse. For some, retirement means a life of leisure, which can take many forms. For others, retirement is an opportunity to become self-employed. Others retire to a life of community service. An increasing number retire into the family by taking on responsibility for caregiving of grandchildren or providing long-term care to older family members. Many retire to a life of couplehood. As people live out retirement as a life stage, they may experience several of these different lifestyles. Increasingly, retirement is coming to be seen as an active life stage that occurs between the cessation of employment and the onset of the frailties that can come with old age. When frailty becomes the organizing principle of one's lifestyle,

the idea of a retirement lifestyle diminishes in importance, even though the person is still retired and receiving a pension.

Effects of Retirement on Individuals and Households

Early gerontologists thought that retirement had a great number of negative effects. In addition to financial difficulties, retirement was said to cause demoralization and a loss of self-esteem, reduced activity levels, increased isolation and loneliness, increased feelings of uselessness, and declining physical and mental health. Many gerontologists thought that the root of these negative outcomes was psychic damage caused by the loss of an occupational identity. It is true that demoralization, low activity levels, and so on could be found among retired people, but most of these unfortunate outcomes were caused by the extremely low retirement incomes of the 1950s. By 1975, cross-national studies that followed people through the retirement transition were finding that retirement had little or no effect on physical or mental health, overall activity levels, social participation, or life satisfaction. It became increasingly clear that depression attributable to retirement was a rare outcome. Given adequate retirement income, most adults were found to adjust very well to the life changes associated with retirement.

Likewise, early literature on retirement assumed that retirement represented a major upheaval for most married couple households, particularly due to the invasion of a traditional 'wife's domain' by newly retired husbands. Again, research showed a different picture. Although there are certainly adjustments that must be made when a working household becomes a retired household, most couples adapt to many significant changes in the course of their marriage, and retirement is well within their coping capacity as a couple. Those couples who have a troublesome relationship in retirement tend to have had troublesome relationships in earlier life stages as well.

Why is retirement such an easy adjustment for most people? First, given adequate retirement income, people can relax about the adjustment process because they do not have to worry about securing the next month's income. Second, most people anticipate retirement and have watched others retire before them. As a result, they do not feel that they are stepping into unmapped territory. There are many clearly marked paths and effective role models. Third, retirement is a morally sanctioned life change. The cultural life course concept in industrial societies defines retirement as an earned reward financed from the productivity of an economic system that individual workers helped to create through their lengthy employment, a reward that individuals ought to and do feel good about accepting. Fourth, as a cultural life stage, retirement still requires individuals to have goals and to engage in productive work, even though it may not be for pay. This expectation of continued productive activity maintains the sense of self as competent and worthy.

Although a large majority of people who willingly retire accomplish the transition with minimal stress and find a satisfying retirement lifestyle within a relatively short time, the small proportion who are coerced into retirement are more likely to experience difficulty. For example, although the practice is often illegal, some workers are given two unattractive choices: retire before they are ready or see their jobs be terminated. Most choose retirement over unemployment, but some cannot be happy about the circumstances under which they retired. They may still have unfinished occupational goals, retirement earlier than expected may result in retirement income lower than they see as adequate, and they may not be ready to relinquish the position of worker. Nevertheless, within a year or two, most reluctant retirees have either found another full-time job or have adjusted well to life in retirement.

Another category of unhappy retirees consists of those who retired for health reasons. If health deteriorates to the point of being so disabling that it forces an individual to retire, no one should be surprised that disability and the constraints on activity that come with it continue into retirement. In these cases, disability, not retirement, is the cause of constricted life space and any attendant psychological distress. Fortunately, the proportion of people retiring for health reasons has dropped dramatically since the 1960s.

Explanations of Retirement

Why does retirement exist? What factors have been responsible for the rapid evolution of retirement and the directions this evolution has taken? What accounts for the rapid public acceptance of retirement, especially in work-oriented societies? Why has retirement been called into question by the very economic, governmental, and political interests that gave rise to it in the first place? These central questions have stimulated social gerontologists to develop a number of explanations.

Why does retirement exist? The idea of retirement from the pressures of economic and social life in one's 60s to lead a life of contemplation and spiritual

growth can be traced back more than 4000 years to the Hindu Vedas. A few medieval farmers deeded their land to their sons or to the church in exchange for a guarantee of food, shelter, and care in retirement. Wealthy merchants could retire and live on the proceeds of their wealth. But retirement has been an economic possibility for most workers only since the advent of modern industrial societies. Why did we create such ambitious and effective systems of financing to provide retirement for the masses? Explanations center around functionalist and exchange theories. Functional theory presumes that retirement is caused by functional needs, particularly the need to control unemployment. As mentioned previously, industrial societies have historically had difficulty providing full employment, and retirement serves an important unemployment control function by systematically removing a sizable segment of the adult population from labor market competition. However, in democratic societies, retirement must primarily be implemented by persuasion and incentive rather than by coercion. Thus, government pensions systems must provide pensions generous enough to attract large numbers of older workers into retirement.

Exchange theory argues that retirement is a result of age discrimination. According to this theory, employers want to hire workers who will give the greatest value in exchange for wages. People in the labor market are not viewed as individuals with unique talents and skills; instead, employers sort potential employees into categories and arrange these categories into a hierarchy of relative desirability in terms of the resources people in the category are assumed to bring to the exchange. In this context, the category of 'older worker' begins at about age 50. Older workers are widely believed to bring fewer resources to the employment transaction in comparison with other categories of adults. Older workers are assumed to have less stamina, less up-to-date education, less ambition, and less creativity. They are assumed to cost more, bring a lower return on training, derive less benefit from training, and resist new technologies. Research evidence indicates that these beliefs are inaccurate, but what matters in the exchange is that managers and policy makers act on these beliefs as if they were true and do not want or need proof in order to act.

Thus, organizations are motivated to create ways of keeping to a minimum the number of employees in the older worker category. They do not hire older workers if they have other alternatives, and they seek ways of moving older workers out of the organization as soon as possible once they enter the older category. To many managers, the only good older worker is a retired older worker. Retirement was developed to provide a means of humanely disposing of workers presumed to be less effective. Again, in industrial democracies, incentives are preferred over coercive policies.

Functional and exchange theories of retirement complement one another. Both accept the notion that older workers are a category that can be legitimately excluded from the labor force. Functional theory focuses on effects of this exclusion on unemployment in the economy as a whole, whereas exchange theory focuses on the presumed benefits of this exclusion for employer organizations. The widespread acceptance of cultural myths about negative effects of aging on employability is foundational for both theories. These theories also help to explain why retirement is encouraged at an age long before the frailties of old age become prevalent in a population cohort.

Some functionalists argue that retirement serves the function of humanely removing people disabled by aging from the labor force. But as a social institution, retirement is not primarily concerned with disabled elders. Indeed, in most societies, disability retirement is handled by a completely different system than service retirement. Retirement policies are designed to encourage older workers, who are assumed to be less effective but who are not usually disabled, to withdraw from employment. Elders who are physically or mentally unable to work can be dealt with through disability pensions, so retirement pensions are not needed for this function.

Other functionalists argue that retirement arose to meet workers' desires for leisure. But this argument has a substantial causal order problem, because retirement pension systems were developed long before a majority of industrial workers began to see retirement as a legitimate individual goal.

But if retirement's major function is simply to remove workers from the labor force, how do we explain the fact that retirement institutions in most societies deliver pensions more generous than would be needed simply to allow people to survive outside the labor force? Pension benefits are usually much more generous than means-tested welfare benefits. Evidence indicates that a large number of workers can be attracted from the labor force with pensions amounting to only 40% of preretirement earnings, but many public retirement systems in the industrial world provide 60% or more earnings replacement. The theoretical answers to this question come from political economy theory, moral economy theory, and social justice theory.

The political economy theory of the dynamics of retirement as an institution starts from several basic

assumptions: most industrial societies are capitalist, capitalist economies exploit workers unless confronted by organized opposition from labor, most industrial societies are democracies, and democratic politics provides a vehicle through which labor, organized or not, can achieve just treatment in the form of adequate retirement benefits. In this frame of reference, the adequacy of retirement benefits is a function of the political power of wage and salary workers. This power can be exercised in one of two ways: through direct negotiations between organized labor and management or through the capacity of advocates for the interests of workers to influence the legislative processes through which public pension formulas are set and rules governing employer pensions are made.

Moral economy theory assumes that raw economic power or political power is not enough to explain the generosity of retirement pensions. Moral economy theory holds that the economy is not just a matter of financial obligations and that for a highly interdependent industrial economy to function, there must also be moral commitments that go beyond simple payment of wages or salaries. These extended commitments provide a sense of security needed for workers to be able to concentrate on doing their jobs productively. Thus, moral economy theory assumes that current wages and other benefits do not fully compensate workers for their labor and that part of their just compensation consists of moral commitments by the society to provide both protection from unemployment and adequate income in retirement. Retirement income is not the only benefit that comes under the moral economy. In the United States, retirees and their dependants are the only major social category covered by national health insurance.

Social justice theory is based on the concept of civil rights. It assumes that eligibility for adequate retirement benefits is a right earned by all residents who participate in the workforce throughout a major portion of their adult lives. The rationale is that in affluent industrial societies, there is no justification for retirees to be disadvantaged by being forced by age discrimination to survive on less than adequate retirement benefits. This perspective helped fuel the successful movement for more adequate Social Security pensions, which began in the 1960s when a large proportion of Social Security pensioners had incomes below the poverty line.

Note that the issue is not whether retirement should exist. That tends to be taken as a given by political economy, moral economy, and social justice theories alike. The issue is the adequacy and fairness of the compensation retirees should receive for leaving the workforce. Evidence indicates that each of these perspectives helps explain the development of retirement.

The nature industrial capitalist economies and political democracy may explain why retirement is needed by society and how retirement benefits came to be at least adequate if not generous. But why does such a large majority of individuals go willingly into retirement, especially if retirement is not mandatory? This question is addressed by theories of individualism and human development.

Individualism as a personal philosophy is at the heart of industrial societies. Young people are socialized to pursue their own individual talents and aggressively seek opportunities in the complex division of labor. Individual freedom and self-determination are held up as high rewards. Retirement may have been created initially as a way to institutionalize age discrimination in employment, but so long as the payoff is adequate, many employees are quite willing to take even a sizable pay cut in exchange for the level of freedom and self-determination that retirement offers.

Adult development theory also offers explanations for why individuals might be attracted to retirement. Few career ladders extend indefinitely. In fact, the concept of career probably poorly describes the succession of jobs that many individuals experience. For those stuck in career or job plateaus, switching job fields is constrained by age discrimination in employment. And even if new jobs were available, the person still may feel at the mercy of another boss. Retirement is a growth option because it offers a secure income and a chance to become one's own boss.

Movement away from a focus on material acquisition and social position represents another developmental support for individual acceptance of retirement. Many adults find that the preoccupation with material acquisition and social position that characterized young and middle adulthood becomes less satisfying over time. These people see more meaning in the quality of everyday life, and retirement gives them more control over that quality than they can achieve if they are still integrated into employer organizations, particularly in a time of growing employer pressures for ever-increasing pace and amount of productivity. For example, as leisure time contracts in the face of job demands, many adults experience a degradation in their quality of life, and they see retirement as an attractive way to restore a better balance of both control and life quality. They also have experienced material acquisition and achievement of social position and often find them overrated as sources of ongoing life satisfaction. They increasingly find themselves drawn to

what they see as a more relaxed and humane pace of life, more control over their personal life goals, and more time for personal relationships and satisfying activities. The informal relationship networks of retired people often resemble a congenial extended family, and the lifestyles of most retired people revolve around meaningful and satisfying activities.

The advantages of retirement have become institutionalized through the packaging, marketing, and advertising of retirement as prepaid leisure. Industries that have formed around individual retirement needs include retirement planning, retirement personal finance, and retirement housing. In recent years, a worldwide network of programs has developed to satisfy the needs of retirees for ongoing education. The offerings of this network span an enormous variety of subjects and are offered all over the world.

Thus, adults go willingly into retirement even though it represents a decline in social status and nothing less than institutionalized age discrimination because for them the benefits, in the form of freedom and enhanced quality of life at the personal level, far outweigh the costs in terms of lost abstract social status.

Why has retirement been called into question by both business and government in many industrial societies? In the United States, the institution of retirement has been under a sustained political and managerial attack since the late 1970s. Part of this assault is based on philosophical opposition to government operations in areas in which private enterprise sees potential business opportunities. Thus, Social Security is criticized on the grounds that private retirement programs could bring workers a better 'return on investment.' That Social Security is social insurance and not intended to be an investment is ignored. These critics also usually ignore survivor, disability, and health benefits that are part of Social Security and imply that retirement benefits are the only return workers get for their Social Security taxes. These arguments are put forward by a financial services industry made up of insurance companies, banks, and securities firms who want to 'privatize' all or part of Social Security in order to increase their own business opportunities.

Employers also want to reduce their Social Security tax liabilities. Corporate income taxes have fallen much faster that individual income taxes in the United States since 1970, whereas the employer's share of Social Security payroll taxes increased from 3% of earnings up to $4200 per year in 1960 to 7.65% of earnings up to $60 600 in 2004. Reducing Social Security taxes is a major policy objective of the American business community. Employers want Social Security to continue to draw older workers out of the labor force, but employers do not want to pay their share of the cost of this benefit.

The financial services industry and business advocates joined forces to mount a well-organized campaign to convince the public that Social Security could not be sustained economically. According to their argument, the rapid increase in older population that will come with the entry of the baby boom population into retirement is bound to bankrupt the system; therefore, people who are currently paying Social Security taxes are unlikely to get their full Social Security pensions. This argument flies in the face of many studies showing that under current benefit formulas, providing Social Security pensions for the baby boomers will require only modest changes to the system under any likely economic scenario. Nevertheless, the propaganda campaign has been very successful in that a large proportion of younger workers in the United States thinks that Social Security will not be there when they reach retirement age, even though a very large majority of workers want the program to remain and express willingness to pay higher taxes in order to maintain it. But as more and more younger workers come to believe that the collapse of Social Security is inevitable, resentment of those who currently enjoy Social Security benefits rises and willingness to pay Social Security taxes falls.

Understanding the multidimensional assault on Social Security demands a conflict theory perspective. The history of retirement in the United States illustrates the potential for conflict between opposing philosophies of government. At one extreme are those who feel that the best government is the least government. A procedural state that allows for peaceful resolution of disputes and a common monetary system are about all that is necessary according to this view. A less extreme but still conservative position would add armed forces, police and fire protection, and perhaps education to the list of public institutions. At the other pole are those who wish for a strong national government to protect the public in a number of areas, including pensions, health care, housing, education, science, commerce, banking, environmental protections, public welfare and transportation. The assault on retirement, especially Social Security, can be seen in a context of a general social movement to scale back the resources going into national government. This movement is being partially fueled by pressures on revenues and wages in an increasingly global system of production. This shift is vigorously opposed by those who believe that there are certain functions, such as national retirement pension systems, that only government can perform adequately.

The power of membership organizations or interest groups made up of retired people to assert a voice in favor of retirement protections is unclear. Again, the United States offers a useful example. On the one hand, the media frequently refer to AARP (formerly the American Association of Retired Persons) as 'the most powerful lobby in Washington.' But AARP is a large and diverse organization of 30 million members with all sorts of political orientations. Most AARP members joined to take advantage of AARP's insurance, financial, travel, and pharmacy services, not to be part of a social movement. To protect its non-profit status, AARP cannot give financial support to political candidates. This is in stark contrast to other powerful lobbies such as the National Chamber of Commerce. AARP does not participate in setting political agendas, but instead reacts to political proposals.

In the 1970s, AARP and other organizations advocating for retirees' interests were effective in shaping the national agendas of the congress and various administrations because the climate was sympathetic to government oversight and programming. By 2005, the public remained sympathetic to the need for Social Security and protections for retirees' pension and health-care benefits, but was apathetic or skeptical about the ability of the national government to deliver. The result of this shift has been a steady erosion of government protections and initiatives aimed at adapting the retirement institution to changing circumstances.

The weight of the evidence suggests that regardless of political or economic philosophy, industrial nations generate policies that move a very large proportion of their older populations into retirement. Therefore, political conflict tends to be about the relative generosity of national pensions, not whether or not to have them. There is no reason to expect that the long-standing tension between advocates of strong government and advocates of weak government will abate, and as this ongoing conflict focuses on public pension generosity, Social Security-type retirement systems will change.

The Future of Retirement

The future of retirement is uncertain. It will emerge from the interaction of a number of opposing economic, political, demographic, and social policy concerns. The key question is whether retirement is or even should be sustainable.

At the turn of the twenty-first century, industrial economies of the United States, Europe, and Japan are not the robust forces they were in 1960. Worldwide decentralization of industrial production has destabilized wages and benefits for large segments of the labor forces in industrial nations. Demassification processes have drastically reduced the scale of many types of economic activity, particularly the types of professional, managerial, and technical jobs that formerly carried access to adequate retirement benefits. Retirement institutions are no longer shaped by negotiations among representatives of huge labor unions, large corporations, and national governments. In the United States, as a result of declines in organized labor, reductions in availability of pension coverage, shifting of pensions from defined benefit to defined contribution approaches, shifting of pension plan contributions from being deferred compensation from employers to being an employee responsibility, and rules that allow employees to withdraw their funds from pension programs when they change employers, access to adequate employer pensions among younger workers is becoming increasingly problematic. This increases the pressure for Social Security alone to deliver adequate retirement pensions. Because of the fragmentation of retirement policy, young workers have little faith in retirement as a social institution they can count on.

The longevity revolution is rapidly increasing the proportion of the population surviving beyond age 85. The retired population begins chronologically as early as age 45, but most people retire in their 60s. This means that retirement income programs must be designed to deliver secure retirement income for up to 25 years on average and for up to 50 in many cases. Policy makers have generally advanced two scenarios for responding to the impending masses of retirees: keeping aging people in the workforce longer, and plan to reduce benefits. Institutional supports for adequate retirement benefits are becoming less reliable, particularly for middle- and lower-income workers.

There is no sign that age discrimination in employment will be reversed or that elders will be welcomed to remain employed. Labor shortages resulting from low birth rates among the middle and upper classes are more likely to be offset by increased immigration or by increased use of technology than by creating more job opportunities for older workers. However, if benefits are reduced, many older people, especially those under age 75, may be forced by economic circumstances to stay in the labor force, where for the most part they will compete with immigrants and young people for low-wage jobs in retail and service sectors of the economy. In any case, keeping more elders in the labor force is not likely to be a satisfactory solution should the increased size of the older population outstrip the will of nations to provide retirement income.

The other possibility is to reduce benefits. Currently, those elders in the United States whose

retirement incomes are mainly from Social Security live just above the poverty line. Benefit cuts would make this population eligible for public assistance, which would simply shift the liability for their income from one government program to another. Sharp reduction of Social Security benefits for middle- and upper-income retirees would reduce the revenues needed to sustain Social Security retirement, but middle- and upper-income retirees feel that they have earned their pensions and expect to receive them. They also have the economic resources and educational background to mount effective political action. Across the industrial nations of the world, public support for public retirement pensions is strong, and political opposition to substantial benefit reductions could be expected.

The sheer number of future elders in the baby boom generation scares policy makers, who picture a huge phalanx of older baby boomers taking to the streets to demand adequate retirement benefits. To head off this possibility in the United States, two major actions were taken in 1983: the age for full Social Security benefits was scheduled to increase gradually from 65 to 67, and the scheduled increases in Social Security taxes were advanced in order to build up a sizable surplus in the retirement trust fund that could be used in conjunction with payroll taxes to pay pensions for the baby boomers. But because projections of survival rates among elders have consistently underestimated the number of future older people, the Social Security system has consistently experienced minor shortfalls that have led to calls for revamping the system. Those opposed to public retirement systems claim it is unsustainable, and those favoring the system claim that only minor adjustments would suffice to keep the system solvent. Similar debates are being held in most industrial societies and are difficult to resolve because there is growing disagreement about what constitute the 'facts' and how to interpret them. Relativism and postmodernism undercut the discourse needed to come to societal consensus about most social institutions, including retirement.

The long-term financial viability of public Social Security-type retirement programs depends on the continued voting support of national legislators. For many decades legislative support for Social Security-type public retirement programs has been unwavering in industrial countries, but in recent years economic pressures have caused legislatures to have second thoughts about pension generosity. Questions about the long-term sustainability of these programs in an environment of economic globalization have been a major factor in softening legislative support. As corporations increasingly operate freely across national boundaries, claims on corporate economic surpluses by national governments become more difficult to enforce. If countries push too hard for a share of economic revenue, the fear is that corporations will move operations elsewhere.

At the same time, pubic demand for retirement is showing no signs of diminishing. In the United States, most people retire in their early 60s, before the age of eligibility for full benefits under Social Security. The concept of retirement as an earned right and as prepaid leisure is widespread. People continue to desire the freedom and autonomy of retirement and to feel that they have earned the opportunity. Despite negative images about retirement and aging in the media, most Americans have very positive images of their own lives in retirement. Their major concern is maintaining adequate income and health care in an uncertain economy with high health-care inflation.

In the United States, public and private pension policies are on opposite courses. The political rhetoric advocating changes in Social Security emphasizes keeping people in the labor force longer and reducing retirement benefits. But employer pensions, nearly all of which are subsidized by tax shelters, are geared toward encouraging older workers to exit the labor force at the earliest age possible. These conflicting philosophies reflect a national ambivalence about retirement that is present in most industrial societies. On the one hand, most people who retire could continue to work. On the other hand, there is not likely to be enough work to go around. Long-term unemployment, which was once mainly something that happened to working class people, is beginning to be widespread within the white collar professional and managerial classes as well. The question is whether the political process will adequately compensate elders for leaving the workforce, force them into a lower-income retirement, or require them to stay in the labor force and risk an open struggle with younger people for jobs on the margins of the economy.

What is the alternative to retirement? Legislators and administration policy makers in the developed world cannot expect the public to sit quietly by and watch barely adequate retirement benefits be replaced by predatory employment or poverty. As retirement becomes more problematic, political conflict over retirement will intensify. Nevertheless, if only because of its unemployment control function, retirement will remain an important social institution in postindustrial or high-tech societies.

Glossary

Cohort – Individuals born in the same time period: either the same year or the same decade.

Cohort-Sequential – A design in which individuals from more than one birth cohort are studied at more than one time point. This design allows for a separation of the effects of aging, cohort membership, and social or cultural events.

Cross-Sectional – A design in which a group of individuals is studied at only one time point. Age effects are assumed when age differences are found between individuals in the group. However, age and cohort effects are confounded in this study design.

Longitudinal – A design in which a group of individuals is studied at more than one time point. Age effects are assumed when the same individuals demonstrate change from one time of measurement to another. However, if this study design is used with a single cohort, then age is confounded with time of measurement.

Repeated Cross-Sectional – A design in which different groups of individuals from the same birth cohort are studied at different times. Aging effects are assumed if differences are found between groups at different time points.

Role – Expectations regarding the rights and duties of an individual holding a certain status position in society.

Introduction

The self-concept refers to the totality of one's attitudes toward the self as an object. It is made up of three parts: cognitive, evaluative, and conative components. The cognitive component refers to the way individuals identify themselves in terms of the roles they play or the characteristics they use to describe themselves. The evaluative component represents the extent to which individuals like or dislike their self-defined identity and reflects their self-esteem. The conative component corresponds to individuals' motivations to maintain or change themselves as a result of discrepancies between their real selves and their ideal selves. Because the majority of the empirical work on the self-concept is on self-esteem, it is the focus of this article.

Of concern to gerontologists is the extent to which self-esteem changes or remains stable across the life course. There are reasons to believe that self-esteem may decline in later life because individuals are more likely to encounter ageism, role loss, or health problems. On the other hand, self-esteem may increase in later life as a result of maturational development. Also of concern are the factors that predict self-esteem in older adults. It is important to know the predictors of self-esteem in later adulthood if interventions are to be made. The primary purpose of this article is to examine the theories, methods, and empirical evidence regarding continuity or change in self-esteem over time. A secondary purpose is to describe the predictors of self-esteem among older adults. While the first part of the article largely deals with inter-age group differences, the second part addresses intra-age group differences.

Due to space limitations, a third issue of interest to gerontologists – the extent to which successful aging is mediated through self-esteem – is not covered in this article. Research is beginning to show that self-esteem may be an important factor in health behaviors, coping, and well-being.

Stability and Change in Self-Esteem across the Life Course

Does self-esteem change with aging? Or is it determined by the time an individual reaches adulthood? Does the aging process have a negative or a positive

impact on self-esteem? If self-esteem does change over the life course, is the pattern linear or curvilinear? What theories are helpful in guiding research on these questions? This section describes the theoretical, methodological, and empirical literature on this topic.

Theories Regarding Stability and/or Change in Self-Esteem over the Life Course

The question of whether self-esteem changes with aging can be approached from a variety of theoretical perspectives. These perspectives do not provide a clear set of propositions to be tested; rather, they suggest whether and when self-esteem would be expected to change, and if so, the direction of that change over the life course. The theoretical approaches include (1) personality trait psychology, (2) life span developmental psychology, (3) role theory, and (4) life course theoretical perspective.

Personality trait theories The question of whether self-esteem changes over the life course could be considered within the larger, ongoing debate in gerontology as to whether personality changes with aging. The extent to which personality changes or remains stable is a long-standing question in the social psychology of aging. Thus, it may be instructive to consider self-esteem and aging within this context since many of the methodological and theoretical issues with regard to stability are the same.

Traditionally, personality traits were defined as the tendency of individuals to behave consistently across situations. Traits could be measured only with projective tests or observations of behavior by trained observers. However, contemporary definitions of personality traits were broadened to include cross-situational consistencies in individuals' thoughts and feelings as well. Consequently, researchers were able to obtain reliable measures of traits with surveys and questionnaires in studies with large samples and longitudinal designs.

Contemporary personality theorists most commonly measure traits by making inferences from respondent's self-reports on a number of scaled survey items. That is, the methods used to measure personality became the same as those used to measure self-concept. This enabled the research on personality to be integrated with the research on the self-concept.

While self-esteem refers to the affective or evaluative component of the self-concept, personality represents the cognitive component. Despite this important distinction, many researchers view self-esteem as a personality trait. Since personality traits are assumed to be stable, at least once the individual reaches adulthood, trait theorists would predict that self-esteem would remain stable across the life course.

Life span developmental theories Developmental life span psychology grew out of the work of Freud, Erikson, and Piaget. These theories share the notion that development, due to its biological basis, is universal and occurs in a sequence of stages generally corresponding to age.

Erikson's eight-stage theory was the first to include adult stages of development. During the sixth stage, intimacy versus isolation, individuals are involved in mate selection, family formation, and career development. Once resolved, individuals move on to the seventh stage, generativity versus stagnation, a time when individuals are concerned with productivity, creativity, and guiding the younger generation. During the last stage, ego integrity versus despair, individuals become less concerned with achievement and more accepting of their life as meaningful.

More recent life span developmental theorists suggest a similar sequence of development. Early and middle adulthood are dominated by a concern with the self, power, accomplishments, and control. Conversely, late adulthood is characterized by a reduction in ego concerns and an increase in self-acceptance. Theories of the stages of adult development suggest that aging is associated with a growing acceptance of self and others.

The life span developmental perspective implies that aging, rather than being merely problematic, is also a positive process. Individuals potentially progress from high levels of ego involvement and self-serving activities in early and middle stages of life to high levels of altruism and interiority in late life. These types of developmental changes lead to a less critical evaluation of self. Thus, based on this perspective, one would predict that self-esteem would progressively increase over the life course.

Role theories Sociologists are critical of theories of life span development for ignoring the contribution of social structure to stability and change across the life course. From a sociological perspective, age-related roles are more important than chronological age for a variety of behaviors and attitudes, including self-esteem.

Roles serve as the link between the individual and society. According to role theory, individuals develop a sense of who they are through interaction with others in the variety of roles they play. Because role relationships are relatively enduring and organized, roles can be a source of stability in self-identity. And because roles are closely connected to the norms

and values of society, having roles not only integrates the individual with society, but also makes life meaningful.

Throughout the different stages of life, individuals are engaged in the process of role acquisition, role transition, and role loss. Age can influence, if not determine, role access and egress. During early and middle adulthood, individuals acquire and transition into many new roles, such as occupational, marital, and parental roles. Involvement in multiple roles provides the individual with many opportunities for social rewards and feelings of competence and achievement. Involvement in social roles results in high levels of self-esteem during these stages in the life cycle. However, during late adulthood individuals experience role loss such as retirement, widowhood, empty nest, and declining health. Consequently, individuals are less integrated with society and have fewer opportunities for social rewards and feelings of competence and achievement. Lack of involvement in social roles would be predicted to lead to low self-esteem toward the end of the life cycle.

This is the same prediction that would be made by activity theory. Activity theory is one application of role theory to the elderly. According to activity theory, social interaction is important for the maintenance of self-esteem. Since the elderly lack formal roles and status within the main institutions of society, it makes it difficult for them to maintain a positive self-evaluation. Continuity theory, another off-shoot of role theory used in gerontology, makes a slightly different prediction. It suggests that a reduction in role activity does not lead to a decrease in self-esteem as long as the individual maintains some continuity between past roles and current interests and behaviors.

From the role perspective, there are two additional reasons why self-esteem would be expected to decline with increasing age. First, the youth-oriented culture in which people live has promoted the development of negative stereotypes of the old. To the extent to which older adults believe and accept these negative expectations, they are cast in unattractive roles. This in turn leads to lower self-esteem. Second, rapid technological advances and social change sometimes make it difficult for older adults to keep pace with society.

Life course theoretical perspective Proponents of the life course theoretical perspective argue that any analysis of individuals must take into account the sociocultural and historical context in which the individuals live. Macro-level events such as the Great Depression, major wars, and various social and political movements interact with the micro-level age-graded role transitions of individuals from different birth cohorts. Different birth cohorts presented with the same events may experience those events in different ways. For example, individuals of draft age during the Vietnam War may have experienced the role transitions of graduation, occupational attainment, marriage, and parenthood differently than individuals who were a decade younger. Both birth cohorts lived during the same historical period, yet the effect of the historical period on the major role transitions of members of each cohort was very different.

This interaction between person and situation can have long-lasting effects and can result in different life course trajectories. This would require studies that would compare different birth cohorts across the long periods of time in order to separate the age, period, and cohort effects.

The importance of this perspective for the study of self-esteem is that it suggests that the level of self-esteem for individuals from a particular birth cohort may, due to sociocultural or historical events, start out lower or higher than other birth cohorts. These events may maintain their influence on the level of self-esteem across the life course and act as a source of stability in self-esteem. For example, individuals born during the Great Depression may have lower self-esteem than individuals who were born after it, and this suppression effect on self-esteem may evidence itself across the life course of this cohort. On the other hand, depending on the stage of life during which the macro-level event occurs, and whether additional events occur at later stages of life, the events could be a major source of change in self-esteem. The direction of the change on self-esteem, either positive or negative, would depend on the event and how it interacted with the age-graded role transitions that were experienced.

Methodological Issues in Studying Self-Esteem and Aging

What are the methodological challenges in examining self-esteem across time? Three methodological issues present challenges to those wishing to study stability and change in self-esteem across the life course: (1) research design, (2) measurement, (3) statistical analysis and data interpretation, and (4) population sampling.

Research design The fundamental problem with cross-sectional studies of self-esteem is that maturation and birth cohort effects are confounded. Thus, it is impossible to determine whether age differences in self-esteem actually represent changes in self-esteem

over time or whether they represent cohort differences. In longitudinal designs the same individuals are studied over a period of time, thereby controlling for intercohort differences.

Although longitudinal studies of self-esteem would be a substantial improvement over cross-sectional studies, several issues still need to be considered. The few existing longitudinal studies of self-esteem have focused on younger age groups to the exclusion of older age groups. Further, these longitudinal studies followed their respondents for relatively short periods of time. To adequately study the effects of aging on self-esteem, mature adults should be included for study, and individuals should ideally be followed across several stages of the life course.

However, even longitudinal designs that span several life stages cannot rule out all alternative explanations. In longitudinal studies of single cohorts, age changes would be confounded with the effects of time of measurement. Further, the unique historical experience of the birth cohort under study (described more fully in the section on contextual analysis) and the possibility of selective attrition could also make the interpretation of aging effects in self-esteem ambiguous.

No design can provide completely unambiguous results regarding the stability of self-esteem across the life course since aging, time of measurement, and birth cohort will always be confounded in any design that is used. However, the optimal method for studying self-esteem and aging would be to use a cohort-sequential design. In a cohort-sequential design, more than one birth cohort would be followed over the same developmental span of time but different historical spans of time, in order to separate out the effects of aging, cohort membership, and social/cultural events on self-esteem. Currently, there are no published cohort-sequential studies of self-esteem.

Measurement One methodological issue is the measurement of self-esteem. Because the majority of the literature on self-concept deals with self-esteem, the terms are often (incorrectly) used interchangeably, leading to a lack of conceptual precision. Similarly, researchers also refer to self-esteem by a variety of other terms, such as self-regard, self-respect, and self-confidence. Without clear definitions, measures cannot adequately represent the constructs under study. Many studies develop their own unique measure of self-esteem rather than use standard scales. Not only do researchers fail to use the same instruments, but they also rarely examine the validity or reliability of these one-shot measures. The practice of using different measures generally produces different information about stability and change in self-esteem across the life course, making it difficult to draw conclusions.

Several standard scales are available to measure self-esteem, the most popular among them being the total positive scale from the Tennessee self-concept scales, the Rosenberg self-esteem scale, and the Monge semantic differential scales. The problem with these scales for age-based analyses is that their validity and reliability, although established on young age groups, have rarely been calculated for older age groups. Without these statistics and evidence of factorial invariance across age groups, intercorrelations between self-esteem and age are difficult to interpret. Low intercorrelations may mean there is no relationship between age and self-esteem or, alternatively, that the scales are inappropriate for use with older age groups.

Statistical analysis There are four ways to assess stability or change in self-esteem: (1) structural invariance, (2) correlational stability, (3) mean level stability, and (4) ipsative stability.

Before other types of stability in self-esteem are assessed, it is necessary to establish that there is structural invariance. Structural invariance refers to the stability in the structure, organization, or dimensionality of self-esteem, typically assessed through factor analysis or cluster analysis. Structural invariance is established when the measure of self-esteem displays the same dimensions and relationships among component elements over time and/or across birth cohorts.

Correlation, the most frequently used method for calculating stability, is a measure of constancy or change in an individual's rank order position on self-esteem over time. Pearsonian, Spearman, or Kendall correlation coefficients are computed between measures of self-esteem at different time points for the same group of individuals. These statistics indicate the extent to which individuals retain their position on self-esteem relative to others from one time of measurement to another.

However, there is no set standard for evaluating whether the level of the coefficients obtained actually represents stability. Consequently, a correlation coefficient of 0.50 may be interpreted by some as an indication of substantial stability in self-esteem, while others may interpret it as an indication of substantial change.

Mean level stability is the constancy or change in the group level of self-esteem over time. In longitudinal

designs, mean scores on self-esteem are compared for the same group of individuals between different time points. Attention is paid to increases or decreases over time in both group mean scores and group variances. No change on group mean scores would indicate stability only if there were also no change in group variances. If there were no change in group mean scores but the variance increased, this would indicate increased individual differences in self-esteem. Change in mean level stability can also be assessed using a repeated cross-sectional design. Aging effects for self-esteem are examined by comparing group means on self-esteem for the same cohorts at different times.

As with correlational stability, there is no agreed-upon standard for deciding whether a statistically significant change in mean level scores is actually substantively significant. That is why a measure of effect size that is independent of sample size should also accompany analyses of mean level or normative stability.

Ipsative stability, a measure of intraindividual continuity in self-esteem, is the least frequently investigated. Based on profile analysis, it provides information as to whether an individual's attributes change their relative position over time.

Depending on the method used to assess stability, the results are likely to be different. Stability using one method does not imply stability using another method. Each method provides different information and likely leads to different conclusions regarding stability or change in self-esteem across the life course. Ideally, studies should report results using all the methods and try to explain any inconsistencies that are found.

Population sampling Substantial heterogeneity exists within the populations sampled for studies of self-esteem. Although respondents vary in sociodemographic characteristics, health, birth cohort membership, and so on, the extent to which these factors contribute to stability or change in self-esteem over the life course is rarely considered. Further, cross-sectional studies that examine age differences in self-esteem do not represent the full spectrum of adulthood among their respondents. For example, some studies compare young adulthood to middle adulthood, while others compare the old to the oldest old. Longitudinal studies have not followed individuals for long periods of time. Without the inclusion of respondents from all age groups or the examination of the same individuals across a large number of life stages, studies can lead to incomplete findings regarding the pattern of stability and change in self-esteem across the life course.

Empirical Studies of Self-Esteem and Aging

What empirical evidence exists on the stability of self-esteem across the life course? Over the last three decades there have been literally thousands of studies published on self-esteem. Given the preponderance of research on this concept, it is surprising how few studies have examined the relationship between self-esteem and aging.

Of the studies looking at age differences in self-esteem that have been published in peer-reviewed journal articles, the majority have employed cross-sectional designs, leaving age and cohort effects confounded. Further, most of these studies have focused on childhood and adolescence. Of the handful of studies that included older adults, the findings were inconsistent: some showed an increase, some showed no change, and some showed a decline.

There have been even fewer longitudinal studies of stability or change in self-esteem across the life course. Those that do exist focused on younger age groups to the exclusion of older age groups and followed their respondents for relatively short periods of time. Only five longitudinal studies published in peer-reviewed journals have included middle-aged and/or older adults. Of these studies, most showed a decline during middle and old age. However, no definitive conclusions can be drawn because the length of follow-up in these studies was only a few years. To adequately address the question of stability and change in self-esteem across the entire life course, long-term longitudinal studies are needed.

Predictors of Self-Esteem in Older Adults

Over the last three decades there have been a greater number of peer-reviewed journal articles investigating the predictors of self-esteem in older adults than those examining stability or change in self-esteem over the life course or the mediating effect of self-esteem on well-being. These studies of the correlates of self-esteem can be grouped on the basis of whether the examined predictor variable was (1) demographic, (2) cognitive, or (3) role related.

Several studies have examined whether race, class, and gender influence the self-esteem of older adults. Some studies have found that these demographic factors interact with age or with one another in their effect on self-esteem. For example, lower social class negatively affects self-esteem among the old but not among the young. Receiving public assistance

lowered the self-esteem of older men but not that of older women. In general, older women have lower self-esteem than older men. Regardless of gender, older adults with higher education have a higher level of self-esteem than their less-educated counterparts.

A growing body of literature has investigated whether cognitive style influences the self-esteem of older adults and whether cognitive style interacts with gender in its effect on self-esteem. Identity assimilation refers to a process by which individuals maintain their identity despite age changes, whereas identity accommodation refers to a process by which individuals change their identity as they age. Researchers have found that identity accommodation was negatively associated with self-esteem for both genders; however, identity assimilation was positively associated with self-esteem only for women. Other researchers have found that older adults who are less introspective or have a negative attitude toward aging also have lower self-esteem.

Another group of studies has examined the influence of roles and/or role behaviors on the self-esteem of older adults. Older adults who experienced widowhood, institutionalization, low religious commitment, physical impairment, or a decline in global health tended to report lower levels of self-esteem than those not experiencing these role changes. On the other hand, self-esteem was higher among older adults who felt competent as a worker, had a commitment to the spouse role, and participated in leisure activities, particularly with friends, than those who did not have a commitment to these roles. Retirement did not necessarily lead to a decline in self-esteem.

As a whole, these studies suggest that there are many ways that older adults maintain self-esteem despite role loss and increased infirmity.

Directions for Future Research

Stability and Change in Self-Esteem across the Life Course

Although the vast majority of the studies of self-esteem focus on global self-esteem, researchers recognize that self-esteem is multidimensional. The dimensions of self-esteem are hierarchically ranked based on their importance to the individual. Since self-esteem is multidimensional and hierarchically ranked, specific components of self-esteem may change over time in response to situational or role changes, while other components may remain stable.

The extent to which changes in any of these specific components affect global self-esteem is not known. Components that are central may affect global self-esteem, while changes in other less central components of self-esteem may have little impact on global self-esteem. Thus, self-esteem may incorporate both stability and change.

Future research should examine whether the aging process results in decreased day-to-day instability in self-esteem and how this relates to long-term stability or instability. Self-esteem may fluctuate day to day or from situation to situation but still retain a stable core. The question for future research should be not only whether self-esteem is stable across the life course but also under what conditions it is stable and under what conditions does it change.

Little is known about the developmental, social structural, contextual processes that influence stability and change in self-esteem across the life course. Future research should be directed at studying how the timing and sequencing of developmental maturation, role change, and life events influence self-esteem over time. In addition, research should be conducted on how the sociocultural and historical context affects the self-esteem of different birth cohorts.

In terms of methodology, the ideal study of stability and change in self-esteem would employ a longitudinal cohort-sequential design that examines different cohorts over the same developmental period but during different historical periods. In terms of theory, the ideal study would combine aspects of all theoretical perspectives to allow for the most fully developed examination of self-esteem and aging.

Predictors of Self-Esteem in Older Adults

Future research on the predictors of self-esteem in older adults should continue to examine the possible interactions between age and other demographic, cognitive, and role-related factors. For example, helping others has been found to increase self-esteem among older adults, but this positive outcome was maintained over time only for respondents whose socioeconomic background was high.

Future research should also compare the relationship between primary aging and self-esteem with that of secondary aging and self-esteem. It may be that self-esteem declines only with secondary aging but not primary aging. Self-esteem may remain high among those who experience only primary aging but not the blows of secondary aging, particularly if they are taught appropriate cognitive styles.

Self-Concept and Body Image

S K Whitbourne, University of Massachusetts, Amherst, MA, USA

Glossary

Body image – Individual's physical sense of self.

Osteoarthritis – Degenerative joint disease.

Photoaging – The damaging effect of ultraviolet rays on the skin.

Sarcopenia – Reduction in muscle fiber associated with aging.

Introduction

A major focus within gerontological research concerns the effects of the aging process on the body's functioning. In view of the extensive research on physical aspects of the aging process, it is somewhat surprising that the psychological implications of these physical changes are as yet relatively unexplored. Investigations of the relationship between physical health and psychological well-being pertain only very generally to the question of how changes in the body affect the individual's sense of self, self-esteem, and ultimately, subjective well-being. Left unanswered are questions regarding more precise links between physical changes that result from aging and the objective and subjective ways that individuals adapt to these changes. Although there is little research and theory on the concept of physical identity per se, it is recognized that the sense of self with regard to physical characteristics is a feature of the self-concept and, furthermore, that satisfaction with the body contributes to overall feelings of self-esteem. The concept of body image holds important promise for understanding these fundamental issues of aging and the self-concept.

Components of Body Image in Adulthood

Most people regard themselves as having completed physical development by the end of their teenage years, but the fact is that the body continuously changes its shape, dimensions, and dynamics up until the time of death. These changes have the potential to alter the individual's physical sense of self, or body image.

The term body image may be thought of in the narrow sense as the mental representation of one's own body and, for example, may be regarded as a problematic area in disorders in which the individual has an inaccurate body image, such as body dysmorphic disorder, or an eating disorder, such as anorexia. Studies of body image identify three central components that make up this sense of the physical self. They are the perception of (1) the appearance of one's own body, (2) competence, or the body's ability to perform tasks needed in daily activities, and (3) physical health or the reflection of the individual's risk of mortality.

Experiences in later adulthood that are relevant to physical identity can take place within a number of contexts of adult life, including relationships with family, the performance of job-related duties, leisure

involvement, and interactions with friends and acquaintances. Events in the outside world may also have relevance, as these influence the individual's ability to function on a daily basis. For example, changes in funding for public transportation can limit the older individual's mobility in an urban setting, further complicating any age-related changes that interfere with self-care and autonomy.

Physical appearance provides important external cues to the self and others. Hair color, skin texture, body weight, body height, and the arrangement of facial features are just a few of the components of physical appearance. Body image with regard to appearance includes the individual's self-perception and appraisal of these outward characteristics. The internal feelings of body competence are based in part on the physical sensations received when the body is applied to particular tasks such as walking, climbing stairs, carrying heavy objects, and being able to see and hear events in the environment. Older adults are theorized to derive their feelings of bodily competence from their ability to engage successfully in such tasks without pain or effort. The third component of body image, physical health, refers to the individual's self-attributions in relation to disease processes. For example, being in constant pain due to arthritis has a negative impact on this component of body image. Fear of the unknown after being diagnosed with a terminal illness can also have a deleterious effect on the individual's bodily self-image. Disease processes seen as posing a threat to life can lead the individual to experience feelings of self-alienation from the body ('why is my body doing this to me?'). Anecdotally, in this regard, individuals often refer to 'my cancer' when talking about this disease. As the cancer has invaded their bodies, it has also invaded their sense of self. On the positive side, for individuals who are fortunate enough to avoid chronic disease in later life, this component of body image can contribute favorably to their overall sense of well-being. They feel vibrant and in control of their destinies.

Normal Age-Related Bodily Changes

Throughout adulthood, individuals experience changes with age in the body that can influence body image through their effects on physical appearance, competence, and health. Clearly, not everyone experiences these changes to the same degree, but knowing that they can occur, even if they do not, can cause the individual's body image to respond accordingly.

Physical Appearance

Looking first at the outward manifestations of aging, changes in appearance occur due to the wrinkling and sagging of the skin, loss of height, and changes in body fat. The skin, in addition to becoming more wrinkled and baggy, changes coloration, particularly on the face. As a result of the process called photoaging (exposure to the sun), dark spots accumulate and small capillaries become more visible on the surface of the face. Fat under the skin diminishes, causing the features to sag, and loss of bone contributes to the shrinking of the jaw. Wrinkles develop particularly as a function of the individual's typical expressions (laugh lines or frown lines), but some wrinkles such as the furrow between the brows develop without any particular instigation, reflecting instead genetic predisposition. Other changes indirectly affect facial appearance, such as loss, shifting, and discoloration of teeth. While all of this is going on, hair becomes more thinly dispersed on the head, its pigmented color is lost, and it may change in texture. Some hairs pop up in unwanted places, such as the ears, chin (in women), and nose. As a contributor to changes in body image, it is difficult to imagine a more potent stimulus than the effect of aging on appearance.

Changes in body build also contribute to the aging of the appearance component of body image. Although there is a total loss of weight beginning in the 60s, typically this net loss is due to a reduction in muscle fiber (called sarcopenia) and an increase in body fat. As body fat increases, it also shifts in its distribution. Subcutaneous fat (the fat under the skin) is reduced and fat around the middle of the body begins to accumulate in the infamous phenomenon known as middle-aged spread.

Competence

Feelings of competence are affected by changes that occur in the body's strength, power, coordination, and ability to have an impact on the environment. The normal aging process results in the loss of muscle strength and aerobic capacity at an average rate of approximately 1% per year. At the same time, the bones become weaker and more brittle as a result of normal loss of bone mineral content. A reduction in cartilage in the joints along with other deleterious changes leads to pain and a loss of joint flexibility. A loss of elasticity in lung tissue translates into the sensation of greater difficulty in breathing and shortness of breath. Within the urinary system, there is also a loss of elasticity in the tissue that composes the bladder, leading to feelings of discomfort. At the level of bodily regulatory systems, there are decreases in the circulating levels of sex hormones in both men and women. These hormonal changes may or not be perceived by the individual, but even if they are not, beginning in middle age there is a recognition that the potential to reproduce declines gradually

(for men) or completely (for women). Other hormonal changes lead to alterations in sleep patterns and a decreased ability to tolerate extreme heat or cold. Individuals vary considerably in the rate at which they experience these changes, but at one point or another, the aging person is likely to encounter most, if not all. Changes in body image relevant to the body's competence would, in this sense, seem theoretically to be virtually inevitable.

Although cognitive functioning is technically not a component of body image, it may be thought of as a contributor to the individual's feelings of competence. Beginning in middle age, adults begin to worry that they are losing their memory, even if they are not experiencing objective declines. Exaggeration of memory declines are most likely related to feelings of distress and a tendency to exaggerate or worry. It is not until later adulthood that memory changes reach significant levels in the laboratory, but from the standpoint of daily experience, the older individual may become convinced that Alzheimer's disease will soon follow these mental slips. Frustration with these cognitive changes may cause the aging adult to feel both hopeless and annoyed. Difficulties in driving ability may contribute further to changes in the individual's feelings of cognitive competence.

Health

The development of chronic illness in later adulthood can lead the aging person to feel disengaged from his or her own body when malfunctions in important functions accumulate, and, even worse, when it seems as though these malfunctions threaten to cut short the individual's life. Although not considered a function of normal aging, there is an accumulation of chronic disease such that the majority of older adults suffer from life-threatening illnesses, such as heart disease and cancer, or painful conditions, such as arthritis.

The functioning of the cardiovascular system is an important influence on the individual's feelings of well-being and identity. Many individuals interpret changes in this system, whether due to disease or to normal aging changes, as significant for the viability of the body or its ability to sustain life. Feelings of mortality are perhaps most closely linked to this system. All adults know that the efficiency of the cardiovascular system is essential to life, so threats to the integrity of this system are perceived as highly dangerous. Awareness of reduced cardiovascular efficiency can therefore serve as a reminder of one's own personal mortality.

In the normal aging process, fat and other substances accumulate in the walls of the arteries throughout the body. In the disease known as atherosclerosis, these deposits collect at an abnormally high rate, to the point that they substantially reduce the width of the arteries. Many people live with atherosclerosis and do not encounter significant health problems. However, the progressive buildup of plaque that occurs with this disease may eventually lead to partial or total blockage of the blood's flow through an artery, causing death or severe impairment. Changes in the arteries associated with atherosclerosis are thought to be due to the damaging effects of hypertension, a condition in which blood pressure is chronically elevated. Although death rates due to heart disease have gone down dramatically in the past 20 years, it is still the case that these are major killers among this age group. Together, heart and cerebrovascular disease accounted for 40% of all deaths in people over the age of 65 in the United States in the year 2002. Cancer is the second leading cause of death among older adults and is one of the most feared forms of disease throughout the adult years. In 2002, it was estimated that about 1.3 million Americans received a diagnosis of cancer and that about 8.9 million were living with the disease. Most cancers become more prevalent with increasing age in adulthood because age is associated with greater cumulative exposure to harmful toxins (carcinogens) in the environment.

Arthritis is the most common chronic illness affecting older adults; the majority of older adults who suffer from this disease are victims of osteoarthritis, a painful, degenerative joint disease that often involves the hips, knees, neck, lower back, or the small joints of the hands. Osteoarthritis typically develops in joints that are injured by repeated overuse in the performance of a particular job or a favorite sport or from obesity and the carrying of excess body weight. Eventually, this injury or repeated impact thins or wears away the cartilage that cushions the ends of the bones in the joint so that the bones rub together. The articular cartilage that protects the surfaces of the bones where they intersect at the joints wears down, and the synovial fluid that fills the joint loses its shock-absorbing properties. Joint flexibility is reduced, bony spurs develop, and the joint swells. These changes in the joint structures and tissues cause the individual to experience pain and loss of movement.

Normal aging is associated with loss of bone mineral content due to an imbalance between bone resorption and bone growth. This loss of bone mineral content is called osteoporosis when it reaches the point at which bone mineral density is more than 2.5 standard deviations below the mean of young White, non-Hispanic women. It is estimated that 10 million individuals in the United States have osteoporosis, 80% of them women. Women are at higher risk than

men because they have lower bone mass in general, and menopause, with its accompanying decrease in estrogen production, accelerates the process. White and Asian women have the highest risk, and Blacks and Hispanics have the lowest. In addition, women who have small bone structures and are underweight have a higher risk than heavier women. Osteoporosis differs from osteoarthritis in that there is no pain associated with the condition itself. However, the weakening of the bone associated with this disease significantly increases the individual's risk of fracture in a fall and may even increase the risk of fractures that in turn cause the individual to fall.

Prevention and Compensation

The changes described thus far seem to present a somewhat pessimistic view of age-related changes in the body. However, not everyone undergoes these changes at the same rate, and many of these changes can be compensated or prevented. Preventative measures include daily use of sunscreen (SPF 15 or higher) and application of moisturizers and creams containing alphahydroxy acids and antioxidants. Individuals can compensate for these changes in the body's appearance through exercise and regulation of diet. Strength training and aerobic conditioning are the primary forms of exercise that can serve to minimize the effect of normal age-related changes in the body.

In addition to the fact that people vary in the rate of change over adulthood, compensation and especially prevention play important roles in minimizing the effects of aging on the body, and hence, body image. For example, losses in aerobic capacity and muscular strength can be cut in half by participating in regular aerobic exercise. Exercise along with dietary control is also an important preventative measure for reducing the risk of heart disease in middle-aged and older adults. Lifestyles factors also contribute to cancer risk; the three greatest risk factors for the development of cancer are exposure to the sun, cigarette smoking, and lack of control over diet. By controlling exposure to these risk factors, middle-aged and older adults can control their likelihood of developing cancer. Finally, there is relatively little that the aging individual can do to prevent osteoarthritis other than to avoid placing excessive strain on the joints. Treatment for osteoarthritis takes the form of a medical intervention involving pain relief or, in cases of extreme joint damage, partial or total replacement. Osteoporosis can be prevented through a number of routes, including taking calcium and vitamin D, engaging in resistance training, and avoiding high-risk behaviors such as smoking.

Memory losses can be compensated by mnemonic strategies, and changes in information processing that would affect decision making, problem solving, and intelligence are generally more than offset by increased experience. Through the actions they take, individuals can slow down or accelerate the aging process. In the case of physical appearance, for instance, individuals can alter the rate at which they experience photoaging, the damaging effect of ultraviolet rays on the skin. It is well known that adults who use preventative measures (including sunscreen) show a slower rate of facial wrinkling than those who do not. Therefore, one of the most significant outward signs of aging can be slowed through actions taken by the individual. With regard to changes within the body, there is a wide range of preventative actions that adults can take, starting in young adulthood and continuing throughout even the oldest of ages. The most successful of these is aerobic exercise. There is now a convincing array of findings testifying to the benefits of active participation in an exercise program. In addition to its effects on the body, involvement in exercise can promote a positive sense of self-esteem. A sense of self-efficacy can develop as the result of exercise participation, which can further enhance the older individual's self-perception of physical attractiveness. The effects of exercise, among other preventative measures, therefore extend to the area of physical health and chronic disease. Thus, through preventative measures, individuals can to some degree control the rate at which both aging and disease progress and can maintain a positive (i.e., healthy and competent) internal body image.

Changes in Body Image and Their Relationship to Psychological Well-Being

The aging process presents a particular challenge to the maintenance of a stable physical identity over time. Events caused by the physical aging process present challenges that are qualitatively different from other experiences in adulthood that are of a more transitory or fleeting nature. An unpleasant encounter in a chance meeting with a stranger that reflects unfavorably upon one's social identity may be dismissed as not having much personal relevance. If this encounter is of a one-time nature, its potential significance to identity will fade with time. Aging, however, is a process that does not fade with time. The changes that occur as a result of the aging process remain present and may in fact grow with importance as the individual must find ways to integrate them into identity throughout adulthood.

Thus, the aging process has the potential to affect all components of body image – appearance, competence, and health. Many adults feel these changes are incompatible with their sense of who they are. Indeed, they may feel that the aging of their bodies has resulted in only superficial changes and that they have really not changed at all on the inside. However, at the same time, aging brings with it the certain knowledge that the body is not functioning the same way it did when the individual was younger. Thus, there is a distinction that needs to be made between the sense of identity in terms of the outward self and the inward sensations in the body.

Adding to the changes within the individual is the impact of social attitudes toward the aging of the body. Society's definitions of the desirable attributes of men and women present significant threats to body image in later adulthood. For women, social attitudes that aging women are unattractive can lead to the development of a negative body image with regard to appearance. It is indeed difficult for aging women to avoid the barrage of advertisements for anti-aging products that promise to erase the effects of aging. For men, aging may pose a threat to body image with regard to feelings of competence. Physical strength is valued as a male attribute, and therefore loss of muscle strength and agility would be perceived as a threat to this component of body image. For aging individuals of both sexes, social attitudes toward health and illness can erode this dimension of body image. Portrayals of aging individuals with long-term chronic illnesses that cause pain, suffering, and prolonged dependence on caregivers heighten the fear of dying from a long-term disabling illness. Similarly, media portrayals of older adults as suffering from Alzheimer's disease and thus being mentally incompetent further prey on the fears of older adults that they will lose their dignity and independence. Self-acceptance and a positive body image across all domains are thus difficult to achieve for men and women, but for different reasons.

With the many changes that seem to occur either inevitably with age or as a result of disease processes that are more probable in later life, then, it would seem as though individuals who maintain that they have not changed even though they clearly have may be living in a world of unreality. However, there may be advantages to maintaining the internal distinction between self-identity (who I am) from bodily identity (what I am). Aging adults can avoid what might otherwise turn into a hopeless pessimism toward the future. When living in Western society, which treasures youth and beauty, such a self-protective mechanism holds a number of potential advantages. If bodily identity were allowed to dictate self-identity, there would be less incentive for the aging individual to take actions to slow down, prevent, or compensate for normal age-related changes in physical functioning.

Previous research has shown that those aging adults who maintain high levels of subjective well-being are able to distinguish between the way they feel about the self and the way they feel about the body. For example, in a study of 242 men and women ranging from 40 to 95 years of age, it was found that older women who mentally discounted the extent to which their bodies were aging, particularly with regard to appearance, had higher levels of self-esteem than women who focused on age-related bodily changes. Thus, not thinking about the meaning of age-related bodily changes seems to be a favorable way of preserving self-esteem. This does not necessarily mean that denial is the optimal strategy to adapt to a changing body. A good case in point is that women who fail to recognize that osteoporosis increases their chances of falling can benefit from greater awareness of the reality of their health risk. Similarly, although being overly preoccupied with thinness can lead women to develop maladaptive body images and related psychological disturbances, women who are well above normal weight are at risk for chronic diseases. However, acknowledging without giving great thought to the psychological meaning of changes seems to serve a positive function. This process may be particularly important as a way of insulating the older adult woman from the bias and stereotypes she faces in society regarding the attractiveness and desirability of aging females.

Managing to avoid viewing the self as aging may also help older individuals maintain their motivation to exercise. If their bodily self-concept becomes overly negative, they may avoid taking the measures described previously that can help offset some of the deleterious changes with age due to a belief that the benefits of exercise are beyond their reach. Conversely, if they feel that it is worthwhile to exercise and then act on this belief, their body image with regard to competence can be enhanced and, ultimately, so can their self-esteem.

Although men may be less likely to suffer from the negative effects of aging on body image with regard to outward appearance, they may be more vulnerable to the effects of aging on feelings of bodily competence and health. Consequently, they may lose the advantage they have over women during earlier years of adulthood in the extent to which their body image is favorable. One area in particular in which older adult men may be particularly vulnerable is that of sexual functioning. Men who experience sexuality as

an important part of their physical identity and who are unaware of the normal effects of aging on sexual function may place themselves at risk for developing secondary impotence, a condition that involves erectile dysfunction resulting from psychogenic rather than physical causes. Because they are not used to accommodating, when they have an occasional episode of erectile dysfunction, they are unable to use this process of adjusting to change. The episode leads them to conclude that they have lost their potency.

Despite the threats to body image from the aging process, it does appear that the majority of older adults manage to separate the who from the what and that body image improves rather than worsens in later adulthood. In one cross-sectional study of over 300 women ranging from 20 to 84 years of age, there were no age differences in body dissatisfaction, but measures of bodily preoccupation, anxiety, and disordered eating were lower in older age groups. Another cross-sectional investigation of 123 young, middle-aged, and older adult women using the Multidimensional Body-Self Relations Questionnaire (MBSRQ) found no age differences in satisfaction with areas of the body and lower scores among the oldest cohort in preoccupation with weight even though these women had the highest reported body mass indexes. It is possible that older adults have become immune to the evidence presented by their own bodies within the social context that they are losing (as socially defined) their attractiveness, strength, and health.

By contrast, middle-aged individuals are more sensitive to fears of aging than the older adults who are actually experiencing the effects of the aging process. In addition to the possibility that aging brings with it a more relaxed and accepting view of physical changes is the idea that the current cohort of older adults never was as concerned about their bodily functioning and appearance as the current cohort of middle-aged individuals. The Baby Boomers are reaching middle adulthood at a time in history when youth and beauty are revered more than ever. Furthermore, this generation has dominated the social and cultural landscape since their coming of age in the 1960s. Having defined social standards of the desirability of youth, it may be particularly hard for this generation to accept the fact that changes happen within their bodies due to forces outside their own control. On the other hand, current cohorts of middle-aged individuals, at least those with higher levels of education, have embraced the values of exercise and dietary control. Therefore, they may actually be less likely to experience the challenges to identity presented by changes observed among historically less fit older cohorts.

In summary, the construct of body image bears central significance to the life of the aging individual. The ways that individuals adapt to the alterations in the internal and external structures of the body involved in the aging process are important mechanisms for promoting the individual's ability to adapt to the changes in health and functioning associated with aging. Current evidence suggests that the majority of older adults have indeed found ways to live comfortably inside their aging bodies.

Glossary

Feel Good Heuristic – Feeling good serves as an indicator of health.

Self-Regulating Model – Model indicating that health risks are likely to be experienced in response to somatic changes, and that symptoms experienced speed the seeking of health care.

Introduction

The title of this article, Self-Regulation, Health and Behavior, implies two broad themes. First, that behavior is a determinant of health outcomes, and second, that individual, self-regulation processes underlie health behaviors. Our goals for the first theme include spelling out specific examples of known causal links between behavior and health, the onset of chronic illness in particular, point to some of the pathways involved in disease onset, and discuss the role of health behaviors in the elderly. For the self-regulation theme we address a number of the mechanisms that underlie self-management practices. We show that self-regulation practices can be helpful or harmful to health depending upon the validity or match between the biology of disease and the perceptions and beliefs about specific diseases and the factors responsible for the future risk and control of existent illness. We emphasize the role of contextual factors, particularly the presence or absence of disease and the nature of the experience created by disease, in moderating the self-management process.

Behavior and Health Outcomes

Genes and Behavior

The current emphasis on genes as the cause of chronic disease may seem inconsistent with the estimate by the Institute for the Future that over half of the variance in health outcomes is determined by behavior. Individuals with common genetic risks may, however, manifest disease onset at very different times in life, since environmental factors and behavior play important roles in gene expression. Behavioral factors can affect disease risk through three pathways: (1) altering physiological processes that affect gene expression and the manifestation of inherited risks, (2) creating genetic mutations that generate disease, and (3) producing physiological changes that have direct effects on the disease process or by weakening or inhibiting somatic defenses. It is not clear that this view of gene–environment interaction has entered the public mind, though statements that genes are not sufficient causes for disease

can be found in the science section of daily newspapers. For example, cigarette smoking affects all three of these pathways, increasing the lifetime risk of chronic illness. The 4500 or more inhaled toxins produced by the combustion of the tobacco and paper in a cigarette can accelerate the mutation of DNA in lung tissue and disrupt mechanisms for reconstructing DNA damage, and this damage proceeds well outside of conscious awareness. Smoking also reduces pulmonary capacity, and the toxins stimulate processes involved in damaging coronary arteries. While individuals may be aware of some of these changes, they may not attribute them to smoking or may not see them as serious even if their attributions are correct. Thus, smoking is a risk factor for many of the 200 or more types of cancer and a multiplier of risk for cardiovascular and pulmonary disease. Obesity, often used as a marker for disease risk, is a product of caloric intake exceeding caloric consumption and is typically due to high quantities of junk foods in the diet and lack of physical activity. Dietary issues are complex, and disease risk varies with the intake of specific nutrients. For example, fats affect gene expression, some, e.g., omega 6 fatty acids, creating and others, e.g., omega 3, reducing risk of prostate cancer. Physical activity or exercise reduces risk across a wide spectrum of diseases; indeed, it can improve the ability to perform activities of daily living in women over 70 years of age. The extent to which diet and physical activity can impact rates of chronic disease is clear from the current epidemic of obesity and the appearance in teenaged adolescents of type 2 diabetes, a disease formerly exclusive to the elderly.

Life Span, Disease Risk, and Disease Management

The interaction of behavioral factors with genetic variables in the development of chronic illnesses highlights the life span, developmental aspect of these diseases. Type 2 diabetes and cardiovascular diseases develop over years and decades; they do not occur all at once. Deficits in mechanisms for transporting and storing glucose, glycogen, and lipids in cellular depots, rather than circulating at high levels in the bloodstream, lead to the gradual accumulation of cellular damage and the arterial occlusion underlying cardiovascular disease. The high level of blood sugar in type 2 diabetes destroys the neural networks for vision and sensation in the feet and kills the capillary-sized vessels in the kidney essential for filtering the blood; blindness, foot amputation, and kidney loss and dialysis or death are the consequences of each of these collateral effects of uncontrolled diabetes. The picture is similar for cancer. Clinically detectable disease is the end product of a sequence of changes in cellular processes, and the escape or metastasis throughout the body involves interactions of death-defying cancer cells with the vasculature. These changes take place over years and decades, and while some of these changes are partially reversible, many are not. Accumulating evidence strongly suggests that the fetal environment and the experience of infectious disease early in life can affect vulnerability to coronary disease (e.g., elevated blood pressure) and other chronic conditions at far later times in life.

Lifestyles are critical factors for disease risk and therefore for disease prevention. Whether we smoke cigarettes and use drugs, what we eat and drink, and whether we are immobile in front of TV and computer screens, driving, and taking elevators, or walking, climbing steps, and exercising are major influences on whether disease risk is high or low. If patients are non-adherent to treatment, fail to self-regulate, and take medication to control blood pressure or insulin to lower and maintain acceptable levels of blood sugar, they will risk stroke and cardiovascular disease and the complications of diabetes, i.e., blindness, kidney loss, and foot amputation.

Behavior and Health Outcomes in the Elderly

The young rather than the elderly are often seen as the appropriate target for improving health outcomes via behavioral change. The idea that the young and not the elderly are the appropriate target for health behavioral change reflects three beliefs. The first, and probably most important, is the belief that implementing healthy behaviors will not lead to reductions in disease or improvement in health among elderly populations because the damage has already been done and is irreversible. Second, as research suggests, the elderly are already more actively engaged in some health promotion behaviors and therefore are not in need of intervention. A third is the belief that elderly individuals are not interested in making behavioral changes, a belief consistent with the frequently reported finding that elderly persons are difficult to recruit into behavioral interventions.

In reality, health behaviors are an integral component of quality aging, influencing disease progression, disease onset, and quality of both mental and physical life throughout the life span. Maintaining activity levels, including exercise, is suggested to protect against Alzheimer's disease, controls weight, acts to maintain or increase social support, which is associated with increased longevity and quality of life in the elderly, improves functioning, prevents myocardial infraction, and is an effective treatment for

depression in the elderly. Similarly, eating a low-fat diet is as effective for reducing rates of coronary disease and all-cause mortality among those in their the fifth and sixth decades as it is among younger populations. And while rates of some health behaviors do appear to be higher in elderly populations, we are nowhere near an optimal level or universal compliance. For example, Myer *et al*. used yearly mailings for 2 years to encourage fecal occult blood tests to detect colon cancer. In the first year both the young and old had a 50% response rate; in the second year only 25% of those under 65 years of age responded, while the same 50% of those over 65 responded. While it is impressive that the elderly population maintains their screening habits, it is disturbing that 50% of those in the highest risk group did not get screened. While this study highlights the need for interventions in the elderly, it also provides evidence against the idea that the elderly are resistant to change and unmotivated to participate in interventions. It is our belief that an incomplete understanding of the self-regulatory process among the elderly often leads to assumptions of disinterest or poor motivation. Interventions that take into account a complete understanding of the self-regulatory process will be able to target the unique motivations of the elderly.

Self-Regulation and the Control of Disease and Disease Risk

The biobehavioral picture is clear: our lifestyles, or how we regulate our systems, affect the risk of future disease and progression and control of current disease. But is there a good match between the system underlying self-regulation and the biological progressions involved in disease risk and progression? Although we are far from the final answer to this complex question, we can see the outlines of an answer by comparing what we know about the self-regulative process and the biology of disease risk and progression. To address this large question we first overview the self-regulation process; i.e., we identify the large sets of variables that shape health behaviors and point to some problems in the interpretation of research findings, focusing on the uniformity of the underlying model across a variety of contexts, including disease prevention and self-regulation of distinct illnesses. Next, we describe how the general model has been and remains to be specified to understand the factors affecting the initiation and maintenance of health behaviors in three health contexts: (1) symptomatic illness experience (coronary conditions such as congestive heart failure [CHF] and myocardial infarction), (2) asymptomatic illness experience (hypertension and type 2 diabetes), and (3) chronic conditions experienced as episodic attacks (e.g., asthma). In these examples we make clear how contextual factors moderate self-regulatory associations; explain how action plans, monitoring, and heuristics are integral and used within the system; and discuss how the same model can underlie a diverse set of situations. Our examples focus on applications among the elderly.

The Self-Regulation Process

Cognitive and emotional factors, their interactions, and the personal and social contexts in which these factors operate shape general lifestyles and the specific behaviors that regulate disease threats (see **Figure 1**). Cognitive factors, the perceptions and beliefs about disease threats, the behaviors for managing threat, and plans for action, are the factors most closely linked to behaviors that create and/or reduce risk. These factors include our perceptions and beliefs about (1) the disease, i.e., the representation of a disease threat, (2) the strengths and vulnerabilities of the self, or its disease and health identities, (3) the behaviors for controlling disease threats and the representations of specific procedures for promoting health and controlling disease, (4) the heuristics or rules of thumb that raise and answer questions about the meaning of somatic experience, (5) action plans for the implementation of specific behaviors, and (6) the criteria for monitoring and evaluating the effectiveness of procedures for reducing the proximity and magnitude of threat or for maintaining self-identity.

Emotional factors, including the person's emotional traits, e.g., whether she or he is an anxious, depressed, or hostile person, and emotionally laden beliefs, e.g., fears of specific diseases such as fears of cancer, heart disease, or asthma and fears or concerns about specific behaviors and treatments, e.g., fear that antidepressant medication is addictive, interact with cognitive factors in affecting health behaviors. Contextual factors, beliefs about the self (beliefs about the vulnerabilities and strengths of the self) and the social and cultural context, can have both direct and indirect effects on health behavior, the indirect effects due to the role of contextual factors in moderating or shaping specific cognitive representations and emotional reactions to both disease threats and behaviors and plans for threat control.

Figure 1 provides a simplified picture of the large array of contextual, individual, emotional, and illness-specific factors affecting health behavior. Just as there are multiple pathways to disease, there are

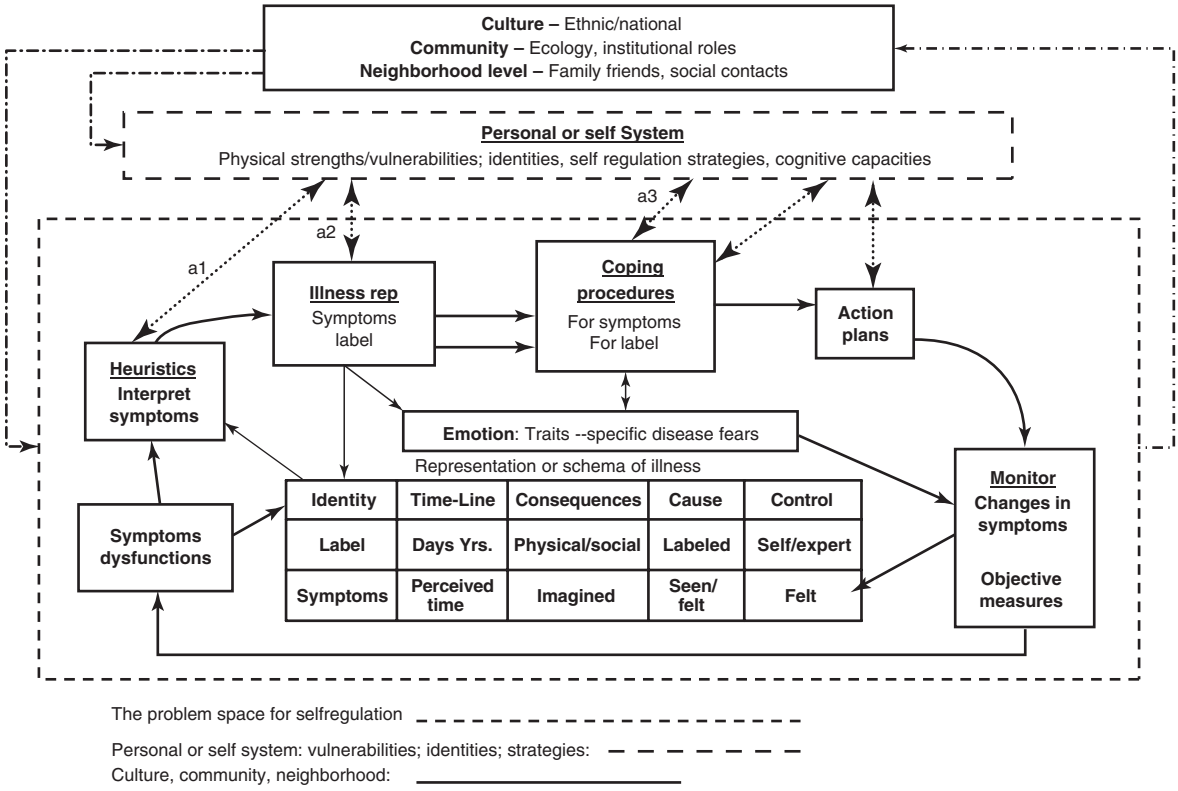

Figure 1 The dynamic feedback process (from the interpretation of symptoms by heuristics through coping procedures to monitoring outcomes) is represented in the problem space for self-regulation, as is the representation or schema of illness and treatment, as is emotion and disease-specific fears that arise from and affect the ongoing appraisal process. The focus of problem-solving activity, the risk of illness or its presence, is nested within the personal or self system, and self-perceptions of specific vulnerabilities and strategies for managing threats affect the problem-solving process and are influenced by the outcome of the process: the relationship is bi-directional though likely stronger from the self to the problem space. Finally, both are nested in social and cultural context.

multiple pathways to specific behaviors. Empirical studies to identify and test the effects of specific pathways from contextual or cognitive factors to a health behavior typically focus on a limited set of factors within two or more of the broadly defined categories of illness representations, procedures for self-management, and/or action plans. It is extremely important to recognize that the illness or treatment representations, action plans, and emotional factors affecting health behavior will be modified by contextual factors including the personal makeup of the participants (e.g., age, educational level) and by social and institutional contexts. An often overlooked factor is the illness threat at the focus of self-management; it too is a contextual variable. For example, causal beliefs contribute to variation in health behaviors for prevention and control of type 2 diabetes, a disease that is perceived to be caused by multiple factors, but make little contribution to variation in health behaviors for the prevention and control of multiple sclerosis, a disease that is widely understood to be inherited.

The variation of models across contexts can lead one to believe that it is impossible to generate a common theory for a diverse range of health behaviors when the difficulty resides in the need to conceptualize and assess the moderating factors that alter the degree to which specific variables affect the behavior under study. An important example of a moderator is whether the threat of illness is present or anticipated. It has been argued that different models are needed to account for actions taken in the presence of symptoms of a suspected or diagnosed disease, so-called illness behaviors, and behaviors taken to avoid health threats in the absence of current illness, so-called health behaviors. Self-regulatory approaches argue that the same system underlies both illness and health behaviors and that the absence or presence of disease, knowing one is sick, and experiencing symptoms of sickness are critical moderators affecting the structure of the underlying behavioral system. In short, the models for illness and health behaviors differ because of differences in context, since different contexts activate different factors in the self-regulatory process that underlies and is common to both types of behavior. The analysis of behavioral models for specific conditions clarifies these general assertions.

Health Behavior in the Prevention and Control of Specific Threats to Health

To illustrate the continuity between the processes underlying behaviors for prevention (health behaviors) and treatment or disease management (illness behaviors), we next examine self-regulation processes in three contexts: in the presence of illness and its symptoms, in the presence of illness but the absence of symptoms, and in the absence of both diagnosed disease and symptoms. Each presents a context moderating the specific variables operating in the underlying self-regulating processes affecting the behaviors involved in the control of one or more health threats.

Self-Regulation and Symptomatic Illness Experience

Although they can occur at all ages, cardiovascular diseases such as hypertension, myocardial infarction, and congestive heart failure are chronic conditions with highest incidence and prevalence in later life. For men, the incidence of myocardial infarction increases gradually from 7% per annum in the fifth decade of life to 22% in the eighth decade of life. The incidence for women is lower overall than for men, but it too rises with age, peaking about a decade later than for men. As stated before, smoking, junk food diets high in fat, and genetic vulnerabilities are interacting risk factors. And given the comorbid relationships among diseases, junk foods and diets high in sugars elevate the risk for diabetes and diabetes further increases the risk for cardiovascular disease.

A basic proposition of the self-regulation model is that health risks are likely to be experienced in response to somatic changes, i.e., to the meaning assigned to symptoms, and disruptions of physical function. Chest pain, problems breathing, and sweating fit the rules of thumb, i.e., the heuristics that interpret these symptoms as signs of cardiovascular disease, and connect the symptom experience to an illness representation of cardiac disease (see **Figure 1**). When these symptoms are experienced they speed the seeking of health care. The self-regulation processes underlying these interpretations and care-seeking behaviors are moderated by a contextual factor, the individual's gender, affecting behaviors that increase risk of death. Because the incidence of coronary disease in women peaks a decade later (seventh) than for men (sixth), and because its symptoms overlap with symptoms of emotional upset (anxiety and depression) that are more common in women, women often mistakenly perceive these symptoms as signs of emotional upset, as do the practitioners diagnosing and treating them. The result is delay in care seeking and delay in the receipt of critical treatment in comparison to men reporting the same symptoms. Three aspects of the self-regulation theory are supported by these findings: heuristics (location and pattern) give symptoms meaning (represented as heart attack) and the meaning motivates behavior (care seeking). And gender can moderate the meaning: the symptoms are attributed to emotional distress in women who delay care seeking.

Self-regulation does not stop with diagnosis and treatment; it continues during rehabilitation and with (presumably) full recovery. Exercise and dietary changes, of determined amounts and carefully monitored, are lifestyle changes integral to rehabilitation. But not all patients participate. Physical activity can create symptoms, and ex-patients who interpret these symptoms as indicators of cardiac risk are unlikely to participate and drop out if they do participate. Simple interventions that provide heuristics for differentiating and redefining posttreatment symptoms as signs of healing facilitate a return to rehabilitation. Self-regulation theory also makes the interesting prediction that individuals who are asymptomatic prior to heart attack will be less likely to engage in rehabilitation posttreatment. This prediction is based on the assumption that treatment and rehabilitation are experienced and understood as beneficial when they result in the removal of symptoms and improvement in function. If, however, an individual experiences neither symptoms nor functional disruption prior to treatment, she or he will experience no posttreatment benefit. Indeed, it will be the treatment, such as bypass surgery, that will be experienced as the source of symptoms and dysfunction. In short, the individual has experienced no gain and is in the same state of lack of awareness of somatic risk posttreatment as he or she was pretreatment, undercutting the motivation for rehabilitation. This hypothesis is now being tested in multiple diseases by investigators in Zurich.

Can we support our claim that the same self-regulation approach can account for behaviors to prevent cardiovascular disease and that it is relevant to health behaviors and not just illness behaviors? The presence and experience of diagnosed disease is clearly a major moderating variable; it can motivate major changes in health behaviors. For example, after a heart attack, smokers are five times more likely to quit. The presence of disease provides powerful evidence of the individual's vulnerability motivating behavior perceived as effective for preventing recurrence. When disease is absent, we can expect that a wider range of variables will create the perception of risk that motivates action. Symptoms, however, are

not out of the picture; that they are still at play is evident by the number of visits to emergency rooms and by individuals experiencing chest pains and other symptoms attributed to heart disease. An individual does not need a personal history of coronary disease to interpret symptoms that fit the location and pattern of cardiovascular disease, and these individuals are frequent visitors to emergency rooms. Emergency room use is a health behavior that reduces a somatically generated sense of threat of heart attack. These patients appear to have a disease-specific fear, perhaps based upon a history of exposure to people with cardiac complaints, and they are not overly fearful of non-cardiac symptoms. Symptoms can motivate protective behavior in individuals with no personal disease history who have a disease-specific fear of coronary disease (see **Figure 1**).

Self-Regulation with Asymptomatic Disease and in the Absence of Disease

There is a relative scarcity of published research on self-regulation processes and health behaviors among elderly individuals in the absence of symptoms and/or a diagnosed or suspected disease. Areas with a rich array of studies, e.g., diet, exercise, and smoking cessation, generally focus on participants less than 65 years of age. The dearth of studies reflects difficulties in the recruitment of healthy elderly, a problem highlighted in the randomized trial of benefits of aspirin conducted in the Northwest region of the Kaiser health plan. In this study conducted by Boles et al., a highly skilled team of investigators sought recruits from the 47 453 individuals over 65 years of age in the Kaiser catchment: 31% of the sample was eliminated at the outset due to a history of cardiac problems and another 10% was participating in other studies. Carefully constructed recruitment material was then mailed to 3600 of the 27 947 remaining healthy individuals in the recruitment pool. The final result of the mailing and phone calls was the randomization to aspirin and placebo of 117 of the 347 elderly who indicated an interest in participation. Two factors were responsible for this outcome. Most elderly have multiple chronic conditions, so their self-regulative processes occur under an illness framework; and most are not interested in participating in research, which was true for the vast majority of the 3000-plus non-responders in the aspirin trial. Boles et al. persuaded 32 of their disinterested, healthy elders to participate in focus groups and discovered that the elderly were wary about participating in trials, did not want to take a placebo or an aspirin, and were uninterested and wary of changing what they were now doing: they were in good health and saw no reason to change direction.

The experience of these investigators is not dramatically different from efforts to recruit for studies of exercise, e.g., stretching and/or walking programs. In the absence of a diagnosis or symptoms, critical triggers of self-regulation processes, there is little incentive to enter a behavioral study. The actual presence of symptoms of disease is not essential, however, for engagement in studies of behavior change. Objective indicators such as difficulties in managing blood sugar loads, indicating risk of diabetes, can serve as a context for recruitment and the activation of self-regulation processes that lead to behavioral changes that reduce the shift from risk to active diabetes. Indeed, the reduction of diagnosed disease is greater for behavioral change than medication. The cognitive-behavioral techniques involved in maintaining self-regulative activities (e.g., 16 direct contacts and numerous phone calls) were, however, far more intensive than could be achieved in the vast majority of real-world practice settings. The absence of studies providing detailed views of the self-regulative processes among healthy elderly is somewhat compensated for by what can be learned from studies of self-regulative processes in studies of management of conditions that are asymptomatic or episodic.

Asymptomatic and Episodic Conditions

Self-management for asymptomatic and episodic conditions allows us to view some of the processes that are involved in primary prevention, i.e., behavior in the absence of disease. These studies highlight three issues: (1) symptoms and emotions are used as indicators for health when they are not; (2) symptom-free intervals are treated as disease-free periods for episodic conditions; and (3) monitoring objective indicators can supplant subjective cues when coupled with behavioral controls.

Hypertension and Diabetes: Using Symptoms When None Exist Studies of hypertension show how people rely on experiential cues as initiators of self-regulation. Hypertension is asymptomatic, and although 80% of the hypertensive patients in Meyer et al.'s 1985 study, most of whom were elderly, agreed that "people can't tell when their blood pressure is up," 92% said that they could tell for themselves. They reported the typical array of symptoms, warm face, tension, etc., as indicators, and 70% of the patients who believed that their medication reduced symptoms were adherent compared to 30% of patients who did not see an effect of medication on their symptoms; thus, 70% of the latter group did

not adhere to treatment. An additional problem for medically correct management arises when patients tell physicians that they use their symptoms to monitor blood pressure; 9 months after beginning treatment 60% of these patients had left treatment! Discrepancies between practitioner and patients undermine treatment.

There is also substantial evidence that individuals use symptoms to motivate behaviors for diabetes that may be maladaptive. Although elevated blood sugar provides few if any somatic cues, there are indications that diabetics use their subjective states as signs of control: if they feel good, they assume they are in good control. Although it is nice to feel good, positive feelings are inadequate indicators for diabetes and for hypertension. The positive feeling heuristic is flawed, as elevations in both blood sugar levels and blood pressure can lead to mild euphoria. Positive feelings may be reassuring because they contrast with the negative symptoms that are clear signs of excessively low blood sugar, severe hypoglycemia, which can lead to unconsciousness and death. Fear of hypoglycemia can be assessed, and as expected individuals reporting high levels of this specific fear also have blood sugar above recommended levels.

The challenge for effective self-regulation for both hypertension and diabetes is to transition from subjective cues, symptoms, and moods to objective indicators: blood pressure and blood glucose readings. Relatively little is known, however, as to how this transition can be created. The substantial success in reducing diabetes for at-risk individuals reported by the Diabetes Prevention Project was extremely labor intensive. It is clear that monitoring and connecting objective measures such as blood glucose readings to specific health behaviors may be sufficient to lead to better self-management in asymptomatic patients. The key will be to connect the objective indicators to daily life activities, and gradually adjusting those activities so their effects are seen in objective blood sugar levels that approach desired targets, e.g., reductions in meal size, not putting sugar in coffee or tea, and taking the stairs instead of using the elevator. Many of these tactics have proven effective for managing affective disorders such as depression. In this case, however, subjective mood is more readily available for monitoring, as there is no need for a special device such as a glucometer or blood pressure cuff. The diabetic and hypertensive also have the challenge of learning to discount their affective states, which are likely inadequate indicators of their underlying physiology.

Chronic Illnesses That Are Experienced as Episodic: Asthma Self-regulation of asthma provides insights into two other features of the self-regulation process, both of which are age related with one more strongly so. Having asthma is seen as occurring out of time for older persons lacking an asthma history, as asthma is widely perceived as an illness of children and adolescents. Late-onset asthma, however, is a reality and is possibly different in its pathophysiology from early-onset disease. More important for self-management is the episodic nature of asthma flares; unless the person is a careful self-observer, the life experience of both the old and young asthmatic is one of normal, symptom-free periods punctuated by attacks. Not surprisingly, many asthmatics, even those hospitalized with severe attacks, behave as if no symptoms means no asthma. In a study of hospitalized patients, middle aged and elderly, they were using both of their medications, preventers that are to be used when asymptomatic and controllers to be used during an attack, only when they were having attacks. The schema or pattern underlying their behavior fits the model of no symptoms, no asthma. They also verbalized what might seem contradictory beliefs: they believed that they would have asthma for the rest of their lives (80% of the 200 patients), but they also believed that they had it only when they had symptoms (53% of the patients), a chronic, episodic disease, and that was treated as such. The underlying schema of the self with disease was the framework of inadequate self-management.

Health Behavior in the Absence of Disease
