Multiple case histories can be found of the adoption of health behavior in the absence of diagnosed disease and, presumably, the absence of disease symptoms. An article in the Science section of the *New York Times* described the daily exercise routine of Bernyce Edward, a 73-year-old exercise zealot who begins her daily hour-long routine of walking and running at 5 a.m. The trigger for this late life regimen was the death from breast cancer of her 42-year-old daughter, a fatality that occurred 69 days after diagnosis. In this article, Kolata cited epidemiological and physiological research that provides support, albeit tenuous, for the elder Ms. Edward's beliefs and health behavior. Although the all-too-obvious trigger, her daughter's death, is hardly a claim for the scientific power of self-regulation models, its presence is consistent with the model's assumption that concrete, experiential factors, symptoms, and serious consequences observed in self and others are triggers for health action. We do not know what sustains Ms. Edward's exercise zealotry, but a self-regulation model would make

the following prediction: the sense of safety is likely critical, but more importantly, this sense is based upon concrete feelings of vigor generated by exercise and by the reassurance generated by the absence of symptoms and signs of disease.

The Feel-Good Heuristic If feeling good serves as an indicator of health, we can imagine that healthy behaviors that stimulate these feelings will be adopted to promote health. Exercise is clearly such a behavior; exercise can elevate feelings of wellness and help to overcome severe depression, though it seems to be more effective in this regard for men than for women. However, good feelings can reinforce unhealthy behaviors, and healthy behaviors may elicit negative feelings. Exercise is a source of aches and pains that are likely to discourage the behavior, particularly among the elderly. And the comfort of the couch and comfort foods can be positive for the sedentary, both young and old, and dangerous for health in both. Whether the comfort of inactivity and the mild aches and pains of activity are seen, respectively, as healthful and harmful or as harmful and healthful depends upon how these cues are interpreted. Good feelings may usually seem a positive, healthy sign, but the meaning of each is also dependent upon the image of the experiencing self, the network of meanings linked to beliefs about who one is and the sense of self as a viable, energetic being. Persons who see themselves as vigorous and active are less likely to associate positive health with feeling good from hours on the couch or negative health with the aches and sweat following exercise. The meaning created by these somatic sensations is created by their embedding in a self-schema. This reflects an accumulated history of images of the self as alive and vigorous following intense, sweaty exercise, rather than feeling profoundly exhausted and lacking physical resources (**Figure 1**, arrows a1 and a2). Self-regulatory strategies such as conservation and use it or lose it linked to these self-schemata will affect the choice of response to the perception of a health risk (**Figure 1**, arrow a3). Belief in conservation among elderly individuals deters taking on new activities to substitute for more vigorous behaviors (walking instead of jogging) that were given up following serious illness. Although the strategy of conservation is somewhat more common among the elderly and that of use it or lose it is more common among the young, the age differences in these strategies may be less pronounced than one might expect. It also seems reasonable to expect that exercise-induced muscle fatigue or pain is more likely to be interpreted positively, as a sign of a good workout, in the young and as a possible indicator of harm in the elderly, especially among elderly with symptomatic osteoarthritis; the younger are monitoring benefit while the elderly are monitoring injury.

By connecting the self-regulation process to the maintenance of self-identity we can see that the same self-regulatory system underlies health behaviors during illness as well as in anticipation of, and in the absence of, a health threat. The role of symptom experience in triggering health actions may be taken over by assessments of the self as being in poor or fair health rather than excellent health, with negative appraisals of health increasing the elderly person's willingness to adopt active, health-promoting behaviors such as reducing fat intake. But self-assessment of health is an abstraction and is likely to be less potent in motivating healthy actions than the experience of increasing frailty or its opposite, the experience of well-being in response to specific physical demands. Unfortunately, feeling good is not a reliable cue to health benefit.

Action Plans Discussion of action plans for self-regulation has been deferred to this section on management of behaviors in the absence of illness or illness threats not because plans are unimportant during illness, but because the plans seem more salient for action in the healthy state. Although plans do not seem sufficient to motivate behavior, they are critical for its implementation. Plans have an exceptionally powerful effect on translating motivation into performance, and they seem to do so for the following reasons. First, they automate behavior. A good plan will identify specific cues, times, and places for initiating action. As the action is often the first in a sequence, its occurrence both cues and motivates subsequent behaviors; e.g., heading to the gym or exercise bicycle is likely to follow the automatic search and donning of gym clothes and sneakers at the usual time of day. Second, whether it is exercise, shopping for fruits and vegetables, or cooking a low-fat dinner, plans integrate the behaviors into the ongoing daily framework of activities. Defining the framework, isolating the place for the behavior, selecting the time frame for action, and developing (thinking of) expectations for outcomes are part of routinizing the behavior; making it part of necessary life conditions. Given the diversity and range of events from subjective feelings, through observations of the behavior of others to media exposures, it is much more difficult to identify a specific basis for motivating health-relevant actions. We suspect, however, that subjective feelings of the presence or absence of well-being play an important role.

Conclusion: Is There a Good Match between the Self-Regulation System and the Biological Progression of Disease Risk?

Our focus has been on the factors involved in the self-regulation process and the variation in the salience of different factors as a function of context. The context of major concern was the presence or absence of diagnosed or suspected disease, and the presence or absence of symptoms or functional indicators of disease. Symptoms and function play a major role in the individual's initiation and evaluation of behaviors, often more so than objective disease indicators. Indeed, the match and/or mismatch of experiential factors guiding behavior and the objective impact of behavior are central to understanding how self-management can produce benefit or harm over the long term. Behavioral management is increasingly complex for asymptomatic chronic illnesses as well as chronic episodic conditions. The lack of experienced benefit for behavioral self-management in hypertension and diabetes makes it difficult to sustain motivation and behavior for control over the longer term. To date, behavioral techniques for shifting control from subjective to objective indicators have proven of modest benefit, as have techniques for motivating behaviors for promoting health in individuals who are disease-free and asymptomatic. The match and mismatch of subjective feelings to objective status, e.g., smoking cigarettes feeling stress reducing and relaxing to practiced smokers, presents both opportunities and barriers to programs of healthy action. Plans that facilitate the automation and integration of behavior into the daily routine play a critical role in all contexts.

Finally, placing the topic of health behaviors within a self-regulation context has led to the emphasis on individual factors, the representations of illness threats, heuristics for appraisal, plans for implementation, and self-appraisals of health. The social context was touched upon as a trigger motivating health behaviors, but a fuller treatment of the interactions among social and individual-level factors within the self-regulation framework requires separate treatment.

Sexuality, Sensuality, and Intimacy

M Stones and L Stones, Lakehead University, Thunder Bay, ON, Canada

Glossary

Culture – Global social influences that moderate the expression of hard-wired dispositions.

Inclusive Fitness – The survival to reproductive age of succeeding generations of offspring.

Love – Includes passion, intimacy, and commitment.

Successful Aging – A concept to describe how personal control, life style, and social support may enable older people to retain vigor and activity even with disability or disease.

Introduction

This article examines sexuality, sensuality, and intimacy in later life. This topic received considerable public attention during the past decade because of advances in the treatment of erectile dysfunction in men. The present era of openness contrasts with centuries of sexual ageism that was supported by religious beliefs in Western countries. Although aging has effects on sexual functioning, the main influences on sexuality in later life include opportunities and attitudes, health and disability, and the use of effective treatment for sexual problems. The article also includes discussion of sexual preferences and satisfaction in older people and issues about sexuality in institutions.

Perspectives on Sexuality and Intimacy

One of the great debates of past and present times concerns the effects of nature and nurture on human behavior and feelings. With regard to sexuality, it may seem surprising that those whose beliefs descend directly from Darwin's theory of evolution – the nature group – are bedfellows with those whose beliefs devolve from the traditions of Western religion. Both types of belief inform us that sexuality is hard-wired into our bodies for the purpose of procreation; once the age for procreation has passed, sexuality that fails to fade to inconsequence may be deviant. To other scientists and humanitarians – the nurture group – sexuality has as much to do with love as with procreation. A concept about love that continues to influence psychologists includes three main qualities of passion, intimacy, and commitment. Early love is usually passionate, lasting love is committed, and intimacy fosters caring. From this perspective, sexuality can promote bonding and commitment in partners of any age to provide care for each other and succeeding generations.

Modern interpretations of evolutionary theory (i.e., termed neo-Darwinian) include beliefs consistent with those of the nurture group. Although Darwin thought that the currency of evolution was reproductive success, neo-Darwinians refer to inclusive fitness as the survival to reproductive age of succeeding generations of offspring. Consequently, genes to extend the human life span beyond the age of reproduction probably proliferated in our species because the prolonged immaturity of offspring necessitates an enduring period of nurturing to ensure their survival. If sexuality provides a glue to help maintain the commitment of parents (and grandparents) within a familial context, it would be surprising if genes to prolong sexuality beyond the reproductive span did not proliferate accordingly.

A premise widely accepted within science is that sexual behavior, like other behaviors, reflects an interaction between nature and nurture. The term culture is used to describe global social influences that moderate the expression of hard-wired dispositions. Major cultural changes in Western countries in the 1960s coincided with a wider acceptance of contraception, the advent of efficient birth control that provided women with the means to regulate their reproduction, accumulated successes of the suffrage/feminist movements, and the transition to adulthood of the first wave of the post-World War II Baby Boomers. Following the sexual revolution of that era were changes in behavior and social customs that include an earlier age for first intercourse, lower fertility, more frequent divorce, a declining rate of heterosexual marriage, and the acceptance of gay and lesbian marriage in some countries (e.g., Canada). The older Baby Boomers who participated in that revolution are now near the cusp of later life. We can be sure that their transition into old age will bring significant new changes to the culture surrounding later life sexuality.

A symbolic dividing line that brought later life sexuality into public consciousness was the appearance of the drug sildenafil (Viagra) in 1998. This drug was the first effective oral medication to assist men with erection; however, its impact on social beliefs and attitudes extended well beyond the therapeutic paradigm. Viagra emerged toward the end of

an era of widespread re-evaluation of beliefs and attitudes about aging. The life and social sciences had accepted that earlier research findings were overly pessimistic about the effects of aging on functional capabilities. Successful aging had become a widely used concept to describe how personal control, lifestyle, and social support enabled older people to retain vigor and activity even with disability or disease. This concept provided an impetus for scientists to correct the fallacious beliefs that later life was a period of pervasive decline with limited opportunities for personal growth and development. Trends toward a more optimistic outlook on aging were also apparent in the arts, humanities, and governmental policies of many Western countries. Such changes provided the context for a reappraisal of sexuality in later life.

Academic and popular publications from the pre-Viagra era concluded that ageism had dominated considerations of later life sexuality in Western countries for centuries. Scientists reached a similar conclusion that ageism had hindered the progress of scientific research on later-life sexuality. Clinicians railed against the harmful effects of sexual ageism to advance a self-fulfilling prophesy – people may inhibit their sexuality because they expect it to decline – and provided abundant evidence that sexual interest persists into old age. However, it took the release of Viagra to bring these appraisals to full public awareness.

The publicity unleashed by Viagra transformed the cultural standing of later-life sexuality from a nearly taboo topic to the forefront of public consciousness as a normal, acceptable, and desirable form of behavior. We should have no doubts that the early years of the twenty-first century will continue to reflect the influences of this drug on the attitudes, sexual behavior, and social customs of an aging population. However, the cumulative effects of this cultural transition are likely to be gradual rather than abrupt. During any period of cultural change, an elderly cohort may be more prone to retain the attitudes and behaviors of an earlier time than upcoming elderly cohorts. Evidence for such disparity already exists: a belief that sexual intercourse outside marriage is wrong (in later life) is more frequent within cohorts already old at the turn of the millennium. This belief limits the opportunities for sexual activity during widowhood and has origins in sexually ageist religious philosophy. Because it is impossible to understand or anticipate changes in sexual attitudes, beliefs, desires, cognitions, and behaviors outside of the cultural context that informs them, this article includes a review of sexual ageism from historical and cross-cultural perspectives.

Ageism and Sexuality

The Scope of Sexual Ageism

Ageism refers to stereotypical attitudes toward older people. Many authors have noted that nowhere is ageism more apparent than in attitudes toward sexuality. Depictions of elderly people in the folklore of Western countries show both positive and negative stereotypes. The positive stereotypes depict Grandma bustling around the kitchen baking cookies for succeeding generations of offspring while Grandpa reminisces about good old times with his cronies. Neither of these mythical folk figures needs ongoing sexuality to sustain commitment and intimacy, with sexual passion having run its course long before. The stereotypes are less benign for old people who retain sexual interest and involvement. Behaviors considered lusty or virile in a young man become described as lecherous if shown by an older male, who according to traditional beliefs is supposed to have become asexual. Sexually provocative or seductive behavior in an old woman is evidence in folk culture for emotional disorder, depravity, or a grim and sorry attempt to retain hold on a long-lost youth.

Art, history, and science show similar stereotyping. Most Western literature until recent times showed indifference or pathos toward sexuality in later life. When sexual inclination was portrayed, the main image of the older man was of a pathetic creature and the older woman as depraved. Chaucer's *Merchant's Tale* relates the sorry story of a boastful old knight called January. January married a younger wife who cuckolds him, with her infidelity due to January's impotence. The inability of the lecherous "old fool" to attract and keep faithful a beautiful young woman is common to literature and painting in the medieval era. Many paintings were variants of Lucas Van Leyden's *The Fool and the Young Women* (1520) or Massey's (1446–1530) *Ill-Matched Pair*. The latter shows an old man trying to seduce a young woman with the help of his moneybag. The theme is that an old man's sexual aspirations are well beyond his capabilities.

The most violent period in history that accompanied an alleged association between depravity and sexuality in older women occurred during the witch-hunting era in Europe, which continued throughout the fifteenth to seventeenth centuries. The official manual on witch hunting was the *Malleus Maleficarum* (*Hammer of Witches*, 1486). The premises of this manual include beliefs that witchcraft originates from carnal lust and that deviant sexuality provides evidence for witchcraft. Records indicate that an overwhelming majority of witches (e.g., approximately 90%) were women, mostly aged in their 50s or 60s, with many occupied as midwives.

In science, the pioneering studies of human sexuality in the mid-twentieth century were largely indifferent to later-life sexuality. Kinsey and his colleagues collected less than 1% of their data from people aged over 60 years, and they devoted only 7 pages out of 1646 in their books on male and female sexual behavior to sexuality in later life. Masters and Johnson studied few older people in their seminal research. It is probable that the same sexual ageism that informed popular opinion influenced these pioneering scientists.

The Relevance of Religious Philosophies

Most writers on sexuality blame the early Christian church for propagating the idea that sex is sinful outside the contexts of marriage and procreation. Such commentators consider the originator of Western religious teaching to be St. Augustine (354–430), whose ideas resonated with those of influential medieval theologians like Albertus Magnus (1206–80) and St. Thomas Aquinas (1225–74). Although St. Augustine's doctrines came under attack from the Protestant reformers in later centuries, aspects of his teaching continue to endure in our culture. Of particular significance to the present discussion, the teaching that sex for purposes other than procreation (e.g., enjoyment, comfort) is wrong connotes an attitude that later-life sexuality is likely to be sinful.

St. Augustine's most influential book was *De Civitate Dei* (*City of God*), which he completed after 14 years of writing at the age of 72 years. This book portrays the Garden of Eden as a place without lust, passion, or pain. This serene existence, St. Augustine wrote, would have been possible for everyone had Adam and Eve not sinned, with the whole procreation process from conception to childbirth meant to be harmonious and contemplative. Lust, passion, and pain had no place in St. Augustine's Eden, being both sinful and consequences of sin. The notion that sex is sinful but tolerable only for purposes of procreation is central to St. Augustine's philosophy.

There can be little doubt that the notions about sexuality proposed by St. Augustine and his successors would have been contested vigorously had they been propagated during an era when clerics exerted less authority over the populace. However, conditions of diminished literacy and learning in the classical world resulted in few challenges to these teachings, which eventually became accepted as lore and dogma. Although the Roman Catholic Church remains somewhat faithful to St. Augustine's ideas, such sixteenth-century reformers as Calvin and Martin Luther saw little wrong in sex that was confined to the marriage bed. Jeremy Taylor commented in the nineteenth century that the reformers welcomed sex as a means to produce legitimate children, avoid fornication, provide solace, and promote bonding of husband and wife. Although the reformers' prescription does not disparage later-life sexuality as deviant, outside of the marital mode St. Augustine's veto prevailed.

The belief that sex is sinful finds no place in other major religious philosophies (e.g., Taoism, Confucianism, Hinduism, Buddhism, and Islam). These religions embrace rather than reject sexuality, and some consider sexuality a means to enlightenment. The *Li-Chi* (*Book of Rites*) even contained prescriptions for the sexual welfare of the older woman: for an aging concubine of less than 50 years, the *Li-Chi* recommends that her husband have intercourse with her once every 5 days.

The traditions established by the early Christian church provide more support for sexual ageism than those of other religions, with this legacy continuing to endure in Western culture. However, it seems likely that adherence to those traditions will diminish in the coming decades.

Age Trends in Sexuality

Physical Age Changes

The full range of sexual behaviors includes preparatory behaviors (e.g., cuddling, hugging, kissing, petting) that may lead to intercourse and subsequent orgasm. Humans respond positively to benevolent tactile stimulation from the cradle to the grave, with no evidence to suggest that the capacity to enjoy sensual experience is lost with age. Although age changes in physiological functions have effects on sexual capability, neither intercourse nor orgasm is difficult to achieve for the majority of older people. **Table 1** shows some frequent physiological age changes that pertain to sexual performance and advice on dealing with such changes. The main age changes for men and women include delayed arousal, less intense orgasm, and a more rapid return to quiescence. The man may need extra stimulation to achieve erection and a longer recovery period between repeated intercourses. The woman may require external lubrication, more stimulation of the clitoris, and regular sexual activity to continue to enjoy sexual intercourse without discomfort. Despite a loss of sexual vigor compared with younger times, many authors point to the perils of a fallacious self-fulfilling prophesy that intercourse becomes all but impossible in later life.

Table 1 Age changes affecting male and female sexuality and ways to deal with such changes

Changes in men	*Changes in women*
The man is aroused less easily	Vaginal lubrication is both slower and diminished
Erection takes longer	The vaginal walls thin and become irritated more easily
The erection may not be as hard	The vagina may change shape to become shorter and narrower with less expansion
The ejaculation takes longer, with slower urethral contractions that may feel less intense	The clitoris becomes more exposed to irritation and may decrease in size very late in life
Return to a pre-arousal state after ejaculation takes a shorter time	The bladder and urethra (through which urine passes) become more susceptible to irritation and bacterial infection
It takes longer after ejaculation before the penis can come erect again	Vaginal contractions in orgasm are less frequent and may be painful
Practical advice about physiological changes	The older woman should take extra care to maintain cleanliness, use lubricants, and keep sexually active. Even a short abstinence may cause older women to experience temporary discomfort when resuming sex
A positive effect of these changes is that an older man is more in control of his sexuality than when younger. He can prolong the duration of intercourse more easily. The negative effects are that the man may need extra stimulation for arousal and intercourse may be less frequent	

Table 2 Percentages of male and female respondents in three cohorts with at least weekly occurrences on measures of sexuality; percentage of respondents with an available sexual partner

Measure	*Males*			*Females*		
	Youngest	*Middle*	*Oldest*	*Youngest*	*Middle*	*Oldest*
Sexual thoughts	83%	53%	36%	42%	14%	4%
Sexual desires	86%	54%	37%	41%	21%	8%
Kissing or hugging	77%	73%	63%	72%	49%	28%
Sexual touching or caressing	69%	61%	45%	61%	37%	15%
Sexual intercourse	55%	31%	19%	50%	24%	7%
Oral sex	20%	6%	9%	19%	2%	1%
Self stimulation	33%	14%	5%	4%	2%	1%
Sexual partner available	84%	79%	58%	78%	53%	21%

Sexual Desires, Cognitions, and Behaviors

Studies of later-life sexuality became a frequent focus of research only during the 1980s. Several surveys refuted earlier beliefs that sexual dysfunction and a loss of sexual interest inevitably accompany aging. Limitations to these studies included inadequate sampling and measures of sexual behavior confined to the self-reported frequency of intercourse. Several studies in the 1990s and later were methodologically stronger, with representative sampling and measures of multiple modes of sexual behavior and cognition. Good examples include extensive surveys by the American Association of Retired Persons/*Modern Maturity* Sexuality Study in 1999 and 2004. The earlier study (termed the AARP study in this article) included 639 males and 745 females randomly sampled from a panel of people aged 45 years and older that was broadly representative of American households. The response rate for panelists providing data was 76% of those who satisfied a set of inclusion criteria. The analysis of age effects compared cohorts termed here as the youngest (45–59 years), middle (60–74 years), and oldest cohorts (75+ years). Because the AARP study provides what may be the most accurate portrayal of later-life sexuality in modern America, subsequent discussion uses findings from that study to illustrate age trends.

The measures indicative of sexual interest and activity in the AARP study included sexual thoughts and desires and multiple measures of sexual behavior. **Table 2** shows the percentages of respondents with at least weekly occurrences of these measures. With respect to sexual thoughts and desires, the upper two rows of **Table 2** show two main trends. First, the levels are higher for males than females at all ages. This trend is consistent with other findings that sexual cognitions tend to be higher in men than women regardless of age. Second, the frequencies of sexual thoughts decrease with age in both gender groups.

The sexual behaviors surveyed in the AARP study included kissing and hugging, sexual touching and caressing, sexual intercourse, oral sex, and masturbation. With the exception of self-stimulation, which

was rare in women of any age, inspection of rows 3–7 in **Table 2** shows that the frequencies of men and women with at least weekly occurrences of the other sexual behaviors were nearly identical in the youngest cohort. The most frequent behaviors were kissing and hugging, followed by sexual touching or caressing, sexual intercourse, and oral sex. The frequencies of each of these behaviors decreased with age, with the decreases generally higher in women than in men. Several other findings show comparable age declines in the frequency of sexual intercourse. Although most studies compared cohorts of different ages, longitudinal research shows a similar trend: over the course of a decade, the decreases in sexual intercourse per month were three times higher for men in their 60s than for men in their 40s.

The potential for orgasm during intercourse may decline with age but remains within the realm of experience for the majority of older people. Over 75% of men of any age in the AARP study reported that they always or usually experienced orgasm during sexual activity. The proportion of women reporting orgasms was lower, with 46% of women from the oldest cohort reporting that they rarely or never had orgasms.

These findings on age trend suggest that middle-aged men desire sex, think about sex, and masturbate more frequently than women of similar age. Middle-aged men are also more likely to report orgasm than middle-aged women. All other forms of sexual behavior (kissing and hugging, sexual touching and caressing, sexual intercourse, oral sex) are of comparable frequency between the gender groups. Declines with age occur on all measures of sexuality, with the losses greater for women than for men on most measures. However, these declines are a function of multiple factors, not merely age alone.

Influences on Sexual Age Trends

Opportunities and Attitudes

The reasons for declining rates of sexual activity with age in men and (particularly) women include opportunity and attitudes. The opportunity to engage in sexual behavior depends on the availability of a partner. Most publications on sexuality in later life cite the lack of an available partner as the main reason for lower levels of sexual activity in older women than in older men. The origins of this discrepancy are demographic: spousal age differences, gender differences in life expectancy, and gender differences in rates of remarriage after widowhood all contribute to a surplus of elderly widows over widowers.

The bottom row of **Table 2** shows the proportions of men and women in the AARP study with a sexual partner. The frequencies in the youngest cohort are similar between men and women at 84 and 78%, respectively. However, many more men (58%) than women (21%) in the oldest cohort had a sexual partner. These percentages approximate the marital rates for men and women in the different cohorts, suggesting that sex outside of marriage was infrequent in the sample. Other findings showed that men and women with a partner had nearly identical frequencies on all measures of sexual behavior except for masturbation. The frequencies were lower in men without partners than with partners and at near-zero levels on most measures for women without partners. These findings support the supposition that the lack of a sexual partner contributes to age decline in sexual activities.

Negative attitudes toward sex outside marriage can restrict opportunities for sexual involvement by unmarried people. The AARP study showed that more women than men thought that sex outside marriage was wrong, with adherence to this attitude higher in the older cohorts. In the oldest cohort, half of the men and two-thirds of the women thought sex outside marriage was wrong.

Health and Disability

Numerous diseases, disabilities, surgeries, medications, and sources of pain or discomfort affect sexual behavior either directly or through a lowering of libido. Consequently, it is unsurprising that the AARP study showed the highest frequencies for sexual cognitions, desires, and behaviors in people reporting that they were disease-free and taking no medications. Although the direct effects of many illnesses on sexuality are acute rather than chronic and diminish after successful treatment of the precipitating condition, psychological reactions to illness or during the recovery period may prolong the period of disorder. Recent publications refer to the effects on sexuality of depression, adverse psychological reaction following a stroke or heart attack, and the treatment of breast cancer. During periods of treatment or recovery, intervention may be necessary to counter myths that sexual exertion may be harmful, sexual performance compromised, or interest in sexuality and intimacy diminished following a successfully treated illness.

Medications (e.g., beta-blockers, tricyclic antidepressants, corticosteroids, and major tranquilizers), recreational drugs (e.g., alcohol), and pain and discomfort (e.g., arthritis, back pain) may inhibit sexuality. Many publications discuss ways to alleviate these problems.

Chronic neurological conditions such as dementia may affect sexuality and the capacity for intimacy. Research on sexuality in people with dementia suggests that half or more of patients show negative sexual behavior changes during the illness, although their frequency of intercourse may remain at rates comparable to those of age peers until the final stages of the disease. Some people with dementia show a decrease in sexual manners, with less consideration for their partner than formerly. Some have an increased interest in sex or become sexually overdemanding, aggressive, or inappropriate. Others display a decreased interest in sex although they are likely to retain a need for physical contact (e.g., hugging, kissing, and cuddling). Throughout the course of the illness, the nature of sexual intimacy between the patient and partner requires continual redefinition, with help from support groups or professional assistance sought if necessary.

Although many spouses of dementia patients experience the caring process as a time of burden and regret the loss of intimacy brought about by the effects of the disease on cognition and personality, other caregivers react differently. These caregivers report increased intimacy with the patient, particularly during the earlier stages of the illness. The enhancement in intimacy appears to result from their devotion to the patient during that time.

Other research examined the positive effect of sexuality on the prevention of subsequent illness. Whether a person is healthy or handicapped at baseline assessment, sexually active people may experience lower frequencies of subsequent incidents compared with less-active age peers.

Treatments for Sexual Dysfunction

The main sources of sexual dysfunction in older men include erectile difficulties and low libido. A problem reported in the clinical literature is that the shame that sometimes accompanies erectile failure can inhibit sexual interest and cause a cessation of sexual behavior. Many clinicians noted that if a couple ceases to be sexually active, treatable erectile failure is among the most common causes. Findings on reported impotence in the AARP study showed that the proportion of men reporting complete impotence increased from 2% in the youngest cohort to 38% in the oldest cohort. Recognized categories of sexual problems in women include hypoactive sexual desire, sexual arousal disorder, orgasmic disorder, and sexual pain. Although some authors warn against the use of medical taxonomy to describe individual differences in female sexuality, relatively few older people of either gender seek advice or obtain treatment for sexual difficulties.

Findings from the 1999 AARP study showed that only 13% of men and 6% of women sought treatment for sexual dysfunction from their personal physician. Those who received treatment from any source comprised 10% of men and 7% of women, with the most frequent treatments being Viagra and Premarin, respectively. At the time of the 2004 AARP survey, the number of men and women that sought information about sexuality or received treatment for a sexual functioning problem increased significantly.

Earlier treatments for erectile problems in men included alprostadil injection and penile implant surgery. After 1998, the use of these treatments diminished considerably in favor of Viagra and other phosphodiesterase inhibitors (e.g., tadalafil, varenafil) that assist erection. Viagra showed an 84% increase in the number of commercially insured users in the United States within 4 years of its introduction, with the growth in use increasing particularly in males aged 45 years or younger. Research on the effectiveness of Viagra shows an improvement in erectile function compared with placebo. Studies of therapeutic success show that half or more of the older men with erectile difficulties report gains in sexual performance after a course of treatment.

In addition to improved sexual performance, treatment by Viagra may improve the quality of relationships with a sexual partner. In multiple studies, the satisfaction with intercourse was higher in the partners of men using Viagra than in partners of men using a placebo. The partners of men using Viagra report other positive changes that included increases in feelings of closeness and togetherness and a decrease in the frequency of quarrels. However, a proportion of successfully treated men discontinue usage of Viagra. The main reasons for discontinuation include the lack of a partner and emotional disinclination to resume a sexual relationship either by the man or by his partner.

Although phosphodiesterase inhibitors like Viagra assist the erection process, they may be ineffective in the presence of low testosterone (i.e., hypogonadism), which contributes to low libido, failure of erection, depressed mood, fatigue, osteoporosis, and loss of lean body mass. Men with low testosterone, including those who failed to respond to sildenafil therapy alone, may respond well to testosterone replacement therapy.

Emotional readiness for intimacy is a necessary precondition for a satisfying sexual relationship. Sexual therapists use counseling to help older men and women correct relationship problems and

alleviate sexual difficulties. One aspect of counseling concerns sources of sexual arousal, which are more visual and tactile in men but emotional in women. Another concerns the achievement of sexual satisfaction in cases in which penetration is improbable. Shortcomings in the treatment of sexual disorder by family physicians include an overreliance on physical treatments without the requisite counseling to provide an inclusive therapeutic context.

Sexual Preferences and Satisfaction

Sexual Preferences

Heterosexual men typically have sexual partners of a similar age or younger, whereas women have sexual partners of a similar age or older. An evolutionary perspective on mate selection suggests that such preferences reflect gender differences in reproductive strategy. Men may select women for their youth and attractiveness; women may select men for their potential to supply resources. Partner preferences in later life also reflect needs for companionship.

Qualitative studies on the reasons for dating found that older people cite companionship as a main reason. Quantitative analysis of advertisements placed in the personal columns of community newspapers shows that men and women of all ages differ in the preferred age for partners in directions predicted by evolutionary theory. However, the same advertisements showed that people from older cohorts mainly cited friendship as the desired quality in a relationship, with older women particularly disinclined to mention longer-term commitment.

Older gay, lesbian, bisexual, and transgender individuals remain a largely invisible population with respect to research on geriatric sexuality. Although such individuals comprise a minority among the population, the proportion among the older cohorts willing to participate in research on sexuality may be lower than at younger ages. Although the recent medical literature includes several studies with an emphasis on risk factors for sexually transmitted diseases, much of the other research focuses on the health, social service, and community needs of older gay and lesbian people.

Sexual Satisfaction

Even though reported satisfaction decreased with cohort age, more respondents in the AARP study reported satisfaction than dissatisfaction with their sex lives. The presence of a sexual partner, not surprisingly, resulted in higher levels of satisfaction. More women than men were satisfied with their sex lives (and fewer women were dissatisfied) regardless of the presence or absence of a partner, with a similar gender difference found in other research. These findings are consistent with other studies showing that sexual satisfaction is normal in older cohorts. The strongest predictors of sexual satisfaction at any age include the sexual satisfaction of the respondent's partner.

Sexuality in Institutions

Long-term care brings special challenges because a significant proportion of residents have some form of dementia. For people without dementia, privacy should be primary to their ability to enjoy sexual relations. Although many institutions provide privacy rooms to facilitate sexual enjoyment by residents, the attitudes of other people may provide barriers to pleasurable sexual expression. First, the families of sexually active residents of a long-term care home may be unsupportive or hostile toward those residents and berate staff for allowing such behavior. Second, sexual activity by some residents may evoke feelings of disapproval or jealousy in other residents and contribute to conflict and disharmony within the home. Third, sexually ageist attitudes by staff may result in neglect or ostracism of sexually active residents. Some commentators consider such reactions by staff as a form of emotional abuse.

Sexual behavior in dementia brings special ethical challenges in addition to social and professional concerns. For people with dementia, questions of their desire and competency take precedence. Although there is no good reason to prevent people with dementia from enjoying a sexual relationship, it is important to respect their desires and ensure an absence of coercion or unwanted persuasion. Examples of unwanted sexual activity include sexual advances by another resident or by the spouse of a resident living outside the home. There have been cases where criminal prosecution for sexual assault was possible against spouses who demanded the right to a conjugal relationship that threatened the well-being of demented residents.

Staff members bring to a long-term care home their own attitudes and beliefs about unseemly sexual behavior. Sexual display by residents may offend some staff members, especially if they consider such behavior to be socially inappropriate. Staff members assign some level of personal responsibility even to demented residents and may mistakenly attribute inappropriate sexual expression to the character of the resident rather than poor judgment caused by illness.

Staff members also perceive their own responsibility not to expose themselves to sexual advances by residents, and these feelings may affect their behavior toward some residents. Because many staff in long-term care homes receive only rudimentary training about residents' sexuality as part of their educational programs, the need for ongoing in-service training is essential.

Conclusions

The evidence is unequivocal that, contrary to Western traditions of sexual ageism, sexual interest and behavior persist though middle age and into later life. Although physiological changes have qualitative effects on sexuality, quantitative declines with age are associated with limited opportunity, illness and disability, and failure to procure treatment for problems. Findings on attitudes show the significance of sexuality in the lives of middle-aged and older people. Most of those with a partner believe that sexual activity is critical to the quality of their relationship; those without a partner assign less importance to intimacy and report a lower quality of life.

Because sexual activity is so important to intimate bonding, findings that relatively few older people sought help for sexual difficulties as recently as 1999 may seem surprising. There are several reasons for such disinclination. First, sexual ageism contributes to a self-fulfilling prophesy that sexual limitation is normal in old age. Second, effective oral medication to treat sexual dysfunction is of recent origin and targeted only toward men. Third, the opportunity and quality of relationship are limiting factors for sexual enjoyment, particularly in women. Finally, the effects of disuse appear to apply as much to sexuality as to other spheres of activity: sexual disengagement contributes to disinterest.

Cultural changes of relevance to later-life sexuality are both apparent and impending. Such changes concern treatment of problems and opportunities for sexual participation. First, sexual ageism weakened after the introduction of Viagra, with sexuality in later life reappraised as normal and desirable. A consequence concerns the treatment of sexual dysfunction in upcoming cohorts of the elderly. Because of the use of Viagra as an aphrodisiac within younger cohorts of men and women, future cohorts of the elderly may have fewer inhibitions about procuring help for sexual problems. Second, awareness and sensitivity about the effects of illness and disability on sexual behavior are increasing within medicine. These changes should provide a supportive context to facilitate treatment. Third, opinions that sex outside marriage is wrong are weaker within younger cohorts. These cohorts are also more accepting of alternative sexual preferences and lifestyles. Likely consequences are that widowhood and status as a single person may be less formidable barriers to sexual opportunity in the future.

Anticipated effects of these cultural changes include a gradual turnaround of the ageist convention that sexuality normally dissipates in later life. The perspective that replaces it will likely consider sexuality that endures until very late in life to be a normal human option, sexual dysfunction a condition often amenable to treatment, and sexual disinterest an unfortunate but not necessarily deviant state of mind.

Skill Acquisition

D L Strayer and J M Cooper, University of Utah, Salt Lake City, UT, USA

Glossary

Associative Learning – The process of strengthening the associative link between a stimulus and a response that underlies automatic processing.

Consistent Practice – A type of practice in which the stimulus–response associations are consistently maintained throughout training.

Part-Task Training – A training procedure in which the consistent components of a task are practiced separately from the complete task.

Priority Learning – The process of modifying the attention-capturing properties of a stimulus leading to the automatic capture of attention.

Proactive Interference – A situation in which prior learning interferes with learning new material.

Variable Priority Training – A training procedure in which subjects are trained to flexibly share attention between two tasks performed concurrently.

Introduction

One of the most important properties of human behavior is the ability to acquire skills that allow people to perform complex operations quickly and accurately with little thought or effort. For example, consider the task of driving an automobile. New drivers often find driving quite demanding, and the rate of traffic accidents is remarkably high for these individuals. Analysis of fatal accidents indicates that it takes several years for drivers to become proficient. Once they have mastered this skill, people are often able to perform several multitasking operations while driving without running off the road (although in many instances these multitasking activities do increase the overall risk of accidents). Indeed, skilled performance is often characterized as fast, effortless, and relatively free of capacity limitations. Given the importance of skill in everyday behavior, a critical issue is how normal aging influences the ability to learn new skills. Is there any merit to the old adage that 'you can't teach an old dog new tricks'?

In contemporary society, new technologies often obligate people to learn new skills. For example, the introduction of the computer into the workplace in the mid-1980s necessitated the acquisition of a new class of skills for a large segment of society. Computers in one form or another now play a central role in almost every aspect of daily life. Using the Internet has become a critical skill, needed for online banking, making travel plans, communicating via e-mail, etc., and there are often penalties for not using this new technology (e.g., some airlines charge a fee when tickets are purchased through a customer representative rather than via the Internet). Are older adults as facile at learning the skills necessary to use these new technologies as their younger counterparts? The purpose of this article is to examine the role of normal aging in the ability to acquire new skills. The article also considers the extent to which skills acquired early in life are maintained across the age range and several strategies that may be helpful in reducing age-related differences in skill acquisition.

Skill Acquisition

Skill is thought to involve the coordination and integration of a number of component automatic processes with strategic knowledge about when and how to use these procedures. Anderson suggested that there are three phases of skill acquisition. The first phase of skill acquisition is the declarative phase. In this phase, heavy demands are placed on attention, and performance is thought to be dependent upon the general problem-solving abilities of the individual (this phase of skill is also referred to as controlled processing). The second phase is the knowledge compilation phase. Knowledge compilation involves several mechanisms for building productions that directly control behavior (e.g., composition and proceduralization) and is thought to be dependent on an individual's perceptual speed ability. The third phase is the procedural phase, which involves a gradual tuning and strengthening of productions in procedural memory, resulting in a speedup in performance, and is thought to be dependent upon psychomotor ability (this phase of skill acquisition is also referred to as automatic processing).

Ackerman developed a theoretical framework incorporating differences in general ability, perceptual speed ability, and psychomotor ability to better understand the role individual differences play in skill acquisition. Individual differences in general ability are thought to indicate differences in the efficiency of general information-processing operations and are

commonly measured with tests of general intelligence. Individual differences in perceptual speed ability are commonly measured with tasks such as the digit-symbol test and are thought to involve "the generation of very simple production systems that must be used to efficiently solve test items" (Ackerman, 1988: 290). Individual differences in psychomotor ability are reflected in measures of elementary processing speed, using, for example, simple reaction time. As the consistency of the operations within a task increases, the role that these ability differences play in skill acquisition grows. Ackerman's framework builds on the three phases of skill acquisition developed by Anderson. From this framework, differences in novice performance are largely governed by differences in general ability; differences in the rate at which individuals can acquire skill are determined by perceptual speed ability; and differences in expert performance are largely governed by differences in psychomotor ability.

The individual differences framework can also be profitably applied to the study of age-related differences in the acquisition of cognitive skill. If general, perceptual speed, or psychomotor abilities change with senescence, then it follows that there should be age-related differences in skill acquisition. Moreover, the degree to which there are age-related differences in each of these abilities will determine which phases of skill acquisition will be most affected by age. What evidence is there for age-related decline in each of these abilities? Schaie studied general ability by examining longitudinal data from more than 5000 individuals and found systematic declines in each of five primary measures of mental ability (i.e., verbal meaning, spatial orienting, inductive reasoning, number skill, word fluency), with the declines becoming most pronounced after the age of 60. In fact, the cumulative proportion of the population that exhibited declines in one or more primary mental abilities increased systematically after the age of 32. Hoyer *et al*. studied perceptual speed ability by performing a meta-analysis of 141 studies of older and younger adults on the digit-symbol subtask taken from the Wechsler Adult Intelligence Scale-Revised. The results indicated substantial declines in perceptual speed ability, with age accounting for 86% of the observed variance in test performance. Finally, Kerr and Blais observed gradual declines in psychomotor performance up to age 60, whereupon psychomotor slowing increased dramatically. Similarly, Fozard *et al*. used both cross-sectional and longitudinal analyses of 1265 adults ranging in age from 17 to 96 and found systematic increases in simple reaction time across the adult life span. Taken together, these results provide a clear indication of age-related declines in general, perceptual speed, and psychomotor abilities, suggesting that older adults should not be able to acquire skills as efficiently as younger adults and that there should be age-related differences in each phase of the skill acquisition process. Despite the fact that older adults as a group acquire skills less readily than the younger cohort, there are often cases in which some older adults perform better than some younger adults, at least on certain specific aspects of performance. However, the longitudinal studies that have been performed suggest that, relative to an individual's own baseline, his or her ability to acquire novel skills should decline as he or she grows older.

A complementary approach to examining skill acquisition and aging is to examine learning curves for younger and older adults. It is commonly believed that the acquisition of skill follows a power function, such that the improvements in performance are greater earlier in training than later in training. The generalized equation for a power function is

$$T = a + b(x)^{-c}$$

In this equation, time, T, is a monotonically decreasing function of the number of trials of practice, x, raised to the power $-c$, multiplied by the total amount of improvement, b, plus a constant, a, reflecting the lower bound of performance.

Figure 1 presents several examples of power functions that illustrate possible age–skill relationships. Note that in each of the theoretical curves in the figure, the initial level of performance is slower for older adults than for younger adults due to the ubiquitous slowing of behavior with age (i.e., general

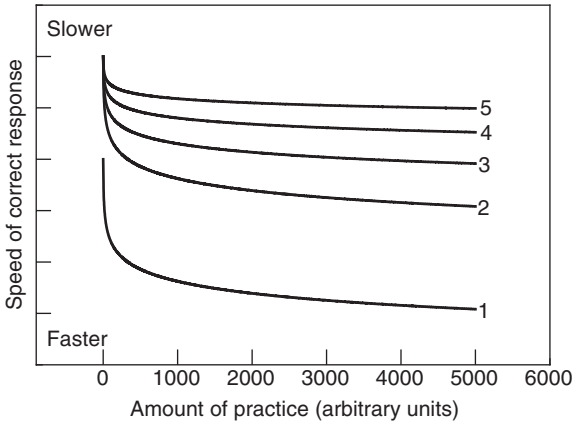

Figure 1 Theoretical power function curves illustrating four possible relationships between younger and older adults in skill acquisition. Curve 1 represents the theoretical performance of younger adults. Curves 2–5 represent the theoretical performance of older adults.

slowing). In the figure, curve 1 illustrates the theoretical performance of younger adults. Curve 2 illustrates a situation in which older adults learn the same amount and at the same rate as younger adults, but there are differences in the asymptotic level of performance (due to general slowing). That is, the *a* parameter of the power function differs with age, but neither the *b* nor the *c* parameter is age sensitive; the curves are simply displaced by the degree of generalized slowing. In such a case, a reasonable conclusion would be that there is little or no decline in the ability to acquire skills with senescence.

Curve 3 illustrates a case in which older adults learn the same amount as younger adults, but both the rate of learning and asymptotic levels of performance differ with age. In this situation, both the *a* and *c* parameters of the power function change with age, but the *b* parameter is not age sensitive. In this circumstance, providing additional practice for older adults would reduce (but not eliminate) the age-related differences. Note that differences in asymptotic performance due to general slowing would still result in slower performance for older adults and that the disparity in performance between younger and older adults grows with practice.

Curve 4 represents a situation in which older adults learn at the same rate as younger adults, but both the amount of learning and asymptotic levels of performance differ with age. This indicates a situation in which both the *a* and *b* parameters of the power function change with age, but the ***c*** parameter is not age sensitive. This case suggests that there was some limit on the amount of learning for older adults, but that the performance of younger and older adults improves at the same relative rate. Here again, the disparity in performance between younger and older adults grows with practice.

Finally, curve 5 represents a case in which all three parameters of the power function are age sensitive. This situation would indicate that there are differences in asymptotic performance associated with general slowing, there are age-related differences in the rate of learning, and there are age-related differences in the amount of learning. Like the two previous cases, the disparity in performance between younger and older adults increases with practice.

The curves depicted in **Figure 1** illustrate four theoretically possible age–skill relationships generated from the generalized power function. In each case, it is clear that older adults do acquire new skills, although in the latter three cases, the difference in performance between older and younger adults grows with practice. There is a good correspondence between the parameters of the generalized power function and the different phases of skill acquisition as described by Anderson. Differences in the declarative stage of skill acquisition are reflected largely in the *b* parameter (i.e., before practice, performance can be defined by the sum of the *b* and *a* parameters of the power function), the knowledge compilation phase is captured well by the *c* parameter, and the procedural phase is indexed by the asymptotic power function parameter *a*. The age-related differences in general ability, perceptual speed ability, and psychomotor ability described previously therefore suggest that each of the parameters of the generalized power function will be age sensitive. The following paragraphs review several studies that have empirically examined skill acquisition in younger and older adults. These studies generally find that older adults are able to acquire new skills, but that the amount of learning, the rate of acquisition, and the asymptotic level of performance are poorer for older adults than for younger adults.

Researchers have used a variety of laboratory paradigms to study age-related differences in the ability to learn new skills. One laboratory paradigm used to study skill acquisition involves having participants search visual displays for critical target stimuli (this is commonly referred to as a visual search task). With younger adults, practice searching for one or more consistently mapped targets leads to improvement in target detection, such that performance becomes insensitive to both the size of the target set and the number of distractors in the display. The performance of older adults also improves with consistent practice; however, their performance remains sensitive to both the size of the target set and the number of distractors in the display. These differences in performance have been interpreted as reflecting age-related differences in priority learning. With priority learning, consistently attending to a target is thought to lead to an increase in the strength of the attentional weight (i.e., priority) associated with the target, and consistently ignoring a distractor is thought to lead to a decrease in the strength of the attentional weight associated with the distractor. With practice, younger adults often report that targets appear to 'pop out' of the display, yielding highly efficient visual search performance. Fisk *et al*. reported additional evidence for age-related priority learning deficits using a reversal condition in which the mapping of prior targets and distractors was reversed after several sessions of consistent practice. Younger adults exhibited greater disruption of visual search performance in the reversal condition than older adults, providing evidence for greater priority learning in younger adults than in older adults. However, the pattern is complicated somewhat by reports from Scialfa and colleagues showing efficient

performance for both younger and older adults in feature and conjunctive visual search tasks.

The memory search task is another paradigm that has been used to study age-related differences in skill acquisition. In the memory search task, a set of items is presented for memorization. A series of probe stimuli is then presented, and the participant must decide whether each probe stimulus was one of the items in the memorized set. Younger adults improve with practice, searching memory for consistently mapped items, such that performance becomes insensitive to the number of items in the memory set. Older adults also improve with consistent practice; however, older adults do not improve as much as younger adults, and their performance improves at a rate slower than that of younger adults. These age-related differences in performance have been interpreted as differences in associative learning. According to strength theories of automaticity, when there is a consistent relationship between a stimulus and a response, the associative link between the stimulus and the response is strengthened. With high levels of practice, younger adults often report that the response comes to mind automatically without their having to think of a solution. Age-related declines in associative learning have also been reported by Salthouse, who used a continuous paired-associates procedure and found that much of the age-related impairments could be attributed to a failure to retain relevant information (i.e., encoding deficits that were correlated with age-related differences in processing speed). Similarly, Fisk and Warr reported age-related differences in associative learning that were linked to the inability of older adults to form new associations as rapidly as younger adults. An alternative retrieval-based interpretation of the age-related differences in memory search is that older adults may be reluctant to switch from inefficient rule-based processing to more efficient retrieval-based processing. The implication of this strategic difference between younger and older adults is explored in greater detail in the next section.

It is also instructive to consider the neuropsychological mechanisms underlying the age-related differences in skill acquisition (and the related declines in general, perceptual speed, and psychomotor abilities). Several neuropsychological factors have been postulated to underlie the age-related difference in skill acquisition. For example, it is well documented through magnetic resonance imaging (MRI) techniques and autopsy studies that there is a systematic decrease in brain volume with senescence. Ventricular volumes increase and temporal and frontal lobe volumes decrease with increasing age, and these changes have been correlated with declines in processing speed measures of intelligence, executive function deficits, and impairments in the early stages of skill acquisition. Using connectionist network simulations designed to evaluate differences in the network architecture and associative learning, it has been found that the amount of information that the network can learn decreases, and the amount of practice necessary to train the network increases as the number and/or connectivity of the neural-like units in the network decreases. Thus, both the rate and the amount of associative learning are predicted to decrease as a consequence of age-related brain atrophy.

Thus far, this review has indicated that older adults do not learn novel skills as proficiently as younger adults. However, as noted by Fisk and Rogers, researchers tend to use novel laboratory-based tasks to attempt to avoid confounds associated with different levels of experience in real-world tasks. A strikingly different picture emerges when performance of skills that have been practiced throughout the life span is measured. In such cases, older adults tend to perform at levels comparable to those of younger adults. For example, Salthouse studied skilled typists between the ages of 19 and 72 and found that typing speed was the same for older and younger adults, whereas the reactions of older adults were significantly slower on novel tapping and choice reaction time tasks. Clancy and Hoyer found that middle-age skilled laboratory technicians were able to search bacterial specimens as proficiently as younger adults, but that they were impaired in a novel computer-based visual search task. Similarly, Krampe and Ericsson found that the performance of older expert pianists on music-related tasks was similar to that of younger expert pianists, whereas the performance of older musicians on non-music-related tasks was significantly impaired. These authors found that the older expert pianists deliberately maintained their proficiency "by engaging in practice activities designed to improve and preserve specific aspects of their domain specific performance" (Krampe and Ericsson, 1996: 357). Finally, Strayer and Drews found that older adults exhibited the same dual-task interference as younger adults when driving an automobile and talking on a cellular telephone. By contrast, with novel dual-task combinations, older adults typically exhibit substantially greater dual-task interference. Thus, it appears that skills acquired as a younger adult that continue to receive deliberate practice over the life span are well maintained in older adults. Unfortunately, the confounding of amount of practice and age makes it difficult to determine if the sparing is due to the retention of previously acquired skills or to the additional practice that older adults have had.

Together, the data from these different methodological approaches provide clear-cut evidence for three conclusions. First, older adults can acquire new skills with consistent practice. Second, older adults do not acquire new skills as proficiently as younger adults. Third, real-world skills acquired in early adulthood that receive deliberate practice over the life span tend to be well maintained in older adults. In general, the data are most consistent with the power function represented by curve 5 in **Figure 1**: there are age-related differences in the rate of learning, there are age-related differences in the amount of learning, and there are age-related differences in asymptotic levels of performance.

Strategies and Skill Acquisition

In many instances, older adults adopt strategies that are counterproductive for acquiring new skills. For example, older adults tend to adopt a conservative response strategy emphasizing accuracy over speed to a greater extent than younger adults. That is, older adults tend to evaluate different amounts (or sources) of information before making their response. It is likely that such a strategy may interfere with learning the procedures necessary to facilitate skilled performance. Support for this interpretation comes from studies of younger adults who adopted conservative response strategies similar to older adults and exhibited sustained deficits in their skill level. Similarly, Strayer and Kramer found that differences in the performance of older and younger adults were reduced when older adults were encouraged to adopt response strategies similar to younger adults. More recently, Touron and colleagues observed that a conservative response strategy may also reduce older adults' willingness to switch processing strategies. In particular, older adults were reluctant to switch from rule-based algorithmic processing to memory/retrieval-based processing and expressed less confidence in their ability to use these memory retrieval strategies. Rogers *et al*. also reported age-related differences in strategy use, with older adults less likely to use memory retrieval strategies. Moreover, these researchers found that age-related differences in performance were reduced when analyses were restricted to those participants who used memory retrieval strategies. It may prove fruitful to identify the strategies adopted by younger adults and encourage older adults to also use these strategies.

Given that the performance of older adults does improve with consistent practice, an effective strategy for enhancing training is to encourage extensive practice on the parts of the task that are amenable to improvement. With part-task training, a task analysis is used to identify the consistent components of a task. These subtasks are practiced in isolation until performance is proficient before being integrated into the whole task. A good example of part-task training is when a musician practices a particularly difficult portion of a score several times before performing the entire piece. When the components of the subtask and the whole task are similar, transfer is expected to be good. Part-task training can be used to provide additional consistent practice for older adults so as to compensate for differences in the rate of learning new skills. For example, Dunlosky and colleagues used a variant of part-task training in which older adults were provided with self-testing techniques for identifying items that could benefit from extra practice. This self-testing procedure resulted in significant improvements in older adults' learning. However, when the demands of integrating task components are high, practicing each portion of the task in isolation may not be any more effective than practicing the whole task and in some instances may result in negative transfer if the integrated whole task goes unpracticed.

A variation on part-task training designed to avoid the limitations associated with part-task–whole-task integration is variable priority training. In variable priority training, participants always perform the whole task, but they are systematically instructed to emphasize some components of the whole task while deemphasizing the other parts of the whole task. Note that with variable priority training, the integrality of the dual-task is maintained while trainees flexibly allocate attention to the different components of the task. Kramer *et al*. compared the effectiveness of variable priority training with a fixed priority training strategy for both older and younger adults. Participants were initially trained to concurrently perform a monitoring task and an alphabet-arithmetic task and then were transferred to a scheduling and a running memory dual-task combination. Not only did variable priority training better facilitate the rate of learning and the level of mastery during the initial training period, but also older adults who received variable priority training actually outperformed younger adults who received fixed priority training. In addition, both younger and older adults showed similar transfer to novel scheduling and running memory tasks. Thus, variable priority training appears to be an effective technique for training older (and younger) adults to flexibly allocate attention in dual-task conditions.

Summary

Older adults can acquire novel skills with consistent practice. However, older adults do not learn these new skills as readily as younger adults. The observed

age-related differences in general, perceptual speed, and psychomotor abilities provide an account from the individual differences perspective of why older adults are not able to acquire skills as efficiently as younger adults. From a neuropsychological perspective, these impairments may stem in large part from brain atrophy associated with senescence. Although older adults exhibit deficits in novel laboratory-based tasks, real-world skills acquired in early adulthood that receive practice over the life span tend to be well maintained in older adults. Thus, there is an intriguing dissociation between acquisition and maintenance of skill in older and younger adults. A number of approaches can minimize the age-related differences in skill acquisition, including (1) encouraging older adults to adopt processing strategies similar to those used by younger adults, (2) providing additional consistent practice in the form of part-task training, and (3) using a variable priority training procedure to facilitate the coordination and integration of component automatic processes of skill.

Published 2007 by Elsevier Inc.

Glossary

Insomnia – A repeated difficulty with sleep that occurs despite adequate time and opportunity for sleep and results in daytime fatigue. The problem may be with initiation, duration, consolidation, or quality of sleep.

Periodic Limb Movement Disorder (PLMD) – A condition of debilitating, repetitive, stereotypic leg movements occurring in non-REM sleep.

Restless Legs Syndrome (RLS) – a condition of an uncontrollable urge to move one's legs at night.

Sleep Apnea – A sleep-related breathing disorder characterized by periodic reductions in ventilation during sleep.

Introduction

Sleep problems are very common in older people. Surveys suggest that at least half of community-dwelling older people have sleep complaints and a similar number use over-the-counter or prescription sleeping medications. The 2003 National Sleep Foundation survey found that about two-thirds of older adults reported experiencing sleep problems at least a few nights a week. Sleep problems are even more common among older people in institutional settings. Age-related changes in sleep (e.g., more nighttime wakefulness, less time spent in deep sleep) are thought by many experts to reflect a decreased ability to sleep, rather than a decreased need for sleep. In addition, many comorbidities (e.g., depression, dementia) and many medications that are commonly used in older people are associated with sleep problems. Finally, certain sleep disorders (e.g., sleep apnea, restless legs syndrome, REM sleep behavior disorder) are an important cause of sleep complaints in older people. Careful assessment of the older patient with a sleep complaint is often needed to help clarify contributing factors and to identify significant sleep disorders. Referral for polysomnography is indicated if a primary sleep disorder such as sleep apnea or periodic limb movement disorder is suspected, when initial behavioral or pharmacological interventions are failing, or when violent or unusual nighttime behaviors are suspected. Management of the sleep complaint should include patient education, assessment and treatment of primary sleep disorders when warranted, identification and management of other contributing conditions, behavioral interventions, and, if appropriate and chosen carefully, pharmacological treatments.

Age-Related Changes in Sleep

Normal sleep has been characterized as two separate states, including non-rapid eye movement (NREM) sleep and rapid eye movement (REM) sleep; adults normally cycle between these states over approximately 90-min intervals during the night. NREM sleep is further divided into four stages based on electroencephalographic (EEG) criteria; stages 1 and 2 are light sleep and stages 3 and 4 are deep sleep. Stage 1 sleep is characterized by relatively fast-wave EEG, and stage 2 by slowing of EEG frequency, an increase in EEG amplitude, and the appearance of sleep spindles and K complexes. Stages 3 and 4 NREM sleep are characterized by high-amplitude, low-frequency delta (slow) waves on EEG. REM sleep, sometimes referred to as paradoxical sleep, is characterized by EEG activation, muscle atonia, bursts of rapid eye movements, increased oxygen requirements, and autonomic activity and is the period when most dreaming occurs.

Commonly reported subjective and objective changes in sleep among otherwise healthy older people include more difficulty falling asleep, more nighttime wakefulness, earlier bedtime and earlier morning awakening, more daytime napping, and a decrease in stages 3 and 4 sleep (i.e., slow-wave, deep sleep). In fact, stages 3 and 4 sleep may be completely absent in very old people. Most experts believe the evidence suggests that older people have a decreased ability to sleep, rather than a decreased need for sleep. The total sleep time over 24 h either remains stable or may decrease with older age, and there is a decrease in sleep efficiency (i.e., the amount of time asleep over the time in bed). Other changes in older people include an earlier onset of REM sleep during the night, a decrease in total REM sleep, and more equal distribution of REM sleep throughout the night, as compared to the relative increase in amount of time spent in REM as the night progresses in younger people.

There also appears to be an age-associated degradation in circadian rhythms of various physiological parameters, including the sleep–wake cycle, which

may be related to neuronal loss in the internal biological clock seated in the suprachiasmatic nucleus of the anterior hypothalamus. In fact, an advanced sleep phase (e.g., feeling sleepy earlier in the evening and awakening earlier in the morning) is a common finding in older people. Various models of sleep regulation have been proposed. For example, sleep–wake pattern disturbance can be understood in terms of the two-process model of sleep regulation. A homeostatic sleep–wake mechanism (process S; i.e., the longer one is awake, the sleepier one becomes) interacts with a circadian process (process C; i.e., variability across the 24-h day where one is more alert earlier in the day than at night).

Classification of Sleep Problems

Various systems to classify sleep disorders have been developed. The International Classification of Sleep Disorders (ICSD-2) is widely recognized and was recently revised. The ICSD-2 Diagnostic and Coding Manual sorts sleep disorders into eight categories, including (1) insomnias, (2) sleep-related breathing disorders (e.g., central or obstructive sleep apnea), (3) hypersomnias of central origin not due to a circadian rhythm sleep disorder, sleep-related breathing disorder, or other cause of disturbed nocturnal sleep (e.g., narcolepsy), (4) circadian rhythm sleep disorders (e.g., advanced sleep phase disorder), (5) parasomnias (i.e., undesirable physical events or experiences at sleep onset, during sleep, or during awakening; e.g., REM sleep behavior disorder), (6) sleep-related movement disorders (e.g., restless legs syndrome, periodic limb movement disorder), (7) isolated symptoms, apparently normal variants, and unresolved issues, and (8) other sleep disorders.

The Diagnostic and Statistical Manual of Mental Disorders, 4th edition (DSM-IV) (and the Text Revision, DSM-IV-TR, published in 2000) organizes sleep disorders into four major sections based on presumed etiology: (1) primary sleep disorders (dyssomnias and parasomnias), (2) sleep disorders related to another mental condition (e.g., mood disorder or anxiety disorder), (3) sleep disorders due to a general medical condition, and (4) substance-induced sleep disorder (including substances of abuse and medications).

Insomnia is the most common sleep complaint in younger and older adults. It has been variably defined over time, but the definition of insomnia provided in the ICSD-2 is a repeated difficulty with sleep that occurs despite adequate time and opportunity for sleep and results in daytime dysfunction (e.g., fatigue or malaise, inattention, daytime sleepiness). The sleeping difficulty of insomnia is generally a problem with initiation, duration, consolidation, or quality of sleep. Adults with insomnia typically complain of difficulties with initiating or maintaining sleep or, less commonly, complaints of poor-quality or non-restorative sleep. ICSD-2 lists several types of insomnia. For example, adjustment (i.e., acute) insomnia occurs in response to an identifiable stressor and is generally of a few days or a few weeks duration and, by definition (ICSD-2), lasts for less than 3 months. Psychophysiological (i.e., chronic) insomnia is defined as an insomnia that is present for at least 1 month and is characterized by conditioned sleep difficulty and/or heightened arousal in bed (e.g., excessive focus and anxiety about sleep), and the sleep disturbance is not better explained by another sleep disorder. The 2005 National Institutes of Health State-of-the-Science Conference Statement on chronic insomnia in adults recommended also defining chronic insomnia as a duration of 30 days or more of symptoms.

Evaluation of the Older Person with a Sleep Complaint

In evaluating an older person with sleep complaints, it can be particularly helpful to query whether the person primarily has symptoms of poor or unsatisfactory sleep, or excessive daytime sleepiness, and to clarify whether there is a suspicion of unusual behavior during sleep such as loud snoring, interrupted breathing, leg movements, or other unusual behaviors. The duration of the complaint is also helpful, since transient sleep problems are usually situational; persistent sleep problems are often more serious and require more detailed evaluation. In order to obtain a careful description of the sleep complaint, it may be helpful to have the patient keep a sleep log or sleep diary in which each morning he or she records time in bed, estimated amount of sleep, number of awakenings, time of morning awakening, and any symptoms that occurred during the night. Any daytime napping and use of medications should also be recorded. This should be supplemented by information from the spouse, bed partner, or others that may have observed unusual symptoms during the night. Validated sleep questionnaires are also available to help obtain additional information to guide further testing and treatment.

The sleep assessment should consider whether an underlying medical condition, substance abuse, or another mental health problem such as depression and/or anxiety is contributing to the sleep complaint. In the older adult with sleep problems, careful mental status testing is also indicated in most cases.

Evaluation should also address whether relocation, bereavement, or other acute stressors precipitated the sleep complaint. A careful review of systems should include questions about pain, nocturia, nocturnal cough, orthopnea, and other symptoms that might interrupt sleep. All medications should be reviewed, including prescription, over-the-counter, and herbal products. The focused physical examination will depend on evidence from the history. For example, a report of painful joints should be followed by a careful examination of the affected areas. A report of nighttime urination disrupting sleep should be followed by evaluation for cardiac, renal or prostatic disease, or diabetes.

Indications for Referral to a Sleep Specialist

Certain situations warrant referral to a sleep specialist for further evaluation and/or to consider diagnostic polysomnography. Polysomnography is generally performed in a sleep laboratory (but portable systems that can be performed at home are available) at night and involves the simultaneous recording of several physiological variables including EEG, electromyogram, electrooculogram, electrocardiogram, airflow at the nose and mouth, microphone for snoring, abdominal and chest respiratory effort, and pulse oximetry measurement of oxygen saturation. A daytime study to assess daytime sleepiness (e.g., the Multiple Sleep Latency Test for the diagnosis of narcolepsy and other disorders) and other studies may also be performed.

In 2005, the American Academy of Sleep Medicine published revised practice parameters on the indications for polysomnography. Based on these recommendations, referral for polysomnography is routinely indicated (1) for suspected sleep-related breathing disorders (including for diagnosis, for titration of treatment with continuous positive airway pressure, and, in some cases, for assessment of treatment results); (2) for suspected narcolepsy; (3) for evaluating sleep-related behaviors that are violent or otherwise potentially injurious to the patient or others; and (4) in certain parasomnias. The recommendations go on to state that polysomnography may be indicated in patients with neuromuscular disorders and sleep-related symptoms, to diagnose sleep disruptions thought to be seizure related, in a presumed parasomnia or sleep-related seizure disorder that does not respond to conventional therapy, or when there is a strong clinical suspicion of periodic limb movement disorder.

Additional methods to measure sleep are available, including validated sleep questionnaires, sleep logs or sleep diaries, ambulatory sleep-monitoring devices (which measure selected parameters performed during polysomnography), and wrist actigraphy (which estimates patterns of sleeping–waking based on wrist movement). A sleep specialist can also be helpful in the evaluation and management of chronic sleep complaints, even if polysomnography is not indicated.

Common Causes of Sleep Complaints in Older People

Large descriptive studies of patients of all ages referred to sleep disorder centers have generally found that insomnia was most commonly due to psychiatric illness, psychophysiological problems, drug and alcohol dependence, and restless legs syndrome, whereas excessive daytime sleepiness was most commonly due to sleep apnea, periodic limb movement disorder, or narcolepsy. However, there can be significant overlap of presenting symptoms with these disorders in older people. In addition, patients referred to sleep centers are a select population, and the most common causes of excessive sleepiness in the community are probably chronic insufficient sleep (either voluntarily or due to lifestyle schedules), or medical, toxic, and environmental conditions. However, one should not rule out a primary sleep disorder (such as sleep apnea) in the patient presenting primarily with insomnia, and likewise one should probably not refer every patient with daytime sleepiness to a sleep laboratory.

Psychiatric Disorders and Psychosocial Problems

Many studies report that psychiatric disorders are the etiology of sleep problems in over half of patients presenting with insomnia. Research suggests that sleep disturbance itself is a predictor of depression in community-dwelling older people. Even more disturbing, an analysis of data from the Established Populations for Epidemiologic Studies of the Elderly (EPESE) found that poor sleep quality was a significant predictor of suicide in older people. Sleep impairment is a common symptom in depression, in which early morning awakening is the most characteristic pattern, although other changes in sleep can be seen, such as increased sleep latency and more nighttime wakefulness. However, these changes may not be present or may be less marked in depressed individuals not seeking medical care. Conversely, sleep disturbance in older people who are not currently depressed may be an important predictor of future depression. In depressed older patients with sleep disturbance, treatment of depression may also improve the sleep abnormalities. Some studies have found changes in sleep electroencephalography

toward a more normal sleep structure with antidepressant medications, which authors suggest indicates that antidepressant drug efficacy may depend to some extent on regulation of sleep and changes in REM sleep regulation. However, some studies have found that subjective (i.e., self-report) and objective (i.e., by polysomnography) measures of changes in sleep with certain antidepressant medications do not necessarily agree.

Bereavement can also affect sleep. Bereavement without major depression may not be associated with significant changes in sleep measures, but people with bereavement plus depression have sleep patterns similar to those found in major depression. These sleep abnormalities may improve with treatment of depression. Anxiety and stress can also be associated with sleeping difficulty, usually difficulty with initiating sleep or perhaps early awakening. Patients may have difficulty falling asleep because of excessive worrying at bedtime. Research has found that older caregivers report more sleep complaints than similarly aged healthy adults. In one study, nearly 40% of older women who were family caregivers of an older adult with dementia reported using a sleeping medication for themselves in the past month.

Drug and Alcohol Dependency

Drug and alcohol use is thought to account for 10 to 15% of cases of insomnia. Chronic use of sedatives may cause light, fragmented sleep. Most sleeping medications, when used chronically, lead to tolerance of the therapeutic effects (i.e., the medication no longer helps sleep) and the potential for increasing doses. When chronic hypnotic use is suddenly stopped, there may be a rebound insomnia that leads to restarting the medication. There is some evidence that there are fewer problems with tolerance to therapeutic effects with the newer benzodiazepine receptor agonists (e.g., zolpidem, zaleplon, eszopiclone).

Alcohol abuse is often associated with lighter and shorter duration sleep. In addition, some people try to treat their sleeping difficulties with alcohol. Older people with poor sleep should be instructed to avoid nighttime alcohol, because although alcohol causes an initial drowsiness, it can impair sleep architecture later in the night. Finally, it is important to remember that sedatives and alcohol can worsen sleep apnea; these agents should be avoided in older people with documented or suspected but untreated sleep apnea.

Changes in Sleep with Dementia

Sleep disturbance is common in older people with dementia. This is likely in part related to medications and comorbidities that can also affect sleep in non-demented older people, in addition to age-related changes in sleep. In addition, there appear to be changes in sleep structure associated with dementia itself; however, the baseline slowing of EEG activity often seen with dementia can cloud the distinction between sleep versus wakefulness and various stages of non-REM sleep on polysomnography. Compared to non-demented older people, those with dementia have more sleep disruption and arousals, lower sleep efficiency, higher percentage of stage 1 sleep, and decreases in stage 3 and 4 sleep. Some authors have noted a decreased percentage of sleep spent in REM, but this has not been reported in all studies. Some studies suggest that older demented individuals actually have less sleep disturbance than older depressed people. In fact, some suggest that sleep disturbance may be an indicator of depression in older people with cognitive impairment. Disturbances of the sleep–wake cycle are common with dementia, resulting in daytime sleep and nighttime wakefulness. Sundowning, the term used to describe a worsening of confusion at night, if present, may have a neurological basis.

Medical Problems and Other Neurological Disorders

Examples of treatable medical problems that may contribute to sleep difficulty in older people include pain from arthritis and other conditions, paresthesias, cough, dyspnea from cardiac or pulmonary illness, gastroesophageal reflux, and nighttime urination. In patients with sleeping difficulties who describe pain at night, assessment and management of the painful condition is the appropriate approach. Nighttime urination may be associated with increased sleep disorders, poorer quality of sleep, nighttime thirst, and increased fatigue in the daytime.

Sleep can be impaired by certain medications taken near bedtime, such as diuretics or stimulating agents (e.g., caffeine, sympathomimetics, and bronchodilators). Certain medications can induce nightmares and impair sleep, such as some antidepressants, antiparkinson agents, certain antihypertensives (e.g., propranolol), and anticholinesterase inhibitors. Necessary sedating medications (e.g., sedating antidepressants) should be given at bedtime if possible. But all medications should be reviewed as potential culprits. For example, there is some evidence that testosterone therapy reduces total sleep time and worsens sleep apnea in older men.

There is increasing evidence of sleep abnormalities with neurological illness. Excessive daytime sleepiness is common with many neurological disorders,

such as neurodegenerative disorders and neuromuscular diseases. For example, sleep problems are common in people with Parkinson's disease. It is likely that both the pathology of Parkinson's disease and its medication treatment may contribute to sleep problems. In addition, certain parasomnias can occur in Parkinson's disease, such as REM sleep behavior disorder or vivid dreaming. Excessive daytime sleepiness is common with Parkinson's disease, with a reported prevalence of 15%. Although rare, sleep attacks have been reported as a possible manifestation of the disease or its medication treatment, but consequences can be severe.

Sleep-Related Breathing Disorders

Excessive daytime sleepiness is a common complaint in the patient with a sleep-related breathing disorder (i.e., commonly referred to as sleep apnea). This condition is characterized by periodic reductions in ventilation during sleep. Sleep apnea may be characterized as central (simultaneous cessation of breathing effort and nasal and oral airflow), obstructive (breathing effort persists without normal airflow), or mixed. In sleep laboratories, obstructive sleep apnea is more commonly diagnosed than central. Patients with obstructive sleep apnea usually present with excessive daytime sleepiness and are typically unaware of the frequent arousals associated with reductions in ventilation. Patients are often obese and may have morning headache and personality changes. Other frequently reported changes in cognition and thinking include poor memory, confusion, and irritability. There is some evidence that older people with sleep apnea have greater (negative) quality of life effects from sleep apnea compared to younger people with a similar disease severity. Other symptoms of sleep apnea that can be helpful in recognizing this syndrome and may be noted by a bed partner include loud snoring, cessation of breathing, and choking sounds during sleep. Cheynes-Stokes respiration is a form of central sleep apnea in which there is a crescendo–decrescendo respiratory pattern. This condition is more common in older people with congestive heart failure, and its presence may indicate a poor prognosis.

The reported prevalence of sleep apnea among older people varies from 20 to 70%, depending on the population studied and the specific criteria used to define sleep apnea. The lower prevalence rates are probably more valid estimates for the general aged population. The prevalence of sleep apnea increases with age, and there is an increase in the apnea–hypoponea index (AHI, a measure of sleep apnea severity) with advanced age. The importance of mild degrees of sleep-disordered breathing in older people is unclear. One study found no association between mild or moderate sleep-disordered breathing and subjective sleep–wake disturbance. The long-term consequences of asymptomatic sleep-disordered breathing in older people are also unclear. Studies suggest that milder increases in the AHI are not associated with increased mortality; however, severe increases in AHI in older people are associated with increased morbidity and mortality.

Sleep apnea is very common among patients referred to sleep centers for evaluation of daytime sleepiness. The most important predictor of sleep apnea in both younger and older adults is large body mass; however, there is not as close a relationship between obesity and sleep apnea in older people. Other risk factors include male gender and family history of sleep apnea. In addition, smoking, use of alcohol and sedative hypnotics, supine body sleeping position, sleep deprivation, medical comorbidity, and acromegaly are also associated with or may aggravate sleep apnea. The classic sleep apnea patient is the obese sleepy snorer with hypertension. Large neck circumference has also been reported as a marker for sleep apnea.

Alcoholism is an important risk factor for sleep apnea, and sleep-disordered breathing is a significant contributor to sleep disturbance in male alcoholics over age 40. Finally, there appears to be an association between sleep apnea and dementia. One nursing home study found that sleep apnea was associated with dementia, and the sleep disorder was positively correlated with the severity of dementia. However, another study concluded that sleep-disordered breathing in Alzheimer's patients is mild and not associated with mental status or behavioral changes.

Patients suspected of having sleep apnea should be referred to a sleep laboratory for evaluation, and if the diagnosis is documented, treatment. There is conflicting evidence whether older patients tolerate the main treatment of obstructive sleep apnea, nasal continuous positive airway pressure (CPAP), as well as middle-aged patients. However, research suggests that an early, positive experience with nasal CPAP may predict better patient adherence with the treatment in long-term follow-up. Research has demonstrated that CPAP can be administered successfully and tolerated even in older patients with mild to moderate dementia. Also, discomfort with a particular CPAP face appliance or interface may be improved by trying other units or devices. Unfortunately, some clinicians may not recommend nasal CPAP in older patients, perhaps due to assumptions that the treatment will not be tolerated or

successful in this population. Oral or dental devices (without CPAP) are sometimes considered for patients with mild sleep apnea or those who cannot tolerate CPAP.

Periodic Limb Movement Disorder and Restless Legs Syndrome

Periodic limb movement disorder (PLMD) is a condition of debilitating, repetitive, stereotypic leg movements may occurring in non-REM sleep and associated with disturbed sleep that is not explained by another sleep disorder. The leg movements may occur every 20 to 40 s and can last hours or even much of the night, and each movement may be associated with an arousal. The occurrence of periodic limb movements in sleep (PLMS) seems to increase with age and may or may not be associated with sleep impairment in different individuals. Whether these movements are of clinical significance has come under some recent scrutiny. One study found evidence of PLMS in over one-third of community-dwelling older people. Correlates of PLMS included dissatisfaction with sleep, sleeping alone, and reported kicking at night. Some authors have suggested that the high prevalence of PLMS with age is associated with delayed motor and sensory latencies noted on nerve conduction testing. PLMD may present as difficulty maintaining sleep or excessive daytime sleepiness, and the diagnosis is generally made based on findings during polysomnography. A bed partner may be aware of the leg movements, or these movements may remain occult until identified in a sleep laboratory.

Restless legs syndrome (RLS) is a condition of an uncontrollable urge to move one's legs at night. The symptoms can also involve the arms. The diagnosis is made based on the patient's description of symptoms, and the sleep complaint is usually difficulty in initiating sleep. Polysomnography is not needed to establish this diagnosis, which is made based on clinical presentation. There may be a family history of the condition and, in some cases, an underlying medical disorder (e.g., renal, neurological, or cardiovascular disease). The prevalence of RLS also increases with age. Many patients with RLS also have PLMS. There is some evidence that RLS symptoms in people with a low serum ferritin level may respond to iron replacement therapy.

In older patients with PLMS or RLS, dopaminergic agents are the initial agents of choice for both conditions. Nighttime doses of carbidopa/levodopa can be used on an as-needed basis for infrequent symptoms. However, chronic symptoms are best treated with a dopamine agonist (e.g., pramipexole or ropinirole), which may be given about 2 h prior to bedtime. Some patients may describe a shift of their symptoms to daytime hours with successful treatment of symptoms at night. Benzodiazepines or opiates have also been used for these conditions but may carry greater risk of side effects in older people.

Disturbances in the Sleep–Wake Cycle

Disturbances in the sleep–wake cycle may be transient, as in jet lag, or associated with an obvious cause, as in shift work. Some patients have persistent disturbance with either a delayed sleep phase (fall asleep late and awaken late) or an advanced sleep phase (fall asleep early and awaken early). The advanced sleep phase is particularly common in older people. Some patients have persistent sleep phase disturbance, in which circadian rhythms and sleeping period have become completely desynchronized (e.g., people who are always asleep during the day and awake at night), or have irregular sleep–wake cycles and very disjointed sleep habits.

It is unclear to what degree that changes in sleep pattern in older people (such as increased daytime napping and disrupted nighttime sleep) are due to alterations in circadian rhythms. Results have been mixed, but several studies have shown age-related decreases in hormonal levels and evidence of earlier circadian rises in certain hormones, suggesting age-related alteration in circadian rhythm. Problems related to an advanced sleep phase may respond to appropriately timed (i.e., evening) bright light exposure. Patients with a significant sleep phase cycle disturbance should be referred to a sleep laboratory for evaluation. Dementia and delirium may also cause sleep–wake disturbance, in addition to increased nighttime awakenings, nighttime wandering, and nighttime agitation.

REM Sleep Behavior Disorder

REM sleep behavior disorder is characterized by excessive motor activities during sleep, with the pathological absence of the normal muscle atonia during REM sleep. The presenting symptoms are usually vigorous sleep behaviors associated with vivid dreams, with injury to the patient or their bed partner. The condition may be acute or chronic and is more common in older men, and there may be a family predisposition. Reported cases of acute transient REM sleep behavior disorder have been primarily drug induced (e.g., antidepressant medications, caffeine) or related to drug withdrawal. The chronic form of REM sleep behavior disorder may be idiopathic or associated with a neurological abnormality

(e.g., Parkinson's disease) or psychiatric illness. Polysomnography is recommended to establish the diagnosis of REM sleep behavior disorder. Clonazepam is reported to be highly effective for the treatment of REM sleep behavior disorder, with little evidence of tolerance or abuse over long periods of treatment. Alternatively, there is some evidence for the use of melatonin for REM sleep behavior disorder in older patients with underlying Parkinson's disease. Environmental safety interventions are also indicated, such as removing dangerous objects from the bedroom, putting cushions on the floor around the bed, protecting windows, and, in some cases, putting the mattress on the floor.

Sleep Disturbance in the Nursing Home Setting

Studies of sleep in nursing home residents have demonstrated marked disruption in sleep with frequent arousals during the night and excessive daytime sleeping. In addition, sleep-related problems are a common reason for institutionalization. Up to 70% of caregivers report that nighttime difficulties played a significant role in their decision to institutionalize their older loved one, often because the sleep of the caregiver was being disrupted. Once in the nursing home, many residents sleep during much of the day and have frequent awakenings during the night. One study found the average duration of sleep episodes during the night in nursing home residents to be only 20 min. Another study found that 65% of residents reported problems with their sleep and hypnotic use was common, but there was no association between sedative/hypnotic use and the presence, absence, or change in sleep complaints after 6 months of follow-up. Common conditions in nursing home residents that may contribute to these sleep difficulties include multiple physical illnesses, psychoactive medications, debility and inactivity, increased prevalence of sleep disorders, and environmental factors such as nighttime noise, light, and disruptive nursing care activities. Lack of bright light exposure during the day may also be a factor, and there is some evidence for improvement in circadian rhythms of activity with bright light exposure in demented older nursing home residents. Non-pharmacological and environmental interventions can be effective in decreasing excessive daytime sleeping but have had modest effect on nighttime sleep parameters in this setting.

Management of Insomnia in Older People

The appropriate treatment of sleep problems must be guided by knowledge of likely etiologies and potential contributing factors. It is not appropriate to start an older person with sleep complaints on a sedative/hypnotic agent without a careful clinical assessment to identify a likely cause of the sleep complaint. Most sedative/hypnotics, particularly benzodiazepines, have a documented association with falls, hip fracture, and daytime carryover symptoms in older people. Newer non-benzodiazepine hypnotics seem to have a better profile than older benzodiazepines and have been studied in healthy older people, but have not been studied in frail older people with significant comorbidity. If the initial history and physical examination do not suggest a serious underlying cause for the sleep problem, a trial of improved sleep hygiene and behavioral interventions is usually the best first approach (see **Tables 1** and **2**). If the patient takes daytime naps, it is important to clarify whether these are needed rest periods or if they are due to inactivity, boredom, or sedating medications. It is important to explain to the patient that daytime naps and dozing will decrease nighttime sleep.

Short-term hypnotic therapy may be appropriate in conjunction with improved sleep hygiene in some

Table 1 Commonly recommended sleep hygiene measures to improve sleep

Maintain a regular rising time
Maintain a regular sleeping time, but do not go to bed unless sleepy
Decrease or eliminate naps, unless necessary part of sleeping schedule
Exercise daily, but not immediately prior to bedtime
Use bed for sleeping or intercourse only, i.e., do not read or watch television in bed
Relax mentally prior to sleep, do not use bedtime as worry time
If hungry, have a light snack before bed (unless there are symptoms of gastroesophageal reflux or medically contraindicated) but avoid heavy meals at bedtime
Limit or eliminate alcohol, caffeine, and nicotine, especially prior to bedtime
Wind down prior to bedtime and maintain a routine period of preparation for bed (e.g., washing up, going to the bathroom)
Control the nighttime environment with comfortable temperature, quiet, and dark
Trial of a familiar background noise, e.g., fan or other appliance or a white noise machine
Wear comfortable bed clothing
If unable to fall asleep within 30 min, get out of bed and perform a soothing activity such as listening to soft music or light reading (but avoid exposure to bright light during these times), then return to bed when sleepy
Get adequate exposure to bright light during the day

Table 2 Examples of behavioral interventions to improve sleep

Intervention	*Goal*	*Description*
Stimulus control therapy	To recondition maladaptive sleep-related behaviors	Patient instructed to go to bed only when sleepy; use the bed only for sleep or intercourse (not for eating or watching television); get out of bed if unable to fall asleep; return to bed only when sleepy; get up at the same time each morning; do not take naps during the day
Sleep restriction therapy	To improve sleep efficiency (time asleep over time in bed) by causing sleep deprivation	Patient first collects a 2-week sleep diary to determine average total daily sleep time; patient stays in bed only for that duration plus 15 min; get up at same time each morning; no napping during the daytime, gradually increase allowed in-bed time as sleep efficiency improves
Cognitive interventions	To change misunderstandings and false beliefs regarding sleep	Patient's dysfunctional beliefs and attitudes about sleep are identified; patient is educated to change these false beliefs and attitudes, including normal changes in sleep with increased age and changes that are pathological
Relaxation techniques	To recognize and relieve tension and anxiety	In progressive muscle relaxation, patient is taught to tense and relax each muscle group in a systematic way. In electromyographic biofeedback, the patient is given feedback regarding muscle tension and learns techniques to relieve this tension. Meditation or imagery techniques are taught to relieve racing thoughts or anxiety
Cognitive-behavioral therapy	Combines therapies to improve symptoms of insomnia	Cognitive-behavioral therapy includes various combinations of both cognitive as well as behavioral interventions. As noted above, the cognitive component is aimed at changing patients' dysfunctional beliefs and attitudes about sleep, and the behavioral component may include therapies such as stimulus control therapy, sleep restriction, or relaxation training. Sleep hygiene education is often also included

cases of transient, situational insomnia, particularly during bereavement, acute hospitalization, and other periods of temporary acute stress. The clinician should not withhold appropriate hypnotic medication treatment in situations in which it is clearly indicated, as long as the clinician has addressed the potential risks and benefits, particularly in older people who are frail. In chronic insomnia, it is imperative that the clinician rule out primary sleep disorders and review medications and other medical conditions that may be contributory. In the patient with symptoms of chronic insomnia, sedative/hypnotic agents should be considered cautiously in the older patient because of the potential complications associated with long-term use of these agents. However, some sleep experts believe that evidence suggests that the newer non-benzodiazepine hypnotics are much safer than older benzodiazepines when used chronically; adequate research to address this question in frail older patients is not yet available.

Non-pharmacological Interventions to Improve Sleep in Older People

Measures to improve sleep hygiene are often recommended, but effectiveness may be modest (see **Table 1**). However, several controlled trials have shown that other behavioral interventions can be quite effective in improving insomnia in older people (see **Table 2**). Several studies of behavioral interventions in community-dwelling older people with insomnia concluded that these interventions produce reliable and durable therapeutic benefits, including improved sleep efficiency, sleep continuity, and satisfaction with sleep; treatment is also helpful in reducing chronic hypnotic use. Stimulus control and sleep restriction therapy, which focus on improving poor sleep habits, can be very effective in older people. Cognitive and educational interventions are also important in changing inaccurate beliefs and attitudes about sleep. Research suggests that sleep benefits from behavioral interventions are sustained over the long term, and patients often prefer behavioral to pharmacological interventions. Several randomized controlled trials have demonstrated that behavioral therapies, particularly cognitive-behavioral therapy (which combines cognitive therapy with aspects of other behavioral interventions such as sleep restriction and stimulus control therapy), are effective in improving sleep problems in older people with insomnia that is either primary or associated with comorbid conditions. The cognitive-behavioral model for insomnia posits that a precipitating factor (e.g., stress, illness) initially disrupts sleep, and perpetuating factors (e.g., maladaptive behaviors such as excessive time in bed, frequent dozing during the day, and false beliefs about sleep) maintain sleep disturbance long after the precipitating event resolves. Cognitive-behavioral strategies address these issues, for example, sleep restriction (reducing time in bed

to approximate total sleep time) and correcting inappropriate thoughts about sleep (e.g., "spending more time in bed will help me to sleep better"). A major limitation to use of these behavioral interventions has been lack of expertise among providers, but limited primary care friendly versions of these interventions are under development and may prove useful.

Several small studies have tested the effectiveness of bright light exposure (generally provided by commercially available light boxes; however, sunlight exposure may also be effective) on sleep in older insomniacs. Positive effects on sleep have been demonstrated with light exposure of various intensities for various durations and at various times during the day, but the timing of exposure should be based on the underlying condition. Evening bright light exposure seems to be particularly useful in the older person with an advanced sleep phase (i.e., the person goes to sleep early and wakes up early), whereas early morning bright light exposure is potentially useful for a delayed sleep phase (i.e., the person goes to sleep late and wakes up late). One author recommends that older people with sleep maintenance insomnia should be treated with 2 h of bright light exposure, equal to the amount of outdoor light found at mid-day or artificial bright light of at least 2500 lux in the evening. However, even short durations of bright light have been shown to improve sleep complaints in healthy older people. A routine eye examination is recommended prior to bright light treatment, and one should avoid light boxes with UV exposure. There is also a growing literature suggesting beneficial effects (in terms of sleep patterns and circadian rhythms of activity) of bright light therapy in demented nursing home residents with disturbed sleep.

Other interventions may also be helpful. For example, bathing before sleep has been demonstrated to enhance the quality of sleep in older people, perhaps related to an increase in body temperature with bathing. In addition, exercise has been studied as a possible intervention to improve sleep. Moderate-intensity exercise has been shown to improve sleep in healthy, sedentary people aged 50 and older with moderate sleep complaints at baseline. But rigorous exercise right before bedtime may interfere with sleep. A randomized controlled trial demonstrated that older adults with moderate sleep complaints had improvement in self-reported sleep quality with a 6-month, low- to moderate-intensity tai chi program.

Non-pharmacological interventions on sleep have also been studied in institutional settings. A study in institutionalized demented residents with sleep and behavior problems found that morning bright light exposure was associated with better nighttime sleep and less daytime agitation. Another study of nursing home residents with dementia and behavioral problems found that a program of social interaction with nurses was effective in reducing behavioral problems and sleep–wake rhythm disorders in 30% of the subjects. A small trial in incontinent nursing home residents demonstrated increased nighttime percent sleep and less agitation among nursing home residents randomized to receive a combined daytime physical activity program plus nighttime intervention to decrease noise and light disruption in residents' rooms. In a larger sample, a similar multimodal intervention combining these interventions with daytime bright light exposure (sunlight) and a bedtime sleep routine demonstrated decreased daytime sleeping as the major sleep outcome. Another trial combining an enforced schedule of structured social and physical activity for 2 weeks in a small sample of assisted living residents found that treated residents had enhanced slow-wave sleep and improved performance in memory-oriented tasks compared to controls.

Non-pharmacological interventions may also be important in the acute hospital setting. A large study testing the feasibility of a non-pharmacological sleep protocol for hospitalized older patients (consisting of a back rub, warm drink, and relaxation tapes) administered by nursing personnel was successful in reducing sedative/hypnotic drug use and had a stronger association with improved quality of sleep than sedative/hypnotic drugs.

Pharmacotherapy for Sleep Problems in Older People

Benzodiazepine receptor agonists (including benzodiazepines such as temazepam and estazolam, and non-benzodiazepine hypnotics such as zolpidem, zaleplon, and eszopiclone) are the most commonly suggested agents for sleep in older people (see **Table 3**). These medications should be used as briefly as possible, and all (except eszopiclone and modified release zolpidem) have an FDA indication for short-term treatment of insomnia that mentions that hypnotic use should generally be limited to 7 to 10 days of use, and re-evaluation of the patient is recommended if these agents are to be taken for more than 2 to 3 weeks. Care should be taken to avoid dependence on these medications, since continued use results in tolerance with many of these agents and may result in increasing dosages. Imbalance (and increased risk of falls), daytime sedation, and cognitive effects are all particular concerns in using sleeping pills in older people. However, there is some evidence that insomnia itself may increase risk of falls.

Table 3 Examples of hypnotic medications

Drug	*Class*	*Starting dose*	*Usual dose*	*Half-life*
Temazepam	Intermediate-acting benzodiazepine	7.5 mg	7.5–30 mg	8–10 h (can be as long as 20–30 h in elderly)
Estazolam	Intermediate-acting benzodiazepine	0.5–1.0 mg	0.5–2.0 mg	12–18 h
Zolpidem	Non-benzodiazepine, imidazopyridine (short-acting)	5 mg (6.25 mg for modified-release formulation)	5–10 mg (6.25–12.5 mg for modified-release formulation)	2.5 h (range 1.4–4.5 h; longer in liver disease); reported half-life for modified-release formulation is 2.5–2.8 h
Zaleplon	Non-benzodiazepine, pyrazolopyrimidine (short-acting)	5 mg	5–10 mg	1 h (reportedly unchanged in elderly)
Eszopiclone	Non-benzodiazepine, pyrrolopyrazine derivative	1 mg	1–3 mg (2 mg max in elderly)	6 h
Ramelteon	Melatonin receptor agonist	8 mg	8 mg	1–2.6 h (active metabolite 2–5 h)

Different hypnotics seem to vary in the extent to which these potentially serious side effects occur, but the cautious clinician should assume that any of these agents may cause these effects to some extent, particularly in older patients who are frail. For example, increased body sway (as measured by clinical stabilometric platform tests) occurred with all three hypnotic agents tested in one study of the acute effects of hypnotics (including a newer, non-benzodiazepine hypnotic), although the effects disappeared more quickly with the shorter-acting agent.

Short-acting benzodiazepines are recommended for problems initiating sleep, and intermediate-acting agents are recommended for problems with sleep maintenance. Short-acting agents appear to be less likely to be associated with falls and hip fractures. However, agents with rapid elimination in general also produce the most pronounced rebound and withdrawal syndromes after discontinuation of the agent. Rebound insomnia after cessation of short-acting agents is dose dependent and can be reduced by tapering the dosage prior to discontinuing the drug. The short-acting benzodiazepine triazolam has been associated with nocturnal amnesia and confusion in older people and is therefore generally not recommended for this population.

Intermediate-acting agents have less association with daytime drowsiness than long-acting agents. If the patient also has difficulty falling asleep, these agents should be given 30 min before bedtime. Temazepam has an intermediate half-life and no known active metabolites, and its metabolism is not thought to be affected by aging. However, daytime sedation may occur with this agent. Estazolam is a benzodiazepine with rapid onset and intermediate duration of action, so it may be effective in both initiating and maintaining sleep. This agent has slightly active metabolites, and some accumulation may occur. The most common adverse effects are somnolence and hypokinesia. Estazolam is thought to have little effect on daytime psychomotor performance.

Long-acting benzodiazepines such as quazepam and flurazepam (which has an active metabolite with a half-life of more than 100 h in older people) should not be used in older people because of associated daytime sedation, lethargy, ataxia, falls, and cognitive and psychomotor impairment. The use of shorter-acting agents seems to greatly reduce the frequency of these effects.

Three non-benzodiazepine hypnotics available include zolpidem, zaleplon, and eszopiclone. Although these agents are structurally unrelated to the benzodiazepines, they share some of the pharmacological properties of benzodiazepines and have been shown to interact with the central nervous system GABA receptor complex at benzodiazepine (GABA-BZ) receptors. The selectivity of these newer agents to the GABA-BZ receptor may account for the decreased muscle relaxant, anxiolytic, and anticonvulsant effects compared with benzodiazepines in some studies. All three agents have been tested in healthy older people and appear to have low potential for tolerance, abuse, or dependence. As with most other hypnotics, these agents have not been well studied in very frail or very old people. Despite evidence of greater safety with use of these newer agents, there is still considerable debate over the risks and benefits of these agents in older people (particularly those who are frail).

Zolpidem is a non-benzodiazepine imidazopyridine that has been studied in older insomniacs. It is available in 5 mg and 10 mg tablets. Studies suggest that in older patients, zolpidem does not produce rebound insomnia, agitation, or anxiety with cessation; does not seem to produce impaired daytime

performance on cognitive and psychomotor performance tests; and the therapeutic effect may outlast the period of drug treatment. Zolpidem is a short-acting hypnotic. A modified-release formulation of zolpidem is also available (recommended doses of 12.5 mg for adults and 6.25 mg for elderly). It is marketed as an agent that can improve sleep onset and sleep maintenance; however, the clinical differences between these formulations appear rather modest.

Zaleplon is a non-benzodiazepine hypnotic from the pyrazolopyrimidine class that has also been studied in older insomniacs for short-term use. It is available in 5 mg and 10 mg tablets. Because of its rapid onset of action and short half-life, zaleplon should be taken immediately prior to bedtime (e.g., kept securely in a bedside table) or may be taken after the patient has gone to bed and has been unable to fall asleep.

Eszopiclone is the S isomer of zopiclone, which has been available as a hypnotic in countries outside the United States for many years. It is recommended at an initial dose of 1 mg for older patients; patients with difficulty staying asleep may need a 2 mg dose. Although a 3 mg dose of eszopiclone is available, recommendations suggest that the dose does not exceed 2 mg in older people. Ingestion of a heavy or high-fat meal with eszopiclone may slow the absorption and reduce effects of the drug. An unpleasant taste in the mouth has also been reported with this drug. The manufacturer of eszopiclone sponsored a 6-month trial that suggested that there was no tolerance to the hypnotic effects and no withdrawal symptoms after up to 6 months of therapy. For this reason, in the United States, eszopiclone has been approved for use without a limit on the duration of therapy.

Low doses of sedating antidepressants (e.g., trazodone, doxepin, and mirtazapine) at bedtime have been used by some clinicians as a sleep aid (off-label use), particularly in patients with depression (off-label use). Low-dose trazodone at bedtime has been studied as a nighttime adjuvant for sleep in depressed patients receiving another antidepressant at therapeutic doses during the daytime, but there has been little other study of this and other antidepressants used as a hypnotic. Daytime carryover and sedation, particularly with long-acting agents such as mirtazapine, may be a significant problem in some older people. Situations where one might consider off-label use of low-dose sedating antidepressants for sleep include patients who have had problems with benzodiazepine receptor agonists, people with fibromyalgia, or those with a history of substance abuse for whom there is concern about use of a benzodiazepine receptor agonist.

A melatonin receptor agonist, ramelteon, is also available for insomnia and is approved for use to improve difficulty falling asleep. Ramelteon (available in an 8 mg dose) is highly selective for melatonin receptors type 1 (which in animal models may regulate sleepiness) and type 2 (which may mediate the phase-shifting effects of melatonin on the 24-h biological clock). Ramelteon was approved by the FDA without a time restriction for duration of use. The hypnotic effects of ramelteon appear to be modest. In addition, it may increase serum prolactin levels, but the significance of this finding is unclear. Ramelteon has been tested in older patients with insomnia. Ramelteon is not a controlled substance and does not have abuse potential. Its role in the management of sleep complaints in older people has not yet been clarified.

Chronic Hypnotic Use

Studies suggest that the bulk of prescription hypnotic use is occurring among chronic users, rather than for transient or short-term insomnia. In addition, chronic use of hypnotics appears to be more common in older adults than in younger adults, and more common in women than in men. Several older studies have shown evidence for increased morbidity and mortality with chronic use of sleeping pills. Epidemiological evidence suggests that there is an increased risk of falls and hip fracture with use of benzodiazepines. However, there is debate among sleep experts over the risks of chronic hypnotic use, particularly with the availability of the newer, non-benzodiazepine hypnotics. Some studies suggest that insomnia, separate from hypnotic use, may also be a risk factor for falls in older people. Regardless of these controversies, it is likely prudent for the clinician to consider helping older chronic hypnotic users to reduce their use of these agents, particularly when there is evidence of adverse side effects. Studies suggest that protocols to taper the hypnotic dose slowly, substitution of the nightly pill ritual, and behavioral interventions (e.g., cognitive-behavioral therapy) may help reduce or eliminate prescription hypnotic use.

Non-prescription Sleeping Agents

Nearly half of older people report using non-prescription sleeping products. The most frequently used products are sedating antihistamines, acetaminophen, alcohol, and melatonin. Sedating antihistamines (e.g., diphenhydramine) are common ingredients in over-the-counter sleeping agents as well as combination analgesic–sleeping agents that are marketed for nighttime use. Diphenhydramine

has potent anticholinergic effects and tolerance develops after several weeks, and use of these agents is strongly discouraged for older people by most geriatricians. Patients with mild discomfort and sleeping difficulties may have adequate relief with a simple pain reliever (e.g., acetaminophen) at bedtime, rather than risking side effects with the combination agent. As mentioned previously, although alcohol causes some initial drowsiness, it can interfere with sleep later in the night and may actually worsen sleeping difficulties.

Evidence is mixed regarding the effectiveness of melatonin as a treatment for insomnia. There is some evidence in older people with insomnia that melatonin administration decreases sleep latency (time to fall asleep) and wake time after sleep onset, and increases sleep efficiency (time asleep over time in bed). However, a small trial in which subjects over 55 years of age with sleep maintenance insomnia were treated with either transbuccal melatonin or placebo did not find polysomnographic evidence of improved sleep. Other research has suggested that older people with insomnia who also have low melatonin levels (e.g., as measured by urinary 6-sulfatoxymelatonin) may be more likely to respond to melatonin replacement therapy. Because of these mixed results and the lack of regulative control in the currently available melatonin products, it is difficult for the clinician to recommend use of these products. However, there is evidence for use of melatonin in blind people with a disturbed sleep–wake cycle and in jet lag and shift workers. Valerian is a herbal product with several active compounds that causes mild sedation of unknown mechanism. Some tested products labeled as valerian had little or no valerian, and it should probably not be recommended because of inadequate study and lack of regulation. One study found valerian no different from placebo on measures of sedative effects.

Slowing of Aging

S Alavez, G J Lithgow, and M Muranjan, The Buck Institute, Novato, CA, USA

Glossary

Free Radical Theory of Aging – Theory that postulates that metabolic activities involving oxygen create toxic reactive oxygen species that damage cells.

Hormesis – The anti-aging and longevity promoting effects resulting from the cellular response to mild repeated stress.

Molecular Chaperones – Proteins involved in folding newly made proteins and that repair the potential damage caused by misfolding under stressful conditions.

Introduction

The ability to slow the aging of an organism in a laboratory is now commonplace. Prior to the late 1980s, the only reproducible demonstration of slowed aging was the caloric restriction of rodents. Genetic selection and recombinant inbred line generation in model organisms gave the first insights into the genetic basis of life span, but the identification of the single gene mutations that extended life span in the nematode *Caenorhabditis elegans* resulted in a vast expansion of the aging field during the 1990s. It is now trivial to extend the life span by genetic or environmental manipulations in the fruit fly, the nematode, and budding yeast. Although, mechanisms of aging remain poorly characterized, a wealth of information has become available from these systems, and as a result, long-lived mouse models are being created and studied. Early indications are that the life span of diverse species, including mammals, is influenced by similar genetic and environmental interventions.

Genetic Determination of Life Span

Aging is a non-adaptive trait that has arisen because long-term maintenance is not necessarily a feature of optimal fitness. The action of genes on aging is therefore either through enhancing maintenance functions or reducing or postponing a major cause of death. In contrast to programmed cell death, aging mechanisms have not evolved to cause organismal death but rather are the indirect effects of selection on early life traits.

Many hundreds of genes have been identified that when altered by mutation or overexpression extend life span by slowing aging in the budding yeast *Saccharomyces cerevisiae*, the nematode *C. elegans*, and the fruit fly *D. Melanogaster*. The genes encode proteins involved in a large variety of different processes, including development, reproduction, metabolism, intracellular signaling, and endocrine signaling. A few prominent examples are discussed here.

Insulin/IGF-1 Signaling Determines Life Span

During the past years, classical studies have revealed a key role of insulin or insulin-like growth factor-1 (IGF-1) signaling in the life span of several organisms from yeast to rodents. This suggests that the physiological processes controlled by these hormones are conserved and influence common aging mechanisms in a wide variety of species. While a sustained blockade of insulin receptor pathways can be detrimental, less severe modulation may positively affect human life span. Work has begun to address whether genetic variation impacting on insulin/IGF-1 signaling in human populations affects life span.

Mammalian Insulin/IGF Signaling

Since its discovery in 1921, the vast majority of studies have focused on the role of insulin in glucose homeostasis and general metabolism. Interestingly, the two main pathologies related to this hormone, obesity and diabetes, have been also associated with a decrease in life expectancy. It has been also reported that human centenarians have an exceptional insulin sensitivity and a reduced incidence of diabetes.

Insulin (from Latin *insula*, 'island', because it is produced by the β cells in the Islets of Langerhans in the pancreas) is a polypeptide hormone that bears homology to the insulin-like growth factors (IGF-I and IGF-II), a family of hormones/growth factors that regulate metabolism, growth, cell differentiation, and survival of most tissues in mammals. These effects are mediated by the insulin receptors (IRs) and type 1 IGF receptors (IGFRs) that initiate their action through a highly conserved signaling system. The receptors are tyrosine kinases. Insulin and/or IGF-I/II ligand binding to the receptors causes dimerization and activation of the cytoplasmic kinase domain, producing an autophosphorylation on tyrosine residues. This phosphorylation produces conformational modifications that

allow receptors to bind intracellular substrate proteins. At least 10 intracellular substrates, also named adaptor proteins, for the insulin and IGF-1 receptors have been identified in mammals, and the best characterized are the four insulin receptor substrate (IRS) proteins. In addition, adaptor proteins contain an amino-terminal PH (pleckstrin homology) domain and several phosphotyrosine motifs that serve as binding sites for SH2 (Src-homology 2) domain-containing proteins. Two important SH2 molecules related to the insulin action are the enzyme phosphatidylinositol 3-kinase (PI 3-kinase) and the adaptor molecule Grb2. PI 3-kinase is the link between IR and the metabolic effects of the hormone by activating Akt/protein kinase B (PKB) and protein kinase C (PKC), which produces the activation of p70 S6 K and glycogen synthase kinase 3 (GSK3). This generates a glycogen/lipid stimulation, protein synthesis, and glucose transporter translocation to the plasma membrane with a consequent increase in glucose transport. Meanwhile, Grb2 links the hormone action to the Ras-MAP kinase pathway and is critical for the ability of insulin to stimulate cell growth and differentiation.

Insulin Signaling in Simple Organisms

During the past two decades *C. elegans* has become one of the most popular model systems for gerontological research. A primary advantage of the system is the short 20-day life span and a wealth of genetic resources.

Mutations that increase longevity were first identified in this nematode in a classical study looking for long-lived mutants carried out by Klass in 1983. Later analysis of the long-lived mutants by Thomas E. Johnson revealed that a single gene was responsible for the observed 70% life span extension. The gene, *age-1*, was later cloned in Gary Ruvkun's laboratory and identified as the nematode homologue of the p110 phosphoinositode-3-OH kinase (PI3 K) that is able to generate 3-phosphoinositides, including phosphatidylinositol-3,4-biphosphate ($PI(3,4)P_2$) and phosphatidylinositol-3,4,5-triphosphate ($PI(3,4,5)P_3$). These second messengers activate the PDK-1 and AKT-1 and AKT-2 kinases. Worm orthologs of these genes were identified and shown to affect life span.

Cynthia Kenyon's laboratory made the observation in 1993 that the *daf-2* mutation in *C. elegans* increases life span by approximately 100%. *daf-2* is upstream of *age-1* and encodes an insulin/IGFR, suggesting that reducing the activity of the insulin signaling pathway increases longevity in this nematode. DAF-16, a forkhead transcription factor, is a downstream target of the AKT signaling and is a key molecule for the influence of insulin/IGF-I-like metabolism on longevity (**Figure 1**). All life span extending mutations identified in the insulin/IGF-I pathway require functional DAF-16 activity, including mutations in *age-1* and *daf-2*. Thirty-seven insulin-like genes have been reported in this animal model. It has been shown that life span may be influenced in a tissue-specific way and that the nervous system and the intestine could play a major role in determining the rate of aging.

In *Drosophila melanogaster*, seven insulin-like peptide (dilp) genes have been reported. Three of these genes are expressed in two paired clusters of seven neurosecretory cells in the brain that send axonic projections to the corpora cardiaca, a component of the principal endocrine gland, and to the aorta, where these peptides are released into the insect blood, the hemolymph. Selective ablation of these neurosecretory cells produces a significant reduction in body size. Interestingly, the expression and release of these peptides are regulated by hemolymph glucose levels, suggesting that these cells could be functionally equivalent to the pancreatic β cells in mammals. Consistent with this, a hormone related to glucagon called adipokinetic hormone is produced by cells in the corpora cardiaca, and its release is similar to the glucagon release from pancreatic β cells.

Recently, some lines of *Drosophila* displaying extended longevity have been reported. The *Drosophila*

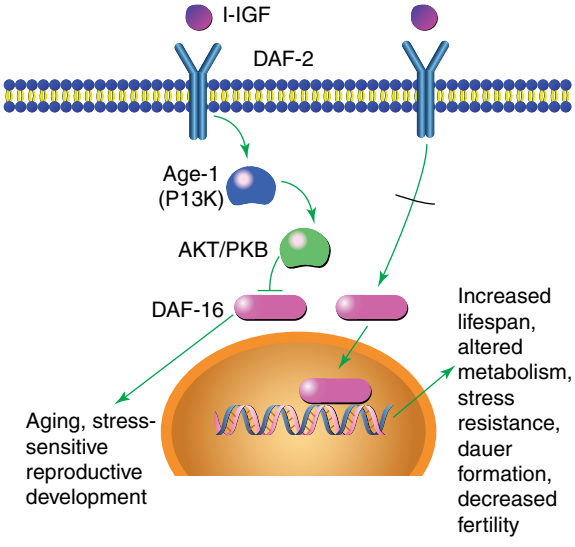

Figure 1 I-IGF control of life span in the nematode *C. elegans*. After insulin or insulin-like peptides bind the insulin-like receptor DAF-2, it undergoes autophosphorylation and catalyzes the phosphorylation of several proteins, resulting in the activation of PIK3-Akt signaling pathway. Akt phosphorylation of the forkhead-like transcription factor DAF-16 inhibits the translocation of this factor to the nucleus, eliciting aging and stress sensitivity and maximal reproductive development. Inhibition of this pathway produces an increase in stress resistance and life span but decreases fertility through the translocation and activation of DAF-16.

insulin-like receptor (InR) is homologous to mammalian insulin and IGF-1 receptors, as well as to *daf-2*. Mutation of InR in the fly significantly extends adult longevity. Females with an InR heteroallelic hypomorphic genotype are small and infertile and live 85% longer than wild-type. Mutation of the IRS homologue *chico* also increases adult maximum life span of *Drosophila* females by around 41%. Experiments involving genetic rescue of the effects of *chico* on somatic growth in transgenic flies and crosses with flies heterozygous for a dominant mutation causing female sterility have provided evidence that neither the dwarf phenotype nor infertility is required for the increased longevity of *chico* minus flies.

Another single mutation of the gene named *Indy* ('I'm not dead yet') was found to extend the heterozygote life span in *Drosophila*. This gene encodes a homologue of the mammalian sodium dicarboxylate cotransporter, a protein that seems to be critical for energy supply, metabolite absorption, and intermediary metabolism. This suggests that this mutant could be under a caloric restriction process that could contribute to the increased life span observed.

Mutation in the *methuselah* gene produces an increase of 35% in life span and also confers resistance to a variety of stressors (e.g., heat shock, starvation, and oxidative stress). The *methuselah* gene encodes a novel G-protein-coupled receptor; however, the mechanism triggered by this gene in order to increase *Drosophila* life span remains unclear.

The homologue of mammalian FOXO and *C. elegans* DAF-16, dFOXO, has been identified in *Drosophila*. Expression of this gene during larval development produces a decrease in larval growth and some alterations in feeding behavior that lead to a reduction in adult body size due to decrease in cell size and in the total amount of cells. Interestingly, this phenotype may be rescued by coexpression of dPI 3-kinase and dAkt, two upstream insulin signaling components. Activation of dFOXO in the adult pericerebral fat body of *Drosophila* is sufficient to increase both male and female life span, to increase resistance to oxidative challenge, and to alter whole-animal lipid metabolism.

Insulin Signaling in the Mouse

Blüher and colleagues have generated a mouse with a mutation of the IR gene in adipose tissue (FIRKO mice) reducing IR by 85–90% in the adipose tissue alone. FIRKO mice present an increase of nearly 18% in median and maximum life span as compared to wild-type littermates. This study suggests a correlation between reduced insulin signaling in adipose tissue and increased life span. Mice null for IGF-1R are not viable and die at birth. However, Holzenberger and colleagues have produced the mice heterozygous for the IGFR gene ($Igf1r^{+/-}$) and showed several phenotypic similarities with the *daf-2* mutants of *C. elegans*, in which the function of the insulin/IGF-1-like receptor is lost. Data pooled from males and females indicate that the $Igf1r^{+/-}$ mice have a mean life span that is 26% longer than that of wild-type mice. Female $Igf1r^{+/-}$ mice present a statistically significant increase of 33% in mean life span as compared to female wild-type mice. However, the increase (16%) in the life span of male $Igf1r^{+/-}$ mice is not statistically significant, probably due to a glucose intolerance developed in males.

These results provide the first evidence that reduced function in insulin and/or IGF-1 signaling pathways produces an increased life span in mammals. Thus, modulators of aging processes in organisms as evolutionarily distant as invertebrates and mammals may be mediated, at least partially, through a similar hormone signaling pathway.

Life Span Extension by Enhanced Stress Resistance

There is a causal relationship between resistance to stress and longevity in several animal models. Almost all animal models respond to acute stress by synthesizing stress proteins. For example, heat shock results in the upregulation of genes encoding members of the heat shock protein (HSP) family, many of which exhibit chaperone functions that protect the organism against thermal stress. Other forms of stress, including oxidative stress, also induce the heat shock response. All known long-lived mutants exhibit increased resistance to environmental stresses, such as oxidative stress, heat shock, UV irradiation, and heavy metal stress. Several manipulations that enhance stress tolerance in *C. elegans* also result in longevity (see **Figure 2**).

Heat shock factor-1 (HSF-1) is a transcription factor required for the expression of some heat shock proteins, and overexpression of *hsf-1* produces an increase of 40% in life span as compared with wild-type animals. HSF interacts with the insulin signaling pathway such that DAF-16 is required for HSF-associated life span extension. Under stress conditions, DAF-16 proteins relocalize from the cytoplasm to the nucleus, where they possibly activate the transcription of stress response and metabolic genes.

Molecular chaperones are proteins involved in folding newly made proteins and repair the potential damage caused by misfolding under stressful

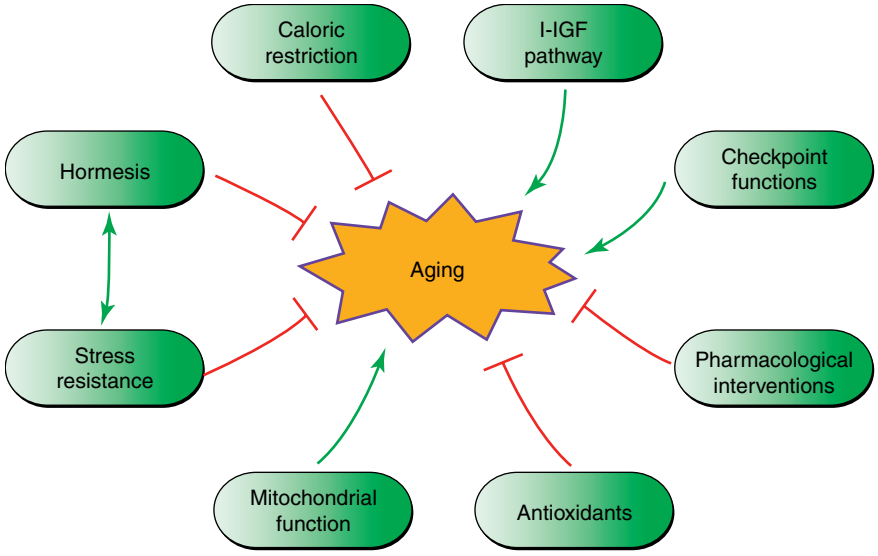

Figure 2 Principal factors that modulate aging. Both genetic and environmental factors determine normal life span. Caloric restriction, hormesis, stress resistance, and antioxidants extend life span, while mitochondrial function, DNA damage cell cycle checkpoint functions, and insulin/IGF-1 signaling shorten life span.

conditions. Gordon J. Lithgow's laboratory proposed and demonstrated that overexpression of molecular chaperones (HSP-16, in this case) was in part responsible for life span extension in insulin-signaling mutants. In addition, HSP-70 levels influence life span of both worms and flies.

There are many examples of connections between stress resistance and longevity in mouse models. For example, the DAF-16 homologue FOXO is regulated by the protein hormone Klotho. Klotho activates FOXO, leading to elevated expression of Mn superoxidase dismutase activity, which in turn leads to oxidative stress resistance. The Klotho overexpressing mouse is also long lived. The long-lived insulin/IGF-1 signaling mouse models are also resistant to oxidative stress suggesting a mechanistic connection.

Hormesis

It has been proposed that if cells and organisms are exposed to brief periods of non-lethal stress, the resulting stress response could produce beneficial effects (**Figure 2**). This phenomenon is known as hormesis. In an aging context, hormesis can be described as the anti-aging and longevity-promoting effects resulting from the cellular response to mild stress. Hormesis has been shown to increase the life span of many different species, including yeast, nematodes, flies, mice, and human cells. Multiple stressors, such as increased heat, high oxygen, and gamma irradiation can induce such a hormetic response in *C. elegans*, and a single pretreatment of heat early in life is sufficient to moderately extend life span. It is clear from this discussion that a simple model organism such as this nematode could be very useful in order to fully understand the molecular mechanisms underlying hormesis.

Interestingly, some beneficial effects of chronic but mild undernutrition have been reported in humans. Peripheral blood lymphocytes from people with low body mass index show high ability of DNA repair and elevated levels of DNA polymerase b that remained during the entire aging process. It has been also reported that sporadic fasting has positive effects on glucose metabolism and neuronal resistance to injury. Two popular lifestyle interventions, exercise and reduced food intake, which could exert their beneficial effects through hormesis, are being recognized as a successful way to achieving a healthy aging.

Caloric Restriction

Throughout history, different cultures have advertised the benefits of food intake limitation. Maybe the first serious scientific work related to restricted diets and their effect in life span was performed by McCay and co-workers in 1935, who fed a diet lacking 20% of total calories and found a significant increase in mean and maximum life span in rodents. A reduction in the total amount of food intake is currently termed caloric restriction (CR), and it has been claimed to be the only effective way to extend life span in mammals without pharmacological or genetic intervention (**Figure 2**). Despite the great interest in CR research during the past years, most of

the theories are not able to explain the complex effects observed in CR experimentation. However, CR has been shown to increase the life span of almost all organisms tested. There are interesting exceptions such as wild mouse strains, mouse populations that have not been subject to lab adaptation, which fail to respond to caloric restriction.

Research performed in yeast and *Drosophila* has targeted the signaling components that respond to different nutritional conditions. Interestingly, the deletion of one of these components, TOR kinase (target of rapamycin), is able to extend life span in *C. elegans*. Life span extension elicited by CR is not fully dependent on the insulin/IGF signaling pathway since it is also observed in worms lacking the forkhead protein DAF-16. However, considerable effort has gone into determining factors important for CR effects in the budding yeast *S. cerevisiae*. Life span is commonly measured as the number of daughter cells produced sequentially during asymmetric cell division. Reduction of glucose in the growth media increases this reproductive life span, and the protein deacetylase SIR2 has been shown to be required for this effect under certain CR conditions. SIR2 overexpression also extends life span in yeast and in *C. elegans*. Whether SIR2-like protein affects mammalian life span and the exact mechanisms of SIR2 action in simple organisms are under intense investigation.

In addition to extending life span, CR could be beneficial for the brain and its function. For example, CR improves the performance of aged rodents on learning, memory, and coordination tasks. In other work, CR improves the function of brain cells in animal models of several neurodegenerative diseases, such as Alzheimer's disease, Parkinson's disease, Huntington's disease, and stroke, suggesting that CR may protect against the effects of age-related brain disease. It has been suggested that CR could produce these protective effect in brain cells by decreasing the amount of destructive free radical molecules.

Finally, assuming that the innate mechanisms that promote health and life span increase during stress, it should be possible to design molecules that can activate them (stress response mimetics). The search for potential CR mimetic molecules has focused on those that could modulate energy metabolism. Two examples include 2-deoxyglucose (2DG) and members of the biguanide class of drugs, which originate from the French lilac (*Galega officinalis*). 2DG is a synthetic glucose analog that inhibits the glycolytic enzyme phosphohexose isomerase. 2DG injected into rodents suppresses tumor growth, decreases insulin and body temperature, and increases glucocorticoids and results in CR. Unfortunately, chronic administration of 2DG has deleterious effects on the heart, making it unlikely to extend life span of the animals in this study. Similar effects occur with metformin, buformin, and phenformin. These findings suggest that mimicking CR in mammals by altering glucose/insulin metabolism may be possible.

Oxidative Stress and Aging

The Mitochondria and the Oxygen Radical Theory of Aging

Mitochondria are the power houses of the cell. These essential double-membraned organelles are vital for energy generation via oxidative phosphorylation, also known as aerobic respiration. The electron transport chain (ETC) is located in the inner mitochondrial membrane. The ETC consists of a series of redox reactions catalyzed by various protein complexes that transfer electrons from reducing equivalents (NADH or $FADH_2$) generated by glycolysis and Kreb's cycle to the final electron acceptor: molecular oxygen. During the translocation of the electrons across the ETC, protons are pumped through the inner mitochondrial membrane. Thus, the mitochondrial matrix is more negatively charged than the cytoplasm, resulting in an electrochemical gradient or voltage generation across the inner mitochondrial membrane. The electrons are transferred from complex I or complex II to III and finally IV. The fourth complex (cytochrome *c* oxidase) transfers electrons to molecular oxygen. The F_1/F_0 ATP synthase (or complex V) permits protons to re-enter the mitochondrial matrix down the established proton gradient. The energy released in this voltage flux is captured by the ATP synthase to phosphorylate ADP to ATP (**Figure 3**).

In 1956, Denham Herman proposed the free radical theory of aging, which postulates that metabolic activities involving oxygen create toxic reactive oxygen species (ROS) that damage cells. At the organismal level the effect is aging. Since 1972 mitochondria have been recognized as a major origin of O_2 radical generation in the cell. ROS include superoxide, peroxide, hydroxyl radical, and several nitrogenous species. ROS causes modifications and denaturation of proteins and lipids. ROS also modifies mitochondrial DNA bases, leading to mutations in genes and hence proteins of the ETC complexes and impairment of ETC efficiency. Aberrant ETC function can lead to increased ROS production and further damage to mitochondrial constituents, including the ETC. A total of 0.4–4% of the molecular oxygen is only partly reduced by the ETC, resulting in superoxide radical ($O_2^{\bullet -}$) production. $O_2^{\bullet -}$ is produced during the two-cycle reoxidation or reduction of

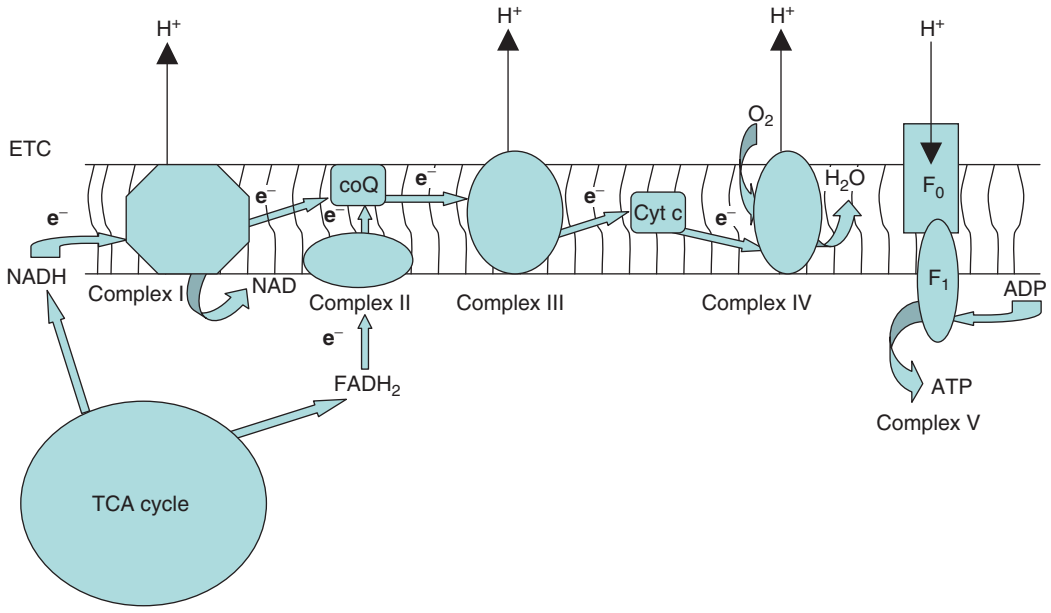

Figure 3 Schematic representation of the mitochondrial electron transport chain located in the inner mitochondrial membrane. The electrons are donated by reducing equivalents generated by the tricarboxylic acid (TCA) cycle, present in the mitochondria. The proton gradient forms as protons are pumped to the cytoplasm by the ETC complexes.

ubiquinone. During this process, semiubiquinone, an intermediate highly reactive toward O_2, is formed.

Mitochondria and the ETC itself are subjected to oxidative damage in a variety of metabolic states. This is thought to decrease mitochondrial functions, including ATP generation during aging. Decreasing ROS generation or increasing ROS-neutralizing mechanisms should therefore protect mitochondria and their functions from oxidative damage, thus slowing the aging process. In support of this idea, ROS scavenging enzymes such as catalase and superoxide dismutase (SOD) are elevated in *C. elegans daf-2* mutants (lacking the insulin/IGF-1 receptor) that live longer than wild-type organisms. Further evidence comes from additional *Drosophila* studies and *C. elegans* studies. The glutathione redox system maintains the optimal redox status in the cell and also detoxifies ROS radicals. This activity is dependent largely on the ratio of reduced/oxidized glutathione. The overexpression of the enzyme involved in synthesis of glutathione-gamma-glutamyl cysteine ligase (*gcl*) increases the glutathione pool and longevity in *Drosophila*. In the worm, daily feeding of catalytic antioxidants leads to thermal stress resistance, paraquat resistance, and extended life span.

Mitochondrial Genes Influence Life Span

New insights into mitochondrial function were obtained from independent RNAi-based approaches that targeted the expression of mitochondrial proteins in *C. elegans*. The RNAi screens suggest that when several essential mitochondrial proteins are absent or undetectable, life span is extended. These proteins included ATP synthase, subunits of ETC complexes I, III, and IV, as well as non-ETC mitochondrial proteins such as leucyl tRNA synthetase and two mitochondrial carrier proteins. In fact, $>50\%$ of genes involved in energy metabolism that when suppressed extend life span encode ETC subunits, and most have human orthologs. Mitochondrial ETC inhibitors also had similar life span-increasing effects. Interestingly the knockdown of glycolysis, triacylglycerol synthesis, or tricarboxylic acid (TCA) cycle genes also extends *C. elegans* life span, although there is no O_2 or ROS production in these reactions.

The mechanism of all of these interventions in metabolism is far from clear. Although counterintuitive, a slower ETC does not result in decreased $O_2^{\bullet -}$ production. On the contrary, slowing down the ETC should increase the half-life of ubisemiquinone (the highly O_2 reactive intermediate) and hence increase ROS production in mitochondrial ETC mutants. The O_2 consumption and ATP levels are decreased in these animals. The ETC mutants are highly resistant to H_2O_2 but hypersensitive to paraquat. Perhaps the high endogenous ROS production expected from a sluggish ETC induces upregulation of ROS scavengers such as catalase, with a resultant hormesis. This would explain resistance to H_2O_2. Hypersensitivity

to paraquat is to be expected in the context of the compromised ETC of these mutants. Paraquat interferes directly with the ETC.

Most ETC mutants show extended life span only when the ETC subunits are suppressed during development. Suppression of an ETC component by RNAi during development permanently decreases ATP levels and O_2 consumption throughout the life cycle. Restoring ETC component levels to normal by removing RNAi during postdevelopmental periods does not restore ATP levels or O_2 consumption to normal, and life span remains extended. On the other hand, decreasing expression of ETC subunits by RNAi knockdown in adulthood does not cause life span extension, even though ATP levels and O_2 consumption decrease. These observations show that impairment of mitochondrial respiration during development establishes a regulatory mechanism that extends life span and maintains ATP production and O_2 consumption rates to match those present during development.

This discovery warrants similar studies in vertebrate models. It has been long established that CR alters metabolism and enhances life span. Mitochondrial retrograde signaling is a pathway of communication from mitochondria to the nucleus that influences many cellular and organismal activities. In yeast it senses mitochondrial dysfunction, which initiates readjustments of carbohydrate and nitrogen metabolism. In the worm, the *sir-2* gene product appears to be involved in the sensory pathway. Hence, it is possible that the partially impaired mitochondrial respiration in ETC mutants induces a metabolic environment similar to CR, leading to an increase in life span.

To complicate matters, there are also short-lived ETC mutants that are hypersensitive to oxidative stressors, e.g., *mev-1*, which encodes cytochrome b, the large subunit of complex II, and *gas-1*, which encodes the iron-containing subunit of complex I. The very first mitochondrial mutant to be discovered was *clk-1* in *C. elegans*. *Clk-1* mutant had a prolonged developmental period. The *clk-1* gene encodes an enzyme involved in the synthesis of coenzyme Q (ubiquinone), an electron carrier that is essential for ETC redox reactions. In yeast, worms, and mice, *clk-1* negative mutants do not synthesize ubiquinone but accumulate its precursor, demethoxyubiquinone (DMQ). The yeast mutant is respiration deficient while mutant mouse embryos become non-viable by day 10.5. Similarly, *clk-1* negative worms undergo developmental arrest. However, *clk-1*$^{+/-}$ heterozygous mice express ubiquinone, yet are long lived. Enhanced life span is also seen in worms that acquire ubiquinone when fed on bacteria that produce the coenzyme. Thus, in both mouse and worm it seems that it is not the absence of ubiquinone that confers longevity. The role of mitochondrial function in life span extension remains elusive.

Summary

Both genetic and environmental influences on life span are being discovered. Aging appears to be a consequence of the action of many hundreds of genes but can be slowed significantly by alterations that affect maintenance and metabolic functions (**Figure 2**). Slowed aging postpones disease, prompting the notion that pharmacological agents that slow aging may be useful in the treatment of age-related disease.

Smell and Taste

S S Schiffman, Duke University Medical School, Durham, NC, USA

Glossary

Chemical Senses – Senses that detect chemical stimuli and encode chemosensory information into neural signals, e.g., smell and taste.

Olfaction – Sense of smell.

Transduction Mechanism – The biochemical process by which stimuli (in this case, chemicals) stimulate the receptors to induce a signal.

Overview

The loss of smell and taste commonly occurs in elderly persons. It can result from normal aging, certain disease states (especially Alzheimer's disease), medications, surgical interventions, and environmental exposure. This article describes the diagnostic terms used to classify these losses and the extent of the losses at threshold and suprathreshold concentrations in older individuals, along with the anatomical and physiological changes that occur in the smell and taste system with age. The contribution of environmental pollutants, medical conditions, and medications to normal age-related changes is also described.

Classification and Consequences of Smell and Taste Loss

The senses of smell and taste are termed chemical senses because they detect chemical stimuli and encode chemosensory information into neural signals. A variety of diagnostic terms have been used to describe smell and taste disorders. Standard classification terms for olfactory disorders are anosmia (absence of smell), hyposmia (diminished sensitivity of smell), and dysosmia (distortion of normal smell). Phantosmia, a type of dysosmia, refers to perception odor in absence of an odor stimulus, and parosmia refers to distortion of odor perception when an odor is present. For taste, diagnostic terms include ageusia (absence of taste), hypogeusia (diminished sensitivity of taste), and dysgeusia (distortion of normal taste). Dysosmia and dysgeusia are not necessarily correlated with decreased ability to perceive chemosensory stimuli. While disorders of smell and taste can occur throughout the life span, they are far more prevalent in an elderly population. The terms presbyosmia and presbygeusia are occasionally used to describe olfactory or taste losses with age. Typically, olfactory perception is more likely to be

disrupted during the aging process than the sense of taste.

The decrements in smell and taste perception that occur with advancing age can have profound effects on integral activities in the daily lives of elderly persons. These chemical senses provide critical information about potential dangers in the environment. For this reason, smell and taste losses are not merely an inconvenience; rather, they leave elderly persons vulnerable to hazards such as spoiled foods, smoke, hazardous chemicals, natural gas leaks, and dangerous fumes. Smell and taste losses can impair the ability to perform routine activities such as food shopping and meal preparation, personal hygiene, and proper handling of household chemicals such as bleach, cleaning products, and pesticides. Loss of the senses of smell and/or taste can also affect elderly who are still working in professions that are best performed by persons with intact chemosensation, such as gourmet chefs, bakers, beauticians, perfumers, wine specialists, chemists, nurses, gardeners, florists, plumbers, or caregivers of infants or small children in diapers. As chemosensory losses progress, alterations in food selection and intake can exacerbate disease states, produce weight loss, and impair nutritional status and immunity. Conversely, nutritional deficits may induce smell or taste losses. Importantly, deficits in the chemical senses can severely impact quality of life because they reduce pleasure and comfort obtained from food, beverages (such as coffee), flowers, fragrances, and natural settings such as forests.

Qualitative Range of Smell and Taste

The qualitative range for odor is extremely broad; it has been suggested that humans can distinguish up to 10 000 different chemicals. There have been many classification schemes for odors, but most are inadequate to encompass the vast qualitative range. For taste, however, most scientific texts state that are only four basic qualities: sweet, sour, salty, and bitter. This 'four-taste' position ignores extensive experimental data in a variety of species, including humans, showing that taste qualities such as metallic (iron salts), astringent (wines), umami (monosodium glutamate/5′-nucleotides), and chalky (calcium salts) are also mediated by taste nerves. Furthermore, amino acids other than monosodium glutamate often have unique taste qualities that cannot be described by sweet, sour, salty, or bitter. Sensations from fats and fatty acids can be detected on the tongue on the lateral posterior sides without tongue movement, and electrophysicological data have shown that fatty acids activate taste nerves. Although the English language lacks the vocabulary to describe the full range of taste sensations, other languages have more descriptors for tastes. For example, the Japanese word *umami* is used to describe the taste of monosodium glutamate as well as the meaty taste of certain fish and broths.

Losses of Smell and Taste Perception in the Elderly

Smell and taste losses have been associated with normal aging, certain disease states (especially Alzheimer's disease), medication use, surgical interventions, and environmental exposure (see **Tables 1–3**). Information regarding some of these losses comes from clinical reports, while other data derive from experimental studies. Both threshold and suprathreshold methodologies have been used experimentally to quantify smell and taste decrements in the elderly. Threshold tasks determine the lowest concentration at which tastes and odors can first be detected or recognized. Suprathreshold studies include identification and discrimination tasks as well as assessment of perceived intensity.

Impairment at Threshold Concentrations

For both smell and taste, detection and recognition thresholds are elevated in older persons. For odors, elevated detection and recognition thresholds have been measured for a broad range of individual volatile compounds as well as mixtures including food odors. An overview of odor threshold studies suggests that thresholds in a healthy elderly cohort are 2 to 15 times higher than in a young group. The degree of olfactory loss tends to be uniform across compounds, independent of their chemical structures. Olfactory losses at the threshold level typically begin to occur in the sixth decade of life, and odor thresholds continue to increase (less sensitivity) from the sixth to the seventh and eighth decades. While olfactory threshold measures are not strongly affected by cognitive losses, suprathreshold performance can be severely impaired.

For taste, elevated thresholds (i.e., reduced sensitivity) for sweet, sour, salty, and bitter as well as for tastes of amino acids including glutamate salts have been quantified in healthy older individuals. The degree of loss varies according to the chemical structure of the compound tested as well as the medical condition, pharmacological regimen, and environmental exposure history of the individual. Threshold measurements for the four prototypical tastes of sweet, sour, salty, and bitter, using sip-and-spit techniques that stimulate the whole mouth, suggest that

Table 1 Representative compounds, dusts, and processes associated with chemosensory disorders in humans with chronic exposure

Metallurgical compounds and processes
Cadmium compounds including oxides
Chromium, including chromate salts and cromium plating
Lead
Magnet production, including iron, aluminum, nickel, cobalt, and chromium powders
Mercury
Nickel, including nickel hydroxide, nickel plating and refining
Silver plating
Steel production
Zinc, including zinc chromate, zinc production
Dusts
Ashes, incinerator

Succimer (lead poisoning)
Ursodiol (gall stone dissolution)
Vitamin D/calcitriol (hypocalcemia)
Vitamin K_1/phytonadione (coagulation disorders)

Adapted from Schiffman SS and Zervakis J (2002) Taste and smell perception in the elderly: effect of medications and disease. *Advances in Food and Nutrition Research* 44: 247–346.

threshold losses are small in elderly who suffer from no diseases and take no medications. Measurable taste losses in non-medicated elderly are often greater, however, for non-prototypical tastes such as salts of calcium, magnesium, and potassium with a variety of anion types. Regional losses in taste sensitivity can also occur over different areas of the tongue for a given individual.

The greatest losses in taste sensitivity at threshold levels are generally found in elderly individuals who take medications. For elderly community-dwelling individuals with one or more medical conditions and taking an average of 3.4 medications, mean 'whole mouth' taste thresholds (using sip-and-spit techniques) have been reported to be 11.6 times higher for sodium salts, 4.3 times higher for acids, 7.0 times higher for bitter compounds, 2.5 times higher for amino acids, 5.0 times higher for glutamate salts, and 2.7 times higher for sweeteners compared with thresholds for a young cohort. For the most part, detection (though not necessarily recognition) thresholds can be found using sip-and-spit methods for most elderly with a broad range of illnesses, which suggests that total absence of taste (ageusia) is relatively rare.

Impairment of Suprathreshold Perception

Impairment of suprathreshold odor perception in the elderly is more pronounced than for taste. Some but not all data suggest that women experience fewer losses than men. Compared to their younger counterparts, the elderly have a reduced capacity to discriminate among odors of different qualities and to identify odors. While performance on tasks that require identification of odors is impaired in many healthy elderly persons, there is heterogeneity among individuals. A population-based cross-sectional study in the United States found that the prevalence of impaired ability to identify odor increases from 17.3% for persons 60 to 69 years of age to 29.2% for persons 70–79, and to 62.5% for 80- to 97-year-olds. Based on these prevalence figures and on United Nations projections of global population growth, the number of individuals projected to have olfactory impairments worldwide by 2050 is at least 230 million. For most persons, the loss in the ability to identify odors occurs gradually over the years, and some older individuals are not aware of the problem until it becomes very troubling. Odor identification is especially impaired in patients with certain neurodegenerative diseases, including Alzheimer's and Parkinson's disease.

Age-related impairments of suprathreshold odors also interfere with the perception of complex food systems, which requires integration of smell and taste sensations. Elderly individuals with olfactory impairment often attribute reduced intensity of foods and beverages to losses in their 'taste' perception. The reason for this incorrect attribution is that they presume that sensations of food in the mouth are tastes; however, they are largely produced by odors. When food is taken into the oral cavity, volatile odorous molecules travel up the back of the throat, and food odors are perceived retronasally. Reduced intensity of odors perceived retronasally interferes with the ability to identify foods. Malnutrition and wasting further exacerbate the ability to identify foods and food ingredients based on sensory cues.

The majority of suprathreshold studies suggest that, compared to a young cohort, elderly persons perceive tastes as being less intense. Any differences in various reports regarding the degree of suprathreshold taste loss probably arise in part from the medical status and pharmaceutical agents used by the subjects, their environmental exposure histories, and their cognitive status. Reductions in perceived suprathreshold taste intensity for sweeteners and amino acids using whole mouth sip-and-spit testing indicate that the degree of loss is dependent upon the chemical structure of the tastant. The ability to

discriminate intensity differences between various concentrations of a tastant is also impaired with age. The prevalence of taste disorders is not yet known, although clinical complaints suggest they are less common than olfactory disorders. Although taste losses may occur less frequently than smell losses, when they do occur, they are more complicated because they can be quality specific or localized to certain areas of the tongue.

Suprathreshold taste losses for sweet and salty qualities can have health consequences for the elderly. For example, if persons with diabetes add more sugar to their foods due to reduced intensity, this could have an adverse effect on their blood sugar. If persons with hypertension add more NaCl to their foods because of reduced salty sensations, this can make it difficult for them to comply with salt-restricted diets. Furthermore, if salt-sensitive hypertensive elderly patients add NaCl to reduce bitterness of foods (NaCl can reduce bitterness), this can elevate blood pressure.

Anatomy and Physiology of Smell and Taste

While both smell and taste sensations are activated when molecules bind to receptors on chemosensory cells, the peripheral anatomy and central neural pathways for the two senses are distinct.

Smell

Olfactory receptor neurons (ORNs) are bipolar neurons that are activated when airborne molecules in inspired air bind to olfactory receptors (ORs) expressed on their cilia. The ORs belong to a G-protein-coupled receptor superfamily. The ORNs are located high within the nasal vault in the olfactory epithelium. The olfactory epithelium is situated on the undersurface of the cribriform plate of the ethmoid bone, on the medial surface of the superior and middle turbinates, and on the upper nasal septum. The turbinates are scrolled spongy bones in the nasal passages that create airflow patterns that allow volatile compounds inhaled through the nares to reach the olfactory epithelium. ORs in the olfactory epithelium can also be activated through 'retronasal olfaction' when molecules from the oral cavity (e.g., from food) pass up through the nasopharynx into the nose.

The axons of the bipolar ORNs pass through small foramina (natural openings) in the cribriform plate joined together in fascicles (bundles), where they synapse in intricate neural masses called glomeruli in the olfactory bulb. Each ORN axon innervates only a single glomerulus. There is considerable convergence at the level of the olfactory bulb, with millions of ORNs converging on far fewer glomeruli. During the aging process, the glomeruli atrophy as fibers degenerate and disappear such that the olfactory bulb takes on a moth-eaten appearance. ORNs are vulnerable to trauma (e.g., blows to head, domestic falls, automobile accidents, and assaults) due to shearing of the axons by the ethmoid bone.

Axons from two principal cell types (mitral and tufted cells) emerge from the olfactory bulb to form the lateral olfactory tract, which subsequently projects to the anterior olfactory nucleus, the olfactory tubercle, the prepyriform cortex, and the amygdala, which are known collectively as the olfactory cortex. Many of these structures constitute the so-called 'limbic system' of the brain, which also processes emotions and memories. The neuroanatomical overlap between neurons that mediate olfaction and emotions provides an anatomical basis for the capacity of odors to produce hedonic responses. Olfactory information is ultimately transmitted to the hypothalamus, an area of the brain that is intricately involved in eating and nutrition.

The direct accessibility of ORNs to airborne agents makes them vulnerable to toxins and infectious agents that occur in breathed air. This vulnerability to the damage from the external environments is probably why ORNs, unlike most other neurons, have the ability to regenerate from a precursor population. ORNs turn over every 30 days on average; they are replaced from a stem cell population of basal cells.

Taste

Taste sensations occur when chemicals come in contact with taste receptor cells that are clustered into taste buds located primarily in structures called papilla on the tongue and on the surfaces of the epithelium of the soft palate, pharynx, larynx, epiglottis, uvula, and the first third of the esophagus. Three types of papilla located on the tongue contain taste buds. Papillae distributed on the anterior two-thirds of the dorsal tongue are called fungiform papillae and generally contain 1–18 taste buds. Foliate papillae are located on the posterior lateral sides of the tongue in vertical folds and contain taste receptor cells that are especially sensitive to sour tastes. Circumvallate papillae are located on the back of the tongue and are arranged in a chevron-shaped form pointing caudally; they are called circumvallate papillae because they are surrounded by 'moats.' Taste buds are composed of 50–100 neuroepithelial cells with apical microvilli that contain receptors in

their membranes. The microvilli project through a central pore in the taste bud to contact chemical stimuli. Chemicals from food stimulate receptors on the microvilli during chewing and swallowing. Tongue movements, such as pressing food (e.g., chocolate candy) against the roof of the mouth, improve and prolong taste sensations on the soft palate. Taste input from the soft palate is impaired in elderly persons who wear dentures that cover the roof of the mouth. Taste receptor cells in the buds have a limited life span and continually regenerate with a turnover time of approximately 10 to 10.5 days. The taste receptor cells are replaced from basal cells, which are proliferative cells that are contained in the buds. This constant replacement of taste receptor cells makes the elderly vulnerable to medical treatments and conditions that impair regeneration such as chemotherapy, radiation therapy, and malnutrition.

A variety of membrane components and second messenger systems in taste cells has been shown to play a role in transduction of taste signals, including sodium channels, potassium channels, and two second messenger systems, the adenylate cyclase system, and the phosphatidylinositol system. However, little is known about how they change during the aging process.

Signals from the tongue and throat transmit taste signals via three cranial nerves (VII, IX, and X) from taste receptor cells to the medulla in the brain stem. Taste buds on fungiform papillae and the anterior walls of the foliate papillae are innervated by the chorda tympani nerve, a branch of the seventh cranial nerve. The majority of the taste buds on the soft palate are innervated by another branch of the seventh cranial nerve called the greater superficial petrosal nerve. The remaining taste buds on the soft palate are innervated by the deep petrosal branch of the ninth cranial nerve. Taste buds on the posterior walls of the foliate papillae, the circumvallate papillae, the pharyngeal part of the tongue, and the oral part of the pharynx are innervated by the ninth (glossopharyngeal) nerve. The superior laryngeal branch of the tenth (vagus) nerve innervates taste buds on the far posterior tongue, the epiglottis, the larynx, and the esophagus. The temporal sequence of stimulation of these nerves during oral manipulation and swallowing of food provides the unique 'melody' of each recipe.

The seventh, ninth, and tenth cranial nerves project to the rostral portion of the nucleus of the solitary tract (NST). The NST is a longitudinally organized column of neurons located in the dorsal medulla; it receives visceral sensory information in the caudal portion originating in the esophagus, stomach, intestines, and liver in addition to gustatory information in the rostral portion. Thus, the NST is the first processing area in which taste signals can have an impact on digestion by inducing gastric secretion, increased pancreatic exocrine secretion, and increased secretion of insulin. For this reason, taste losses can have an impact on a range of digestive processes. Axons from the rostral (gustatory) NST project to the ventroposteromedial nucleus of the thalamus, which then projects to the primary gustatory cortex, which consists of two discontinuous areas: the insula-operculum as well as a spatially separate area on the lateral convexity. Neurons on the anterior insula project to taste secondary cortex located on the orbitofrontal surface.

Common Chemical Sense

Another nerve, the trigeminal nerve, is also involved in the perception of chemicals through the so-called 'common chemical sense' or 'chemesthesis.' The ophthalmic branch and maxillary branches of the trigeminal nerve detect irritancy and pungency in the nasal cavity, which can induce sneezing and breath holding when a noxious odor is inhaled. The inhalation of noxious chemicals also results in release of substance P and calcitonin gene-related peptide, producing nasal mucosal edema and secretion. There are central interconnections in the thalamus between trigeminal and olfactory input.

The mandibular branch of the trigeminal nerve mediates pungency and irritation on the anterior two-thirds of the tongue. Examples of chemesthetic qualities are those from nicotine, capsaicin, and piperine (the chemicals in red and black peppers, respectively). Pungency in the nasal and oral cavities is not considered odor or taste but rather a different sense related to nociception.

Causes of Smell and Taste Losses in Older Individuals

There are a multitude of causes of chemosensory alterations in older persons, including anatomical and physiological changes that accompany normal aging, certain disease states (especially Alzheimer's disease), medications, surgical interventions, and environmental exposure.

Anatomical and Physiological Changes in Normal Aging

Many age-related changes in the anatomy and physiology of the olfactory system occur during the aging process; however, analogous changes in the taste system are more equivocal. In the olfactory system, changes occur in the olfactory epithelium,

olfactory bulb and nerves, hippocampus and amygdaloid complex, and hypothalamus, including reductions in cell number, damage to cells, and diminished levels of neurotransmitters. There is an increase in ORN apoptosis (programmed cell death), a decrease in the rate of basal cell proliferation, decreased thickness of the olfactory epithelium, a decreased number of cilia and supporting microvilli, and increased accumulation of electron-dense granules in supporting cells. As the process of olfactory neurogenesis of ORNs begins to degenerate with increasing age, olfactory epithelium is gradually replaced by non-olfactory epithelium, with a subsequent loss in receptor area. This regeneration is inadequate in some cases to replace fragile ORNs damaged by injury (from shear or viral infections) because regenerating olfactory axons are unable to traverse scar tissue and disrupted foramina to reach the olfactory bulb. Regenerating neurons subsequent to injury can also make aberrant synaptic connections, which leads to dysosmia. The olfactory bulb takes on a moth-eaten appearance as glomeruli atrophy and fibers degenerate and disappear. Furthermore, there can be damage to the structures of the limbic system in normal aging, which is exacerbated in Alzheimer's disease.

Studies of anatomical losses in the structures of the taste system in older individuals have drawn conflicting conclusions. Whereas some studies reported reduced numbers of papillae and/or taste buds, other studies found no changes during normal aging. Spatial or regional taste losses have been reported in older individuals, but little is known about why patches of taste buds disappear. It is possible that some physiological taste losses from normal aging occur at taste cell membranes (e.g., altered functioning of ion channels and receptors) rather than from losses of taste buds.

The greater prevalence of generalized olfactory loss compared with generalized taste loss in the elderly can be explained in part by the difference in their relative vulnerabilities to anatomical and physiological damage. As described previously, axons from the olfactory nerve must traverse the cribriform plate of the ethmoid bone before they reach the olfactory bulb. Thus, axons of the olfactory nerve are vulnerable to severing in any type of blow to the head. Olfactory receptors are exposed to the external environment so they can be affected by inhaled environmental toxins. In addition, olfactory receptor cells are located in a compact area, while taste receptors are spread diffusely throughout the mouth and throat. The dispersion of taste receptors relative to smell receptors probably allows some taste receptors to survive a toxicological challenge.

Medical Conditions and Environmental Exposures

Smell and taste losses from normal aging are exacerbated by a wide range of environmental exposures (see **Table 1**) and medical conditions (see **Table 2**). Age-related olfactory losses can be compounded by conductive losses in which there is obstruction of nasal airflow to the olfactory epithelium, e.g., as in chronic rhinosinusitis, polyps, tumors, or allergic rhinitis. Sensory/neural losses secondary to damage to ORNs, the bulb, or central projection areas resulting from upper respiratory infections, head trauma, and toxins (including acute or chronic exposure) can also exacerbate age-related losses. Neural losses in the bulb and at higher cortical levels can occur because ORNs serve as a direct conduit for environmental substances such as metals or viruses to be transported from the nasal cavity to the brain. Extensive scarring along with replacement of olfactory epithelium by respiratory epithelium that occurs subsequent to postviral olfactory loss exacerbates the gradual reduction in olfactory receptor area that occurs during the normal aging process.

In certain disease states prevalent in an older population, such as Alzheimer's disease (AD) and Parkinson's disease, the olfactory losses can be profound. Measures of olfactory ability can be useful in confirming a diagnosis of AD or in identifying those at risk of AD when used in conjunction with other standard diagnostic tools (such as brain imaging). Meta-analyses of studies on olfactory perception in persons with AD conclude that severe losses can occur in five olfactory domains: threshold detection, recognition, discrimination, identification, and olfactory memory. Losses in the ability to remember, recognize, discriminate, and identify odorants occur in the earliest phases of AD, while losses in sensitivity at the threshold level tend to emerge or become more noticeable later as the disease progresses. The gustatory system is not nearly as vulnerable to the ravages of AD as the sense of smell. This relatively greater loss in smell perception in AD compared to taste is due to the neuroanatomical and neurochemical changes in the olfactory system that are characteristic of AD. Neural degeneration in AD occurs in the olfactory bulb, anterior olfactory nucleus, olfactory tubercle, amygdala, prepiriform cortex, hippocampus, entorhinal cortex, uncus, and subiculum. Histopathological changes also occur in the olfactory epithelium. Olfactory measures are also impaired in persons at risk for AD based on documented multigenerational evidence of the disease. Numerous studies have found that at-risk individuals have impaired smell detection and smell memory scores when compared to age-matched controls.

Age-related taste disorders are frequently associated with a range of medical conditions, including infections in the oral cavity and hypopharyngeal mucosa (viral, bacterial, fungal, and parasitic) along with radiation, chemotherapy, and poor oral hygiene (see **Table 2**). Damage to the chorda tympani nerve subsequent to infections (e.g., Lyme disease, chronic otitis media, Bell's palsy) or surgery (dental or ear surgery) can also exacerbate any age-related taste loss that exists. Some studies suggest that elevated salivary copper levels and reduced salivary zinc and manganese levels occur in patients with taste disorders along with decreased salivary concentrations of a matrix metalloproteinase, MMP-3, which is a zinc-containing enzyme that degrades components of the extracellular matrix. Ageusia or severe generalized hypogeusia across all qualities and gustatory neural fields from medical conditions or toxic exposures is relatively rare. However, specific precipitating factors have been linked to taste losses by patients with ageusia or severe generalized hypogeusia, including upper respiratory tract infections, oleoresin capsicum (pepper gas spray) exposure, pesticide exposure, surgery such as tonsillectomy, and head and facial trauma. The prognosis for severe generalized taste loss is poor, and the majority of patients do not regain their sensitivity.

Medications

Medications can also play a major role in smell and taste losses and distortions in older persons, and their role in chemosensory losses is probably underestimated. According to the *Physicians' Desk Reference* (PDR), hundreds of medications (see **Table 3**) have been associated clinically with chemosensory side effects such as 'loss of taste,' 'altered taste,' 'metallic taste,' and many other alterations of smell and taste sensations. Most major drug classes have been implicated in chemosensory disturbances. However, because quantitative chemosensory assessments of large populations taking specific medications have not been performed, it is not known whether these clinically reported losses are indeed gustatory or olfactory in nature, or if they are caused by medications or the medical conditions the medications are designed to treat. According to the PDR, adverse chemosensory side effects from medications usually occur in a minority of patients, but the actual prevalence of medication-induced losses awaits determination by experimental testing procedures. Prescription medications are consumed disproportionately more frequently by the elderly, with per capita usage three times higher than in their younger counterparts. Community-dwelling elderly over the age of 65 typically use 2.9 to 3.7 medications daily, and this number at least doubles for elderly living in retirement and nursing homes.

Little is known about the site or mechanism of action by which most pharmaceutical compounds induce chemosensory losses, but drugs can interfere with smell and taste systems at several levels, including peripheral receptors (e.g., by blocking sodium or calcium channels), chemosensory neural pathways (e.g., by interfering with propagation of signals), and/or the brain (e.g., by diffusing into the brain or brainstem). Quality-specific losses (e.g., specific elevations in taste threshold for salt) may be due to medications that selectively interfere with sodium channels. Drugs secreted into the saliva in the oral cavity can also exert adverse effects on taste perception either by modifying taste transduction mechanisms or by producing a taste of their own. Drugs dissolved in blood can also diffuse from the circulatory system to activate receptors on the basolateral side of taste receptor cells. Some drugs such as chemotherapeutic agents and some antibiotics can interfere with cell turnover of smell and taste receptors (e.g., by blocking mitosis). Steroids can promote overgrowth of *Candida albicans* in the oral cavity, causing a medical condition that interferes with taste.

Brain imaging studies of drug uptake suggest that drug penetration into smell or taste projection areas of the brain or brain stem may account for some alterations in the chemical senses. When a drug is absorbed or injected into the bloodstream, it can pass into the extravascular interstitial space of most tissues (except the brain) through fenestrations in the capillary endothelium. The rate, extent, and pattern of distribution into the interstitial, cellular, and transcellular fluids depend upon the physicochemical properties of the drug. Lipid-soluble drugs that are readily distributed throughout the body including the brain and brain stem could interfere with taste signals by permeating into taste pathways. It is noteworthy that some highly lipophilic and keratophilic drugs such as the allylamine antifungal agent terbinafine are implicated in taste disorders. The brain (and brain stem), however, does have a protective barrier called the blood–brain barrier that restricts the passage of many drugs (especially lipid-insoluble ones) from the blood to the brain. Only small regions of the brain and brain stem, called the circumventricular organs, such as the area postrema (in the medulla), lack a blood–brain barrier. Thus, lipid-insoluble drugs can potentially slip into the brain or brain stem through circumventricular organs and damage taste or smell neurons located in close proximity. For example, drugs could percolate from the area postrema (which lacks a blood–brain barrier) to

neighboring taste neurons in the nucleus of the solitary tract. Inflammatory conditions, neurodegenerative diseases, and advancing age are known to disrupt the blood–brain barrier and predispose an individual to drug-induced chemosensory disorders.

Potential Treatments

There are no standard treatments for smell or taste losses that occur in elderly individuals. However, smell and taste losses from some medical conditions or medications may be reversed upon return to good health and substitution of medications without chemosensory side effects. Amplification of the flavor of foods with simulated flavors (such as commercial cheese, bacon, or butter flavors) can be helpful for persons with hyposmia. A variety of therapeutic options may be available in the future to treat taste or olfactory losses and restore functioning, including antiapoptotic drugs, stem cell treatments, and use of growth factors that promote neuronal regeneration.

Social Cognition

J E Norris and M W Pratt, Wilfrid Laurier University, Waterloo, Ontario, Canada
S Hebblethwaite, University of Guelph, Guelph, Ontario, Canada

Glossary

Collaborative Cognition – Engaging in joint problem solving or decision making.

Ego Integrity – A sense of accomplishment with regard to the past and the end of life.

Generativity – Concern for and commitment to future generations.

Morality – The judgment of behaviors and relationships with others.

Social Cognition – Thoughts about others and thoughts about the self in relationship to others.

Sociocultural Perspective – A way of understanding human development that emphasizes the role of the social context in promoting or impeding growth.

Socioemotional Selectivity – The selection of emotionally gratifying social encounters or partners as a result of awareness of the foreshortening of one's life span.

What Is Social Cognition?

Social cognitions involve thoughts about others and thoughts about the self in relationship to others. When we consider cognitive aging from this point of view, it leads us away from traditional research methods and theoretical perspectives that have focused on basic information processing and how it is tied to physiological decline. This body of research has been largely experimental and often has taken place in situations designed to remove the effects of the social context. In contrast, research on social cognition and aging typically is designed to consider how social context affects the thinking of adults.

Work on social cognition has raised important issues inherent in understanding what it means to grow old as a social being. Our life stories, experiences, social competence, core values, and general understanding of the social world have a profound effect on our development at any age. To address these issues, we must consider both basic cognitive processes and abilities in the aging adult as well as everyday cognitive functioning in a social context. Cognitive capacity and speed of processing do show losses in old age. Nevertheless, the vast majority of older adults are skilled and effective in their interactions with their social environment. The basic goal of the social cognitive approach is to understand how people make sense of themselves, others, and events in everyday life. This article examines our current understanding of these processes by looking at five different areas of social cognitive research: person perception and stereotypes, socioemotional selectivity, collaborative cognition, morality, and positive psychology.

Person Perception and Stereotypes

The way that we perceive and understand other people is partly determined by our prior understanding of their group memberships or characteristics. Use of this organized prior knowledge, or stereotype, can result in both negative and positive evaluations of others. As a group, old people are the subject of a great deal of negative stereotyping. They are considered to be frail, forgetful, uninterested in sex, and grouchy. On the other hand, they are also the recipients of some positive stereotyping that attributes greater wisdom, generosity, and social responsibility to them than to younger adults. Even if some of these beliefs may hold a kernel of truth, they are not accurate for all, or even most, older adults.

Researchers have considered the effect of this stereotyping and have found that it can impair the functioning of older adults. The communication predicament model provides one model of the processes that lead to this outcome. In a first encounter with an older person, characteristics that indicate age, for example, wrinkled skin, a quavering voice, or evidence of some mild memory impairment, may be noticed by another social actor. This awareness then triggers a stereotyped expectation of cognitive impairment that leads to altered or simplified speech, for example, calling an older woman 'dear' or addressing her in the second person plural ("How are we today?"). In a vulnerable older person, this response can reinforce stereotyped behaviors that he or she may have already been displaying (e.g., dependence on others, social isolation), further constraining opportunities for normal discourse and resulting in more isolation and feelings of powerlessness. Ultimately, these age-appropriate behaviors can confirm a negative stereotype of aging and negatively influence any new encounter, thus maintaining the negative feedback loop. Research has shown that even in healthy, well-functioning older adults, the activation of a negative stereotype regarding memory functioning is sufficient to create performance deficits on memory tasks. Stereotype threat can have powerful effects on vulnerable individuals.

Age-related stereotyping does not always have a negative effect on behavior, however. There is also evidence that exposure to positive stereotypes can enhance the performance of older adults. Social expectations of leadership, wisdom, or kinkeeping have been shown to result in altered performance, even on tests that do not appear directly related to those characteristics, for example, memory. Positive stereotypes of aging provide a kind of lift to the performance of older adults.

As well as being the recipients of stereotyping, older adults may also be more susceptible to applying stereotypes to others. Managing an encounter with a stranger, for example, requires the engagement of a variety of social cognitive processes. We consider what we know of people with similar characteristics, we think about past encounters of a similar nature, and we consider contextual cues that have a potential influence on the nature and outcome of this encounter. For younger adults, this analysis may elicit a stereotype that is then applied to the encounter, but it may also lead to thoughts about how this individual is unlike the stereotype one holds of his or her group, and how previous encounters with strangers are unlike this one in a variety of ways. Older adults, on the other hand, seem less likely to engage in this complex analysis and more likely to rely on previous experience and ready stereotypes to help them through the new situation.

Researchers have suggested a number of explanations for this age difference in social attribution. One possibility involves the interaction of available social schemas and the lessening of cognitive resources. Older adults have accumulated a rich repertoire of social scripts to apply to social encounters. Applying an existing schema requires less cognitive effort to select and apply than the development of a novel approach. Slower and less efficient processing of information may make it difficult for older adults to alter highly scripted forms of social behavior and adapt them to a new situation. They are more likely to process information automatically because of the cognitive demands required of new interpretations. Other researchers, however, have cautioned that this explanation should not be accepted uncritically. They have instead suggested that a variety of social factors influence how an individual will attend to and process information. Attitudes, values, and motivational goals that are more directly connected to context, cohort, and gender than to development have a significant impact on social functioning.

Socioemotional Selectivity

A consideration of the motivational goals of older adults is the underpinning of Carstensen's socioemotional selectivity theory. As adults age, they accumulate social losses through the death of members of their networks and through events such as retirement. This explains, in part, why older adults have fewer social relationships than young people. However, this simple explanation does not consider the role of individual agency or development in producing smaller social networks in later life. Early theorists in the field of social gerontology proposed that a developmental process called disengagement was responsible for initiating a process of withdrawal from social roles, relationships, and responsibilities. This process, begun in mid-life, was considered a desirable and natural part of growing older. In turn, social policies such as mandatory retirement were considered to be consistent with this approach to successful aging because they promoted the withdrawal of older people from the social roles common to earlier points in the life span. Disengagement theory generated controversy, but received little empirical support and was widely disregarded.

Socioemotional selectivity theory picks up on the idea that older individuals are, in part, responsible for their shrinking social networks and that this process is potentially age linked and adaptive. However, there are important differences between selectivity and disengagement. Across the life span, people are motivated to seek social contact for reasons such as information seeking and emotional gratification. These motivations show general age-related patterns. In later life, emotional goals are prominent. For example, older people prefer and seek out emotionally rewarding social encounters with old friends rather than novel interactions with strangers. Younger people, on the other hand, are motivated to expand their networks by maximizing the greatest number of new encounters.

Carstensen believes that the same socioemotional goals guide all of us through life, but that the priority of these goals changes for one important reason: the perceived time left in life. When our horizons are far away and ever expanding, we seek out relationships that add information and novelty and contribute to possible futures. When our horizons are close and our time on earth seems limited, we are much more present oriented and consciously seek out emotionally gratifying and meaningful encounters. This explains why older adults are not as willing as younger people to seek out new relationships, even when they have lost significant numbers in their old networks.

Unlike other developmental theories, the selectivity approach does not require that certain socially motivated behavior be restricted to a chronological period. There is evidence, for example, that younger adults experiencing serious or terminal illness also show a preference for emotionally satisfying versus cognitively challenging relationships. They are highly selective in their choice of social partners and prefer those who are familiar. Consistent with the tenets of the theory, foreshortened time seems to have altered social motivations and goals. Presumably, adults of any age who learned that they were likely to live longer than expected might show the opposite pattern, i.e., a preference for novel encounters and challenging interactions.

Collaborative Cognition

Are two heads better than one? Researchers concerned with the early part of the life span have found considerable evidence that children collaborate with others in play and problem solving and that this collaboration plays a decisive role in cognitive development. The thinking of the Russian psychologist Vygotsky has been influential in guiding this research. From his sociocultural perspective, cognition is not always an individual activity, but often the joint activity of a dyad. Partners – for example, a parent and child – collaborate or distribute a task in a way that creates a zone of proximal development that supports and guides the child's gradual learning and mastery of a skill.

This approach to cognition seems to hold promise for understanding cognitive functioning in later life as well. If processing capacity declines with age in most adults, then perhaps a way to optimize functioning is collaborating with others on cognitively demanding tasks. This is the thinking behind recent research on collaborative cognition in later life. The benefits and costs of collaborating on memory tasks and problem solving have been considered. In general, researchers have found that older adults can help each other with story recall, decision making, and problem solving. When they do so, their performance is typically better than the average performance of their age peers. Indeed, in some research, the memory performance of older participants rivals that of younger adults when they are permitted to collaborate. They appear to use jointly constructed recall processes to enhance their recollection of the target information. In other words, the cognition of older adults may be improved through social interaction.

The effects of collaboration have also been found in activities less directly connected to basic cognitive processing, for example, in the promotion of wisdom-related behavior. Researchers have found that wisdom potential could be activated when the discussion of a standardized wisdom dilemma occurred with an intimate partner or even with a virtual partner in an imagined discussion. Other work has carried this investigation further by considering the real-life dilemmas of adults of various ages and how they attempted to resolve them in collaboration with others.

In a series of studies, researchers asked adults to report on life problems for which they "didn't know what the right thing to do was." Problems ranging from simple and conventional – selecting paint colors for a room – to those more complex and moral in nature – the ethics of euthanasia – were reported. After discussing the problem, participants reported on how extensively and with whom they had consulted. A large majority of these adults consulted with at least one other person about their problems. Even more interestingly, those who consulted widely with others also described their dilemmas in a more complex fashion than those who had not done so, were more satisfied with the solutions they developed, and were less likely to be highly authoritarian in their personality style.

Why does social collaboration have this effect? Research has shown that less complexity in discourse about personal problems is linked to indicators of problems associated with aging, such as lower levels of education and support. Using a sociocultural interpretive perspective, the activity of collaborating about issues and problems can be seen to affect the way they are mentally represented by the individual. Real, imagined, or anticipated conversation might lead people to elaborate more complex presentations of a problem. This complexity of thought would be triggered by the need to consider multiple perspectives: one's own and one's conversational partners'. Such a collaborative process is more likely to be undertaken by those open to considering a wide range of perspectives, for example, those less authoritarian in their viewpoints, and tends to produce a solution that is more satisfying for the problem solver.

Morality

Morality is about the judgment of behaviors and relations with others, not just their cognitive representation, as in the other domains of social thought reviewed here. Much of the research to date on moral development has focused on levels of thinking about courses of action in social situations in which the needs and rights of others and/or the self come into conflict. In addition to this focus on judgments about right and wrong, however, morality is also about behaving consistently (or not) in relation to these personal judgments. In order to make a moral decision, one must appreciate the problem, reason about how to solve it, focus on the values that support a choice, and stick to the decision while carrying it out.

Consequently, it is important to consider moral thinking or reasoning in this larger decision-making context when trying to understand how it develops across adulthood. Moral reasoning appears to be an aspect of social thought that shows considerable development from childhood into mature adulthood. Research on stages of moral reasoning suggests that education and life experience encourage people to move further along in the standard sequence of development that has been described by Lawrence Kohlberg and others. Longitudinal studies with older adults have shown that the levels of reasoning that people can achieve about both standard dilemmas and personal moral problems show advances into middle age, and then tend to plateau and do not decline systematically, at least up until age 75.

How does this moral reasoning capacity relate to people's actual decision making in personal life? Older adults may be less likely to consider systematically the viewpoints of others in a situation when initially gathering information in order to make moral judgments. They also have been shown to prefer less detailed and more generic information about others when they have to make decisions. Nevertheless, in general they do then reason about

information regarding others' needs and rights in ways as sophisticated as those of their midlife and young adult counterparts. They are also equally likely to select moral and prosocial values as their guidelines in making choices in real life. As with other areas of social cognition, older adults may demonstrate some limitations due to processing resources, but still seem well able to cope with the demands of a complex social environment.

Positive Psychology and Well-Being

Though much psychological research traditionally has focused on problems and maladjustment, recently there has been more interest in positive psychology, qualities that promote personal well-being across the life span. In this section, several of the positive aspects of later life social cognition that have received attention within personality psychology are briefly discussed. These include generativity, ego integrity and coping, optimism and perceived control, and wisdom.

Generativity refers to a concern for and commitment to future generations that is typical of a positive style of adaptation in midlife, according to the ego stage model of Erik Erikson. Recent thinking, however, has called the staged nature of generativity into question. It appears that older adults retain caring for future generations as an important life goal. Research has shown that the use of family stories in teaching the young, and family engagement with the grandchild generation, are nurtured by stronger levels of personal generativity. In turn, generativity predicts more satisfaction and a stronger feeling of having learned lessons in life during the later stage of Erikson's model, ego integrity.

Ego integrity represents the individual's capacity to feel a sense of accomplishment with regard to the past and the end of life. Reminiscence is an important function of later life, and appropriate styles of such reminiscence about social life can be integral to successful adjustment and achievement of ego integrity. It is also striking that although there are losses that must be dealt with as people age (e.g., health, physical capacities, and memory skills), they generally report no decrease, and sometimes even improvement, in their sense of life satisfaction. Research suggests that although people may have fewer resources in life, they manage to balance these limitations by being more selective in the life goals that they choose to pursue (similar to findings about socioemotional selectivity described previously). Such selective optimization may help individuals to cope with the challenges of aging.

Optimism is a quality that has been studied in several ways within positive psychology, including the kind of explanations that people typically give for past and current outcomes, as well as the more traditional sense of expecting good things for the future. There is convincing evidence that optimism (vs. pessimism) tends to be associated with more persistence in dealing with problems and with better health outcomes when dealing with disease in early adulthood and midlife. This is likely due at least in part to more positive expectations for the future, including one's social encounters. High levels of pessimism appear to predict less subsequent happiness and more health problems among older adults, too. However, pessimistic explanatory styles may not be so clearly maladaptive in later adulthood, because they may serve as a more realistic way of coping with life problems over which older adults do indeed have less control. Nevertheless, increasing older adults' sense of perceived control over their own lives has been shown to have positive benefits, particularly among those in highly impoverished environments such as traditional nursing home settings. It seems that for the most part, realistic optimism and a sense of self-control are beneficial in later life.

Wisdom is a complex idea with a long cultural history, but generally implies some sort of expertise in solving the difficult practical questions of how to live well. Such a skill is, by its very nature, fundamentally social in character. There is a positive stereotype in many cultures that wisdom is a capacity that grows into later life, unlike so many other cognitive skills. Consistent with this stereotype, adults generally judge themselves to have become wiser with age. When objective ratings of wisdom by observers are used instead, there is not quite as clearly an aging effect. This research suggests significant individual variation, with these skills developing into adulthood and then being maintained quite well into later life. In some studies, people have tended to agree on what constitutes wise advice on a personal problem. This suggests that there is some general sense of a wisdom construct, that it is distinct from cognitive complexity, and that it is related to a balance of cognitive and emotional considerations.

One prototypic aspect of wisdom that has been investigated is advice on child rearing. Older adults did not do as well as younger or middle-aged adults on hypothetical problems given to them, but when asked to discuss their real-life problems, they performed as effectively as other age groups. Consistent with the previous observations about social context, wisdom is often manifested in social contexts, and interactions among people (even imagined interactions) can produce better performance than that of

individuals responding alone. Collaborating on the solution to a problem in later life, it seems, is a useful strategy whatever the nature of the concern.

Conclusions

Much of the research literature on basic cognition in later life points to possible losses over a wide variety of domains such as memory, communication, and decision making. This body of work has focused on information-processing abilities and capacity and has typically been carried out in an environment designed to minimize the effects of the social context. Age differences demonstrated in these traditional experimental studies usually have been interpreted with reference to inevitable biological decline. A social cognitive perspective, on the other hand, leads us to consider how, and how well, older adults function in their social worlds. Following from the pioneering work of Vygotsky on child development, researchers interested in social cognition in later life assume that development is rooted in social processes across the life span. Cognitive losses may be likely as one ages, but there are also gains, and they are both significantly affected by the social context.

This article reviewed the most influential findings in the study of social cognition in later life. In general, researchers have been interested in the kinds of social environments that older people manage or construct for themselves. They have considered what effect declines in cognitive capacity might have on the social thinking and behaviors of older adults. The areas of research from which these findings are drawn target basic social processes: how older people perceive and evaluate other social actors and are evaluated in return; how the perception of one's life and time left in that life affect motivational goals; how social resources can be used to compensate for declining or inadequate cognitive resources; how older adults judge the characteristics and actions of others in arriving at a decision about action; and how well-being can be linked to styles of thought, social appraisal, and perceptions of events. Taken together, a growing body of research on social cognition in later life paints a complex portrait of the average older person as intentional and well-functioning in his or her everyday social world despite the undoubted challenges provided by shrinking social networks and reduced cognitive resources in later life.

Glossary

Buffering Effects of Social Support – Social support buffers or reduces the effect of stress, life events, or crises on an individual's quality of life, well-being, or health.

Convoy Model of Social Relations – Describes how an individual moves through time, age, and history, affecting and being affected by others who have fundamental influences on the individual's development and well-being.

Health Continuum – The continuum of health from a disease-free state through disease onset or health crisis (e.g., heart surgery), to recovery, rehabilitation, or death.

Life Span Developmental Theory – This perspective argues that it is critical to understand the effect of inter- and intra-individual development over time in order to truly understand the individual at any one point in time.

Reciprocity – In the social support literature, used to refer to reciprocal exchanges, that is, exchanges seen as equal in the amount of support provided and received by each participant. Exchanges can be non-reciprocal. Reciprocity is considered the general norm of social relations across most societies.

Social Integration – The degree to which an individual is embedded into the group, organization, or community. This term considers the centrality versus marginality of the individual to the majority group.

Social Networks – Structural characteristics of an individual's social relations. Social networks include the objective aspects of social relationships such as network size, age, sex, relationship (e.g., husband, friend), and frequency of contact.

Social Support – Exchange of instrumental and emotional resources such as money, goods, services, information, and love among social network members. Both the provision and receipt of these exchanges have been studied.

Support Bank – In keeping with the general norm of reciprocity, the support bank describes a type of unconscious savings account through which people build reserves through non-equitable relationships by providing more support than they receive (i.e., making support deposits into the support bank) so that support will be available to them at some time in the future when they are needed (withdrawals).

Introduction

Social relations has been increasingly recognized as a critical element in the adaptation, adjustment, and well-being of older people. Since the mid 1980s, the theoretical basis for the study of social networks, support, and integration has expanded considerably and has significantly benefited from an accumulation of empirical evidence. This article provides an overview of the theoretical and conceptual issues that have guided the research, a consideration of methodological limitations and advancements, and

illustrative examples of the empirical research now available in the field.

Theoretical Issues

There is considerable consensus that a long-term, life span view of social relations is critical for a full understanding of how social relations develop over time and influence other aspects of an individual's life. The convoy model of social relations offers such a life span view, explaining how social relations develop over time – optimally maximizing the individual's health and well-being. The convoy model describes how people's personal (age, race, gender) and situational (roles, environment, circumstances) characteristics both shape and determine the nature of social relations experienced. Social relations, in turn, affect people's health and well-being. Convoys grow, develop, and change with the individual and, under optimal conditions, help, support, and socialize people, providing them with a firm base from which to face the challenges of life. Unfortunately, convoys of social relations are not always optimal and under some circumstances can make individuals more vulnerable to stress, health problems, and poor well-being.

A related theory, the socioemotional selectivity theory, also takes a life span perspective, suggesting that people's goals and aspirations with respect to social relations change over time. This theory proposes that young people, who feel they have a long future ahead of them, are likely to seek out new relationships and continually expand their social networks. As people get older, however, they become more selective about the relationships they wish to maintain. With age, the theory argues, people wish to maintain relationships only with those significant others with whom they have a good relationship. They are, therefore, less likely to seek out new relationships and more likely to deeply invest in the ones they value.

Recent theoretical perspectives regarding social relations have suggested the importance of moving beyond description to a more fundamental understanding of the process by which social relations affect health and well being. The support/efficacy theory suggests that social relations affect health and well-being by instilling in the individual a sense of self-worth and self-efficacy. In essence, an optimal convoy of support communicates to the individual that he or she is a person of value and worth, of ability and skill. Significant others communicate that they believe the individual is capable of successfully meeting the challenges confronted in life. This consistent feedback of expectation of success eventually results in the individual's accumulated and internalized feelings of competency, success, and well-being. Of course, not all people have this type of positive support network or convoy. Under less optimal conditions, social relations can threaten and undermine people, constantly making them feel less competent and less able and, thus, unable to successfully confront the problems or challenges they face. Rather than improving their health and well-being, such convoys of social relations can only serve to make the individual feel less worthy and less able, in short, less efficacious. It should be noted that often convoys are neither completely positive nor completely negative. It is more likely that a convoy consists of both positive and negative characteristics, with some convoys including both supportive and non-supportive members and others including convoy members who are able to provide support in some areas and thus increase efficacy in these areas but not in others.

Another theoretical perspective suggests that the most important aspect of social relations is the fact that they help the individual learn how to regulate his or her emotions. This emotion regulation perspective suggests that people learn from their interactions with others how best to control their own emotions, specifically how best to manage and regulate both their positive and negative emotions. This self-regulatory ability allows the individual to more competently navigate the challenges and choices confronted in daily life, thereby optimizing outcomes and overall well-being.

Definitions of Critical Terms

Three terms central to the study of social relations, social network, social support, and social integration, should be clearly defined. Early research frequently blurred the distinctions between these concepts, thus limiting the potential for theoretical advances. The term social network refers to the structural or objective characteristics of the social relationships maintained by the individual, e.g., the number of people in the network, their relationship to the older person, and their age, frequency of contact, and density (i.e., how many network members know each other). Social support refers to the actual exchange of different types of support such as aid, affect, or affirmation within the relationship. Examples include tangible exchanges such as lending money or caring for the sick, or emotional support such as love and affection. And, finally, social integration refers to the degree to which the individual, usually by virtue of social relations with others, feels integrated into the community specifically and society more generally. It is often labeled as

'belongingness' or 'embeddedness' in the literature. Social integration is the exemplification of adaptation, adjustment, and general well-being and might be considered an outcome of optimally functioning social networks and social support.

The term social relations is an umbrella term for the three previously defined concepts. An important issue when considering the role of social relations in the lives of the elderly is the processes through which social relations operate. Two effects of social relations have been identified, described, and investigated. The first, known as the direct or main effect of social support, suggests that having friends and family who think highly of you make you feel good about yourself, which therefore fundamentally improves your adjustment, adaptation, well-being, and mental health. The second is known as the indirect or buffering effect of social support; it suggests that social support is most effective once the individual is confronted with a problem or stressful life event. Under these circumstances, friends and family help the individual, through social support, to cope with problems or crises they encounter. Thus, support from others buffers the impact of negative events, crises, or stresses in the individual's life, thereby improving his or her adjustment, adaptation, well-being, and mental health. Empirical evidence has documented both types of effects.

It is likely that individuals experience direct and buffering effects of social relations. Individuals accumulate relationships over time as well as specific support exchange histories, both of which influence their perspective on current relationships. Although early relationships do not completely predetermine later relationships, it does seem likely that people develop styles of relationships and expectations about them. There appears to be a cumulative element to important, close, enduring relationships that permit the development of expectations concerning reciprocity of exchanges. And, finally, although there is a tendency to assume that social relations have both long- and short-term positive effects, it is important to recognize that these relationships, and expectations about them, may also be negative. Thus, an older person who becomes ill might expect help and support from a spouse or daughter, or, based on previous experience, might realistically recognize that they are unreliable sources of support, especially in times of crises.

Measurement Issues

Measurement has been a weak link in the empirical study of social relations, thereby affecting the quality of the available data. Early measures were often vague and non-specific. Network measures have been considered support measures, and questions that ambivalently assess support concepts have been interpreted definitively. Thus, for example, a network question that establishes marital status has been interpreted as evidence of social support (i.e., the receipt of emotional support from a spouse). However, it is clear that having a spouse does not guarantee that the spouse provides support. An older person might have a spouse, but the quality of the marital relationship might be so poor as to preclude spousal support or the spouse might be too sick to provide any type of support. Measures might be role driven or affect driven, and the reliability of these measures can be quite different. Research has shown that role-based measures of social relations are most reliable. Obviously, if an older person is asked whether they have children, the answer is not likely to change over time and thus is quite reliable. However, an affectively based measure of the relationship can be less stable. How close one feels to one's adult child, for example, may change over time. The child might move out of state, the two might have an argument, or the child might disagree about a specific healthcare or lifestyle choice made by the elder (or vice versa). Under these conditions, how close the older person feels to his or her child could change radically. This change should not be misinterpreted as a lack of measurement reliability.

Although empirical evidence indicates that there can be considerable differences among the existing network and support measures, it should not be assumed that this problem has a simple solution or that a 'correct' measure of these concepts exists. In fact, the most 'correct' measure may not be solely based on psychometric criteria but rather also considering the theoretical or conceptual purpose of the study. Thus, if the purpose of the study is to identify the structure of a social network of an older person, a simple network assessment by measures such as the number of network linkages and social contacts would be most appropriate. However, if the purpose of the assessment is to design an intervention strategy or assess the supportive potential of specific relationships, it would be critical to assess both the affective as well as instrumental aspects of the relationship. For example, if attempting to develop a discharge plan for an elderly person recovering from a stroke and facing an intense rehabilitation program that requires significant assistance with activities of daily living, it would be critical to determine whether the elderly person has children, whether they have a good relationship, and whether the children are available to help with the elderly person's rehabilitation once he or she is discharged.

Knowing that the older person has ten adult children does not necessarily answer the question of their availability, either emotionally or instrumentally, to provide support. For the most part, researchers now understand that there are different types of social relations, each of which, under most circumstances, must be measured separately. It is also clearly recognized that deciding which measure is optimal depends almost entirely on the research question being asked.

Data Sources

Social relations interest scientists come from a wide variety of disciplines, each of which uses diverse approaches to study design and sample development. Anthropologists, sociologists, psychologists, epidemiologists, psychiatrists, and gerontologists have studied social relations across the life span generally and among older people specifically. Thus, major studies in the field incorporate very different types of samples, a fact that is fundamentally important when assessing both the quantity and the quality of what is known about social relations. Anthropologists have used ethnographic techniques to study social relations among select small groups of people, whereas epidemiologists have studied thousands of people who are randomly selected to represent designated segments of the population. Clinically based samples might study people being treated for a specific disease or inpatients with a specific medical diagnosis. Some samples are very small but are studied intensely, while others are exceedingly large with only a few questions addressing the topic of support relations. Similarly, a body of empirical evidence is now accumulating targeted at people at a specific stage of the life course, such as mothers and infants, school-age children, young and middle-aged adults, as well as older people. Although there may be some lifetime continuity in relationships, it should not be assumed that evidence based on a sample of younger people can be applied to specific issues of concern among the elderly. For example, the evidence that a school-age child is most advantaged by instrumental support from parents may provide general information about the importance of family, but cannot be unconditionally generalized to the elderly or to a specific older person. Whereas the young might feel comfortable, for example, receiving financial support from their parents, assuming it to be developmentally appropriate, an elderly person might not feel comfortable receiving money from a child. The older person might consider it developmentally inappropriate, indeed a symbol of failure, to take money from one's children rather than being able to provide it. Similarly, knowing that the social relations of those suffering from schizophrenia are characterized by certain patterns may or may not provide useful information about older non-schizophrenic people.

In sum, application and relevance of previous research to the elderly should be assessed with an awareness of both sample quality and population characteristics of the previous research. These issues affect the degree to which research findings are applicable to the elderly or, for that matter, to any specific population of interest.

Social Support and the Health Continuum

A final conceptual issue to consider before reviewing current empirical evidence is the role of social relations at different points on the health continuum. Although health is a major concern among many elderly people, there is clearly a health continuum. Health among the elderly can vary from healthy with few or no health problems to terminally ill with significant comorbidity. There is a great deal of research that argues that social support influences health and well-being. However, it is not appropriate to assume that the same type of social support will meet the needs of the elderly at all points on the health continuum. The healthy elder might need a companion to share an exercise regimen, whereas the terminally ill might need someone to simply sit with them, provide emotional support, or help with the final disposition of their affairs. Elders in an acute health crisis might need someone to recognize the crisis (e.g., recognize abdominal or chest pain as a heart attack as opposed to indigestion) and provide the instrumental support of a ride to the hospital. Similarly, people who have experienced a myocardial infarction might best be supported by individuals who tell them they are tough and able to complete the rehabilitation program as well as to successfully adopt the lifestyle changes required. Support can operate directly or indirectly to affect health and well-being. Although general positive feelings from close and important others are likely to promote overall well-being in the face of a specific crisis or event, types of support, no doubt from specific others, are likely to be the most effective resources. This point is made to emphasize again that the most appropriate methodology for any study must match the goals of the study. There is no one perfect measure that can assess social relations, network, support, or integration under all circumstances for all elders.

The next sections consider the empirical evidence currently available concerning social relations among the elderly. Five bodies of empirical evidence are considered: family and friendship relationships,

social exchange and reciprocity, gender differences, cultural differences, social relations, and well-being.

Family and Friendship Relationships

The study of social relations in adulthood and old age has frequently been divided into family relations versus friend relations. Although early work often described the broad inclusive categories of family, friends, and neighbors, most current research pays more careful attention to the specific relationship. The social support exchanged with specific people has been shown to impact the health and well-being of the older adult. For example, older people who are married are much less likely to need formal supports, such as home nurse care or Meals on Wheels, than unmarried people. Although it is clear that families play important roles in the lives of older adults, providing sometimes extraordinary caregiving efforts and instrumental help, friends are also invaluable resources. Indeed, research initially designed to examine the impact of family members alone often finds that the friends are mentioned as a significant support source.

Initial studies documented the structural characteristics of social networks. It is known from early cross-sectional studies, for example, that younger respondents have more frequent contacts with network members than older respondents, whereas older respondents have known their members longer. Most networks of older people consist of family members, primarily spouses, children, and siblings. Friends, however, often play an important role in their support networks.

Generational differences in network structure and support patterns have also been examined. Older generations include more family members in their networks, whereas younger generations include more friends. Nevertheless, both younger and older family members are named as closest network members, with friends and more distant relatives as somewhat less close. Significantly more support from friends is often reported by younger respondents, whereas middle-aged respondents report more support from family. However, research has shown that when nuclear family members are not present in the social networks of older adults, other close relationships seem to be substituted. This especially appears to be the case for instrumental support. Thus, while friends do not replace family members, they do play an important role in the lives of older people.

In one study of friendships among people over 60, 68% reported long-term friendship ties throughout their lives. There were some gender differences, with more than half the women reporting that they remained friends with a close friend from childhood or adolescence, whereas men showed high levels of continuity with close friendships developed at midlife. There seem to be constraints on and changing definitions of friendship among the 'oldest-old.' In one sample of people over 85 years old, it was found that more than half still had at least one close friend, and three-fourths were in weekly contact with people they considered their friends. Furthermore, almost half reported that they had made new friends after age 85, although the criteria for those friends tended to involve less expectation for intimacy or shared history than was common among younger people.

Studies of support from kin and friends have highlighted the importance of recognizing differences in these relationships. Although research focused on the exchange of social support is more limited, it does seem clear that differing degrees of support are provided depending upon the closeness of the relationship. Spouses/partners are usually rated as most supportive, but best friends and children are also rated as very supportive, significantly above all other categories. Compensation in the event of the loss of a major support person has been investigated as well. It has been found that children, friends, and acquaintances compensate for the loss of a spouse with increased emotional support to the widow. Some protection from loneliness seems to be provided by children and friends, at least for respondents without partners.

Although spouses provide the most support overall, and adult children often give instrumental support, siblings may have a distinct place in the lives of older adults by bridging aspects of both family and friend relations. Continued sibling contact provides opportunities for life span socialization. An interesting race difference is evident among White and African American sibling pairs. White sibling relationships appear to range from very positive, intimate, and congenial to quite negative and hostile. African American sibling pairs, however, exhibit primarily positive interaction patterns. Other studies of siblings indicate that a large number of older people consider their sibling a very close friend. Sibling ties, among the longest social ties in most older people's lives, are the most egalitarian and friend-like of all family relations. Nevertheless, important differences remain since siblings are fundamentally family members.

Studies indicate that most elderly receive substantial support from others. Nevertheless, there is some indication of a pattern suggesting that more support is received from fewer people as people age. This has often been interpreted to be the result of increased physical or functional limitations. Recent theoretical perspectives, however, have offered additional

explanations. Several studies have indicated that there are age differences in how family and friends are valued, with older respondents indicating that friendships increase in importance as compared to younger respondents. Adequate longitudinal data are not yet available to address the question of the changing value of relationships over time, though there are at least two theoretical positions that are suggestive. As noted previously, both the socioemotional selectivity theory and the convoy model predict that close and important friend and family relationships will remain so into old age, and the socioemotional selectivity theory specifically predicts that more superficial relationships are likely to dissipate. Alternatively, because life transitions often provide different opportunities and circumstances, some ties, especially those with friends and siblings, may take on renewed importance as individuals emerge from earlier obligations.

One consistent, almost universal, finding concerns the reported quality of social relations among family and friends. Older people are much more satisfied with the support they receive and with their support network more generally than younger people. One possible explanation is that as people get older they are more likely to evaluate various aspects of their environment positively. Indeed, survey researchers have noted that older people show consistent increases in life satisfaction with age but a leveling off of more affective characteristics such as happiness.

Recent research has examined profiles of social networks, that is, different clusters of social network members. These profiles range from limited family (e.g., spouse only) to more extended family (including spouse, children, and other relatives), isolates (people with few social relations), and diverse profiles (including both family and friends). Interestingly, in these studies of both middle-aged and older adults, people with diverse networks that include significant involvement with both family and friends report the highest levels of well-being, while those with restricted networks consisting of very few people, e.g., just a spouse or very few family members, report the lowest levels of well-being. These findings demonstrate that the ostensible ideal circumstance, i.e., that of older people surrounded by a select few close family members, may no longer be ideal, especially for healthy elders. Interaction with numerous and diverse network members is associated with subjective well-being among the current population of elders, but isolation or limited interactions with others is not. Additional research is needed to examine whether the same profiles are optimal under different circumstances, e.g., among those facing a serious illness or death.

Social Exchange and Reciprocity

To explain the nature and impact of social support requires that consideration be given not merely to its existence, but also to the ways in which it is structured and understood. The concept of reciprocity is central to theories of social support and is approached in terms of the rules that govern support exchanges as well as in terms of the norms that characterize specific types of relationships. In characterizing rules, the theoretical distinction has been drawn between balanced and generalized forms of reciprocity, whereas in characterizing relationship norms, the related theoretical distinction has been drawn between exchange and communal orientations.

Equity theory has provided an overarching theoretical basis for much of this line of research. Equity theory posits that reciprocity is the most equitable status of exchange. It argues that overbenefiting (i.e., receiving more than providing) and underbenefiting (providing more than receiving) are both less than optimal situations, often resulting in guilt or resentment. A life span perspective adds the possibility of assessing reciprocity either in explicitly contemporary terms (balanced reciprocity) or in longitudinal terms (generalized reciprocity). There is evidence in support of both types of reciprocity. Reciprocity within superficial or recent relationships (exchange relationships) is more likely to be short term and immediate. On the other hand, among relationships that share various aspects of life and that have endured over many years (communal relationships), older persons are more likely to use a long-term accounting system. In the former case, one might return a borrowed cup of sugar after the next trip to the grocery. In the latter case, however, one might provide intense sick care for a spouse and expect no immediate return, rather feeling assured that if a similar need arose in the distant future, that spouse would provide the same care. It has been suggested that people maintain an unconscious 'support bank,' much like a savings account, in which they keep track of who owes them and to whom they owe various types of support. Interestingly enough, in Western cultures, most people, even old people, report that they give slightly more than they receive. It appears that the preferred state is what exchange theorists would term the underbenefited state, but what the support bank perspective would consider significant savings or deposits.

Dramatic increases in life expectancy during the past decades have resulted in rapid growth of the oldest-old (80+) population. This segment of the population continues to grow. From an exchange theory perspective, the problems of the oldest-old are that, as a statistical aggregate, they have a lower

income and poorer health than younger people. Consequently, they are physically and financially limited in entering into exchange situations. They may no longer be able to afford to exchange holiday gifts with children and grandchildren in the way they used to or to baby-sit grandchildren in return for the help that they receive from their daughters or daughters-in-law. Many have very little of any instrumental value to exchange.

How do such limitations affect their social relations? Currently, there appear to be no commonly accepted rules for support exchanges involving the oldest-old. Some older people withdraw from exchange situations altogether. This is clearly a coping strategy used to maintain reciprocity. They simply choose not to enter exchange situations, thus preventing the non-reciprocal relationships that would result because they do not have the resources to reciprocate. Other older people apply the long-term reciprocity notion of a social support bank in the face of diminishing commodities. Thus, they can receive a great deal of support from close and important others, potentially for an extended period of time, and yet not feel indebted. In this case, older people can assume that they are simply receiving support due to them from people to whom they have provided support in the past. Some exchange theorists argue that even in contract-oriented societies, such as the US, non-contractual relationships are not completely absent. No longer bound by the norm of reciprocity, older people sometimes benefit from the norm of beneficence (i.e., the provision of support from people with more resources to those with less resources). The continuous growth of the oldest-old population urges modifications of the conventional support exchange rules and the emergence of new rules that are most suitable to the aging society.

Gender Differences

Empirical evidence concerning gender differences in social relations has been accumulating. Originally, these gender differences were assumed to favor women. More recent research has suggested that the question might be considerably more complicated. There tend to be relatively few gender differences in the support networks of men and women. Greater similarity is likely to be obtained if the assessment method focuses on close and supportive others. This is the case because most people list family members (i.e., parents, spouse, and children) as their close and supportive others. However, even these structural characteristics tend to become slightly female-biased when focusing on the oldest old because of women's significantly greater life span.

Greater controversy, or at least complexity, arises with the provision and receipt of social support. When considering specifically who provides what, to whom, and how much of it, greater gender differences are likely to arise. Men tend to report receiving support from and providing support primarily to their wives. Women, in addition to support exchanged with spouses, also tend to provide and receive support from a much larger array of people, including children, other relatives, and friends. Men tend to provide instrumental support, especially financial, while women provide both instrumental (services) and emotional support.

A similarly interesting gender difference exists in terms of the interpretation or perception of support interactions. Women appear to feel greater involvement with most of the people in their networks and feel a greater sense of responsibility concerning the resolution of needs or conflicts among their support network members. Thus, although there is a tendency toward same-sex friendships, both men and women are more likely to mention women as confidants. Such gender differences in the nature of relationships, which are observed across the life course, are directly linked to sex roles in this society and indicate a lifelong impact of socialization on the social relations of men and women. Other research has shown that even when data are from both members of an older couple, reporting on the provisions and receipt of support between them, it is clear that there are significant differences in what men and women report concerning support exchanged with spouse.

These support differences and the discrepancy in the life expectancy of men and women portend important differences in the social relations of older men and women. On the one hand, men are much more likely to be married when they get older. With marriage, social relationships are likely to remain relatively stable and intact. On the other hand, if an older man becomes widowed or has never married, he may find himself in a particularly precarious position with regard to social relations. Single men are more likely to be socially isolated than single women, and are much less likely to replace or be able to sustain the relationships previously maintained by their spouse. The exception to this, of course, is if the widowed man remarries, which then reconnects him to a social network through his new wife. Demographics suggest that older women are quite likely to be widowed. Although widowed women are vulnerable in many ways, they are also more likely to have the skills to continue to maintain social relationships. They may turn to other family members and friends to assist with difficulties that emerge, such as the physical limitations and illnesses that sometimes

accompany old age. Nevertheless, older women of today have lived a relatively traditional lifestyle, which might mean that in old age they find themselves with less money and less access to powerful others or community status than they did when they were respected wives of men well established in their community. One can assume that this will change as women begin to enter old age with a lifetime of experience as members of the labor force and with greater independence in their general lifestyle.

Cultural Differences

The literature has documented some variations in social networks and social support across different societies. Different social structures across societies result in variations in the support networks of older persons. Most notably, different family structures directly affect the social networks of older persons. For example, in societies in which large extended families live together, an entire support network often consists of family members who provide all the support an older person needs. In societies such as the United States, where a larger proportion of the elderly live with their spouse or alone, friends and neighbors are also a vital part of the support network. In most societies, women of younger generations provide support to the elders, but the focal support person may vary by society. Thus, for example, in the United States, this person is usually a daughter, whereas in Japan, due to the structure of the family and living arrangements as well as tradition, this person is more likely to be a daughter-in-law.

Different societal norms influence support exchanges. Reciprocity is the basic rule of support exchanges in most societies. However, specific applications of the norm of reciprocity vary among societies. In the United States, the primary exchange rule of middle class Americans prescribes exchange of support in kind and of equivalent value in a relatively short period of time, especially among non-family members. This rule suppresses one-way transactions of support and thereby reduces the development of dependence, which often leads to the disturbance of stable relationships. By contrast, the exchange rule for close relationships in Japan inhibits complete repayment in support exchanges, thereby maintaining indebtedness and dependence. It consequently serves to sustain relationships based on dependence. This comparison illustrates how the general norm of reciprocity regulates support exchanges in the two societies in quite different ways, yet serving the same goal of maintaining the solidarity of support networks. Data are also available concerning reciprocity among the French elderly. They, too, maintain a norm of reciprocity. In fact, compared to American elderly, a slightly higher percentage of French elderly report reciprocal relationships. However, if a relationship is reported to be non-reciprocal, the French elderly are more likely to say they receive more support than they provide, whereas American elderly tend to report they provide more support than they receive. These findings suggest that there are cultural differences in the optimal level of balance between provision and receipt of support, even among Western societies. American elderly appear to consider it most desirable to maintain slightly overproviding relationships both because 'being a giving person' is valued and reinforced in American society and because it ensures having someone available to provide support if there is need in the future, 'a deposit in the support bank.' Under the French norm, however, it appears to be more acceptable to overbenefit (i.e., to receive more than you provide) in old age. Also interesting are gender differences in social relations across cultures. For example, Japanese men are more committed to maintaining harmony and avoiding conflict in their social relations with family, friends, and colleagues. As a result, although Japanese men, like American men, tend to be less expressive than women, unlike American men they are more likely to extend considerable effort toward maintaining good relationships and avoiding arguments or disagreements.

Data examining subgroups within the United States indicate that many more African American than White elderly report reciprocal relationships. Of their non-reciprocal relationships, the majority of African Americans report that they receive less support than they provide. Although subgroup differences in the perceptions of reciprocity within the United States might seem large when only American data are considered, when compared to Japanese and French data, the differences do not seem nearly as great and the degree to which culture influences reciprocity and dependency norms is noteworthy.

Social Relations and Well-Being

Among the most important and impressive research in this area is that documenting an association between health or well-being and social relations. Substantial evidence has accumulated indicating that people who have larger social networks, have more social supports, and are better integrated into the social fiber of their community do not die as soon as others. Similarly impressive research has documented the association between social relations and various forms of morbidity, including cardiovascular diseases, depression, symptom severity, hospital and

emergency room utilization, preventive health behaviors, and successful rehabilitation. Recent longitudinal research has shown that social relations can help people coping with a chronic illness such as osteoarthritis cope with and buffer the effects of social strain on depressive symptomatology.

The exact nature or characteristics of social relations that are important is a controversial issue. As noted earlier, many studies have simply documented the existence of social ties (i.e., the social network characteristics) and demonstrated a statistical association of these measures with health and well-being. However, some researchers argue that the measure of the existence of these ties simply offers a proxy for support exchanges and, by implication, support satisfaction. Thus, being married often suggests that a significant other exists with whom the older person has a close, supportive, and qualitatively superior relationship. Nevertheless, it is important to recognize that this is not always the case; not all spouses offer that kind of support. Researchers have now begun to consider what specific characteristics of support relationships are most important. It is reasonable to assume that each characteristic of a support relationship offers some insight into the nature and functioning of that relationship. Knowing that an individual is married is helpful. It is also helpful to know whether the partners exchange support (i.e., give and receive different types of support such as emotional and instrumental support from each other). But perhaps the most important measure of the effect of social relations on well-being is the individual's evaluation of, perception of, or satisfaction with that relationship. Although some reviews indicate that size of network is the best predictor of well-being, other research suggests that although objective measures such as social network characteristics are useful, the most predictive measures are those that assess the individual's subjective evaluation of the relationship. Research with both American and French elderly representative populations indicates that although both objective and subjective measures of support are significantly related to depressive symptomatology, subjective measures, such as the satisfaction with the quality of the relationship, have a greater inhibiting effect on depression than more objective measures, such as number of social ties. These findings are increasingly supported by similar findings from various countries around the world.

As noted previously, additional evidence suggests that family and friends may function quite differently, although both play important roles in the well-being of the elderly. Family relationships, under normal circumstances, make an important contribution to well-being when conflict is minimal and normal positive relationships are maintained. Under these conditions, older people report relatively stable levels of well-being. When such relationships either do not exist or are conflictual, a negative impact on well-being is usually evident. Another long-standing finding in the literature is that friend, but not family, relations have significant positive effects on the mental health of the elderly. A number of investigations have concluded that family relations, although critical, are assumed, that is, their presence and the support therein provided are normatively expected. When present, no extraordinary positive effect is apparent. However, when absent or conflictual, their negative impact is substantial. The opposite appears to be the case for friendship relations. When not present, few significant negative effects are evident, but the presence of close supportive friendship relations has a significant positive effect on well-being.

Some have discussed the findings on family versus friend support in terms of the volitional versus obligatory nature of the two types of relationships. Although family ties are often prescribed by roles and expectations, friends are free to enter into a relationship, as well as leave it, at any time. Family members are expected to provide support, therefore when they fail to do so or are unavailable, there is a significant negative impact. Friends, however, are not necessarily required by the relationship to be available for support, thus support from friends is perceived more positively. Also, in contrast to family relationships, friends are chosen rather than ascribed, and most often are chosen on the basis of similarity of interest, experience, or personality. The act of choosing one another also brings with it feelings of being admired and liked over others, which also enhances emotional well-being.

Gender differences in the role of social relations and their effect on well-being should also be noted. The well-being of men is more positively affected by marriage than it is for women. Men seem to garner significantly greater benefits from the marital relationship, than women. In fact, women, much more than men, appear to be at risk for the negative impact of this relationship, should the marital relationship be of poor quality. Furthermore, it is clear that there is a significant gender difference in the role of social relations that transcends the marital relationship. Women's generally high sensitivity to poor-quality social relations affects their mental and physical well-being. Additionally, an intriguing finding suggests that although women often report more sources of support in their network than most men, the effect of larger numbers of close relationships is sometimes negative in that these women report being less happy. It appears that although women have more intimate

relationships from which they receive support, they also are more emotionally involved with and feel a need to provide more support to each of their relationships.

As this latter point suggests, it is important to note that there may be negative, as well as positive, consequences of social interactions. Negative social relations are evident in relationships that are tarnished by conflict or negative affect; or in exchanges in which positive support is unasked for or is provided to a degree that is overwhelming and smothering. Similarly, social relations can be assumed to be negative or to have a negative effect on well-being when support is provided for maladaptive behaviors, such as smoking, drinking, avoiding health care, or not taking medications. Thus, the study of social relations must take into account that convoys of close friends and family members may be both pleasant and unpleasant, supportive and unsupportive. These differences, of course, result in fundamental differences in outcomes.

Summary and Conclusion

In conclusion, social networks, social support, and social integration can play a significant role in the maintenance of the health and well-being of an older person. At the same time, social relations represent only one of the many important factors contributing to the well-being of the elderly. Biological and physical factors also play an important role. However, neither exists in isolation, and the bidirectionality of influence is evident. While a great deal of research in recent years has improved our knowledge of both the conceptual and methodological characteristics of social relations, it must be recognized that because of the idiosyncratic nature of social relations, there are no absolutely correct conceptualizations or measures. Social relations consisting of social networks, support, and integration operate at multiple levels through social networks (each member with individual characteristics), social support (involving interpersonal often dyadic exchanges), and social integration (a community or societal connection) have important influences on health and subjective well-being. Research thus far suggests that social relations can improve the overall quality of life of healthy older persons and can serve to improve the experience of the elderly as they face the physical and psychological challenges of aging.

Social Security

M N Ozawa, Washington University, St. Louis, MO, USA

Glossary

Currently Insured – When one acquires six quarters of coverage in the 13 quarter period ending in the calendar quarter of death, disability, or reaching age 62.

Fully Insured – When one has earned the minimum number of quarters of coverage, which is 40.

Social Security System – Social insurance programs that provide economic security for elderly persons, disabled workers, and workers' dependents and survivors.

Introduction

The Social Security program enacted under the Social Security Act of 1935 has been hailed as one of the most popular laws since the Great Depression of the 1930s. Thanks to the act and its subsequent amendments, millions of beneficiaries have been able to escape poverty. Despite the popularity of the program, the prophesy by Arthur J. Altmeyer, the chairman of the Social Security Board in the 1930s, is becoming a reality: Social Security is a living document and, therefore, needs to be reformed to meet the changing needs of the population and to make it relevant to the changing economic conditions.

Like other developed countries, the United States has been undergoing enormous changes in demographic composition, family structure, and economic conditions. These changes have led the American people to have second thoughts about the scope of the Social Security program and about some of the regulations that have become obsolete and inequitable.

Reflecting the changing attitudes toward Social Security, the United States started, in 1977, to reform the Social Security program so that it could remain financially solvent. Before that time, the thrust of policy changes was to make the Social Security provisions more generous.

This article (1) describes how the Social Security system works, (2) discusses the demographic shifts and actuarial imbalance, (3) reviews the inequities in the current system, (4) describes the 1983 Amendments to the Social Security Act and the recommendations by the 1994–96 Advisory Council on Social Security and the President's Commission to Strengthen Social Security, (5) and discusses the US income support for the elderly in broader perspectives.

Provisions

The US Social Security system includes social insurance programs to provide economic security for elderly persons, disabled workers, and workers' dependants and survivors – Old-Age and Survivors Insurance (OASI) and Disability Insurance (DI), which together are referred to as OASDI. OASI, established under the Social Security Act of 1935 and its 1939 amendments, is designed to provide cash benefits for retired workers, dependants, and survivors, and DI, established by the 1956 amendments, is designed to provide cash benefits for disabled workers and their eligible family members. Medicare benefits (Health Insurance, Part A and Supplementary Medical Insurance, Part B) are also provided under the Social Security Act. However, because the concept of Social Security popularly refers to OASDI, this article addresses only OASDI.

At the end of 2004, 48 million people (16% of the population) were receiving benefits – 33 million retired workers and their dependants, 7 million survivors of deceased workers, and 8 million disabled workers and their dependants – for a total cost of $493 billion. During 2004, 157 million people had earnings that were covered by Social Security and paid payroll taxes.

The US Social Security system is based on several principles. First, beneficiaries have an earned right to benefits and are not subjected to any form of means test or income test. Second, all workers are compelled to make financial contributions to the Social Security program, unless they are specifically exempt, such as state government employees in the states that have opted out of Social Security or those who vow poverty for religious reasons.

Two principles are involved in calculating benefits: individual equity and social adequacy. Individual equity is implemented by relating benefits directly to beneficiaries' prior earnings. Social adequacy is implemented by providing larger benefits to low-wage workers in relation to their contributions and additional benefits to auxiliary beneficiaries (for example, children, dependent parents, and spouses with little or no earnings of their own) without added contributions.

Social Security is funded by payroll tax on employees and employers and has been financed generally on the basis of the pay-as-you-go principle throughout its history. However, the 1983 amendments included the provision to build up the trust fund's assets in anticipation of the large number of Baby Boomers who will reach retirement age starting in 2010.

There are two types of insured status: fully insured and currently insured. Fully insured means that one must have earned the minimum number of quarters of coverage, which is 40. Currently insured means that one must acquire six quarters of coverage in the 13-quarter period ending in the calendar quarter of death, disability, or reaching age 62. These different insured statuses determine who is eligible for which type of benefits:

- Fully insured *or* currently insured: OASI benefits to workers and their spouses and children
- Currently insured: SI (Survivors Insurance) benefits to workers' spouses and children
- Fully insured and currently insured (for blind persons, only fully insured status is required): DI benefits to disabled workers.

In 2006, one quarter of coverage is obtained by earning $970 during a year. Twice this amount provides two quarters of coverage, and so on, so that when the earnings reach four times $970, four quarters of coverage can be attained during the year.

The normal retirement age was 65 and 10 months in 2005. It will increase gradually to age 67 by 2027 for those who attained age 62 in 2022. By 2027, the full, actuarial reduction rates in benefits for those who retire at age 62 will increase to 30% from 24.5% in 2005.

All Social Security benefits are based on the primary insurance amount (PIA), which is derived in two steps. First, the worker's average indexed monthly earnings (AIME) is calculated by indexing the taxable earnings for each year from 1951 and later to the average wage level in the second year before age 62, disability, or death; summing indexed earnings and unindexed earnings in the years after age 60; and dividing the sum by the number of months elapsed after 1950 (or age 21, if later) through age 61 (or the year before the year of disability or death). Five years of the lowest earnings are dropped from the calculation of AIME (fewer dropout years apply to disabled workers). The benefit computation period is 35 years (fewer years apply to disabled workers).

Second, the PIA is then calculated on the basis of AIME. For people who retired at age 62 in 2005, the PIA was calculated as follows:

$$\begin{aligned}\text{PIA} = {} & 90\% \text{ of the first \$627 of AIME} \\ & + 32\% \text{ of the next \$3152 of AIME} \\ & + 15\% \text{ of AIME in excess of \$3779}\end{aligned}$$

The bend points ($627 and $3779) increase each year at the rate of increase in the average wage. Benefits for workers who retire earlier than the normal retirement age are subjected to actuarial reductions in the PIA – a 24.5% reduction for those who retired in 2005 at age 62 and pro rata reductions for those who retired at ages 63 and 64.

Each eligible auxiliary member of a retired worker is entitled to benefits equivalent to 50% of the PIA. But spouses who claim auxiliary benefits before age 65 face an actuarial reduction unless an eligible child is present. In addition, when spouses receive pensions that are based on their own federal, state, or local government work that is not covered by Social Security, their Social Security benefits are reduced by an amount equal to two-thirds of their public pensions. Total family benefits may not exceed the maximum family benefit, which ranges from 150% to 272% of the PIA, depending on the level of the PIA, with paradoxically the lowest percentage (150%) applying to the lowest range of AIME, that is, 0 to $801 in 2005.

Widows or widowers of insured workers are entitled to 100% of the PIA of their deceased spouse if they claim benefits at the normal retirement age or later. Widows and widowers can claim benefits as early as age 60 (or age 50 if disabled), although the benefits are subjected to actuarial reduction.

Children under age 18 (or under 19 if still in high school) and the surviving spouse who is caring for them are entitled to SI benefits. Each eligible survivor is entitled to benefits equal to 75% of the PIA, but the maximum family benefit rule applies. When the youngest child reaches age 18, benefits for the surviving spouse cease, but if any child has a disability that originated in childhood (before age 22), benefits for the child and caretaker parent continue without an age limit.

To receive DI benefits, a worker must be unable to engage in any substantial gainful activity (SGA) because of a severe physical or mental impairment that is expected to last for at least 12 months or to result in death. Education, work experience, and age are taken into account in determining disability. DI beneficiaries must accept rehabilitation services that are offered by state rehabilitation agencies if the Social Security Administration (SSA) determines that these services are likely to be successful.

Eligible disabled workers are entitled to monthly benefits equal to the PIA. Eligible children and the spouse caring for a child under age 18 or children who became disabled before age 22 are each entitled to 50% of the PIA. The total family benefits may not exceed the maximum family benefit.

Unless they recover medically from their disability, disabled people generally are allowed to continue to receive benefits for up to 9 months while they test their ability to work. Benefits are not terminated until the second month following the earliest month after the trial work period in which the individual engages in SGA or is determined by the SSA to be able to engage in SGA.

OASDI is financed by payroll taxes on employers, employees, and the self-employed. The payroll tax is authorized by the Federal Insurance Contribution Act up to the maximum taxable earnings ($94 200 in 2006). The tax rate of 6.2% for OASI and DI combined is levied on employees and employers, totaling 12.4% of the payroll. The self-employed pay at the 12.4% rate. Allocation of the payroll tax is as follows: 5.30% for OASI and 0.90% for DI.

Emerging Problems

Demographic Shifts

The major cause of the increasing difficulty in financing Social Security is demographic shifts in the US population. The old dependency ratio, defined as the ratio of the number of people aged 65 and older to the number of those aged 20 to 64, is rapidly increasing. The ratio is projected to increase from 0.203 in 2005 to 0.350 in 2030 and to 0.431 in 2080 (see **Table 1**). The trend toward higher old dependency ratios will continue even after the Baby Boom generation passes away because the proportion of children will continue to decline.

As **Table 2** shows, the number of OASI beneficiaries is projected to increase from 40 million in 2005 to 95 million in 2080 (or by 138%), and the number of DI beneficiaries is projected to increase from 8 million in 2005 to 15 million (or by 87%). As a result, the total number of the combined OASDI beneficiaries will increase from 48 million in 2005 to 111 million in 2080 (or by 129%). All told, the number of OASDI beneficiaries is projected to increase from 16% to 27% of the US population from 2005 to 2080.

The growing life expectancy at age 65 and the trend toward early retirement are increasing the duration of receipt of OASI benefits. In particular, life expectancy at age 65 increased from 14.0 years in 1980 to 16.2 years in 2004 for men and from 18.4 years in 1980 to 19.0 years in 2004 for women. The percentage of those who retired earlier than the normal retirement age increased from 58% in 1980 to 74% in 2003 for men and from 70% in 1980 to 77% in 2003 for women.

Actuarial Imbalance

The Social Security program is facing a great challenge to remain financially solvent. **Table 3** shows how much the annual income rate and cost rate will diverge in the future as a percentage of the payroll. During the next 25 years (2005–29), the OASI Trust Fund will be financially solvent; that is, annual income exceeds costs, but in the next 50 years (2005–54) and the next 75 years (2005–79), it will face actuarial imbalances equivalent to 0.87% of the

Note: Old-Age Insurance (OAI) beneficiaries include retired workers, spouses, and children. Survivors Insurance (SI) beneficiaries include widows/widowers, mothers/fathers, children, and parents. Disability Insurance (DI) beneficiaries include disabled workers, spouses, and children.

Table 3 Summarized Income rates and cost rates for valuation periods, by trust fund, under intermediate assumptions, calendar years 2005–79 (as a percentage of the taxable payroll)

Summarized periods	*OASI*			*DI*			*Combined*		
	Income rate	*Cost rate*	*Actuarial balance*	*Income rate*	*Cost rate*	*Actuarial balance*	*Income rate*	*Cost rate*	*Actuarial balance*
25 years: 2005–29	12.53	11.59	0.95	2.02	2.14	– 0.12	14.55	13.72	0.83
50 years: 2005–54	12.06	12.93	– 0.87	1.95	2.21	– 0.26	14.02	15.15	– 1.13
75 years: 2005–79	11.93	13.53	– 1.60	1.94	2.26	– 0.32	13.87	15.79	– 1.92

Source: Board of Trustees, OASDI (2005), Tables IV.V4, p. 56.

payroll and 1.60% of the payroll, respectively. This means that for the OASI to remain financially solvent until 2079, income has to increase by the amount equivalent to 1.60% of the payroll.

The DI program will face an even greater challenge. For the 25-year, 50-year, and 75-year periods, the DI Trust Fund will be actuarially imbalanced. For the 75-year horizon, the DI Trust Fund will face an actuarial imbalance equivalent to 0.32% of the payroll, which is considerably larger than the OASI's actuarial imbalance of 1.60% of the payroll, in relative terms.

The combined OASDI Trust Funds will be positively balanced during the 25-year period but will face an actual imbalance of 1.13% of the payroll and 1.92% of payroll during the 50-year and 75-year periods, respectively. The Board of Trustees' projection of the actuarial imbalance for the infinite time horizon will be 3.5% of the payroll, or $11.1 trillion (in present value), or 1.2% of the gross domestic product (GDP).

Taking into account the accumulated assets, which will peak in 2015 at a level equivalent to 469% of the annual expenditures for OASI and in 2005 at the level equivalent to 215% of annual expenditures for DI, the following scenario is projected to occur in the coming years. Starting in 2018, the OASI's outgo will exceed its income (excluding interest on the Trust Fund) – a situation that began in 2005 for the DI Trust Fund. For OASDI as a whole, the outgo will exceed income beginning in 2017. Thereafter, OASI and DI will have to redeem the accumulated interest to supplement the annual income, which are kept in the respective Trust Funds, to keep paying the scheduled benefits. But the accumulated interest will be exhausted in 2028 for OASI, 2014 for DI, and 2017 for the combined OASDI. After these years, OASI and DI will need to redeem the accumulated assets in their respective Trust Funds to supplement their annual income to keep paying the scheduled benefits. Such a condition will continue until 2043 for OASI, 2017 for DI, and 2041 for the combined OASDI programs. In other words, the OASI Trust Fund assets will be exhausted in 2043, the DI Trust Fund assets will be exhausted in 2027, and the combined OASDI Trust Fund assets will be exhausted in 2041. Annual income will be sufficient to finance only 74% of the scheduled annual benefits in 2041 and only 68% in 2079.

These projections are predicated on the assumption that the Federal Treasury will be able to pay back to the OASI and DI Trust Funds what it owes, plus interest, in special issue US government bonds. However, these borrowed funds have never been set aside and have been used to pay for the operation of

other ongoing programs. Therefore, the federal government will have to come up with 'new money' to make it possible for the OASDI Trust Funds to redeem the special issue bonds, plus interest.

Furthermore, the OASDI Trust Funds will need additional income equivalent to 1.92% of the payroll, which is referred to as unfunded liabilities, to pay the scheduled benefits until 2079. To do so, the federal government will need to come up with financial resources in addition to what it has borrowed from the OASDI Trust Funds, plus interest. In short, the real financial struggle will start in 2018 for OASI and started in 2005 for DI, when their annual incomes become less than the annual outgo.

To make sense of the income rate, cost rate, accumulated assets, and unfunded liabilities, the evaluation of OASDI's financial conditions based on the GDP is instructive. **Table 4** shows that the cost of the combined OASDI is projected to increase 50% from 4.26% of the GDP in 2005 to 6.39% of the GDP in 2080, but the income is expected to be stable: 4.82% of the GDP in 2005 and 4.46% in 2080. As a result, the balance will change from +0.56% of the GDP to –1.93% of the GDP (or by 345%) during this period.

With regard to the income, cost, and balance for the 25-year, 50-year, and 75-year periods, the combined OASDI's balance will be +0.31% of the GDP during the 25-year period, –0.42% during the 50-year period, and –0.70% during the 75-year period. The progressively worsening financial problem signals that the earlier that policy initiatives are taken, the easier the financial problem can be solved.

The basic problem is that no matter where the funds come from (annual income, fund assets, or general revenues), the United States will need to spend as much as 6.39% of its GDP to pay for OASDI in 2080, compared with 4.26% of its GDP in 2005. Thus, the basic question that confronts the nation is whether it is willing to spend an increasing proportion of the US GDP for OASDI. On the basis of the initiatives taken by the current and previous administrations to find solutions to make the financing of the OASDI more manageable, it seems clear that the United States is searching for solutions to make the scope of the OASDI smaller.

Table 4 OASDI income, cost, and balance in selected years and in summarized periods: 2005-80 (as a percentage of GDP)

Year	*Income*	*Cost*	*Balance*
2005	4.82	4.26	0.56
2010	4.86	4.28	0.57
2020	4.86	5.24	−0.38
2030	4.83	6.14	−1.31
2040	4.76	6.31	−1.54
2050	4.69	6.24	−1.55
2060	4.61	6.29	−1.67

Other Problems

The Issue of Money's Worth Since later cohorts of workers have been taxed at increasingly higher payroll tax rates, the OASI program has become less effective in providing an adequate return on workers' contributions to the program. C. Eugene Steuerle and Jon M. Bakuja showed that the average-wage, single man who retired in 1960 received $36 500 (in constant dollars) more in retirement benefits during his lifetime than what he paid into the OASI program, whereas his counterpart who will retire in 2030 is expected to receive lifetime benefits that are $56 200 less than his lifetime contributions.

The situation of minority groups poses a different kind of problem. Because Black workers generally receive lower wages during their lifetime, their monthly benefits tend to be higher relative to their AIME than those of White workers. However, on the basis of their lifetime contributions and lifetime benefits, the ratio of their lifetime benefits to lifetime contributions is lower than that of White workers, primarily because they tend to die younger.

One-Earner Couples versus Two-Earner Couples Under the current system, one-earner couples with the identical maximum AIME as that of two-earner couples, with each spouse earning half the maximum, receive larger benefits when they both are alive than when only one is alive.

Table 5 illustrates the situation of one-earner couples and two-earner couples who retire at age 65 in 2004. While they both are alive, the benefit for

Table 5 Monthly benefits for one-earner couples with the maximum average indexed monthly earnings ($5892) and two-earner couples with half that amount ($2946): couples claiming benefits at age 65 in 2004

	One-earner couple	*Two-earner couple*
Benefit when both spouses are alive	$2798	$2596
Benefit when only one spouse is alive	$1865	$1298

Source: Board of Trustees (2004), p. 100; Mercer (2003), pp. 3.
Note: Couples are assumed to be the same age and to retire at age 65.

the one-earner couple is the maximum benefit plus one-half that amount, and the benefit for the two-earner couple is the sum of two identical benefits, with each based on half the maximum AIME. Obviously, 1-1/2 of the maximum benefit is higher than the sum of the two benefits, despite the progressive benefit formula that is applied to low-wage workers. Moreover, the surviving spouse of the one-earner couple receives the maximum benefit, whereas the surviving spouse of the two-earner couple continues to receive the benefit based on his or her own work record.

Research has shown that the probability of a non-working spouse receiving the full spousal benefit is higher among the higher-income classes than among the lower-income classes. The same applied to spouses who received dual benefits. (These benefits represent the partial spousal benefits when spouses' benefits are lower than the half the benefits of the primary beneficiary.) The dual benefit equals half the benefit of the primary beneficiary minus the benefit amount of the spouse based on his or her own work record. Thus, the benefit for the dual beneficiary equals half of the benefit of the primary beneficiary – the same as the benefit for spouses who never worked.

Reform Initiatives and Proposals

The 1983 Amendments to the Social Security Act

The 1983 Amendments to the Social Security Act was the second serious attempt to meet the impending deficit in the trust funds. The major changes were to increase revenue, to decrease benefits, and to reduce the rate of retirement. To increase revenue, previously excluded groups of workers (newly hired federal employees and all members of Congress, employees of non-profit organizations, and some local and state governmental employees) were covered. To decrease benefits, the timing of cost-of-living increases was delayed; a portion of the Social Security benefits of those who had incomes in excess of $25 000, if individuals, and in excess of $32 000, if married, was subjected to income tax; and a different benefit formula was established for governmental employees who became eligible for both civil service pensions and Social Security benefits, in order to prevent them from taking advantage of the progressive benefit formula in calculating PIA under OASI. To reduce the rate of retirement, the normal retirement age (which was 65 years) was increased to gradually reach 67 in 2022.

Perhaps the most important policy initiative in the 1983 Amendments was to increase the tax rate so that a sizable amount of assets would be accumulated in the Trust Fund to pay for the increasing cost of OASI when the Baby Boom generation retires. These accumulated assets have been instrumental in prolonging the year of actuarial exhaustion but are not a permanent solution to maintaining the solvency of OASI.

The 1994–96 Advisory Council on Social Security

To shore up the financial health of OASI, the Clinton administration established an advisory council on Social Security to find viable, alternative solutions to make OASI financially solvent permanently. The council recommended three alternative approaches: the Maintain Benefits (MB) plan, Individual Accounts (IA) plan, and Personal Security Accounts (PSA) plan. Cutting across these three recommendations was the goal not only of establishing a permanent actuarial balance but also of increasing the money's worth ratios for younger generations. Furthermore, all plans recommended that part of Social Security contributions be placed in the equity market.

Under the MB plan, as much of the status quo as possible was to be maintained. The specific reform agenda included extending Social Security coverage to all state and local government workers, using three more years to calculate AIME, and increasing the OASDI payroll tax rate by 0.8% for both employees and employers.

The IA plan incorporated some of the same approaches of the MB plan. In addition, it included more aggressive strategies to make OASDI financially solvent: reducing the second and third multiplying factors from 0.32 and 0.15 to 0.224 and 0.105, respectively, in calculating the PIA; accelerating the increase in the normal retirement age, so it would reach 67 in 2011, after which it would increase automatically according to the increase in life expectancy; reducing the surviving spouse's and aged spouse's benefits as a percentage of the PIA; and, most important, requiring all workers to contribute an extra 1.6% of taxable earnings to establish their own individual retirement accounts (IRAs).

The PSA plan includes the most radical strategies to shore up the financial health of OASI, placing the establishment of personal security accounts as a centerpiece of the reform agenda. The plan would require five percentage points of the OASDI employee payroll taxes to be carved out to enable workers to develop their own PSAs and to change the traditional Social Security benefits, which are based on AIME, to a flat amount benefit. In essence, then, the PSA plan envisions a double-decker scheme for the future Social Security system: the first tier (flat benefits) and

the second tier (a defined-contributions plan). It anticipates the need for additional funds to pay for the transition cost, which would be paid back with interest by 2070.

President's Commission to Strengthen Social Security

This commission was established by the Bush administration. It recommended three alternative plans: Model 1, Model 2, and Model 3. All models incorporate some form of personal retirement accounts (PRAs). Of the three models, Model 2 is the most comprehensive and aggressive in achieving the goal: permanent solvency of OASI.

Model 2 would establish voluntary PRAs by carving out four percentage points of workers' payroll taxes, up to $1000 annually. The cap was meant to make the contribution progressive in favor of low-wage earners. The traditional Social Security benefits would be offset by the workers' PRA contributions, which would be compounded at an interest rate of 2% above inflation. The combined benefits from PRAs and the traditional Social Security program are expected to be greater than the benefits that would be received by those who do not establish PRAs and than the future benefits payable under the current system if it is not reformed.

While Model 2 shifts much of the responsibility for ensuring future retirement benefits from the government to individuals, it also attempts to ensure that long-term low-wage workers would be guaranteed to have above-poverty-line benefits through the traditional Social Security program. The plan recommends that 30-year minimum-wage workers would receive benefits equivalent to 120% of the poverty line. Additional protection for such workers' survivors would be provided as well. Furthermore, to reduce the future traditional Social Security benefits, Model 2 recommends that earnings during working lives would be price indexed instead of wage indexed.

If all these recommendations are implemented, the commission expects that a medium earner who chooses to establish a PRA and retires in 2051 would receive combined benefits that would be 59% higher than the benefits that are paid to today's retirees. At the end of the 75-year period (2079), the PRA system will hold $12.3 trillion (or $1.3 trillion in today's dollars and discounted to the present value). Also, if all these steps are taken, the commission anticipates a positive cash flow by 2079. It should be noted that this plan requires a temporary transfer from general revenue to keep the Trust Fund solvent between 2025 and 2054.

There will be sizable between-cohort variations in the rates of return on the contributions that are made to PRA, as Gary Burtless argued. However, Martin S. Feldstein argued that because the rates of return on contributions would be so high, compared with the rates of return on the contributions to the traditional Social Security program, it is probable that every participant in the PRA plan would be better off than those who are not.

By far the most radical change that the commission recommended is the adoption of price indexing of earnings in prior years in calculating the AIME, which is the basis for calculating the PIA. Under the current system, wages earned in early years (since 1951 or at age 21, whichever is later) are adjusted to account for the rate of increases in average wages. For example, the index factor for earnings made in 1951 is 11.9 to make it equivalent to the earnings made in 2002. To adjust the 1951 earnings for inflation to the 2002 price level, one needs to use the index factor of only 9.9. Thus, the use of the price index, instead of the wage index, would result in lower AIMEs, which would lead to lower Social Security benefits. The commission claimed that the adoption of wage indexing alone would not only help eliminate all unfunded liabilities, but would ensure permanent financial solvency of OASDI.

It is important to note that price indexing would result in the same level of constant purchasing power in Social Security benefits across cohorts, whereas wage indexing would guarantee the same replacement rates of Social Security benefits, which would have a built-in growth in Social Security benefits in later cohorts. It is obvious that Social Security benefits that are based on price indexing of earnings in prior years would be considerably easier to finance than such benefits based on wage indexing.

Some may be concerned about the declining replacement rate envisioned by the commission. However, because there are numerous private retirement plans, such as IRAs, 401(k) plans, and Keogh plans, the replacement rates involving Model 2 plus all these private plans would provide relatively high replacement rates in the future.

The commission stated that the PRA program not only would be effective in establishing individually funded accounts that will be under the control of the participants, but also would increase the national savings. The first part is obvious; the second part may or may not be true because the current system, which is based on pay-as-you-go financing, is not contributing to the national savings. As was reviewed, Model 2 maintains some of the same features that are included in the current system.

Resistance to Radical Changes in Social Security

While the movement toward radical change in Social Security is gradually taking hold in the United States, reviewing the various recommendations to reform Social Security reveals that there is no national consensus on how to reform it. Therefore, the implementation of Model 2, as recommended by the President's Commission to Strengthen Social Security, will not be easy. The sources of resistance are (1) an alternative approach to reform Social Security and (2) persistently strong, positive attitudes toward Social Security.

Alternative Approach An alternative approach to Social Security reform attempts to keep the basic structure of the Social Security program as intact as possible. The plan, recommended by Robert M. Ball, a former commissioner of Social Security who served under Presidents Kennedy, Johnson, and Nixon, exemplifies such an approach. The steps that he recommends include increasing the taxable payrolls, the infusion of general revenue by taxing estates, the extension of coverage to those who are not covered, the investment of the trust funds' assets in the equity market, and the reduction of cost-of-living increases in benefits. These steps, Ball believes, will eliminate the deficit without changing the Social Security program structurally.

Specifically, his plan would attempt to eliminate the deficit (which is 1.9% of the payroll) in the following ways: (1) restoring the 90% maximum taxable payroll from the current 83%, which would reduce the deficit by 0.6%, thus reducing the deficit to 1.3%; (2) earmarking all the revenue from the estate tax that will be imposed on estates in excess of the exempt amount (which will reach $3.5 million for individuals and $7 million for a couple in 2009), which would reduce the deficit by 0.5%, bringing the deficit down to 0.8%; (3) investing 20% of the accumulated Social Security trust funds in the equity market, which would further reduce the deficit by 0.4%, thus bringing the deficit down to 0.4%; (4) extending Social Security coverage to all newly hired state and local government employees, which would reduce the deficit by 0.2%, thus bringing the deficit down to 0.2%; and (5) adopting a lower rate of cost-of-living adjustments, which would reduce the deficit by 0.4%, thus turning the deficit into a positive accumulation of trust funds. In addition, Ball advocates that temporary increases in the payroll tax should be considered when short-term estimates show that the trust funds would begin to decline within the next 5 years.

Ball contends that if all these steps are taken, not only will there be no need to cut benefits, but also the Social Security system will be able to meet the shortfall in the trust funds for the coming 75 years and beyond. He concludes that if these steps are taken, the United States can deal with the financial challenge effectively, and there is no financial crisis in Social Security.

Ball's recommendations are predicated upon his conviction that the American public needs an ultimate safety net in old age and that the Social Security program is the most effective vehicle to achieve this objective. He further argues that Social Security benefits constitute an earned right and hence cannot be cut or taken away.

The Ball plan is specific and seems feasible in terms of maintaining a level of trust funds that is large enough to keep paying the promised benefits to current and future beneficiaries. However, because the Social Security program will still be largely unfunded because the federal government continues to spend the assets that are accumulated in the trust funds to finance ongoing government programs (and the federal government will continue to have deficit budget for many years to come), the question is whether the federal government can redeem the special issues (that is, bonds held by the Social Security trust funds) when that time comes, which is approaching rapidly. Such an uncertainty exists, despite the long-held principle of the full faith and credit of the United States to protect the Social Security contributions that have been made in the past.

Public Opinion The public sentiment toward structural changes seems to be not strong enough for the United States to reform Social Security radically, as advocated by Model 2, which was developed by the President's Commission to Strengthen Social Security. The public's resistance to such a radical reform was substantiated by a recent study by Fay Lomax Cook and Lawrence R. Jacobs, which investigated the outcomes of public opinion surveys regarding Social Security over the past 25 years and also findings of several recent surveys regarding specific questions related to changes in Social Security provisions. Cox and Jacobs observed that the level of public support for Social Security has been high and stable, indicated by the fact that 89 to 95% of the public think that the Social Security expenditures are too little or just about right. Furthermore, they observed that the majority of the public prefer an incremental reform instead of a radical reform; that the public prefers an increase in the Social Security tax instead of benefit cuts; and that if benefits must be cut, only benefits of rich beneficiaries should be cut (58%). Finally, when risks are considered, the majority (51%) of the public oppose the privatization of Social Security, with 44% favoring it and 5% having no opinion. These public opinions seem to be contrary to what Model 2 proposes to do.

US Income Support for the Elderly in Perspective: A Comparison to Other Countries

Due to the intense national debate that was forged by the Bush administration and the media blitz that has accompanied it, some among the public have come to believe that there is a coming crisis in financing Social Security when the Baby Boomers retire that the nation needs to prepare for. However, the gravity of the problem needs to be assessed with some degree of rationality. Comparing the scope of financial support for the aged population in the United States with that of other industrialized countries can place the US situation in perspective. **Figures 1**, **2**, and **3**, which were created using the Organisation for Economic Co-operation and Development (OECD) Social Expenditure Database, illustrate how much (or how little) the United States is providing in cash payments to the elderly (including both social insurance and income-tested benefits) in comparison to Japan, Germany, and Sweden.

It is clear that the United States, along with Japan, has a small welfare state, measured by the percentage of the GDP that is used for all social welfare programs (see **Figure 1**), and that compared with other countries, the percentage of the US GDP that is used to provide cash payments for the elderly is small (see **Figure 2**). Since 1997, the United States has spent the lowest percentage of its GNP on cash payments. Partly because of the small size of the US welfare state, the spending on cash payments constitutes a large percentage of the total social welfare expenditure, second only to Japan's (see **Figure 3**).

These figures indicate that there still is room for the United States to expand income transfer programs for the elderly, of which Social Security is a large part. A more important challenge facing the United States is of a different kind. As the United States expands public spending for income transfer programs for the elderly, the country will face the squeezing effect to the detriment of the non-aged population, especially children, unless it is willing to expand the size of its welfare state. **Figure 3** indicates that in 1998, 34.5% of the total social welfare expenditures was dedicated to providing cash payments to the elderly, second only to Japan, which allocated 37.7% of its total social welfare expenditures for this purpose. Therefore, there is not much left in the US federal budget to pay for programs for children and other sectors of the population. The situation will become worse as the United States spends more for cash payments for the elderly in coming years. The situation will be untenable if one takes into account the rapidly growing spending for Medicare and Medicaid, both of which are mostly targeted to the elderly population.

Partly because of the neglect of the child population, the income status of children, relative to that of

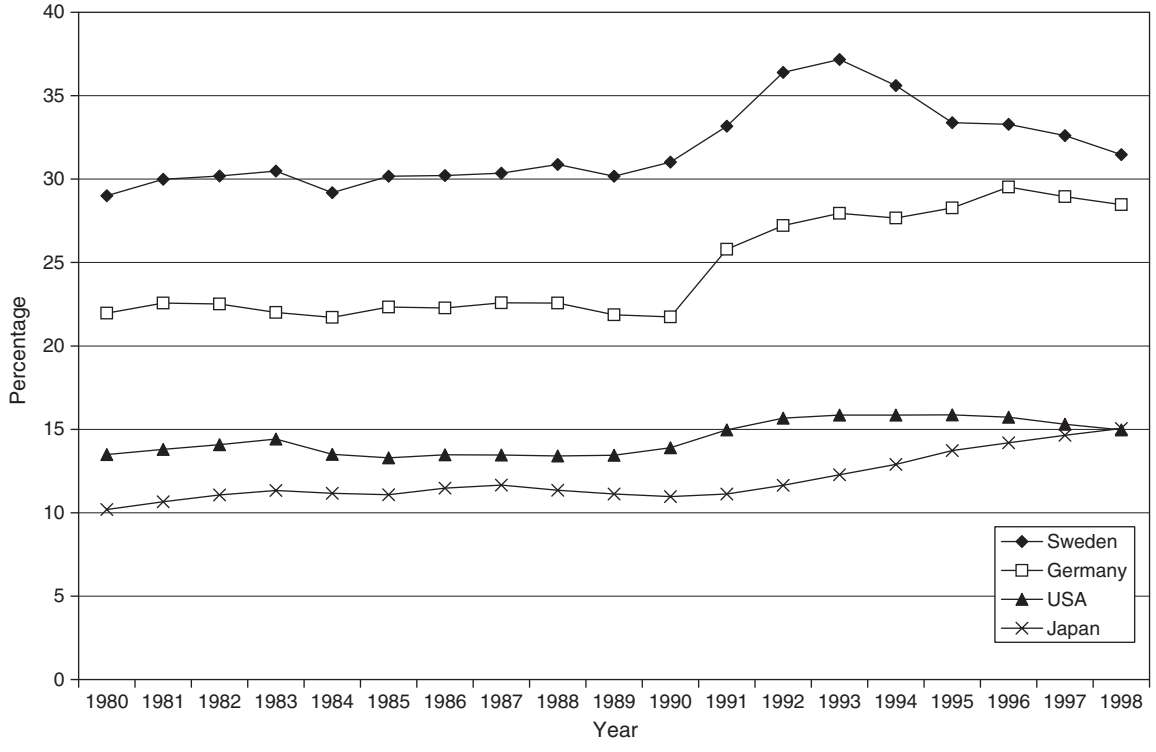

Figure 1 Total social welfare expenditures, 1980–98 (percentage of the GDP).

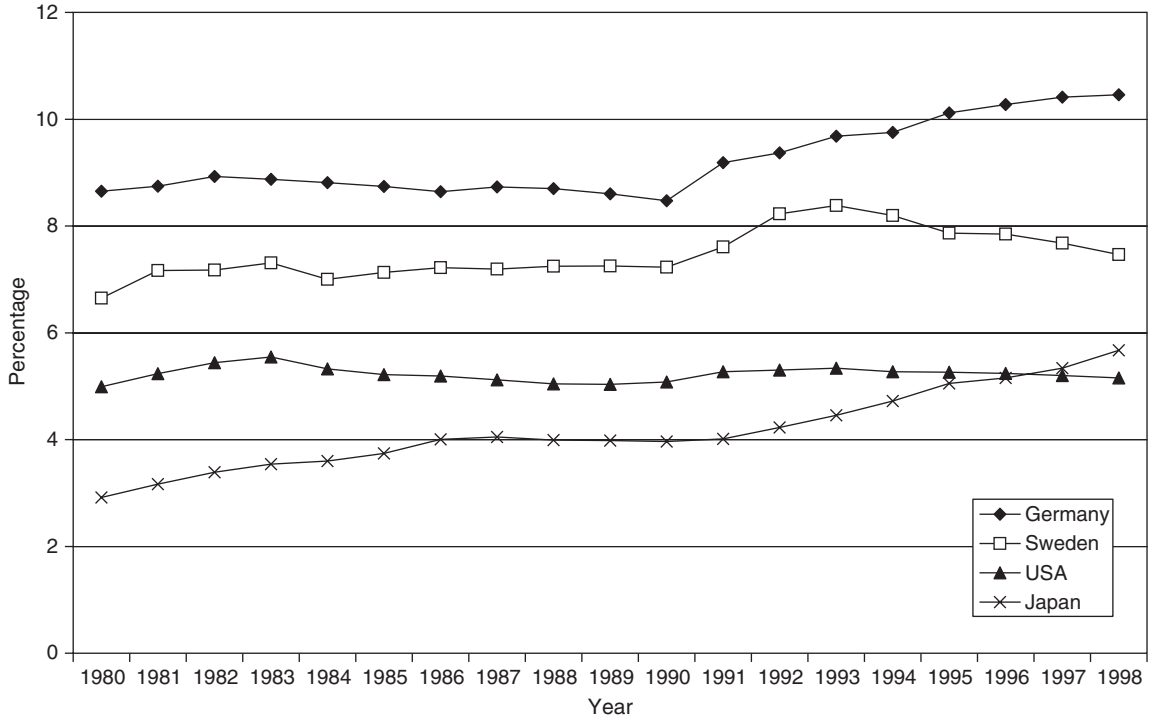

Figure 2 Cash benefits for the elderly, 1980–98 (percentage of the GDP).

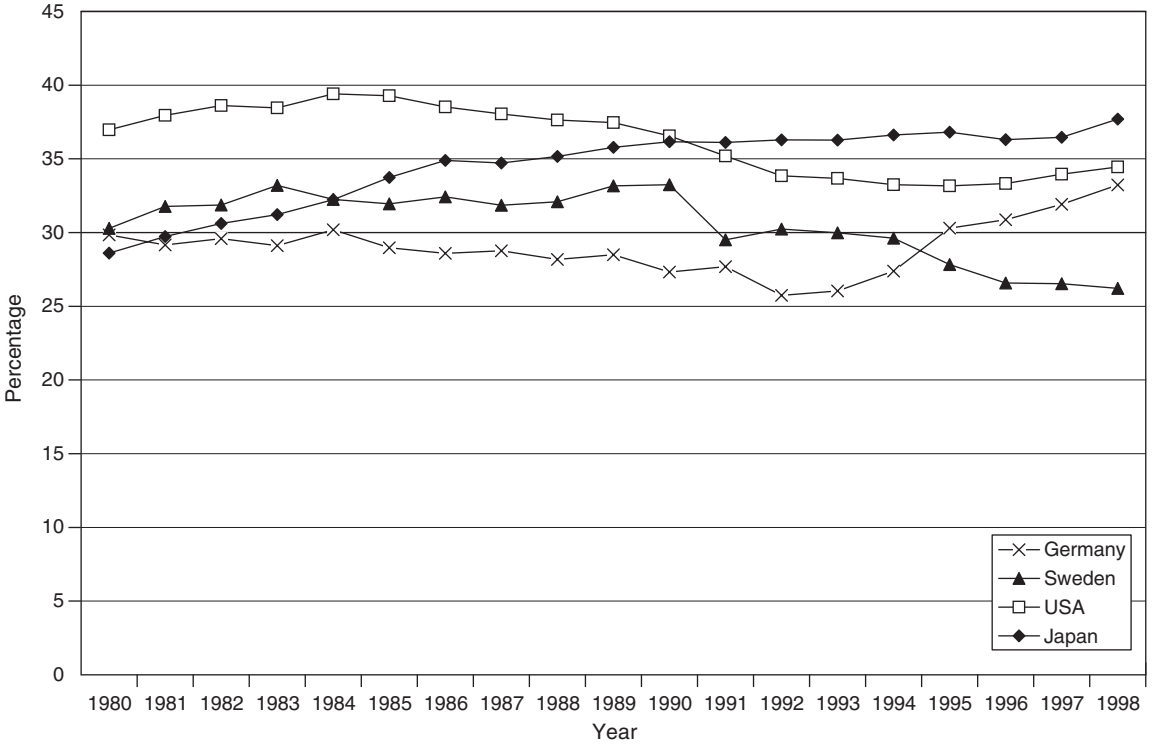

Figure 3 Cash benefits for the elderly relative to total social welfare expenditures, 1980–98 (percentage).

elderly people, has deteriorated in recent decades. Research has shown that children's income status (measured by the income-to-needs ratio) declined from 101.2% in 1969 to 98.9% in 1979 and to 85.5% in 1989 of that of the elderly in the respective years.

Obviously, Model 2 of the President's Commission to Strengthen Social Security would contribute to

balancing the nation's commitment to supporting the young segments of the population as the nation undergoes Social Security reform. Model 2 suggests that a considerable part of Social Security should be individually funded so that the public financing of Social Security would be smaller than otherwise. As a result, the government would prevent the squeezing effect of the expanding Social Security system and, hence, would have greater public financial resources available to fund programs for the non-aged population, particularly the population of children.

Speech and Communication (speech styles)

J A Small, University of British Columbia, Vancouver, BC, Canada

Glossary

Elderspeak – A speech style often employed when addressing elderly adults; speech characteristics may include slower speech rate; exaggerated intonation and increased loudness and pitch; simplified vocabulary, semantics, and grammar; frequent repetition; and the use of diminutives (e.g., sweetie, dearie). Non-verbal expressions accompanying the verbal features may include winking, eyebrow raising, rolling eyes, and sighing. Such accommodations appear to be evoked by perceptions of

physical, cognitive, and/or communicative declines associated with aging and/or dementia. Other terms for elderspeak are secondary baby talk, dependency-supporting communication, and patronizing talk. The first two terms reflect speech traits that one may adopt in addressing infants and other individuals who are (perceived to be) dependent on a caregiver, while the latter term refers to the reaction of older adult recipients to such inappropriate talk. The use of some aspects of elderspeak (e.g., slow speech rate, exaggerated pitch) may create affective barriers and lead to poor communication between older and younger adults, whereas other aspects (e.g., semantic elaboration, less complex sentences) appear to facilitate intergenerational communication because they accommodate to age-related changes in language processing abilities.

Speech – The production of language via the vocal tract or manually for the purpose of communicating a message to another person.

Speech Accommodations – An attempt on the part of one communicator to adapt his or her speech to another communicator based on beliefs and perceptions of that communicator's personal characteristics and social identity. Accommodations serve the purpose of promoting convergence (identifying with) or divergence (distancing from) between communicators. Communicators may underestimate the perceived communication abilities of their interlocutor and speak in a way that is overaccommodating. They may alternatively overestimate their interlocutor's competence, or ignore their needs and engage in underaccommodating speech.

Speech Style – A profile of speech characteristics that show systematic differences from other profiles. The dimensions in which speech styles vary include pronunciation and prosody, choice of vocabulary, and grammatical and discourse features. Speech styles can be associated with particular social groups (e.g., younger vs. older adults, males vs. females), yet the same individual may draw from a repertoire of speech styles, with the use of each dependent on personal characteristics of the interlocutors (e.g., age, appearance, gender, familiarity, social status, ethnic identity) and contextual variables (e.g., topic, purpose of the interaction, formal vs. informal setting).

Stereotype – Perceptions of individuals associated with a particular group based on perceived attributes of that group as a social category (e.g., older people are wise). Stereotypes can be positive or negative, and they play an important role in, and are a reflection of, the social construction of aging.

Introduction

Speech styles are constructed through a complex interplay of diachronic (historical) and synchronic (current) sociocultural forces. Diachronically, language is passed on in a seamless fashion between generations, thereby facilitating communication between generations; however, such transmission does not preclude subtle changes to speech and language, nor more conspicuous sociolinguistic changes over time. For example, in addition to the new words that are coined each generation, old words often take on new meaning across generations (e.g., cool, hot), and speech habits pertaining to certain linguistic forms change from generation to generation (e.g., the off- and on-again generic use of male pronouns across the past few centuries and generations). The usage patterns of these and other forms vary and evolve depending on the speakers involved (e.g., younger vs. older adults), topic of conversation (e.g., politics vs. travel), and context of interaction (e.g., formal vs. informal). In conjunction with these historical changes are synchronic forces, most notably human developmental processes and sociocultural values, beliefs, and practices that find expression in and help differentiate the speech styles of different social groups. For example, the salience of emotion regulation in forming and maintaining interpersonal relationships appears to increase for older adults (according to socioemotional selectivity theory). This change has been attributed in part to adults' perceptions of how much time they have left in life and the increased importance of selecting social partners based on the meaningfulness of a relationship. In contrast to younger adults' more objective fact-finding-relaying orientation, older adults engage more in interpretive and subjective reflections during conversation. These different orientations and conversational goals can lead to age-based preferences for communication partners and, ultimately, to different ways of communicating (speech styles) for and with each age group. Over the course of human development, sociocultural forces serve to create and perpetuate intergenerational differences in age identity and communication style. These include perceptions of and access to roles, power, status, mobility, and vitality, all of which tend to decline in older age relative to middle age and contribute to variations in younger and older adults' speech styles (*see* Generational Differences: Age-Period-Cohort).

In this article, the speech styles most relevant to aging are described and discussed, beginning with an overview of the changes in speech associated with aging. Speech styles in intergenerational interactions are examined from the perspectives of their origins, characteristics, consequences, and cultural variations. The ways in which speech styles are realized in communication between younger and older adults are accounted for by drawing upon principles and models based in communication accommodation theory. The article concludes with suggestions for promoting positive intergenerational communication.

Prior to addressing the speech styles of different age groups, it is first necessary to delineate what ages are encompassed by different age grouping labels (e.g., older adult and younger adult). Traditionally, the classification of older or elderly has been applied to adults age 65 and older and that of younger to those 30 years or younger, with middle-aged falling somewhere in between. In response to the increase in longevity over the past century, a new division of age groupings has emerged between the young-old (65–75) and the old-old (85 and older). In addition, it appears that how adults at different ages classify age groupings shifts as one gets older (i.e., moving boundaries upward). For the purposes of this article, however, the traditional distinction between younger, middle-aged, and older adults will be followed. When referring to younger adult speech addressed to older adults, middle-aged adults are included with the younger adults since some research has shown that both groups engage in a similar speech style when addressing older adults.

Age as a variable is non-negotiable in the sense that we cannot change our age, although some may seek to modify how their age is perceived by others through use of makeup, exercise, diet, social networks, etc. On the other hand, age is negotiable in the sense of age groupings because the boundaries between groupings are fuzzy, and perceptions of age categories vary depending on the age and prototypicality of the respondent. That is, the greater the distance a person is perceived to be from age-grouping boundaries, or the more typical he or she is of a group, the easier it is to render an age-based categorization. The latter can have a significant influence on the nature of communication accommodations observed between individuals of different ages.

Speech Characteristics of Older Adults

Developmental factors, in addition to those mentioned previously, that contribute to different speech styles across the life span include age-related changes in physical (motor, sensory) and cognitive (e.g., language, speed of information processing, memory) attributes. As people age, changes take place in motor functions related to speech, sensory functions of hearing and vision, and cognitive and linguistic functions, all of which may serve as cues in recognizing and defining the speech of older adults (*see* Markers of Aging).

Due to anatomical and physiological changes in aging, including atrophy of muscle tissue, increase in stiffness in the vocal folds, and cartilage degeneration, an older adult's voice may present with jitter and shimmer. Speech rate typically slows down due to both motor and cognitive declines in processing. The fundamental frequency (or pitch) of older adults' speech evolves across the life span and differs for males and females. Whereas male pitch is usually high-low-high over the three life span periods, females tend to present with a high-high-low pitch pattern. Change in amplitude appears to be a more salient perceptual feature of older adult males than change in pitch. Dentures or other orthodontic work may result in additional alterations to articulation and reduced intelligibility. Because of these anatomical and physiological changes, older adults may expend more effort when speaking, which may leave less energy for other levels of processing (e.g., grammatical structure).

Research on younger adults' identification and perception of older adults' voices has shown that older adults can be readily identified based on vocal cues. Moreover, the sound of an older person's voice is associated with negative evaluative responses by younger adults (e.g., an older adult will have a more difficult time understanding). Age-related changes in hearing (presbycusis) and vision (presbyopia) can affect older adults' awareness of their own speech qualities and their ability to benefit from visible speech cues of interlocutors. The consequences of sensory declines on speech production and perception may limit the older adult's desire and/or opportunities for communication and may serve to activate age-based stereotypes (*see* Hearing; Vision).

As mentioned previously, reduced efficiency in motor and sensory processing in aging can have implications for higher level processing such as language. In fact, some research has demonstrated that declines in cognitive and linguistic processing that have previously been attributed to cognitive aging may be largely accounted for by lower level perceptual constraints. Keeping the latter in mind, age-related changes in language production include an increase in word-finding problems, more dysfluencies, a tendency to reminisce (perhaps related to less accessible recent memories relative to remote

memories), a decrease in syntactic complexity and propositional density, and slower delivery (often attributed to declines in working memory and/or speed of processing). These linguistic changes may be exacerbated in demanding contexts and/or by the presence of an age-related neuropathological condition such as Alzheimer's disease or aphasia. On the upbeat side, older adults show gains in vocabulary, narrative and social skills, and world knowledge and experience compared to younger adults. Both the negative and positive changes to language and cognition influence the speech style of older adults, and in turn, younger adults' perceptions of aging and the speech accommodations they make when interacting with older adults (*see* Dementia: Alzheimer's; Information Processing/Cognition; Language and Communication in Aging; Language Disorders: Aphasia).

Speech of Younger Adults Addressing Older Adults

A considerable body of research literature has accumulated over the past two decades documenting the predominant characteristics of younger adults' speech addressed to older adults. The evidence attests to intergenerational differences in speech styles, in particular, how younger (vs. older) adults accommodate their speech to older adult interlocutors. Speech of younger adults to older adults depends in large part on the perceived competence, appearance, and communication behaviors of older adults, as well as on the values, beliefs, and attitudes about aging held by society. Positive perceptions of aging include viewing older adults as wise, good listeners and storytellers, empathic, generous, family oriented, supportive, and sincere. Negative perceptions include older adults as complaining, disapproving, overprotective, closed minded, and physically and/or cognitively on the decline. Such perceptions, or stereotypes, can be held implicitly and/or explicitly.

Although both positive and negative stereotypes of aging exist, research indicates that negative stereotypes are more prevalent and accessible than positive ones. Moreover, negative stereotypes appear to have greater effects on intergenerational communication than positive stereotypes. Negative stereotypes often lead to intergroup over- and underaccommodations in communication, which can adversely affect the quality of communication between younger and older adults. Overaccommodating speech to older adults, commonly referred to as elderspeak, is characterized by a number of simplifications to and exaggerations of normal speech. Most notable are reductions in grammatical and semantic complexity, exaggerated prosody and repetitiveness, and the use of diminutives (*see* Ageism and Discrimination).

As a speech style, elderspeak should not be thought of as exclusive or invariable in the sense that younger adults always (and only) use it when speaking with all older adults. Rather, it is a style that may be triggered by certain personal and contextual cues associated with the target interlocutor (e.g., appearance, body movement, voice quality, gender, cognitive and communication ability, topic/content of conversation, relationship of persons, and setting) and negative stereotypes related to these cues. Hence elderspeak is more likely to surface when interacting with an individual who exhibits more of the following characteristics: looks, sounds, and moves like an older person; is in a care facility; and has hearing, vision, and communication problems. On the other hand, just one salient aging cue, such as hearing loss, may be sufficient to elicit the use of elderspeak by a younger interlocutor. In fact, younger adults have been found to modify their speech to community-dwelling adults even when the older adult gives no indication of difficulty in comprehending or is otherwise portrayed positively.

The use of elderspeak by younger adults may be motivated by good intentions to accommodate to the perceived needs of the interlocutor (a compensating dimension of elderspeak); moreover, its use may often be out of the awareness of the speaker and be driven more by implicitly than consciously held stereotypes of aging. Nevertheless, because perceptions of aging are strongly associated with negative stereotypes, adjustments to speech and language by younger adults may be inappropriate for a particular older adult, in which case their communication behavior is said to be overaccommodating. On the other hand, elderspeak may be used instrumentally to control or gain the cooperation of others. For example, in long-term care settings, there is a power differential between staff and residents that may lead to interpersonal conflict when staff try to get residents to comply with requests. To mitigate or cover up the potential negative effects of this power imbalance, staff may use elderspeak because of its caring and nurturing dimension (*see* Caregiving and Caring; Long Term Care).

Experimental research has shown that some aspects of elderspeak (e.g., reduced syntactic complexity, semantic elaboration) may facilitate communication between younger and older adults, with and without dementia, whereas other aspects do not (e.g., exaggerated prosody, slower speech). The latter may also lead to negative perceptions of communication by older adults, loss of self-esteem, reduced social

interaction, and the reinforcement of age-based stereotypes. A further consequence of the use of elderspeak is that it limits older adults' exposure to more complex linguistic forms and thereby threatens the maintenance of their existing communicative competence. For these reasons, it is important to consider the appropriateness and effectiveness of elderspeak on an individual basis within a particular sociocultural context.

Evaluations by healthy older adults of the use of elderspeak are typically negative, with most viewing it as patronizing. Older adults' responses to younger adults who use elderspeak may be assertive or more passive depending on the context and interlocutors' roles and status. Responses that are extreme (e.g., very assertive or passive) may reinforce negative stereotypes of the older adult as irascible or incompetent and, consequently, perpetuate younger adults' use of elderspeak. More moderate responses, and the use of humor, may be more successful at subverting the use of elderspeak since they uphold the face of the recipient while maintaining the competence of the older adult.

Elderspeak appears to be perceived more favorably by older adults who are physically and/or cognitively frail. Some researchers have attributed this finding to the nurturing and positive affect that certain elderspeak characteristics convey (e.g., use of diminutives between intimates). Others, however, suggest that positive reactions to elderspeak by frail older adults, typically residing in institutions, may simply reflect (1) the habitual use of elderspeak as an institutional register, (2) learned helplessness, and/or (3) the residents' desire for any social contact even if it is demeaning. Sensitivity to appropriate use of speech accommodations is of particular importance when communicating with vulnerable populations such as individuals with dementia, who experience cognitive declines that can accentuate age-related cues and elicit more extreme forms of elderspeak. In addition, persons with dementia may not always be able to clearly indicate preferences for how others address them. Thus, interlocutors need to develop heightened awareness of their own accommodations and the recipient's verbal and non-verbal responses in an effort to support and maintain the individual's dignity and positive construction of self.

Older adults are more likely than younger adults to hold positive stereotypes of aging. For example, aging cues that elicit negative evaluations by younger adults, such as painful self-disclosures, are viewed more positively by older adults. They also seem to have more complex cognitive schemas of aging, which may contribute to the use of more person-centered communication behaviors. On the other hand, older adults also hold negative stereotypes of aging, but the impact of these on communication behavior appears to be different compared to younger adults. That is, older adults addressing other older adults are less likely to endorse the use of patronizing speech, although they may still be perceived as non-accommodating. Nonetheless, older adults may self-stereotype in negative (or positive) ways, and this may have consequences on their cognitive, emotional, physical, and social well-being. It may also lead them to make ageist comments even when talking with others in their age group.

Speech of Older Adults Addressing Younger Adults

Compared to the extensive literature on elderspeak, relatively little research has explored characteristics of older adults' speech when talking with younger adults. Some research reports that older adults hold negative stereotypes about communication with younger adults. For instance, although older adults may perceive younger people as being more open than older people, they also view younger adults as more irresponsible, reckless, naive, self-centered, arrogant, and/or lacking in communication skills. These stereotypes may manifest in underaccommodating speech to younger adults. For example, younger adults report that older adults are less attentive and more verbose in conversation, and their speech is overly protective, disapproving, closed-minded, and complaining. On the other hand, some positive (and in some cases, contradictory) perceptions of older adults' speech and communication portray older adults as good story tellers and patient listeners. As mentioned earlier, these contrasting views may be attributed to variability in younger adults' experiences with older adults.

Older adults' speech addressed to younger (and older) adults has been found to be simplified relative to younger adults' intragroup speech. This suggests that older adults do not accommodate their speech to the preferred level of complexity of younger interlocutors (e.g., faster speech rate). Similar to the case of younger adults' use of elderspeak, older adults' under- or non-accommodating communicative approach to younger adults should not be presumed intentional. Nevertheless, when older adults do not take into account the perceived needs and interests of the younger interlocutor (e.g., are not attentive listeners) and do not or cannot accommodate to some of the younger adult's speech habits (e.g., a faster speech rate), their speech may be perceived by younger adults as non-accommodating and/or

patronizing. The result may be unsatisfying interactions and the laying down of affective barriers to future intergenerational encounters. Interestingly, recent research suggests that some aspects of older adults' non-accommodating stance may carry over to their communication with same-age peers.

Theoretical Accounts of Intergenerational Speech Styles

The speech accommodations that characterize intergenerational communication, and the consequences of their use, can be elegantly accounted for by principles from communication accommodation theory and derivative models. Communication accommodation theory states that individuals adapt their communication behaviors to the perceived needs and desires of a conversational partner in accordance with their own needs and desire to identify with the other person and his or her social group identity. In other words, people engage in communicative behaviors that reflect categorization of others in terms of whether they align with their own personal and social identities (in-group vs. out-group). These intergroup categorizations are driven by the positive and negative stereotypes one has of particular social groups, the attitudes and communicative behaviors that follow from these perceptions, and the frequency and quality of one's interactions with members of each group. For example, younger adults tend to more comfortably and frequently associate with other younger adults than older adults, and vice versa. As a result, young people naturally consider other young people as part of their in-group and older adults as an out-group. Age-based perceptions of oneself in relation to out-group members are reinforced by sociocultural values, beliefs, and practices concerning the aging process, which, if predominantly negative, engender negative stereotypes of and behaviors toward older (or younger) adults. On the other hand, one's personal experiences with out-group members may be more positive than negative (e.g., within a family, or close friends), which may mitigate or reverse one's stereotypes about the out-group and lead to more appropriate accommodating communicative behaviors. It is important to keep in mind, however, that even positive stereotypes may not always lead to desirable communication behaviors and outcomes since each adult may respond differently to being classified according to a particular positive stereotype (e.g., as a doting grandmother, or an open-minded youth).

Misguided stereotypes can lead to inappropriate communication behaviors toward older or younger adults, which in turn creates barriers to effective intergenerational communication. Ryan and colleagues captured the relationships between stereotypes and their triggering cues, behaviors, and consequences in a communication predicament of aging model. **Figure 1** represents a modified version of the predicament (and enhancement) model, integrating many features from the original model and a few additional elements from similar models. In this figure, communication begins with an encounter between an older and a younger interlocutor. Based on a number of personal and contextual factors that link to aging cues (e.g., the older adult's role as a grandfather and/or a person with dementia, living at home or in a nursing home, demonstrating limited physical and/or communicative behaviors), stereotyped expectations may be activated in the younger adult that classify the older person as being intellectually, functionally, and/or socially impaired, none of which may be true. For example, expected declines in the older adult's memory may lead to anticipated poor recall of persons' names, presumed hearing loss may imply difficulty understanding messages and keeping on topic, and perceptions of closed-mindedness may constrain the selection of conversational partners. These perceptions can lead to overaccommodating behaviors (e.g., simplified grammar and vocabulary, louder and slower speech) or underaccommodating behaviors (e.g., deflecting comments, cutting a conversation short, avoiding communication with the person), which position the person as incompetent or incapable of engaging in meaningful communication. The older individual who is the target of such behaviors may infer that he or she is on the decline and, consequently, experience loss of self-esteem and personal control and have less desire for social interaction. These reactions may, in turn, reinforce stereotypes held about and by older adults and perpetuate over- or underaccommodating communication behaviors in subsequent encounters. In a similar negative feedback loop, older adult stereotypes of younger adults as being irresponsible and naive and lacking communication skills may lead to disapproving comments and/or dominating the conversation. Younger adults' reactions to such inappropriate accommodating behaviors may include inattentiveness, withdrawal from the conversation, loss of self-esteem, reluctance to seek out future encounters with older adults, and reinforcement of age-based stereotypes.

In response to the negative feedback loop of the predicament model, Ryan and colleagues introduced a communication enhancement model of aging. In this model, depicted in **Figure 1** by the enhancement loop, the person interacting with a younger or older adult views him or her as an individual rather than as a member of a stereotyped social category, having

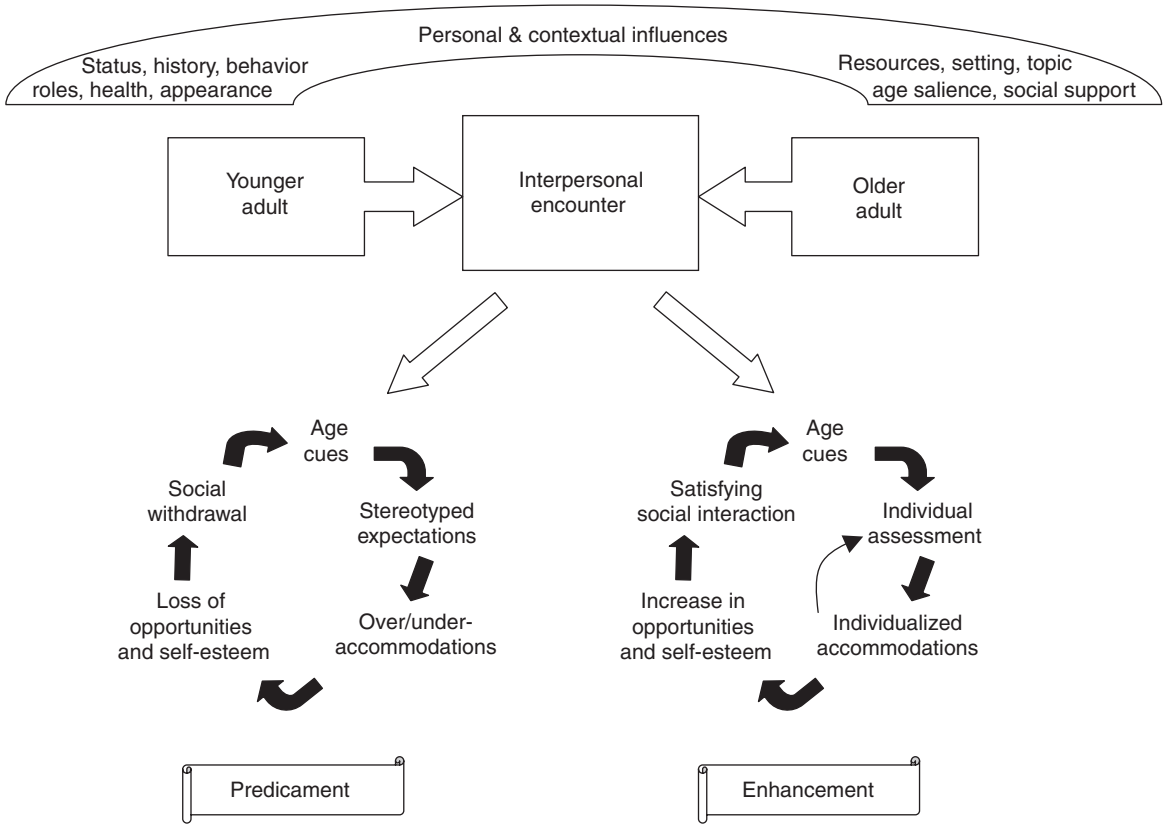

Figure 1 Predicament and enhancement models of intergenerational communication. Adapted, with significant modifications, from Ryan EB, Meredith SD, MacLean MJ, and Orange JB (1995) Changing the way we talk with elders: promoting health using the communication enhancement model. *International Journal of Aging and Human Development* 41(2): 89–107, with permission.

strengths and preferences as well as limitations and needs. The interlocutor actively listens and observes rather than making preconceived judgments. Both verbal and non-verbal behaviors are assessed and reassessed to determine what communication accommodations are appropriate and effective for that individual. The interlocutor elicits and takes into account personal and contextual factors that either support or undermine the individual's value as a human being and his or her opportunities for engaging in meaningful social interaction. For example, if an older adult is perceived to have communication difficulties, the interlocutor could caringly explore the nature and source of these in relation to retained abilities, seek input from family members, and/or find out what strategies or resources are available to facilitate the individual's participation in communication. Should a younger adult be perceived by an older adult as having a naive perspective on a topic, the older adult could encourage the younger adult to share his or her personal experiences related to the topic. In showing such an interest, the older adult may find that his or her own experiences may be solicited by the younger adult. As a result of such individualized assessments, accommodations, and reassessments, older and younger adults are more likely to perceive themselves as competent communication partners, leading to an increase in their self-esteem and a desire for further communication. The positive feedback loop thus ends and begins again with the individual's self image and value reinforced and the communication partners experiencing satisfaction with the encounter.

Cross-Cultural Comparisons of Intergenerational Speech Styles

Much of the research on speech styles has been based on perceptions of intergenerational interactions in North American and European societies. Recently, however, more cross-cultural studies of intergenerational speech styles have been conducted. Comparisons of Western (Australia, Canada, New Zealand, United States) and Eastern (China, Hong Kong, Japan, Korea, Philippines, Thailand) nations have led the way, in part because of predicted East–West differences in the importance placed on interdependence in the family and the degree of respect and honor paid to older adults. Such differences were

expected to yield more positive stereotypes of aging and limited use of elderspeak in societies that have a history of holding stronger views of filial support.

Findings from this research indicated that, contrary to expectations, younger people in East Asian societies viewed communication with non-family older adults as more effortful and problematic and viewed older adults as less accommodating than did younger adults in Western societies. They also reported having fewer positive stereotypes of aging compared to their Western counterparts. At the same time, younger adults in Eastern countries seemed to endorse filial piety. The apparent contradiction in responses can be accounted for by these adults' coexisting private (more autonomous and negative) and public (more collective and positive) views of aging. Research findings also indicated that there may be as much variability across different Eastern nations as there is between the East and West. For example, Japanese young adults showed more positive perceptions of aging than did their Western counterparts. Thus, investigations attempting to examine intergenerational communication through a cultural lens would be wise to take into account social and contextual factors that produce intracultural and intra-individual variability in communication patterns.

Further research is warranted to explore inter- and intracultural variability and how privately voiced stereotypes in different countries play out in public intergenerational interactions. In addition, while comparisons of the East and West are a good start, there is a need for research in other countries and with other cultural groups. Finally, because many interpersonal interactions in Western elder care settings are between staff and residents who do not share linguistic and cultural backgrounds, research is needed that addresses the nature of communication and use of speech accommodations in intergenerational and intercultural interactions (*see* Comparative and Cross-Cultural Studies; Cultural and Ethnic Influences on Aging).

Promoting Positive Communication between Younger and Older Adults

A logical point of intervention for enhancing communication across the life span would target the recognition of and reaction to age-based cues (see **Figure 1**). It is here that attitudes and choices are manifested in either stereotype-based accommodations or individualized accommodations. Since stereotype-based speech accommodations may be employed unconsciously and without malicious intent, the first step in curbing their use would be to raise a person's awareness of what under- and over-accommodations are, why they are employed, and their potentially deleterious consequences on communication outcomes. Nurturing such an awareness will require directing attention to the power and subtlety of stereotypes and ageism as these surface in many forms and contexts in people's lives. In addition, younger and older adults need to acknowledge and respect the legitimacy of their interlocutor's conversational goals and strategies for reaching those goals. Enhancing intergenerational communication will thus require, as noted by Ryan and colleagues, that younger and older people (1) strive for a balance between respect and accommodation by maintaining high expectations for communication of respect, combined with measured assertiveness that guides the conversational partner in selecting appropriate speech accommodations, and (2) promote contexts for interaction that allow time for such adjustments and reward communication successes.

In order to promote positive perceptions of aging through intergenerational interactions it is of course necessary that opportunities for intergenerational contact and communication be available and encouraged. Unfortunately, such opportunities have diminished as a result of greater personal mobility in many societies and the consequent geographic dispersion and institutional segregation in communities and families. To reverse this trend, it will be essential that all sectors of society reconsider the importance and benefits of life span communication and think of creative ways to facilitate younger and older adults coming together for meaningful positive communication. A couple of exemplary efforts in this regard have been older adults from community senior groups visiting and/or helping children in schools and school-aged children visiting seniors in their residences. Through efforts like these, and vigorous advocacy from an increasing older adult population, new opportunities for communication by and with older adults can be realized.

Stress: Physiological

D A Jurivich and X Zhou, University of Illinois, Chicago, IL, USA

Glossary

Heat Shock – Exposure of cells or organisms to elevated temperatures, usually 4–5°C above basal or core temperatures.

Heat Shock Genes – A class of genes preferentially expressed during cellular stress. Classes of heat shock genes are designated by the size (molecular weight) of the proteins that they encode.

Heat Shock Proteins (HSPs) – A collection of proteins also known as molecular chaperones that have multiple and vital functions. These functions include shuttling proteins from within and without the cell, disaggregating damaged proteins, tagging proteins for degradation, protecting newly synthesized polypeptides, folding new and old proteins, enhancing enzymatic activity during stress, and acting as molecular brakes for transcription (e.g., glucocorticoid receptor).

Physiological Stress – Any condition, including perturbations in heat, that creates an unfavorable environment for survival of cells, organs, or organisms.

Introduction

Age can be characterized as a period of declining responses to physiological stress. Conversely, new studies suggest that longevity is linked to a robust response to physiological stress at the cellular and molecular level. Thus, a key question is how age affects cellular stress responses and what measures can prevent its decline.

Under duress, cell and tissue survival depends not only on the severity and type of stress but also on the cellular reaction. Physiological stress occurs with perturbations in the ambient environment such as temperature fluxes or oxygen deprivation. Physiological stress also occurs when cells or organs experience homeostatic perturbations involving nutrient deprivation, osmotic shock, radiant energy, infection, and inflammation. Obviously, extreme environmental conditions limit survival, but fortunately numerous adaptive responses to physiological stress increase the chance of weathering aberrant conditions until they subside. Furthermore, chronic physiological stress may evoke a long-term adaptive process called tolerance. Understanding reactions to stress likely holds the key to solving many acute and chronic conditions afflicting the elderly such as hypoxic heart injury, oxidative brain injury and nephrotoxicity. The fact that stress responses can be pharmacologically manipulated with medications and plant medicinals offers further hope that better

neuro- and cardioprotection can be achieved as one strategy to prevent functional declines with age. With this in mind, an overview is provided here of what is known about the cellular stress response and how age changes fundamental adaptive processes.

Molecular Responses to Stress

The cellular stress response was first dubbed the heat shock response. At least four decades ago, work with fruit flies revealed that transient heat exposure elicited a unique pattern of chromosomal puffing. Later, heat-induced changes in chromosomal structure were associated with increased expression of a class of genes called heat shock genes. Dispersed among several chromosomes as multiple family members, these genes contribute to cellular vitality under normal conditions as well as during stress. Even though initial observations were made in fruit flies, heat shock genes are conserved in all living organisms. Given the importance of these genes, two key issues have been how heat shock gene expression is regulated and how the heat shock proteins function. We now know that the so-called heat shock response is really a subset of a more comprehensive cellular stress response. Specific responses occur during ultraviolet light exposure, oxidant injury, DNA damage, and glucose deprivation. Some of these responses overlap with the heat shock response, and others appear unique. **Table 1** lists many known inducers of the cellular stress response. An intriguing aspect of this list is how so many divergent factors trigger a common cellular response. The net result is enhanced cellular protection from otherwise lethal conditions. Curiously, one stressor can lead to cellular protection from other stressors. For example, heavy metal exposure will result in a response that confers protection from heat. Both these stressors induce protein damage, which signals the cell to shut down usual transcriptional and translational activities and to switch toward expression of heat shock and other stress proteins.

Table 1 Categories of environmental problems and examples of inducers of the heat shock response or its equivalent

Ambient energy	
Heat	
Ultraviolet light	
Toxins and metal accumulation	
Heavy metals	Herbamycin A
Ethanol	Sodium azide
Hemin (iron)	Dinitrophenol
Nicotine	
Lipid perturbations	
Arachidonate	
Synthetic prostaglandins	
Sphingosine	
Protein damage	
Nutrient deprivation	
Hypoglycemia	
Hypocalcemia	
Amino acid analogs	
Pharmacological agents	
Sodium salicylate	
Indometacin	
Alkylating agents	
Pathogens	
Viruses: adenovirus, herpes, influenza	
Bacteria: actinobacillus	

To trigger the cellular stress response, specific DNA-binding proteins or transcription factors are activated. Current evidence suggests that two-thirds or more of heat-inducible genes require activation of an intracellular protein called the heat shock factor (HSF1). Once HSF1 associates with the promoter region of a stress gene, it bends DNA in collaboration with other transcription factors so as to heighten RNA polymerase activity. Consequently, higher levels of messenger RNA (mRNA) encoded by the stress genes are produced and ribosomes preferentially translate these stress mRNAs into stress proteins.

Stress proteins serve multiple functions and historically have been referred to as heat shock proteins (HSPs). These proteins are classified according to their size or molecular mass. Broadly, HSPs are composed of high-, middle-, and low-molecular-mass species, the most common of which is the heat shock protein 70 (hsp70) (molecular mass = 70 kDa). Most HSPs exist under normal conditions, and their levels increase during stress.

HSPs have multiple functions during normal conditions that assume greater importance during stress. One of the functions of cellular stress or HSP is a chaperoning function whereby other proteins are shuttled from one cellular compartment to another. Stress proteins earmark damaged proteins for degradation. They help disaggregate and possibly even refold damaged proteins. Stress proteins protect newly synthesized proteins and help them fold into a functional form. Certain enzymatic activities may be protected or enhanced by stress proteins during aberrant conditions, and in some instances the stress proteins will function as molecular brakes for gene expression.

One of the key features of the cellular stress response is that it is a paradigm of inducible gene expression, thus offering a fairly well understood system for examining the question of whether age affects transcriptional controls. Pivotal to induction of the cellular stress response is the heat shock transcription factor. Several HSFs have been isolated in various species, but HSF1 appears to be the primary

mediator of heat shock gene expression. **Figure 1** depicts a model of how HSF1 functions in human and many eukaryotic cells. Basically, HSF1 exists in the cytoplasm and nucleus of cells as a horseshoe-shaped molecule folded upon itself. Through signals induced by stress, cytoplasmic HSF1 translocates to the nucleus, possibly facilitated by HSP. HSF1 unfolds and associates with other molecules of HSF1 to form a trimeric structure capable of binding DNA. The activated HSF1 trimer binds to specific DNA sequences called heat shock elements located in the promoter region of heat shock and other genes. The heat shock elements are composed of repetitive nucleotide sequences guanine, adenosine, and adenosine (GAA). Interactions between HSF1 and the GAA sequences in the promoter region of the heat shock genes appear to be sufficient to fully increase heat shock gene expression, although other co-factors and protein–protein interactions fine-tune gene expression. HSF1 phosphorylation and HSF1–protein–DNA complexes further affect RNA polymerase processivity and the rate of mRNA production (*see* DNA and Gene Expression).

Despite continuous stress, HSF1–DNA binding attenuates. This is an important observation because how HSF1 falls off the promoter is likely to provide clues as to how age prevents its initial binding to DNA. How HSF1 resumes its inactive form is not clear, but phosphorylation and disassembly by HSPs are touted as two potential means of deactivating HSF1. A putative inhibitor to HSF1–DNA binding may play a role in regulating stress responses, and overactivity of this inhibitor could be a clear mechanism for age to alter the stress response. HSF1 levels do not increase during stress, so this relatively long-lived transcription factor appears to be regulated by post-translational controls. After recovery from an initial stress, HSF1 is less sensitive to reactivation by further stress. This change in HSF1 sensitivity to stressful stimuli has important implications for the aging process. For instance, prolonged exposure to stress, such as when neuronal cells are chronically exposed to neurotoxic amyloid, could very well diminish future cellular stress responses.

Age-Dependent Changes in the Stress Response

Several models of senescence demonstrate that heat shock gene expression is altered with time (see **Table 2**). One of the original observations concerning the cellular stress response was by A. Y.-C. Liu, who found that late-passage, fetal lung-derived fibroblasts (IMR-90) did not express HSP in response to a 42°C heat shock, whereas early passage cells did. Both the

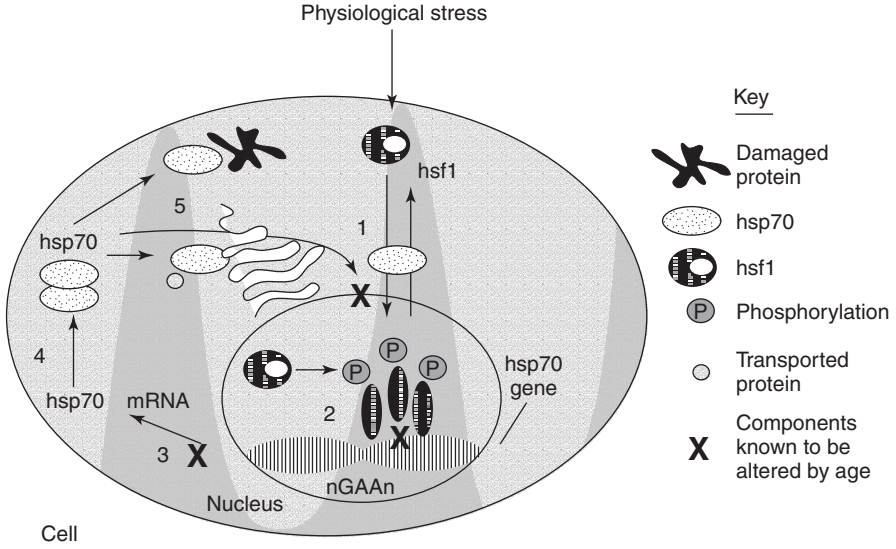

Figure 1 A model of the cellular regulation of the human stress response. Numbers correspond to the various transcriptional and translational steps necessary for induction of the stress response. (1) HSF1 under homeostatic conditions is folded upon itself in the cytoplasm and nucleus. Environmental stress triggers its unfolding, and HSF1 accumulates in the nucleus as a homotrimeric complex that binds to *cis*-acting elements in the promoter region of heat shock and other 'stress genes.' (2) During the course of acquiring DNA binding potential, hsf1 becomes increasingly phosphorylated and drives RNA polymerase II activity to a higher level. (3) Single exon mRNA for heat shock genes such as the hsp70 gene accumulate and are preferentially expressed by the translational apparatus. (4) Heat shock protein levels increase, and the dimeric form of hsp70 dissociates and forms complexes with other proteins. (5) Hsp70 and other molecular chaperones serve multiple functions, including protection of newly synthesized proteins, disaggregation of damaged proteins, protection of essential enzymes, and regulation of specific transcription factors.

Table 2 Representative studies that examined age-dependent changes in heat shock gene expression

Model of senescence	*Type of stress*	*Old versus young response*
Human peripheral blood mononuclear cells (Kishimoto)	42°C heat shock	~30% reduction of maximal hsp70 transcription rate relative to young donor cells
Human diploid fibroblasts IMR-90 (Liu)	42°C heat shock	~30% reduction in levels of hsp70 mRNA in late passage cells
Aged rats (Holbrook)	Whole animal exposure to 40°C	Core body temperature of aged animals is lower than young animals. 60–75% reduction in hsp70 mRNA levels in old rat brain, lung, and skin. No changes noted in whole liver
Rat hepatocytes (Richardson)	42.5°C heat shock	40% reduction in hsp70 mRNA levels in old donor hepatocyes

early- and late-passage cells expressed the same class of HSP after heat shock, but cells of population doubling level (PDL) 51 produced significantly less HSP than PDL 18 cells when incorporation of ^{35}S-methionine into newly synthesized proteins was analyzed by autoradiography of proteins separated by SDS-polyacrylamide gel electrophoresis. Both the initial rate of synthesis and the absolute amounts of many HSPs were reduced in the late-passage cells when compared to the early-passage cells during heat shock. Basal levels of HSPs at 37°C did not change with serial passage of the IMR-90 cells, thus emphasizing the loss of inducible gene expression as cells become senescent. Similar results were found with serial passage of other human diploid cell lines such as TIG-1.

Both Northern blot and nuclear run-off analysis confirmed that the decreased induction of HSP in late-passage cells is due to a transcriptional problem. Because late-passage cells maintain constitutive gene expression such as the β-actin gene, age does not cause a general perturbation in the RNA polymerase activity over time. Rather, age disrupts signaling of heat shock gene expression.

Age-induced attenuation of heat shock gene expression in senescent fibroblasts is attributed to decreased levels of HSF1–DNA binding activity. Either a negative regulator of HSF1 or post-translational modifications that prevent DNA binding appear to be the prime considerations for loss of HSF1–DNA binding with age. 'Mixing' experiments in which extracts from late-passage cells are added to extracts from early-passage cells produce inconclusive results. Most of these experiments do not suggest the presence of a dominant negative inhibitor of DNA binding produced by senescent cells. However, alternative results have been obtained in rat hepatocytes, and serial fractionation of cellular extracts from old animals produce at least two types of inhibitors to HSF1–DNA binding.

An intriguing issue has been whether other members of the HSF family somehow interfere with heat-inducible HSF1 with age. This hypothesis has been tested, and HSF1 was not found to be associated with other family members of HSF1, thus suggesting that unique protein factors or lipid regulators interact with HSF1 and attenuate its DNA-binding capacity.

The relationship of the cell cycle to stress induction of HSF1 may have some relevance to aging. Serum-starved or quiescent cells lack HSF1–DNA binding activity after being stressed by factors other than heat. Thus, the mechanism by which late-passage fibroblasts lose heat-inducible HSF1–DNA binding activity is subject to continued investigation.

Even though an altered heat shock response has been identified in senescent fibroblasts, a primary concern is whether other models of aging exhibit a similar perturbation. Overall, the consensus is that age does indeed attenuate all or some of the heat-inducible responses, especially in humans. The reason for variation in the observations is that different cell types and different conditions are analyzed. For example, Zurivich and Zhou found that proliferating human T cells have a much more robust heat shock response than quiescent T cells. Part of the reason is that transformation of T lymphocytes into T lymphoblasts increases HSF1 levels, thus age-dependent differences between T lymphocytes and lymphoblasts are greater in the former than in the latter. Likewise, quiescent B cells have little to no HSF1, thus making it impossible to replicate observations in T cells. Thus, even within one organ system, e.g., the immune system, significant variation in the stress response needs to be understood before criticizing the literature for divergent results on the aging stress response. Much of our understanding of how age affects the stress response comes from rodent studies. The laboratories of N. Holbrook and A. Richardson each have shown how restraint stress and *in vitro* rodent cell cultures are impacted by age and stress. Growing fibroblasts isolated from young and aged donor rats have comparable levels of thermal-inducible heat shock gene expression; however, when cells became confluent, little to no hsp70 gene expression occurred in old donor fibroblasts. After the examination of more than 20 individual animal cultures, it was concluded that age led to approximately a 50%

decline in hsp70 mRNA levels after heat shock. This decline in hsp70 mRNA levels appeared to occur in both skin and lung fibroblasts, with the largest age-dependent difference in hsp70 mRNA levels manifested in skin fibroblasts. Whole tissue analysis of inducible hsp70 mRNA levels showed results similar to cultured cells. Importantly, no age-dependent decline in β-actin mRNA was found, thus confirming that quantitative decreases in hsp70 mRNA after stress are specific and not general age-related problems with RNA polymerase activity.

In contrast to human cells, rodent mRNA for the high- and low-molecular-weight HSPs did not show an age-dependent decrease in their expression after heat shock. The reason for this discrepancy is not clear. Differences in culture conditions and the fact that the aged donor rodent fibroblasts retain their proliferative potential, whereas the late-passage human fibroblasts do not, suggest that the growth state of cells intersects with the aging process. The fact that the vast majority of tissue exists in a postmitotic state also suggests that age-dependent changes in gene expression during stress are likely to be most apparent in non-regenerative organs.

An interesting result of whole animal studies and physiological stress is that physical restraint of male Wistar rats induces a neurohormonal stress response, resulting in elevated heat shock gene expression. Although there may be strain-specific variations in this response, age causes nearly a 75% reduction of inducible mRNA levels in adrenal tissue of restrained rats. The induction of hsp70 mRNA seems to be linked to ACTH because hypophysectomized animals did not exhibit increased hsp70 mRNA levels after restraint. Paradoxically, cultured adrenal cells do not exhibit a stress response when exposed to various concentrations of ACTH, thus other circulating factors may be involved. Alternatively, neurohormonal stress may sensitize the adrenal glands to hypoxic damage, which in turn activates the stress response. This paradox represents one of the difficulties in correlating *in vivo* findings with observations from tissue culture experiments. Nevertheless, induction of the heat shock response in restrained Wistar rats is an encouraging observation regarding the biological relevance of heat shock gene expression. Additional experiments on exercising rodents show that vigorous physical activity increases the heat shock response in muscle tissue. Consistent with many similar studies, aging attenuates the myocyte stress response in both muscle and heart.

Heat is not the only regulator of HSF1 and the stress response. In addressing the issue of whether HSF1–DNA binding can be triggered by physiologically relevant elevations in temperature (39–40°C), it was found that exposure of cells to inflammatory modulators such as arachidonate can activate HSF1–DNA binding at temperatures that normally do not do so. Furthermore, HSF1–DNA binding can be detected in the peripheral blood mononuclear cells from a febrile human donor. Activation of HSF1 by 42°C in cultured cells appears to be recapitulated by febrile temperatures *in vivo* and thus reinforces the link between *in vitro* research models and actual human responses to heat.

Mechanistically, loss of heat shock gene expression during senescence is multifactorial. Because the expression of many other genes such as β-actin does not appear to be affected by senescence, altered heat shock gene expression results from age-dependent changes in the signaling of the stress response. A putative candidate in the signaling cascade is HSF itself. Most studies to date indicate that aging is accompanied by a diminution in HSF–DNA binding activity. The lower levels of HSF–DNA binding activity have been documented in gel shift assays that utilize a short synthetic piece of DNA. To date, no one has directly proven loss of HSF1–DNA binding with age in intact cells, but *in situ* studies show loss of intranuclear HSF1 with age and provide the best evidence that cell culture results recapitulate actual aging processes. Perhaps the biggest ongoing controversy is whether diminished HSF–DNA binding with age is due to an inhibitor. This inhibitor is proposed by some investigators who found that extracts from old donor or senescent cells partially block HSF–DNA binding in extracts from young donor cells. Others have not found an inhibitor in these mixing experiments, but this is not surprising since known inhibitors of other transcription factors are not always revealed by this method. Shamovsky and Gershon have found three novel factors that regulate HSF1: an HSF1 inhibitor, elongation factor 1 alpha, and a large non-coding RNA. The HSF1 inhibitor blocks HSF1 trimerization, whereas the other two factors promote HSF1 activation. An increase in activity of the former and/or decreased activity of the latter is thought to account for age-dependent loss of HSF1–DNA binding in aging rats. Jurivich and Zhou have found that extracts from old donor human T cells that exhibit low levels of HSF1–DNA binding also have the capacity to block HSF1 trimerization *in vitro*.

In addition to HSF1 co-factors, post-translational modifications of HSF1 during senescence may render it less capable of binding to DNA. In yeast, phosphorylation of a specific amino acid residue will attenuate HSF–DNA binding, thus the possibility exists that age-dependent modifications of HSF1 alter its capacity to bind to the promoter region of the

heat shock genes. Stress-induced transient modification of HSF1 by one or more protein kinases has been observed in cultured cells. The purpose of HSF1 phosphorylation is generally thought to be to enhance expression of heat shock genes. A handful of stress-inducible kinases have been identified, and at least one of these was found to have a lower activity in senescent cells during heat shock.

Although age-dependent perturbations in the regulation of HSF1 are likely to account for changes in heat shock gene expression, other possibilities may disrupt inducible gene expression. Protein–protein interactions in the promoter region of the heat shock genes may be altered during senescence, and proteins constitutively bound to the heat shock promoter may be modified in a fashion that does not fully support transactivation of the genes. Consistent with these possibilities, one of the proximal heat shock promoter proteins (Sp1) declines in its DNA binding with age. Furthermore, mitogen activation of heat shock gene expression is reduced in elderly donor peripheral blood lymphocytes. Because the proximal promoter controls growth-mediated heat shock gene expression, it can be inferred that control of the proximal heat shock promoter is affected by age.

As investigators seek the mechanism for altered heat shock gene expression during senescence, it is important to ask whether there is a functional consequence of age-dependent changes in this response. One question is whether altered gene expression leads to changes in the basal or inducible levels of one or more HSPs. Thus far, both the human senescent fibroblast model and rodent models of aging reveal that HSP levels are not affected by age in the non-stressed state. Experiments consistently show that inducible hsp70 levels are diminished with age. The affect on other HSPs is less clear-cut, and in one instance there appeared to be an increase in the number of HSPs in old fruit flies. Nevertheless, changes in levels of hsp70 or other HSPs could alter the sensitivity of aged donor cells to injury and death. Research has found that growing primary fibroblasts and lymphocytes from aged donors exhibit a greater sensitivity to heat-induced cellular death when compared to cells from young donors. The growth state of the cell clearly impacts its sensitivity to stress. Growing cells, especially those in the mitotic or DNA synthesis phase of the cell cycle, are most sensitive to stress-induced injury and death. Quiescent cells show a resistance to stress-induced cellular death, and factors other than HSPs may mediate this cytoprotection. Some investigators cite HSP phosphorylation as a means to confer cytoprotection rather than HSP accumulation. The idea that increased levels of HSPs contribute to cytoprotection comes from experiments in which HSPs are overexpressed in a cell line after transfection with a HSP-containing plasmid. The cell line then becomes resistant to cell death induced by extreme heat or cytokines such as tumor necrosis factor. Based upon these studies, a potential goal in clinical gerontology would be to enhance the human heat shock response.

Manipulation of the heat shock response during senescence has several possibilities. Pharmacological stimulation of the heat shock response appears to have the most promise. Non-steroidal anti-inflammatory drugs (NSAIDs) affect the key modulator of the heat shock response, HSF1. Treatment of cells with salicylate and other NSAIDs lowers the temperature set point for activating this transcription factor by heat. Thus, NSAID-treated cells respond to heat stress much more vigorously than untreated cells. The net result is that pretreatment of cultured epithelial cell lines enhances their resistance to thermal stress. Similar to NSAIDs, a select number of plant medicinals and other standard medications enhances transcription factor activation responsible for the heat shock response. These observations give promise to reconstitution of the cellular stress response in the elderly. To do so, we can expect organ protection against chronic and acute conditions such as neuroprotection in face of Alzheimer's dementia and possibly myocardial protection during ischemic events.

Recent studies implicate the heat shock response in longevity. For example, caloric restriction prolongs life and prevents the age-related decline in the induction of hsp70 expression. Human centenarians do not manifest the 50% decline with age in HSF1 activation, and they maintain a robust induction of hsp70 during stress. Remarkably, genetic manipulation of HSF1 in nematodes confers even longer life spans in this short-lived species. Further understanding of the heat shock response during senescence has the potential to lead to improved cellular function with age and ultimately extend an active life span.

Conclusions

Aging alters the molecular response to physiological stress. The diminished induction of hsp70 gene expression during senescence primarily results from perturbations in triggering the heat shock transcription factor. Both the proximal and distal promoter of the hsp70 gene are affected by age. The functional consequence of altered heat shock gene expression during aging includes accumulation of damaged protein and cell death. The fact that baseline HSP gene expression increases with senescence suggests that age is a low-grade inflammatory and stressed state. Prolonged accumulation of damaged proteins may

act as endogenous toxins such as with amyloid. Accumulated damage in cells under low-grade stress further attenuates the inducible heat shock response. Thus, age results in maladaptive stress responses that further decrease the chances of cellular survival in aged donor organs.

Loss of cellular stress responses with age may have an evolutionary twist. Aberrant cellular stress responses with age may be a genetic means of heightening cellular or whole organism death due to environmental stress, thus assuring a continuous turnover of a population. Curiously, long-lived strains of nematodes and yeast have higher levels of HSPs than the wild-type strains, thus suggesting a critical link between longevity and stress proteins.

Finally, a recent observation that HSPs reverse prion protein malformations in yeast suggests that clinical strategies to upregulate HSP in the human population could be a valuable adjunct to treat neurodegenerative disorders associated with age. Additional knowledge of basic molecular responses to physiological stress potentially could lead to new clinical interventions that would help reverse age-dependent decrements in cytoprotection (*see* Cellular Aging: Growth Factors and Cellular Senescence).

Stroke

P B Gorelick, V Shanmugam and A K Pajeau, Rush Medical College, Chicago, IL, USA

Glossary

Antiplatelet Agents – Medications such as aspirin and ticlopidine that reduce stroke risk by preventing platelets from clumping or aggregating.

Carotid Endarterectomy – A surgical procedure to reduce stroke risk by removal of atherosclerotic blockage in the carotid artery.

Risk Factors – Antecedent physiologic (genetic), lifestyle, or dietary factors that increase the likelihood of developing a disease.

Stroke – The sudden or subacute onset of neurologic deficit caused by occlusion or rupture of a cerebral artery.

Stroke Subtypes – Specific pathophysiologic mechanisms that underline cerebral ischemia or hemorrhage.

Vascular Dementia – Dementia caused by stroke.

Introduction

Stroke is the sudden onset of neurologic deficit caused by occlusion or spontaneous rupture of a cerebral artery. Stroke is the third leading cause of death in the United States and ranks as the most common disabling and lethal neurologic disease of adult life. It is estimated that there are 400 000–500 000 new strokes, 3 million stroke survivors, 150 000 deaths attributable to stroke annually in the United States. Furthermore, the direct and indirect health-care costs are estimated to total $30 billion yearly.

Stroke is unique among neurologic diseases as it has a high prevelance and burden of illness, high economic cost, and safe and effective prevention measures. Although stroke may occur at any age, it is most common among the elderly. There is an exponential rise of stroke with age that leads to an approximate doubling of stroke frequency in each successive decade from middle age onward. Thus, the elderly, the most rapidly expanding segment of our society, are most likely to be afflicted by stroke and its disabling complications.

This article will review stroke epidemiology, clasification and pathophysiology, treatment and prevention, and consequences. Topical discussions will emphasize how stroke affects the elderly.

Stroke Epidemiology

Epidemiology is the study of the distribution and determinants (causes) of disease in our population. Epidemiologic study helps answer scientific questions relating to who is most likely to be afflicted by a disease, why the disease has occurred, and if there will be an epidemic of the disease. The distribution of disease refers to its prevalence and incidence. Prevalence is the number of persons with the disease in a defined population at a given point in time. Incidence is the number of new cases of disease that develop in a defined population during a specified period of time. Prevalence alerts us about the magnitude of a disease in our society and aids public health planners in making decisions about allocation of health-care resources for the disease. Incidence is an indicator of risk or who is most likely to develop the disease. Finally, disease determinants or risk factors are antecedent physiological, dietary, or lifestyle habits that increase the likelihood of developing a disease. The presence of a risk factor increases the probability of disease. However, not every person with the risk factor will develop the disease, nor will the absence of the risk factor ensure absence of the disease. As a group, the elderly are unique as they often have multiple stroke risk factors (*see* Epidemiology).

Mortality

Stroke death rates have shown a steady decline in the United States since the early 1900s with about a 1% per year decline. In the late 1960s and early 1970s death rates from stroke began to fall by 5–7% per year, and the greatest decline has been in the older age groups. However, since 1979 the annual rate of decline of stroke mortality began to slow considerably. Overall, stroke death in the United States increases with age, is higher among men than women except in the oldest age group, and is highest among African Americans.

The reason for the accelerated stroke mortality decline in the United States in the early 1970s has been debated. Possible explanations include improved antihypertensive therapy, declining stroke incidence, improved stroke survival, reduction in the severity of stroke, or some other factor. The precise explanation for the deceleration in stroke mortality trends since 1979 remains uncertain, but it parallels decreasing social and economic conditions for many and a leveling off of a national trend for continued improvement in blood pressure control.

Prevalence

In general, stroke prevalence increases exponentially with advancing age. Stroke prevalence is estimated to range between 500 and 600 per 100 000 in the West but is generally higher in the East.

Incidence

Stroke incidence increases with age and approximately doubles in each successive decade. In general, the incidence of stroke is higher in men than women and is substantially higher in US Blacks as compared to Whites. The relative risk of brain infarction is higher among African American women when compared to white women, and African Americans have a higher incidence of brain hemorrhage. **Table 1** demonstrates the exponential rise in annual stroke incidence with age according to the Framingham Study.

Over time (1950–1979) stroke incidence has declined substantially. However, more recently (1979–1984) it has been noted that stroke incidence may be increasing. Among persons with ischemic heart disease, this may be due to increased survival. Further information is needed about the effect of increased detection of stroke by up-to-date neuroimaging techniques, levels of blood pressure of treated and nontreated persons, and treatment of other cardiovascular disease risk factors.

Table 1 Average annual stroke incidence per 1000 persons by age (Framingham Study 36-year follow-up)

Age[a]	*Atherothrombotic brain infarction*		*Stroke (all types)*	
	Men	*Women*	*Men*	*Women*
45–54	0.8	0.7	2.2	1.2
55–64	2.1	1.2	4.5	2.8
65–74	4.3	3.7	9.3	8.0
75–84	8.5	6.8	19.2	15.0

7. Asymptomatic carotid stenosis
8. Transient ischemic attack

[a] Treatment feasible but benefit for stroke prevention as yet not established.
[b] Classified as less well-documented risk factor for stroke.

Risk Factors

There is a substantial body of epidemiologic knowledge about stroke risk factors. Such factors may be classified as modifiable and non-modifiable and well-documented and less well-documented. The following discussion will emphasize major host risk factors that are well established and potentially modifiable. These factors are listed in **Table 2**. Previously mentioned non-modifiable risk factors such as race, sex, and age will not be reviewed.

Hypertension Hypertension is considered to be the most important treatable risk factor for stroke. The risk of stroke rises with increasing blood pressure, and the relative risk of stroke among hypertensives is about three to four times greater than non-hypertensives. Systolic, diastolic, or combined systolic and diastolic hypertension confer substantial stroke risk.

The prevalence of hypertension increases with age. In the Framingham study, 38.2% of those 50–59 years had hypertension, whereas 71.6% of those 80–89 years were hypertensive. Although hypertension remained an important risk factor for stroke, there was a decline in its estimated relative risk and the number of strokes attributable to it with advancing age. Isolated systolic hypertension is highly prevalent with advancing age, and there is at least a twofold increased risk of brain infarction among those 65–84 years with systolic pressures greater than 160 mmHg and diastolic pressures consistently below 95 mmHg.

Heart disease Coronary heart disease, left ventricular hypertrophy, congestive heart failure (CHF), and atrial fibrillation are all independent risk factors for brain infarction. The prevalence of these factors also generally increases with advancing age but does not attain the magnitude of prevalence in the elderly as does hypertension. However, the estimated relative risk and number of strokes attributable to atrial fibrillation substantially increases with age such that by age 80–89 years atrial fibrillation may increase stroke risk by 4.5 times and account for almost 24% of strokes (*see* Cardiovascular System).

Diabetes mellitus Diabetes mellitus is an independent risk factor for brain infarction. According to the Framingham study the relative impact of diabetes may be greater in women than in men, and its impact on the risk of brain infarction does not diminish with advancing age. Rigorous treatment of diabetes retards some vascular complications but has not been proved conclusively to prevent stroke.

Cigarette smoking Stroke risk increases in a stepwise manner with the number of cigarettes smoked. With cessation of cigarette smoking, stroke risk may reverse after 2–5 years. Cigarette smoking is less prevalent in the elderly, and its impact as a risk factor in the aged may be less obvious. This was the case for men in the Framingham study. However, women aged 65–94 years continued to have a substantial effect from cigarette smoking relative to those 35–64 years.

Alcohol consumption Epidemiologic study suggests that moderate alcohol consumption reduces the risk of brain infarction. Whereas abstention or infrequent alcohol use may increase risk slightly, heavy consumption may increase risk substantially. For brain hemorrhage it seems that the risk of stroke increases directly with the number of daily drinks. The risk of

brain hemorrhage may reverse with reduction in heavy alcohol consumption.

There is a paucity of information about the role of alcohol consumption as a risk factor for stroke in the elderly. It is likely that this factor makes a much smaller relative and absolute contribution toward stroke occurrence in the elderly compared to, for example, hypertension and atrial fibrillation (*see* Alcohol and Drugs).

Hyperlipidemia There is mounting evidence to link blood lipids to risk for brain infarction. Further study will be required to clarify this relationship. Hypercholesterolemia is an important modifiable risk factor for coronary heart disease. However, lower levels of serum cholesterol are associated with an increased risk of brain hemorrhage. The effect of blood lipids on stroke risk may be less substantial in the very old.

Asymptomatic carotid atherosclerosis With advancing age there are degenerative cerebral vessel wall changes termed atherosclerosis. These atherosclerotic deposits or plaques cause the larger cerebral arteries to narrow and may compromise blood flow to the brain. With increasing severity of atherosclerosis in the carotid artery, there is an associated increased risk for stroke and heart attack, and death due to stroke, heart disease, or other vascular cause. Recently, it has been shown that removal of high-grade carotid atherosclerotic plaque by a surgical procedure called carotid endarterectomy may reduce the risk of stroke and death in patients who have had no prior stroke symptoms (*see* Atherosclerosis).

Transient ischemic attack Transient ischemic attack (TIA) is a transient focal neurologic deficit lasting less than 24 hours that is referable to diminished perfusion to a focal area of the brain. It is estimated that the 5-year risk of stroke following TIA is about 33%. Most strokes occur within the first year of TIA with up to 21% in the first month, one-half within 3 months, and two-thirds within 6 months. The occurrence of TIA increases with advancing age.

Storke Classification Pathophysiology

Stroke is not a homogeneous disorder. Rather, it is a group of syndromes with definable subtypes and distinct pathophysiology. The discovery and recognition of stroke subtypes has been one of the leading advances in stroke research. The classification scheme for major stroke subtypes is listed in **Table 3**. The following discussion will review the pathophysiology of individual stroke research. The classification scheme for major stroke subtypes is listed in **Table 3**. The following discussion will review the pathophysiology of individual stroke subtypes. One must keep in mind that stroke-related terms such as TIA, reversible ischemic neurologic deficit (RIND) (partial neurologic deficit that lasts more than 24 hours but resolves completely or almost completely within several days), and completed stroke (focal stroke deficit that comes on abruptly, stabilizes, and does not progress) provide information about the time course of stroke and the extent of the neurologic deficit, but little information about the way in which cerebral blood vessels have become affected. More specific terms that indicate the pathophysiologic mechanism are preferred (see **Table 3**).

Table 3 Classification of stroke by pathophysiologic mechanism

Ischemia
Atherothrombotic brain infarction (cerebral thrombosis)
Lacunar brain infarction
Cerebral embolic brain infarction
Cardiogenic
Artery-to-artery
Infarct of undetermined cause
Non-atherosclerotic brain infarction
Hemorrhage
Subarachnoid hemorrhage
Intraparenchymal hemorrhage
Non-atherosclerotic brain hemorrhage

Stroke may be broadly divided into ischemic and hemorrhagic pathophysiologic subtypes. Ischemic stroke occurs when there is blockage of a cerebral artery by in situ clot (thrombus) or embolism (clot from an artery or the heart, or fragments of the atherosclerotic vessel wall that travel distally to occlude the artery). Brain hemorrhage occurs when a major cerebral vessel ruptures and blood leaks into the brain tissue or surrounding areas. With both ischemic and hemorrhagic stroke, the brain is deprived of blood that carries needed nutrients such as glucose and oxygen. Neurologic deficits such as weakness (hemiparesis), sensory signs and symptoms, visual loss, speech impairment, and language dysfunction (aphasia) may occur. Of the two major stroke subtypes, ischemic stroke constitutes about 85% of cases and hemorrhagic stroke about 15%.

Atherothrombotic Brain Infarction

Atherosclerosis is a degenerative vessel wall disease that results in narrowing of major cranial and systemic arteries. The primary pathology is the atherosclerotic plaque. The plaque contains fat deposits, smooth muscle hyperplasia, and other elements that lead to occlusion of the vessel lumen. As cerebral atherosclerosis progresses, signs of cerebral ischemia

(i.e., lack of blood flow) may develop as the narrowed artery thromboses or as embolic debris dislodges and travels downstream. Atherosclerotic plaques have a predilection for major arterial bifurcations and branch points such as the internal carotid artery origin, junction of the vertebral and basilar arteries, and initial segments of the middle and posterior cerebral arteries.

A leading theory proposes that atherosclerosis occurs in the setting of elevated blood cholesterol and hypertension. The blood vessel wall is damaged by hypertension, and this leads to deposition of fat components from the bloodstream and other atherosclerotic changes. Atherosclerotic plaques are common in the elderly and increase with age.

Lacunar Brain Infarction

In contradistinction to atherothrombotic brain infarction, in which large cerebral artery pathology underlies the stroke, lacunes result from occlusion of deep penetrating branches of the larger cerebral arteries. The infarct (small 'lake') may measure only several cubic millimeters. The vascular pathology underlying this syndrome, lipohyalinosis, differs from atherosclerosis. Lipohyalinosis is a degenerative disease in which lipids and hyaline form in the vessel wall to block blood flow. Lacunar infarction may also be caused by microatheroma that obstructs the orifice of a small penetrating artery at its origin from the large parent artery. In addition, lacunes may be caused by microembolism or other arteriopathies.

Lacunar infarction is often encountered in the clinical setting of sustained hypertension. Multiple lacunar infarction may be an important cause of stroke (vascular) dementia in the elderly.

Cerebral Embolism

Cerebral embolism may arise from two major sources: the heart and the arterial blood vessel wall. Certain cardiac conditions such as atrial fibrillation, myocardial infarct, and cardiomyopathy lead to stasis of blood and clot formation in the major heart chambers. A portion of the clot may dislodge and travel into the cerebral or systemic circulation to cause ischemia. Cardiac valve disease (e.g., rheumatic heart disease) can also serve as a source for cardiac embolism. Finally, atherosclerotic debris (fragments of cholesterol, thrombus, and fibrin-platelet material) from the aorta or carotid artery may embolize to cause cerebral ischemia.

Cardiac source embolism is now considered a major cause of cerebral ischemia (causing up to 30% of cases) and has reached this status with modern advances in cardiac diagnostic technology. Non-valvular atrial fibrillation (i.e., atrial fibrillation not related to valvular heart disease) is the most important source of cardiac embolism to the brain and is an important risk factor for stroke in the elderly.

Infarct of Undetermined Cause

Despite advances in stroke diagnostic technology, a disproportionately high percentage of cases cannot be classified as one of the traditional stroke subtypes. Infarct of undetermined cause (IUC) includes both those cases of undetermined cause with extensive stroke diagnostic workup and those with less extensive work-up. This category of stroke may include up to 40% of cases. Some are thought to be caused by a non-atherosclerotic stroke mechanism, and many are probably a form of occult cerebral embolism.

Non-atherosclerotic Brain Infarction

This type of stroke usually occurs when there are underlying systemic disorders that cause stroke by secondary mechanisms. The secondary mechanism may be a systemic illness with associated cerebral arteriopathy, vasculitis, cardiac involvement, or hypercoagulable state. Brain infarction associated with street-drug abuse and consequent cerebral arteriopathy is such an example. Infarction of hemorrhage may occur. These disorders are generally more prevalent in young adults and have less importance in the elderly.

Subarachnoid Hemorrhage

The most common cause of primary subarachnoid hemorrhage (SAH) is ruptured intracranial aneurysm. The usual type of aneurysm is saccular in form and projects as a tiny outpouching or blister-like structure from the cerebral artery. Most saccular aneurysms arise from the carotid artery at the level of the posterior communicating artery, the anterior communicating artery region, or the middle cerebral artery bifurcation. The cerebral territory bound by these blood vessels and some from the vertebrobasilar circulation has been collectively called the circle of Willis.

Clinically, the onset of SAH is abrupt and associated invariably with headache. Blood under arterial pressure ruptures into the subarachnoid space (the protective cerebrospinal fluid-filled space bound by a thin membrane) or adjacent brain tissue and causes neurologic damage. The major cerebral arteries that course through the blood-laden subarachnoid space may develop 'vasospasm' that leads to cerebral infarction.

The incidence of aneurysmal SAH rises with age. However, when compared with ischemic stroke subtypes, there is a disproportionate number of aneurysmal SAH among women and the young.

Intraparenchymal Hemorrhage

Intraparenchymal hemorrhage (IH) arises commonly from deep penetrating cerebral arteries affected by lipohyalinosis, microaneurysm formation, and arteriosclerosis with severe degeneration of medial smooth muscle cells. As blood extravasates from the ruptured artery, neurologic deficit arises as adjacent brain tissue is disrupted, displaced, and compressed. The sites of predilection of IH are similar to those of lacunar infarction as in both cases the deep penetrating arteries are involved. These sites include commonly the putamen, thalamus, pons, and cerebellum.

IH usually occurs in the setting of chronic hypertension. In the elderly it may also occur in association with cerebral amyloid angiopathy (CAA). CAA is characterized by deposits of amyloid in the media and adventia of small and medium-sized cerebral arteries usually located in the superficial layers of the cerebral cortex and leptomeninges. The resultant cerebral hemorrhage is usually located superficially in one of the major brain lobes (so-called lobar hemorrhage). Lobar hemorrhage may also occur with other conditions including hypertension, bleeding disorders, and arteriovenous malformation. CAA increases with advancing age and is associated with histopathologic and clinical features of Alzheimer's disease.

Diagnostic Studies

An elderly patient who has had a brain infarct, TIA, RIND, or brain hemorrhage will undergo a stroke diagnostic workup to define the underlying stroke mechanism. Once the underlying cause of stroke is determined, stroke treatment can be tailored appropriately. There are different levels of diagnostic stroke workup based on the risk associated with the procedure. One usually proceeds in a stepwise manner ordering non-invasive tests before invasive ones. The goal is to avoid higher risk invasive procedures if possible. Before obtaining stroke diagnostic studies in the elderly, one must weigh the following questions: (a) Is the patient's stroke condition so severe that an extensive battery of stroke-diagnostic studies would be contraindicated or would not alter one's treatment plan? (b) Are there comorbid conditions that would contraindicate stroke diagnostic or therapeutic modalities? (c) Are the patient and caregiver aware of and in agreement with the proposed diagnostic and treatment options given the inherent risks and benefits?

The vigorous or well-selected geriatric patients are good candidates for stroke diagnostic procedures and treatments. However, discretion must be exercised by the clinician before embarking on an aggressive and extensive stroke diagnostic workup in these patients.

Table 4 lists stroke diagnostic studies by ischemic and hemorrhagic stroke subtype and level of invasiveness. Cranial computed tomography (CT) is usually performed on an emergent basis as it is an excellent tool for distinguishing infarct from hemorrhage. Once this distinction is made, the workup may proceed according to the algorithm in **Figure 1**. Magnetic resonance imaging (MRI) of the brain is generally more sensitive than CT in stroke diagnosis but may not diagnose hemorrhagic stroke until well after its onset.

Treatment and Prevention

Treatment of stroke may be divided into three stages: (a) the hyperacute period; (b) the secondary

Table 4 Stroke diagnostic studies

	Invasive?
Brain infarction	
Neuroimaging	
Cranial computed tomography (CT)	No
Magnetic resonance imaging (MRI)	No
Magnetic resonance angiography (MRA)	No
Single photon emission computed tomography (SPECT)	No
Conventional cerebral angiography	Yes
Carotid duplex ultrasound	No
Transcranial doppler (TCD)	No
Cardiac studies	
Ambulatory electrocardiogram (EKG)	No
Echocardiography	
Conventional (transthoracic)	No
Transesophageal (TEE)	Yes
Procoagulant blood studies and other studies	
Lupus anticoagulant, anticardiolipin antibodies, proteins S and C, antithrombin III, homocysteine	No
Lumbar puncture	Yes
Brain hemorrhage	
Neuroimaging	
CT	No
MRI	No
MRA	No
Conventional cerebral angiography	Yes
Other studies	
Lumbar puncture	Yes

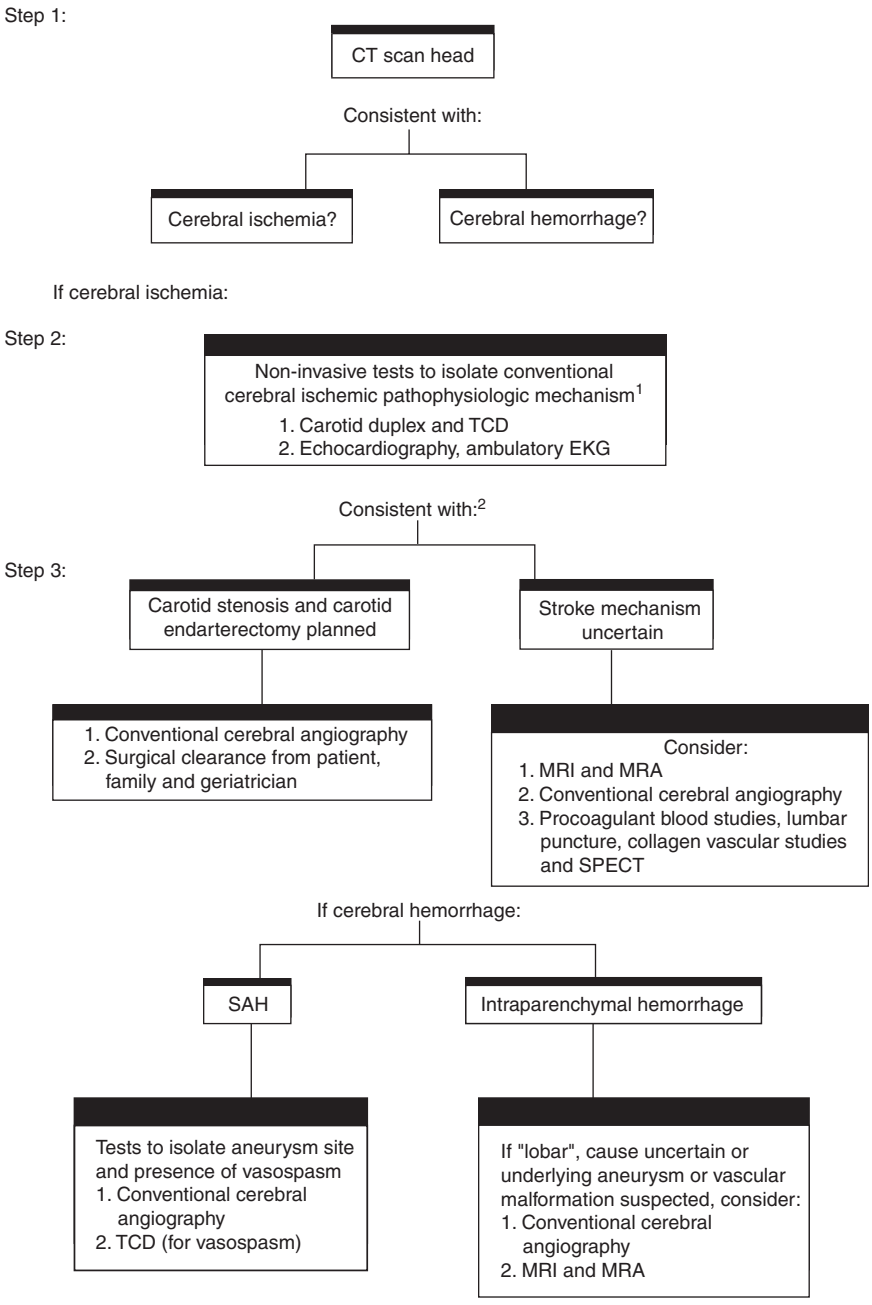

Figure 1 Stroke diagnostic algorithm. If CT is negative for SAH, perform lumbar puncture to isolate blood in cerebrospinal fluid if clinical presentation is consistent with SAH; MRI and MRA may be performed but are not the most sensitive procedures to isolate aneurysm site. Routine blood studies should include a screen for bleeding diathesis; MRI is useful as a follow-up study to rule-out underlying lesions such as neoplasm and to chart the course of hemorrhage resolution. [1]To be performed in conjunction with routine blood studies, electrocardiogram and chest X-ray. Some experts would consider MRI and MRA as Step 2 tests. [2]Carotid duplex and TCD are used to define high-grade extracranial and intracranial large artery atherosclerotic occlusive disease. Echocardiography and ambulatory EKG define cardiac source embolism. Lacunar infarction is generally diagnosed in the absence of atherosclerotic mechanism or cardiac source embolism and in the presence of typical lacunar syndrome (eg., pure motor hemiparesis, pure sensory stroke, clumsy-hand dysarthria, ataxic hemisparesis).

prevention period; and (c) the primary prevention stage. The hyperacute period encompasses the earliest stage and generally includes the time from onset of cerebral ischemia or hemorrhage through the first 7 days. During this stage the brain is vulnerable to cerebral ischemia. A window of opportunity exists to rescue marginally functioning brain cells in the 'ischemic penumbra' (i.e., the brain tissue at risk in the

shadow zone of the compromised cerebral blood flow). The exact therapeutic window of opportunity for hyperacute cerebral treatment is debated, but may be less than 12–24 hours. After the hyperacute period efforts are aimed at preventing recurrent stroke (secondary prevention) and at rehabilitation. During the hyperacute and early secondary stroke prevention phases, high-quality medical, nursing, and rehabilitative management is critical to prevent aspiration pneumonia, deep venous thrombosis and pulmonary embolism, urinary tract infection, cardiac complications, and other medical consequences of acute stroke. These are listed in **Table 5**. The primary prevention stage aims to prevent a *first* stroke by dietary, lifestyle, and medical strategies designed to alter the community's and individual's risk of stroke.

The following discussion will focus on acute treatment and prevention of ischemic stroke. The reader is referred to several excellent references for a review treatment and prevention of brain hemorrhage.

Hyperacute Treatment

Acute loss of blood flow to the brain results in synaptic transmission failure when blood flow drops to about 18 ml/100 g/min and membrane pump failure and cell death at about 8 ml/100 g/min. The mainstay of hyperacute management is administration of medication to protect the neuron against cell death or improve brain blood flow and delivery of oxygen, glucose, and other nutrients. Most hyperacute agents are classified as pharmacologic or cell protectants, antithrombotics, thrombolytics, or hemorheologic treatments based on their mechanism of action. Many are still undergoing clinical trial testing. As of yet there is only one hyperacute stroke treatment, tPA when given within 180 min of ischemic stroke onset, that has been proved conclusively to reduce stroke morbidity or death. Most experts believe that hyperacute stroke treatment should be administered as soon as possible ('Time is brain') and no later than 6–8 hours after stroke onset.

Table 6 summarizes key hyperacute stroke treatments and their status with regard to clinical testing. Should these agents prove to be effective, the future of hyperacute treatment may include combination therapy.

Secondary Prevention

There is substantial clinical trial literature on antiplatelet agents and recurrent stroke prevention. It is widely held that the risk of recurrent stroke or death is reduced significantly in TIA or mild stroke patients who take the antiplatelet agents aspirin or ticlopidine. In the first 2 years of treatment, ticlopidine may be more effective than aspirin in secondary stroke prevention; however, its adverse event profile may be less favorable. The latter factor plus cost and monitoring considerations have engendered controversy about the indications for ticlopidine based on risk–benefit analysis. There is also controversy about the proper dose of aspirin of secondary stroke prevention. Some experts argue for lower doses (e.g., 75–325 mg), whereas others adhere to higher dose regimens (500 mg or 975–1300 mg).

Table 5 Medical complications of acute stroke and their prevention

Complication	*Prevention measure*
Aspiration pneumonia	1. Frequent oral-pharyngeal suctioning if indicated 2. Swallow evaluation and appropriate diet 3. Frequent turning and positioning 4. Protect airway and intubate if indicated
Loss of cerebral autoregulation	1. Maintain mild to moderate arterial hypertension 2. Avoid rapid lowering of blood pressure unless a vital organ is compromised
Dehydration	1. Maintain hydration status with 0.45 or 0.9 normal saline 2. Avoid hypotonic fluids or those containing glucose
Skin breakdown/decubitus ulcer formation	1. Regular examination of skin, especially dependent portions, for evidence of breakdown 2. Special pressure mattress and frequent turning of patient
Urinary tract infection	1. Avoid indwelling urinary catheters
Venous thromboembolism	1. Pressure-gradient stockings or pneumatic-compression stockings 2. Anticoagulant if not contraindicated
Seizure	1. Observe for occurrence of seizure 2. Anticonvulsant administration if seizure occurs
Cardiac arrhythmia	1. Ambulatory electrocardiogram

Table 6 Major hyperacute stroke therapies

Type	*Results of clinical trial testing*
Cytoprotectants	
Calcium channel blockers	No major benefit
Opiate receptor antagonists	No major clinical trial underway
Barbiturates	No established benefit
N-methyl-D-aspartate antagonists	Clinical trial testing underway
Antithrombotics	
Heparin	No established benefit
Heparinoids	Clinical trial testing underway
Prostacyclin	No major benefit
Thrombolytics	
Streptokinase	No established benefit
Tissue-type plasminogen activator (t-PA)	Established benefit with administration within 3 h
Urokinase	Clinical trial testing underway
Hemorheologic treatment	
Hemodilution	No major benefit
Ancrod	Clinical trial testing underway
Pentoxifylline	No major benefit
Other	
Ganglioside (GM_1)	No major benefit

The anticoagulant warfarin is beneficial for the prevention of stroke in patients with non-valvular atrial fibrillation. Carotid endarterectomy, a surgical procedure to remove atherosclerotic plaque from the carotid artery, is the treatment of choice when there is high-grade (70–99%) ipsilateral symptomatic carotid stenosis in patients with TIA or minor stroke. For low-grade carotid stenosis (0–29%), the surgical risks outweigh the benefits, and antiplatelet therapy is recommended. For medium-grade carotid stenosis (30–69%), the answer is as yet uncertain but is the focus of ongoing study.

Secondary stroke preventatives have been studied most extensively in those in the 60–65-year age range. Clinical trial experience in the very elderly is limited. It has been shown that aspirin may not be an effective stroke preventative in patients over 75 years of age with atrial fibrillation, yet warfarin may be dangerous in this group. Carotid endarterectomy may be safely performed in well-selected older patients.

Primary Prevention

Generally, stroke, a chronic disease, has a long latent period, and primary prevention is possible. Public health strategies to prevent stroke by modification of risk factors amenable to medication, diet, or other interventions include the mass and high-risk approaches. The mass approach emphasizes lifestyle modification to achieve modest reductions in the level of the risk factor in all individuals in the population. The high-risk approach identifies individuals with high levels of a risk factor or multiple risk factors, and medication is usually prescribed to achieve substantial reductions in the risk factors(s).

There is substantial primary prevention data to show a major benefit for treatment of hypertension and use of warfarin in atrial fibrillation. More recently it has been shown that carotid endarterectomy is safe and effective in patients with high-grade (50 or 60–99%) asymptomatic carotid stenosis. Observational epidemiologic studies support the contention that cessation of smoking and heavy alcohol consumption is beneficial in reducing stroke risk. Debate exists about the efficacy of treatment of hypercholesterolemia and other blood lipid abnormalities.

There is clear evidence for substantial stroke risk reduction by treating isolated systolic hypertension in the elderly. However, in the very old the window of opportunity for primary prevention may have lapsed in regard to treatment of some modifiable risk factors. Cerebrovascular disease may be too far advanced, treatments are not safe or effective, or the absolute benefit for risk factor modification is small, as the risk factor has low prevalence and relative risk in the very old.

Consequences of Stroke

It is estimated that more than half of stroke survivors have significant residual physical disability and functional impairment. Among long-term survivors in the Framingham Study the following deficits were observed: decreased vocation function (63%), decreased socialization outside the home (59%), limitations in household tasks (56%), decrease in interests and hobbies (47%), decreased ability to use outside transportation (44%), decreased socialization at home (43%), dependence in activities of daily living (32%), dependence in mobility (22%), and relocation to a nursing home or other institutional setting (15%).

Age is an important predictor of functional prognosis in stroke. Although age does not preclude good functional outcome, it is associated with shorter survival, more comorbidity, and adverse psychosocial conditions. The most powerful determinant of functional outcome in stroke seems to be specific neurologic deficit. Severity of stroke deficit and comorbidity (medical and psychosocial) are crucial to functional outcome. Other factors that may play a role include sex, race, marital status, etiology of stroke, educational level, vocation status, financial status, and other 'intrinsic' factors such as family support and available community services.

Dementia is an important consequence of stroke. It is estimated that vascular dementia is the second

leading cause of progressive and irreversible dementia, accounting for approximately 10–20% of cases. The frequency of vascular dementia rises exponentially with age. It is generally held to be more common among men than women and may be more prevalent than Alzheimer's disease in Asia and among the very old in some countries (e.g., Sweden). In addition to age and possibly education, risk factors for vascular dementia seem to be those cardiovascular determinants that underlie stroke.

At present, vascular dementia is the only preventable form of dementia of late life. As stroke leads to vascular dementia, the prevention of stroke by modification of treatable risk factors is anticipated to result in a significant reduction in vascular dementia. However, once vascular dementia is diagnosed, there is no proven secondary preventative to reduce its debilitating cognitive effects (*see* Dementia).

Suicide

S S Canetto, Colorado State University, Fort Collins, CO, USA

Glossary

Non-fatal Suicidal Behavior – A suicidal act that the person survives.

Psychological Autopsy – The retrospective reconstruction of possible psychological causes of a suicide via interviews with family members and/or friends of the deceased. The psychological autopsy interview typically focuses on events perceived by the informants to lead to the suicide as well as possible mental disorder symptoms in the deceased.

Suicidal Ideation – Thinking or talking about killing oneself.

Suicide – Self-inflicted death.

Introduction

Suicide is self-inflicted death. In most countries reporting to the World Health Organization (WHO), including the United States, suicide rates are highest among older adults. Older men are more likely to die of suicide than older women. Of the approximately 31,000 suicides recorded annually in the United States, about 5,500 are by older adults. Most of these older adult suicides involve men of European American descent. There is variability in gender rates of suicide across ethnicities. There is also considerable variation in international rates of older adult non-fatal suicidal behavior. In general, rates of non-fatal suicidal behavior tend to be lower in older adults than in young adults. At the same time, among older adults, suicidal behavior may be indirect, involving food refusal or non-adherence to therapy. Older adults may be less communicative about their suicidal thoughts, which may increase mortality risk.

Suicide is usually defined as self-inflicted death. The term non-fatal suicidal behavior refers to the situation in which an individual survives a suicidal act. Other terms for non-fatal suicidal behavior are attempted suicide, deliberate self-harm, and parasuicide. Suicidal ideation means thinking or talking about killing oneself.

Many factors influence whether a suicidal act is fatal, including the immediate lethality potential of the suicide method as well as access to medical care. The outcome of a suicidal act is not a reliable measure of intent. Not all persons who survive a suicidal act intended to live; conversely, not all suicidal deaths are deliberate.

Terms such as attempted suicide and successful suicide should be avoided because they confound outcome with intent. Another reason for avoiding these terms is that they imply that surviving a suicidal act is a negative outcome, a failure, and that killing oneself is a positive outcome, a success.

The classification of a death or behavior as suicidal is influenced by social values and political factors. There are significant variations, both within and across countries, in the type of evidence required for a behavior to be considered suicidal. For example, in some cultures it is not even necessary for a death to be self-inflicted to be viewed as a suicide. Consider the case of ritual killing of Lusi widows by male kin in the Kaliai district of Papua New Guinea. Locals view the ritual killings of Lusi widows suicides because the widows presumably demand to be killed, as a way to avoid becoming dependent on their children. By contrast, the German and Australian authorities consider the killing of widows by kin to be murder. This example demonstrates that for an act to be recognized, reported, and recorded as a suicide, a complex cultural negotiation is required, across private and public domains, and involving the meaning and consequences of suicide within a community. This complexity should not simply be treated as a source of error in epidemiological data but rather as useful information through which understanding of suicide can be obtained and then applied to planning for suicide prevention.

This article begins with a review of the national and international epidemiology of older adult suicidal behaviors. It then considers theories and evidence on risk factors for older adult suicide in the United States. Next, it reviews dominant suicide prevention practices and proposes new directions for suicide prevention, as suggested by the research findings. The article concludes with a summary of main issues in older adult suicidal behavior and prevention.

Epidemiology

In the United States, suicide rates are highest among older adults. For example, in 2002 the suicide mortality rate for persons age 65 and older was 15.6 per 100 000, higher than the national cross-age rate of 9.9

per 100 000, and higher than the rate of 11 per 100 000 for persons age 15 to 24. This means that in 2002, older adult suicide rates exceeded those of young adults as well as national rates by 42% and 58%, respectively. Suicide is disproportionately more common among older adults as compared to young adults and the general population. Specifically, older adults represent about 12% of the population, but they account for 18% of suicides. By contrast, young adults represent 13% of the population and account for 14% of suicides. At the same time, it is noteworthy that, over the past several decades, older adult suicide rates have been declining, while young adult suicide rates have been increasing. Older adult suicide rates vary by region of the country and are highest in the west. Older adult suicide rates also vary by gender. In the United States, men age 65 and older take their own lives at six times the rate of same-aged women. Men account for over 80% of suicides among persons aged 65 and older. Among older men, those of European American descent have the highest suicide mortality. Suicide is particularly rare among older women of Native American descent. While there is a gender gap in suicide rates across ethnicities, both the magnitude of the gender gap and the specific suicide rates vary depending on ethnicity (see **Figures 1** and **2**).

Firearms are the most common suicide method among older men and women – though firearms are used in a much larger proportion of men's suicides (79%) compared to women's suicides (33%). Choice of method varies depending on ethnicity, immigration status, as well as cohort. Among Asian-Americans, for example, hanging is being replaced by firearms, concomitant with the individual's immigration status and assimilation into US culture.

According to data from countries reporting to the World Health Organization (WHO), international suicide rates are also highest among older adults. One exception is Poland. Older adult suicide rates are particularly high in Hungary, Lithuania, Latvia, and other Eastern and Central European countries, with relatively low rates in Southern European countries. Furthermore, internationally, older men are more likely to die of suicide than older women. It is important to note that information about suicide mortality, like information about non-fatal suicidal behavior and ideation, is available primarily from industrialized countries. Therefore, international suicidal behavior trends, including those available via the WHO, reflect the suicidal behavior of a unique sample of countries and may not be generalizable beyond those countries(**Figure 3**).

The significance of cultural factors in suicidal behavior is highlighted by the findings of studies of suicide among immigrants. These studies, which were conducted in countries such as the United States, Australia, and the United Kingdom, indicate that suicide rates of recent immigrants are similar to the suicide rates of country-of-origin peers than the rates of host country peers.

Information about non-fatal suicidal behavior and suicidal ideation is more limited because there are no national records of non-fatal suicidal behavior and ideation. Community studies conducted in the United States suggest that rates of explicit non-fatal suicidal behavior are lower in older adults. Among older adults, suicidal behavior may be indirect, for example, food refusal or non-adherence to therapy. Older adults may be less likely to discuss their suicidal thoughts with others, which may be a factor in their high suicide mortality. The patterns of older adult suicidal ideation and non-fatal suicidal behavior recorded in the United States may not be universal. As evidence of that, a recent multicenter European study found considerable national variation in rates of non-fatal suicidal behavior in older adults, from 14 per 100 000 in Würzburg, Germany to 111 per 100 000 in Huddinge, Sweden (**Figure 3**).

The variability in older adult patterns of suicidal behavior (non-fatal and fatal) between and within countries as well as by gender, ethnicity, and geographical region indicates that suicidal behavior is not an inevitable consequence of aging. There are clearly cultural elements in the risk for suicidal behavior among older adults. Given the cultural variability in older adult patterns of suicidal behavior, this article next focuses on older adult suicidal behavior in one country, the United States. Specifically, it critically examines theories and evidence on risk factors for older adult suicidal behavior in the United States. This approach allows exploration of risk factors within cultural context, that is, in light of local ideologies and experiences of aging and suicide. This is critical because suicide and aging may have different meanings and consequences in different cultures. Once the cultural principles of aging and suicide are understood in one national context, those principles can be applied to decoding the dynamics of aging and suicide in a different national context.

Theories and Evidence

Two theories of older adult suicide dominate the US literature. The first theory states that older adult suicide is based on mental disorders, particularly affective disorders. The second theory states that the high rates of older adult suicide can be blamed on the burdens and losses of aging, that is, aging-related losses in health, economic resources, employment, and companionship.

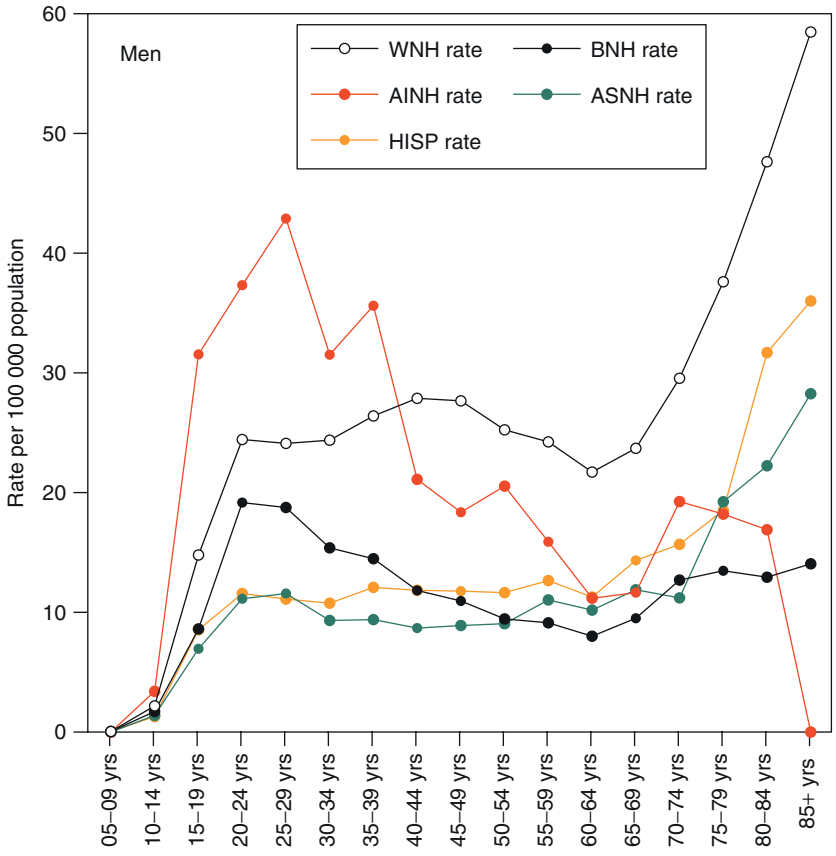

Figure 1 Men's suicide rates by ethnicity and age, 1999–2002. WNH, White non-Hispanic; AINH, American Indian non-Hispanic; HISP, Hispanic; BNH, Black non-Hispanic; ASNH, Asian American non-Hispanic. Courtesy of John L. McIntosh, Ph.D.; based on data from the Centers for Disease Control's WISQARS (Web-based Injury Statistics Query and Reporting System), February, 2005.

Retrospective, psychological autopsy studies of many individuals who died by suicide indicate that prior to their death, many of these individuals may have been diagnosable with a mental disorder. Psychological autopsy evidence suggests that some older adults who killed themselves also experienced significant health and family discord problems. These findings have been interpreted by some as suggesting that mental disorders and negative life events are in fact the main culprits for older adult suicide. A key limitation of the psychological autopsy evidence is that it is *post facto* and indirect, as it is based on post mortem interviews with family members and friends of the deceased.

If it were true that aging is intrinsically psychopathogenic and suicidogenic, then mental disorders and suicide should be most common among older adults, as compared to other age groups, and should be independent of culture. Mental disorders and suicide should also be most prevalent among the older adults who are most exposed to, and impacted by aging losses. The patterns in the United States of mental disorders and suicide across age, sex, and culture, however, do not support these predictions.

First, young adults have higher rates of mental disorders but lower rates of suicide than older adults. Second, in the United States, the highest suicide rates are found among those older adults who, as a group, and by historical privilege, have been most protected from aging losses, that is, older men of European American descent. Consider, for example, economic adversities. Older women, particularly ethnic minority older women, are more likely to be poor but are less likely to die of suicide than older men. The same is true of employment or retirement difficulties. Women (and ethnic minorities) experience more adverse employment conditions (e.g., low pay) throughout their work history, and yet they have lower rates of suicide than men. Similarly, the transition to retirement is more stressful for women than men, and yet suicide rates are lower in older women than in older men. What about interpersonal losses? Older women are more likely than older men to be exposed to, and impacted by aging-related interpersonal adversities. For example, they are more likely than men to experience widowhood, to not remarry after widowhood, and to live alone after widowhood. However, widowhood and living alone are more significant suicide

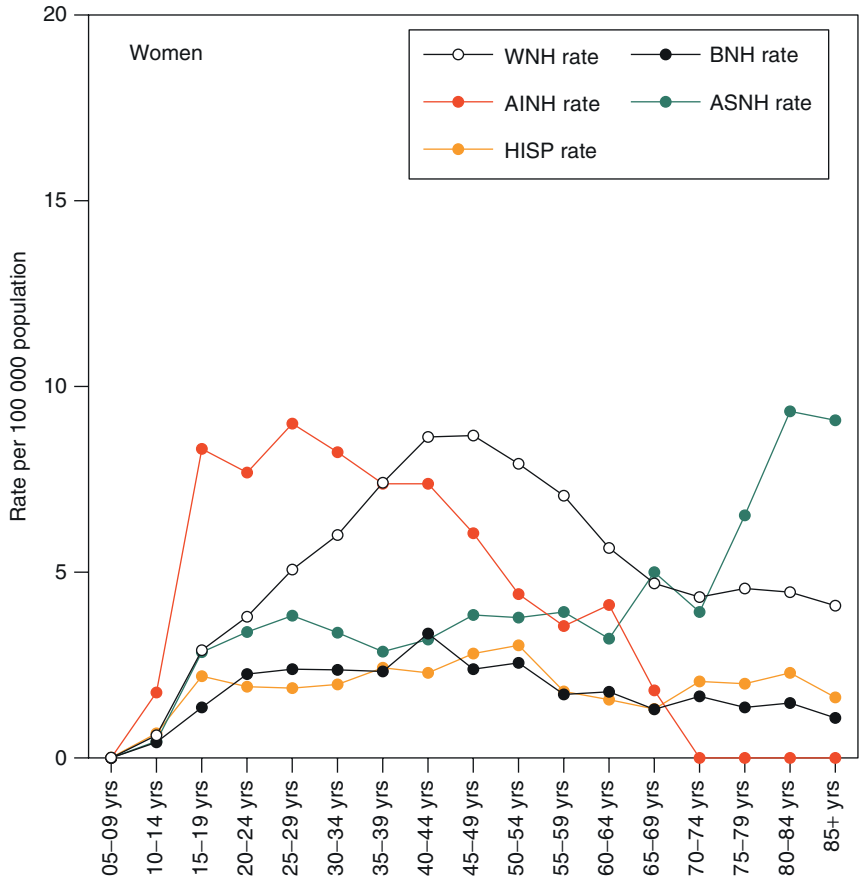

Figure 2 Women's suicide rates by ethnicity and age, 1999–2002. risk factors for men than for women. Finally, the data on health and disability show greater exposure to and impact of illnesses and disabilities in women as compared to men. And yet physical illness is a more important suicide risk factor for men than for women. In conclusion, women and ethnic minorities are more, not less, exposed than men to the economic, interpersonal, and health losses and adversities that have been blamed for the high rates of older adult suicide, and yet they have lower rates of suicide than men. Men, particularly men of European American descent, are more protected from aging adversities but are more likely to die of suicide than women. Stated differently, men are more vulnerable to suicide when facing interpersonal loss, interpersonal discord, social isolation, and health adversities.

One way to make sense of the gender and cultural paradox of older adult suicidal behavior in the United States is to consider dominant gender meanings of aging and suicide. Studies conducted among primarily European American respondents indicate that older adult suicide is perceived as more acceptable than suicide in other age groups. Second, suicide in response to a physical illness is viewed as more understandable than suicide following any other stressor. In fact, suicidal persons are generally perceived as less maladjusted if their suicidal behavior was precipitated by a physical illness.

Clues to understanding the overrepresentation of males among the suicides can be found in studies of gender meanings of suicide. There is evidence of a dominant assumption, in Western countries, that suicide is a masculine act. Durkheim, a historically influential European sociologist, formulated a theory stating that killing oneself requires a kind of intelligence and courage that, according to him, could only be found in men. Studies conducted with predominantly European American samples confirm that suicide is considered male behavior. These studies reveal that male suicide is considered less foolish, less wrong, and more powerful and permissible than female suicide. They also show that suicide is viewed as more masculine and more potent than non-fatal suicidal behavior (so-called 'attempted suicide'). Among European Americans, suicide 'attempts' are treated as feminine behavior. In addition, feminine persons are expected to 'attempt' suicide more than masculine persons. Males have been found to be particularly critical of other males who 'attempt' suicide and 'fail' to kill themselves. Finally, there is evidence that suicide by older men of European American descent is interpreted as a sign of masculine courage and determination.

Some have argued that men's suicide mortality is simply a function of males being more likely than females to use immediately lethal suicide methods, such as firearms. Men's use of firearms is also taken by some as an indication that males have higher suicidal intent than females. Studies do indeed show that, in the United States, firearm access increases suicide risk, particularly for males. It is important to remember, however, that males' choice of suicide method takes place in a culture that considers guns a 'hard,' masculine method and that views surviving a suicidal act as unmasculine. In addition, guns are highly accessible in the United States, especially to men. In industrialized countries outside the United States firearms are much less likely to be used in suicide, by either males or females. In developing countries, the most common suicide method for both males and females tends to be poisoning.

Finally, psychological autopsy personality evidence shows that older adults who kill themselves (who are usually men) may be particularly rigid, conscientious, traditional, habit driven, emotionally unaware, and unable to access and articulate affect, including negative affect (and thus potentially more able to hide their distress from friends, family and providers). From a gender perspective, it may be seen that the personality characteristics associated with suicide risk are consistent with socially expected masculine behavior. Thus, once again it appears that adoption of conventional male behavior may be a factor in males' heightened risk for suicide, particularly in late adulthood.

In conclusion, the findings on the cultural meanings of gender, aging, and suicide generated by studies with primarily European American samples suggest that older male suicide may be encouraged by the dominant belief that suicide is more acceptable for older adults and for males. Given prevailing ideologies, males, particularly males of European American descent, may feel that if they engage in suicidal behavior, they can not allow themselves to survive it, because that would mean failing at suicide, even though success in this case means death. The association of suicide with physical illness, which has emerged in psychological autopsy studies and which is particularly strong for males, is not surprising considering dominant ideologies of masculinity. European American men may be particularly vulnerable to killing themselves following an illness or disability due to a connection, in their culture, between physical integrity, physical power, physical autonomy, and masculinity.

Prevention

Dominant theories of older adult suicide have focused on mental disorders and the stresses of aging. Consistent with these theories, suicide prevention has

tended to reach out to populations and individuals who are at risk, especially as related to mental disorders and stressful life events. In other words, suicide prevention programs have privileged a secondary and tertiary focus and used selective or indicated approaches so as to reduce the immediate risk of symptomatic individuals or vulnerable groups. For example, there is also substantial literature on the treatment of suicidal and/or depressed individuals. Both biological (psychopharmacological as well as electroconvulsive therapy) and psychotherapy approaches have been explored. In addition, there is a growing literature on educating front-line providers, particularly physicians, in detecting suicidality and depression in older adults presenting for medical care. This latter approach was triggered by findings that many older adults made contact with physicians within 1 month of killing themselves.

A key axiom in prevention is that targeting pathogens (via a primary prevention program) before they have a chance to generate morbidity or mortality is more parsimonious than treating individuals (via secondary and tertiary prevention programs) after they have been affected. A second axiom is that a universal approach to prevention, that is, an approach that focuses on reducing risk and enhancing resilience for the entire population, is more efficient than an indicated approach focusing on symptomatic, high-risk individuals. The argument is that large numbers of individuals at small risk will give rise to more morbidity than small numbers of high-risk individuals.

The variability in susceptibility to suicidal behaviors depending on gender, culture, and geographical location certainly makes a case for universal primary prevention approaches. One tested universal primary prevention approach has been to reduce firearm access. Evidence shows that the 1994 Brady Handgun Violence Prevention Act has reduced firearm suicides in individuals age 55 and older. A potentially fruitful and yet untried avenue for universal primary prevention of older adult suicide is public education. A public education campaign for the prevention of older adult suicide could start with promoting awareness about the unique vulnerability of older adults to suicide. In addition, this campaign could educate about the variability in older adult suicide risk depending on sex, ethnicity, and geographical location. Furthermore, a public education campaign should address the pervasive cultural acceptability of older adult suicide and the association of suicide and masculinity. More nuanced educational programs should also be developed for professionals who have contact with older adults, including care providers. These programs for professionals should start with an assessment of the professionals' beliefs about gender, aging, and suicidal behavior. Building on this information, the educational programs should then educate professionals about dominant ideologies of gender, aging, and suicide (including the idea that suicide is relatively acceptable under conditions of physical illness) as well as address misinformation these professionals may believe about older adult suicide (such as the idea that suicidal ideation and hopelessness are a normal experience of aging). Finally, professionals involved in secondary prevention (e.g., clinicians working with suicidal clients) should be trained to add an educational component to their therapy. This may involve exploring and then challenging their older clients' dysfunctional beliefs about gender, aging, and suicide, including the belief that killing oneself is a relatively powerful masculine behavior. In all cases, educational messages should build on an understanding of the gender, aging, and suicide beliefs of the group they target, because these group cultural beliefs may be unique, and also because cultural beliefs constantly change and evolve.

Summary

In the United States and in nearly all countries reporting suicide mortality data to the WHO, older adults have the highest suicide rates of all age groups. It is important, however, to keep in mind that our knowledge of older adult suicidal behavior comes primarily from Western and/or industrialized countries and that, therefore, older adult vulnerability to suicidal behavior can not be assumed to be universal. What we know for sure is that there is significant variability in older adult fatal and non-fatal suicidal behavior within countries (based on gender, ethnicity, and geographical location) as well as over time. Also, data from the United States reveal an interesting paradox: suicide is most prevalent among those older adults, men of European American descent, who by historical privilege have been most sheltered from the adversities of aging. In other words, older women and ethnic minorities experience more aging adversities but are less likely to die of suicide than older men. Collectively, this evidence indicates that suicide is not an inevitable consequence of aging, illness, disability, or even depression, as it has long been theorized in Western countries, including the United States. There are clear cultural factors in the risk for, and expression of suicidal behavior for women and men, and across cultures. Studies on the cultural meaning of gender, aging, and suicide have provided some light on the culture and gender paradox of older adult suicidal behavior. A dominant belief among European Americans is that suicide is a relatively powerful masculine response to aging adversities.

Older adult suicide prevention has tended to focus on at-risk individuals and vulnerable groups and to use strategies aimed at reducing morbidity in affected individuals and groups (secondary prevention) or at minimizing impact and reducing morbidity recurrence (tertiary prevention). A reduction in the prevalence of older adult suicide, however, also requires universal primary prevention approaches. One tested universal primary prevention approach is to reduce firearm access. A promising but yet-untested primary prevention strategy with older adult involves developing a public educational campaign. One aim of the campaign would be to educate about the unique vulnerability of older adults to suicide. Another aim would be to challenge dysfunctional social beliefs about suicide, such as the belief that suicide is a masculine act, or the belief that suicide is relatively permissible and understandable for older adults, particularly when they suffer from illnesses and disabilities.

Syncope

F Puisieux, Hôpital Gériatrique les Bateliers, CHRU de Lille, Lille, France

Glossary

Neurally Mediated Syncope – Syncope believed to result from an exaggerated cardiac and neurocardiac reflex that leads to acute vasodilation of the arterial and venous beds and relative or absolute bradycardia.

Presyncope (also called Near Syncope) – A condition in which patients feel as though syncope is imminent.

Syncope – A sudden, transient, self-limited loss of consciousness associated with the inability to maintain postural tone, usually leading to falling.

Tilt Table Testing – A non-invasive provocative test used to determine a patient's susceptibility to neural mediated syncope.

Introduction

Syncope, which is defined as a self-limited loss of consciousness, is more common in older persons than in any other age group. Age-related physiological changes of heart function, blood pressure, baroreflex sensitivity, and cerebral blood flow, together with the

high prevalence of chronic illnesses and the use of multiple medications, predispose older adults to syncope. The main causes of syncope in this population are orthostatic hypotension, carotid sinus hypersensitivity, vasovagal/situational syncope, and cardiac arrhythmias. In practice, for lack of a thoughtful diagnostic strategy, many syncopal episodes remain unexplained. The initial clinical assessment is essential to make the diagnosis. It includes a comprehensive medical history, preferably with an eyewitness account, a thorough physical examination including supine and standing blood pressure measurements, and an electrocardiogram. After this initial step, carotid massage must be performed unless contraindicated because carotid sinus hypersensitivity is a frequent syndrome in the elderly. In the absence of an established diagnosis, the decision for further investigation depends on whether there is evidence of underlying heart disease. When heart disease is present or suspected, cardiac investigations are recommended. When heart disease is absent, a cardiac cause is unlikely and evaluation for neurally mediated syndromes is recommended in case of recurrent or severe syncope. Treatment depends on the etiology.

Definition

Syncope is defined as a sudden, transient, self-limited loss of consciousness associated with the inability to maintain postural tone, usually leading to falling.

Loss of consciousness may occur with or without premonitory symptoms (e.g., lightheadedness, nausea, sweating, weakness, and visual disturbances). The onset of syncope is relatively rapid. Although the duration of syncope is rarely accurately estimated, typical syncopal episodes are generally brief and shorter than 20 s. The subsequent recovery is spontaneous, usually rapid, and complete with restoration of appropriate behavior and orientation. In older persons retrograde amnesia is not uncommon.

Presyncope or near-syncope refers to a condition in which patients feel as though syncope is imminent. Symptoms associated with presyncope may be relatively non-specific (e.g., dizziness) and tend to overlap with those associated with the premonitory phase of true syncope. Syncope and presyncope share the same etiologies.

Classification and Main Etiologies in Older Persons

The principal groups of causes of syncope are the following:

1. Neurally mediated syncopes
2. Orthostatic and postprandial hypotensions
3. Cardiac causes: arrhythmias and mechanical causes
4. Cerebrovascular, psychiatric, and metabolic disorders.

Main etiologies of syncope in the older persons are listed in **Table 1**.

Studies have shown that, in older persons, the commonest causes of syncope are orthostatic hypotension, carotid sinus hypersensitivity, vasovagal/situational syncope, and cardiac arrhythmias. However, the prevalence of each cause varies widely from one study to another. Reasons for variability include aggressiveness of diagnostic evaluation, diagnostic criteria for causes, patient populations (e.g., all patients, emergency room visits, hospitalized patients),

Table 1 Main causes of syncope in the elderly

Neurally mediated syncopes	• Vasovagal syncope • Carotid sinus hypersensitivity • Situational syncope • Micturition • Defecation • Cough
Orthostatic and postprandial hypotensions	• Orthostatic hypotension • Autonomic failure • Primary autonomic failure syndromes (e.g., pure autonomic failure, multiple system atrophy, Parkinson's disease with autonomic failure) • Secondary autonomic failure syndromes (e.g., diabetic neuropathy, amyloid neuropathy) • Drug (and alcohol)-induced orthostatic syncope • Volume depletion • Hemorrhage, diarrhea, Addison's disease • Postprandial hypotension
Electrical cardiac causes	• Sinus node disease • Second- or third-degree heart block • Pacemaker malfunction • Drug-induced proarrythmias • Ventricular tachycardia • Torsade de pointes • Supraventricular tachycardia
Mechanical cardiac causes	• Aortic stenosis • Hypertrophic cardiomyopathy • Pulmonary embolism
Neurological causes	Rare
Psychiatric causes	Rare
Metabolic causes	Rare

and whether patients with a likely seizure disorder were included or not.

In older frail patients, coexisting illnesses and medications may interact to cause syncope.

Neurally Mediated Syncopes

The neurally mediated syncopes encompass a number of disorders including vasovagal syncope, situational syncope, and carotid sinus hypersensitivity. Although the precise mechanism is poorly understood, these syndromes are believed to result from an exaggerated cardiac and neurocardiac reflex that leads to acute vasodilatation of the arterial and venous beds and relative or absolute bradycardia. The triggering factors for neurally mediated syncope are various, including orthostatic stress, emotional stress, urination, coughing, swallowing, physical exercise, and stimulation of the carotid sinus in susceptible persons.

Vasovagal Syncope Vasovagal syncope is the most common cause of fainting in both children and young adults. It is less frequent in older persons.

Although the underlying mechanism of vasovagal syncope is not totally understood, it is believed that the venous pooling in the lower extremities while in an upright position is the trigger mechanism. This shift in blood volume can markedly decrease the cardiac output that is sensed by arterial baroreceptors located in the aortic arch and carotid sinus. These receptors transmit signals to the nervous system and result in reflex-increased sympathetic output with increased heart rate and hypercontractility. In addition, the vascular system responds locally by restricting blood flow to non-vital organs such as the skin, muscles, and adipose tissue, thereby enhancing peripheral resistance. Cardiac mechanoreceptors found in ventricles, atria, and pulmonary artery, which are usually activated by distension of the heart, undergo abnormal stimulation that is believed to result from the combined hypercontractility and emptiness of the ventricle. The afferent fibers (unmyelinated C fibers) project abnormal mechanoreceptor stimulation centrally to the brain stem (tractus nucleus solitarius and other centers). The efferent part of the reflex results in parasympathetic stimulation leading to vasodilation (vasodepressor effect) and sympathetic withdrawal leading to bradycardia (cardioinhibitory effect) with ensuing syncope. In addition, several neuroendocrine changes are observed during orthostatic stress. At the time of syncope, a higher level of epinephrine and a decreased renin activity is found in patients with neurally mediated syncope. In the case of the emotionally induced vasovagal faint, higher cortical sites are believed to be the predominant triggers of the afferent limb of the reflex arc.

Typically, loss of consciousness in vasovagal syncope occurs in the upright position and is preceded by prodroma such as nausea, warmth, diaphoresis, lightheadedness, blurred vision, headaches, palpitations, paresthesia, and pallor. Prodroma may last from less than 1 s to several minutes. Occasional patients may not exhibit any symptoms at all. The recovery is almost immediate when the patient assumes the supine position. After recovery, patients may complain of a washed-out and tired feeling. When necessary, the diagnosis can be confirmed by a tilt table test that is the diagnostic technique of choice for clinically assessing susceptibility to neurally mediated syncope, particularly of the vasovagal type.

Treatment strategies for vasovagal syncope remain controversial. Many single episodes do not warrant treatment unless physical injury has occurred or a high-risk occupation or avocation is involved. Patients should be principally assured of the condition's benign nature, informed of the likelihood of syncope recurrence, and educated to recognize warning signs of an imminent faint and to avoid situations that predispose to syncope. Chronic vasodilator treatments must be discontinued when possible because they have been shown to enhance susceptibility to vasovagal syncope.

Because no single large, randomized study has been undertaken to test the efficacy of pharmacological therapy (e.g., beta-adrenergic blockers, disopyramide, serotonin reuptake blockers, theophylline, fludrocortisone, ephedrine, etilephrine, midodrine, clonidine) or pacing therapy, therapeutic strategy is not well defined. Therapy is guided by symptom recurrence and the benefit/risk ratio. If symptoms are severe, recurrent, and refractory to medical treatment, with a documented bradyarrhythmia, pacemaker implantation may be considered.

Situational Syncope Situational syncope refers to those forms of neurally mediated syncope that occur after cough, defecation, and micturition or associated with throat or facial pain (glossopharyngeal or trigeminal neuralgia). In situational syncope, the activation of peripheral receptors in the bladder, the esophagus, and the respiratory tract similar to ventricular mechanical receptors may lead to a reflex increase in vagal efferent activity and sympathetic withdrawal. In these conditions, it may be impossible to avoid exposure to the trigger. Other treatment strategies may be advocated, including maintenance of central volume, protected posture (e.g., sitting rather than standing), slower changes of posture

(e.g., waiting after a bowel movement before arising), avoidance of excessive fluid intake (especially alcohol) just prior to bedtime in postmicturition syncope, and elimination of excessive cold drinks or large boluses of food in swallow syncope.

Carotid Sinus Hypersensitivity Carotid sinus hypersensitivity, also called carotid sinus syndrome, is an underrecognized cause of recurrent unexplained syncope and of recurrent falls in the elderly. When carotid sinus massage is systematically performed, carotid sinus hypersensitivity is diagnosed in approximately 20% of older people who presented with unexplained syncope. The prevalence of carotid sinus hypersensitivity increases with advancing age and with cardiovascular, cerebrovascular, and neurodegenerative comorbidity. Studies have shown that 5–25% of asymptomatic older men have carotid sinus hypersensitivity. At the same time, only 5–20% of patients showing carotid sinus hypersensitivity actually have syncope of carotid sinus origin.

Diagnosis of carotid sinus syncope requires that spontaneous symptoms of presyncope or syncope be reproduced by carotid sinus massage. Normal response to the external stimulation of the carotid sinus consists of slowing of the sinus rate and impaired atrioventricular node conduction. In carotid sinus hypersensitivity this reflex is exaggerated. The underlying mechanisms that lead to this hypersensitivity of the carotid sinus remain debated.

Clinical presentation may be typical when syncope occurs with rotation or turning of the head or pressure on the carotid sinus (for example, carotid massage, shaving, tight collars or neckwear, or tumor compression). A previous neck surgery reinforces the diagnosis. More often, recurrent unexplained syncope and unexplained falls are the clinical presentation of patients with carotid sinus hypersensitivity without a specific trigger.

Carotid sinus massage is contraindicated in patients with the presence of a carotid bruit, stroke, or myocardial infarction within the previous 6 months, or a history of ventricular tachycardia or ventricular fibrillation. Carotid sinus massage is performed by applying longitudinal digital pressure at the bifurcation of the internal and external carotid artery or the area of greatest arterial pulsation for 5 s. Blood pressure and pulse rate must be monitored. A venous access is required. The right carotid sinus is stimulated first, followed by the left a few minutes later. Massage should be done in the supine position and, if negative, in the upright position, because in up to a third of patients a diagnostic cardioinhibitory response is only present when upright. With a good technique, complications are rare, ranging from visual disturbances to hemiplegia in rare cases, most of which are transient and result in full recovery. Carotid sinus hypersensitivity is defined as asystole of 3 s or more (cardioinhibitory form), or a fall in systolic pressure of 50 mmHg or more (vasodepressor form), or the association of both (mixed form) during carotid sinus massage. Carotid sinus syndrome of predominantly vasodepressor form is probably as prevalent as cardioinhibitory form, but its potential role in causing syncope is much less certain.

Available information indicates that pacing may have a strong beneficial effect and prevents recurrence of syncope in patients with cardioinhibitory form. A variety of medical therapies has been used with unclear effects in vasodepressor form. Recently, a pilot study of crossover design in 10 older adults with a history of unexplained syncope and vasodepressor form of carotid sinus hypersensitivity has suggested that treatment of the vasodepressor form with midodrine significantly reduces the rate of symptom reporting and attenuates systolic blood pressure decrease after carotid sinus massage.

Orthostatic and Postprandial Hypotensions

Orthostatic Hypotension Orthostatic hypotension is a frequent blood pressure disorder in the elderly that has been shown to be an attributable cause of syncope in 20 to 30% of older patients.

Since the consensus meeting in 1996 of the American Autonomic Society and the American Academy of Neurology, orthostatic hypotension is defined as a drop in systolic blood pressure of $>$ or $=20$ mmHg and/or diastolic blood pressure of $>$ or $=10$ mmHg, 1, 2, or 3 min after the person moves from a supine to a sitting or standing position. In a volume-depleted patient, the heart rate should rise on standing. In a patient with dysautonomic syncope, the blood pressure can drop over several minutes while upright with no concomitant change in heart rate. Because the within-day and day-to-day intra-individual reproducibility of the diagnosis of orthostatic hypotension is poor, postural test should be repeated.

In orthostatic syncope, the triggering mechanism is the blood shift of 300 to 800 ml from the thorax to the lower extremities that occurs upon changing from a supine to an upright position. Following a change in posture to the upright position, baroreceptors provoke an increase in medullary sympathetic outflow. This leads to vasoconstriction of the systemic resistance vessels and the splanchnic capacitance vessels. Compensation for continued orthostatic stress depends principally on the arterial baroreceptors.

Orthostatic hypotension may be due to volume depletion and/or abnormal vasomotor compensatory mechanisms. Medications that alter vascular tone and heart rate increase the risk of orthostatic hypotension. Disorders of autonomic vasomotor control leading to orthostatic hypotension may be primary (pure autonomic failure and multiple system atrophy) or, more commonly, secondary to diabetic neuropathy or amyloidosis.

Older adults are predisposed to orthostatic hypotension because of the association of the blunted age-related autoregulatory mechanisms, medications (e.g., diuretics, vasodilators), chronic diseases (such as systolic hypertension, diabetes mellitus, Parkinson's disease), or frequent medical conditions in geriatrics (anemia, dehydration, bed rest). The prevalence of orthostatic hypotension increases with age but also varies according to the population being studied. A range of 5 to 60% has been reported, with the lower rate in vigorous old persons living in the community and higher rates in those living in an institution or in the acute care setting.

The treatment of orthostatic hypotension relies on non-pharmacological and pharmacological approaches: patient's education (avoiding sudden head-up postural change [especially on waking]; raising the head of the bed; physical countermaneuvers such as leg crossing and squatting; avoiding large meals, especially with alcohol; physical exercise, especially swimming), wearing of elastic stockings, reducing dosage or elimination of the responsible medication (diuretics, vasodilators, etc.), and, at a later stage, when non-pharmacological methods are unsuccessful, drug therapy. Fludrocortisone, a salt-retaining steroid, and midodrine, a sympathetic vasoconstrictor drug, are considered first and can be used in combination if necessary.

Postprandial Hypotension Over the past decade, postprandial hypotension, which is defined as a decrease in systolic blood pressure of 20 mmHg or more within 2 h of ingestion of a meal, has been recognized as a common cause of syncope and falls in the elderly. In one study, postprandial hypotension accounted for 8% of syncope cases in older nursing home patients. Postprandial hypotension can coexist with orthostatic hypotension in the same individual.

Although the precise pathophysiological mechanism is not fully understood, postprandial hypotension is probably the consequence of an alteration in the compensatory mechanisms for meal-induced splanchnic blood pooling and the lowering of peripheral vascular resistance following ingestion of food. A number of vasoactive gastrointestinal peptides have also been thought to play a role in the pathogenesis of postprandial hypotension since it has been established that the magnitude of the fall in blood pressure is related to the amount of glucose ingested during the meal and to the rate at which glucose enters the small intestine.

Treatment of postprandial hypotension, which may be non-pharmacological and pharmacological, is not well codified, because too few rigorous studies have been conducted on symptomatic patients. Large meals with refined carbohydrates, alcohol consumption, and drugs with vasodepressor properties should be avoided by the patients. In healthy older participants, it has been demonstrated that the magnitude of the blood pressure fall induced by intraduodenal glucose is attenuated by the concomitant absorption of guar.

Cardiac Causes

Cardiac syncope results from inadequate effective cardiac output and may reflect serious underlying structural heart disease. The causes may be electrical (arrhythmic) or mechanical (obstructive).

Cardiac Arrhythmias Cardiac arrhythmias are among the most common and potentially hazardous causes of syncope in patients with structural heart disease. Syncope from arrhythmias may result from ventricular tachycardia, supraventricular tachycardia, polymorphic ventricular tachycardia related to a long QT interval (torsade de pointes), bradyarrhythmias caused by sinus node dysfunction, or conduction system disease. Persistent or episodic high-grade atrioventicular block may result in sufficient loss of cardiac output to cause syncope.

The high prevalence of ischemic heart disease, cardiomyopathy, hypertension, valvular heart disease, and heart failure among the elderly predispose them to a broad range of tachyarrhythmias and bradyarrhythmias. An age-related fall in nodal myocytes, particularly in the sino-atrial node, increases the incidence of atrial fibrillation, heart block, and sick sinus syndrome. Polypharmacy in the elderly is another predisposing factor. Diuretics may cause electrolyte imbalance, which predisposes to arrhythmias. Many drugs have proarrhythmic effects such as digoxin, antiarrhythmic drugs, beta-2 agonist bronchodilators, and tricyclic antidepressants. Torsade de pointes in the setting of acquired prolonged QT interval is also typically associated with drugs including amiodarone, beta-blockers, neuroleptics, and class 1 anti-arrhythmic agents.

Mechanical Causes Main causes in the elderly are aortic stenosis and hypertrophic cardiomyopathy. In

these conditions, syncope is believed to be due to a combination of reduced cardiac output and neurally mediated reflex factors involving the ventricular mechanoreceptors. Vasodilator drugs or even vasodilatation after a hot bath can induce syncope in these patients.

Syncope also may be due to obstruction of the pulmonary artery secondary to pulmonary embolism. Syncope occurs in over 10% of patients with pulmonary embolism and is more likely to occur with massive embolism and in the elderly.

Other rare cardiac mechanical causes of syncope include atrial myxoma, severe mitral stenosis, prosthetic valve dysfunction, and pulmonary stenosis.

Cerebrovascular, Psychiatric, and Metabolic Causes

Syncope is rarely due to cerebrovascular disease in the absence of accompanying focal neurological deficits. Occasionally, transient ischemic attacks in the vertebrobasilar territory may cause syncope, but there are usually concurrent neurological symptoms including diplopia, vertigo, dysarthria, or hemiparesis.

Vascular steal syndromes are rare cerebrovascular causes of syncope in the elderly.

Psychiatric disturbances including hysterical reaction and panic attack with hyperventilation can either mimic or may lead to true syncope. But psychiatric causes of syncope are relatively rare in the elderly.

Metabolic disturbances are relatively infrequent causes of true loss of consciousness. More often these disturbances are responsible for confusional states or behavioral problems.

Epidemiology and Prognosis

Syncope accounts for 1–6% of visits to emergency departments in Europe and in the United States and 1–5% of all admissions to hospital. Elders and patients with associated cardiovascular diagnoses are admitted more frequently. In a large epidemiological study in the United States, 58% of patients older than 80 years of age with syncope presenting to emergency departments were admitted. In one study, syncope and collapse were the sixth most common reason for admission of adults aged over 65 years to acute medical hospital beds.

The prevalence of syncope increases with advancing age, ranging from 15% in children under 18 years to 23% in elderly patients over 70. Furthermore, data in the elderly are probably underestimates because of the exclusion of syncopal episodes that present as falls. The highest frequency of syncope occurs in patients with cardiovascular comorbidity and older patients in institutional care settings. In a study, among elderly persons living in long-term care institutions, annual incidence of syncope was as high as 6%, 10 times greater than the incidence observed in the Framingham Heart Study population.

Other important risks associated with recurrent syncope in the elderly are the fracture risk linked to falls and the risk of progressive restriction of activity due to the loss of confidence, leading to the inability to live alone.

In a recent study in the United States, a nationally representative sample of hospital discharges and reported charges was analyzed, and costs were estimated using Medicare cost-to-charge ratios. A conservative estimate of total annual costs for syncope-related hospitalizations was $2.4 billion, with a mean cost of $5400 per hospitalization.

The prognosis is dependent on the cause of syncope. Several population-based studies have shown that persons with cardiac syncope are at increased risk for death from any cause and cardiovascular events as compared with patients with non-cardiac syncope. In the Framingham Heart Study, among 822 syncopes in 7814 participants, the most frequently identified causes were vasovagal (21.2%), cardiac (9.5%), and orthostatic (9.4%); for 36.6% the cause was unknown. The multivariable-adjusted hazard ratios among participants with cardiac syncope, as compared with those who did not have syncope, were 2.01 (CI 95%: 1.48 to 2.73) for death from any cause, 2.66 (CI 95%: 1.69 to 4.19) for myocardial infarction or death from coronary heart disease, and 2.01 (CI 95%: 1.06 to 3.80) for fatal or non-fatal stroke. Participants with syncope of unknown cause and those with neurological syncope had increased risks of death from any cause, with multivariable-adjusted hazard ratios of 1.32 (CI 95%: 1.09 to 1.60) and 1.54 (CI 95%: 1.12 to 2.12), respectively. There was no increased risk of cardiovascular morbidity or mortality associated with vasovagal (including orthostatic and medication-related) syncope.

However, the higher mortality observed in the population with cardiac syncope is largely due to the underlying cardiac disease, irrespective of the precise cause of syncope. Indeed, a study comparing patients with and without syncope matched for cardiac disease and other important clinical variables found that cardiac syncope was not a significant predictor of overall or cardiac 1-year survival.

Pathophysiology

Although causes of syncope are multiple, the underlying mechanism is unique; syncope is the consequence

of a transient global decrease of cerebral blood flow. Cerebral vascular autoregulation ensures that the cerebral blood flow is maintained within a large range of systemic blood pressure. In elderly people, especially in those with chronic hypertension, cerebral vascular autoregulation system is altered, leading to an increased incidence of syncope in this population. A number of other factors increase the risk of developing syncope among the elderly, such as age-related physiological changes in heart function, blood pressure, baroreflex sensitivity, intravascular volume regulation, comorbid conditions, and concurrent medications. The main age-related physiological changes that predispose to syncope are listed in **Table 2**.

Clinical Approach

The main goals in the management of the patient with syncope are the following:

- To establish whether the patient had syncope or not
- To determine the cause of syncope
- To decide whether the patient needs to be hospitalized
- To treat the causes of syncope.

Table 2 Main age-related physiological changes that predispose to syncope

Blood vessels	• Impaired endothelial (NO)-dependent vasorelaxation • Increased endothelin release in the aging vessels, promoting vasoconstriction
Heart	• Age-related stiffening of arterial vessels leading to increased afterload pressures and cardiac concentric hypertrophy • Subsequent alteration in ventricular walls compliance and in diastolic function • Age alterations of nodal tissue, increasing the incidence of atrial fibrillation, heart block, and sick sinus syndrome • Atrial dilatation and fibrosis, increasing the risk of atrial fibrillation
Autonomic nervous system	• Diminished beta-adrenergic responses leading to reduced cardioacceleration • Altered baroreflex responsiveness
Endocrinal changes	• Impaired renin and aldosterone production • Impaired thirst response contributing to hypovolemia

Diagnostic and Management Strategy

Because syncope is a symptom, not a disease, identification of the cause is essential for successful management. Ordinarily, the evaluation and treatment of patients with syncope often do not rely on an appropriate well-defined management strategy. The consequences are multiple: too many useless diagnostic tests, too many hospital admissions, increased costs, and too many patients in whom the diagnosis remains undetermined.

In the older patients, particularly, the identification of the cause must be difficult because of multiple potentially causal factors, amnesia of the episode, lack of witness, overlap with falls, and additional cognitive impairment.

Several guidelines have been published for the diagnostic approach to patients with syncope. None has been validated prospectively. However, it has been demonstrated that the use of a diagnostic algorithm, especially in the setting of syncope units, may improve significantly the use of appropriate investigations, reduce the number of syncope remaining without a defined etiology at discharge, and reduce the number of hospital admissions and total length of hospital stay without affecting recurrent syncope and all-cause mortality.

The European Society of Cardiology published in 2001 high-quality guidelines for the management (diagnosis and treatment) of syncope, and in 2004, an update of the text. Important recommendations of this guideline include the following:

- A detailed history, physical examination, and an electrocardiogram (ECG) are the components of the initial evaluation of a syncopal episode. This first step may lead to a diagnosis (e.g., orthostatic hypotension, situational syncope, drug-induced syncope, complete atrioventricular block) or suggest a diagnosis that can be confirmed or excluded with directed investigations. If the diagnosis is not confirmed, these patients are approached as unexplained syncope.
- After the initial evaluation, when syncope remains unexplained, in the absence of contraindications, a carotid sinus massage should be performed in all elderly persons, given the high prevalence of carotid sinus syndrome as a cause of syncope in this age group.
- The decision for further diagnostic tests depends on whether there is evidence of underlying structural heart disease (**Figure 1**). In the young adult, clinical evaluation (history, physical examination, and ECG) is sufficient to identify or exclude the presence of heart disease. In older persons, given

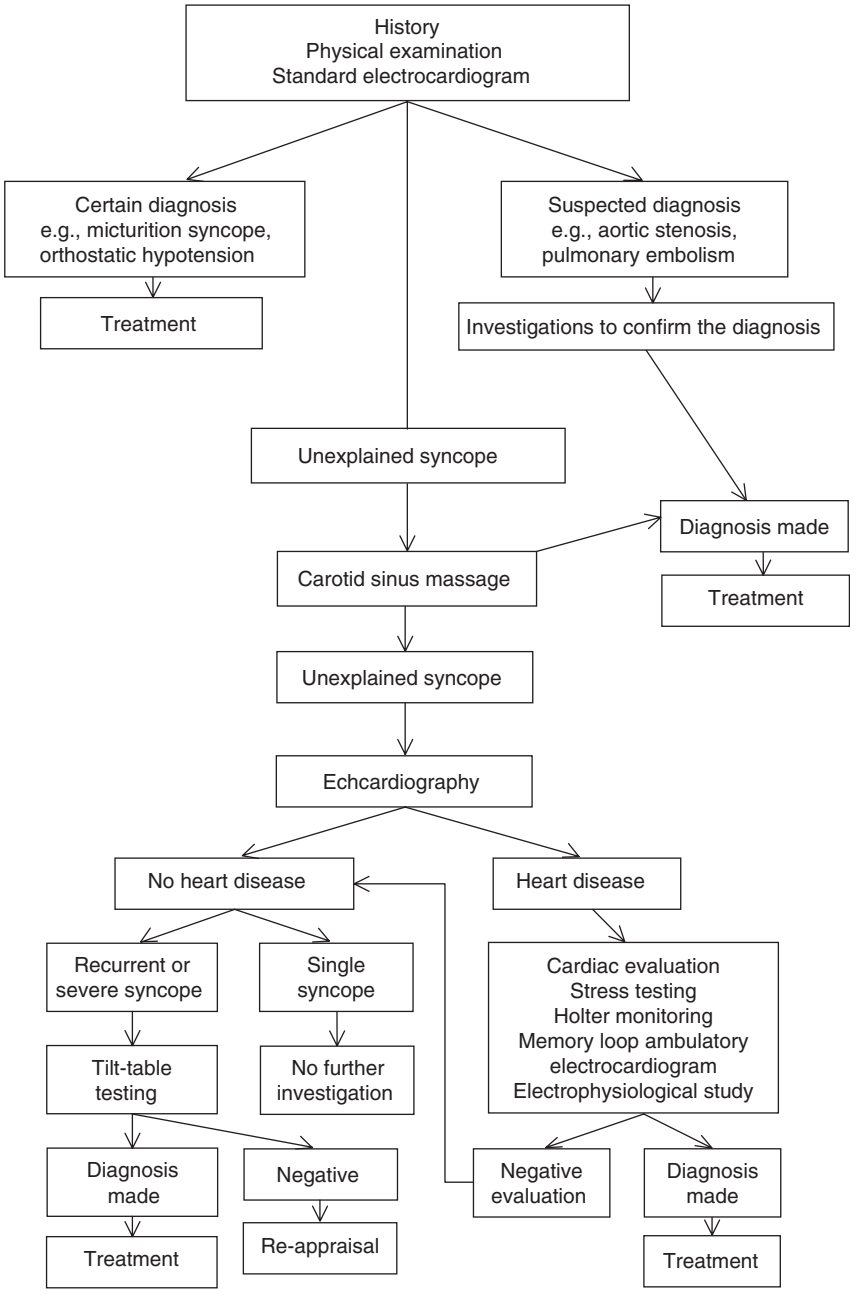

Figure 1 Diagnostic algorithm for syncope.

the high prevalence of cardiac diseases, an echocardiogram, a stress testing, or both are recommended to determine the presence or absence of underlying cardiac disease. But this question has not been addressed by valuable studies.

- The presence of heart disease is a strong predictor of cardiac cause of syncope. Consequently, patients who have evidence or suspicion of organic heart disease are at much higher risk for bad outcomes associated with syncope, with a higher risk of arrhythmias and a higher mortality at 1 year. In these patients, cardiac evaluation (consisting of echocardiography, stress testing, and tests for arrhythmia detection such as Holter monitoring and memory loop ambulatory ECG, and electrophysiological study) is recommended.
- When heart disease is absent, a cardiac cause is unlikely unless syncope is preceded by palpitations, which could be due to paroxysmal tachycardia. In the other cases, evaluation for neurally mediated syndromes by a tilt table test is recommended in those with recurrent or severe syncope.
- Generally, a cause of syncope can only be concluded if there is a sufficiently strong correlation

between syncopal symptoms and the detected abnormalities on investigations.

- In vigorous older patients with syncope, the clinical approach and the assessment are the same as for younger adults, with the exception of routine carotid sinus massage. In frailer older adults, evaluation should be modified according to functional status, prognosis, and compliance with tests. When multiple abnormalities are identified, they should be treated with the presumption that the syncope may be multifactorial.
- If the evaluation remains negative, the entire approach should be reappraised. Reevaluation may include the retaking of a history and the interviewing of witnesses to obtain more additional information. Close follow-up of patients with syncope of unknown cause is recommended, and a complete reassessment should be undertaken if the patient has recurrences.
- While most younger patients (without heart disease) can be effectively evaluated and managed as outpatients, a majority of older patients with syncope must be hospitalized:
  - for a rapid diagnostic evaluation in the presence of a known or suspected heart disease because of concerns about serious arrhythmias and sudden death
  - for the treatment of the cause when this treatment requires hospital admission (e.g., pulmonary embolism or severe orthostatic hypotension).
- The goals of the treatment of patients with syncope are, first, the prevention of symptom recurrence and associated injuries, and, second, the improvement of quality of life. Treatment (discussed earlier) depends on the underlying cause of the symptom.

Initial Evaluation

History A detailed account of the associated symptoms and the symptoms preceding and following the loss of consciousness is crucial to the diagnosis. These events and symptoms were described in detail previously for each cause of syncope and are summarized in **Table 3**. In addition to the history given by the patient, information available from a witness of the event is very important because of the problem of frequent amnesia of the episode in older adults.

Past medical history, especially of cardiac diseases and non-cardiac diseases or risk factors that increase the likelihood of cardiovascular syncope (diabetes, anemia, hypertension), must be recorded.

The history should include details of medication use, in particular, changes in medication. Usually, the differential diagnosis between syncope and non-syncopal disorders (**Table 4**) is rather easy. However, epilepsy may be difficult to distinguish from syncope. Features that help to distinguish syncope and epilepsy are the precipitants of the episode, the prodromal symptoms, the symptoms that accompany the episode, and the events that follow it. The presence of confusion after the event is the single most powerful discriminator between seizure and syncope.

Loss of consciousness precipitated by pain, exercise, micturition, defecation, or stressful events is generally due to syncope. Aura such as typical unpleasant smell may precede a seizure. Aura patterns are usually repetitive over time in patients, who will therefore learn to recognize them as such. Symptoms

Table 3 Events preceding and following the loss of consciousness

Cause of Syncope	*Prodromal symptoms*	*Situations and precipitating factors*	*Symptoms following the loss of consciousness*
Neurally mediated syncope	Nausea, pallor, diaphoresis, visual blurring, light headedness, hearing loss, weakness	Neck turning, stressful or emotional situations, pain, fear, crowding, prolonged upright posture, cough, micturition, swallowing, defecation	Lack of postsyncope drowsiness
Cardiac syncope	Sudden onset, effort, or exertion, preceding chest pain, palpitations	Drug-related arrhythmia: anti-arrhythmics, neuroleptics, digoxin, beta-blockers, alcohol, illicit drugs	Rapid resolution of symptoms
Orthostatic hypotension	Abrupt changes in posture	Drug-related: angiotensin converting enzyme (ACE) inhibitors, nitrates, diuretics, alcohol	

Table 4 Non-syncopal disorders from which syncope or pre-syncope must be distinguished

Non-syncopal disorders with impairment or loss of consciousness	• Metabolic disorders, including hypoglycemia, hypoxia, hyperventilation with hypocapnia ○ Epilepsy ○ Intoxications ○ Vertebro-basilar transient ischemic attack
Non-syncopal disorders without loss of consciousness	• Cataplexy • Drop attacks • Vertigo • Psychogenic syncope (somatization disorders)

such as sweating, nausea, and vomiting before or after the event are associated with syncope. A long duration of loss of consciousness ($\geqslant 5$ min), aching muscle, tongue biting, and prolonged confusion after the event suggest a seizure. Urinary incontinence is not useful in the distinction. Witnesses should be asked to describe any movements. A loss of consciousness without any movement makes epilepsy unlikely, and rhythmic movements (such as clonic or myoclonic jerks) suggest seizure. However, movements do not exclude the diagnosis of syncope. In syncope, tonic-clonic movements are always of short duration (<15 s) and they start after the loss of consciousness, while in epilepsy, tonic-clonic movements are usually prolonged and their onset coincides with loss of consciousness.

Physical Examination The physical examination includes a search for trauma and assessment of severity. Cardiovascular examination may give some clues about the presence or absence of an underlying cardiac or pulmonary pathology. Blood pressure and pulse measurements should be taken both in the supine and standing positions. Special attention also should be paid to neurological signs and locomotor systems, including observation of gait and standing. If cognitive impairment is suspected, this should be formally determined. The Mini Mental State Examination is a useful tool for the initial evaluation of the cognitive status.

Electrocardiogram Electrocardiogram is recommended in all elderly patients. It is commonly abnormal, revealing, for example, sinus node dysfunction, tachycardia–bradycardia syndrome, or abnormal conduction (prolonged PR interval, bundle-branch block), old myocardial infarction, or ventricular hypertrophy. But in most patients, ECG is not diagnostic (in less than 5% of patients). However, a normal ECG reduces the likelihood of cardiac syncope.

Current Investigations Used to Assess Syncope

Echocardiography Echocardiography is a non-invasive test that is well tolerated even by frail elderly patients. When a cardiac disease is suspected due to history, physical examination, or ECG, the echocardiography can be very useful to identify potential causes of cardiac syncope. In the elderly, echocardiography is essential to exclude the presence of a structural heart disease. Echocardiography reveals frequently unsuspected abnormalities such as left ventricular global and regional wall dysfunction, dilated or hypertrophic cardiomyopathy, and aortic and mitral valve disease, all of which predispose the patient to arrhythmias and cardiogenic syncope. However, the discovery of such abnormalities does not necessarily lead to the diagnosis of a cause.

Exercise Stress Testing Exercise stress testing is principally useful in patients who experience syncope on exertion. The test should be closely monitored during the exercise and recovery phases. It can reveal catecholamine-sensitive ventricular tachycardia, rate-dependent atrioventricular block, or exercise induced neurally mediated syncope.

Ambulatory Continuous Electrocardiography In patients with structural heart disease or abnormal ECG, arrhythmias are the major concern. Holter monitoring and memory loop ambulatory ECG recording are used in the evaluation of these patients.

Because Holter monitoring allows recording of ECG during 24 h, it is most useful in patients with multiple or frequent episodes of syncope over a short period of time. When typical symptoms occur while the ECG is being recorded, it either identifies the arrhythmia causing the syncope or excludes arrhythmia as a cause of the symptoms. However, this situation is very rare. Extending the recording to 72 h did not increase dramatically the yield for symptomatic arrhythmias. A normal Holter monitoring without symptoms does not exclude the possibility that the syncope is due to an arrhythmia. The interpretation of an arrhythmia without associated symptoms must be cautious because a wide range of arrhythmias have been reported in healthy asymptomatic individuals. However, complete heart block, sinus pauses of more than 2 s, and ventricular tachycardia are rarely reported in asymptomatic patients.

Memory loop ambulatory ECG recording is more useful than Holter monitoring in patients with infrequent symptoms. The memory loop recorders allow

the recorded ECG data to be stored. The device is worn continuously. When the patient activates the device, an ECG recording from 1 to 4 min before and 30–60 s following pressing the recording button is obtained. The data can be transmitted over the telephone at the patient's convenience. Unfortunately, many older patients are not compliant, and up to 20% of patients do not wear or operate the device appropriately.

The most recent development in this technology is a small implantable loop recorder (ILR) (Reveal; Medtronic, Minneapolis, USA). The device is placed subcutaneously. The compliance is better with this system. The device continuously records the ECG into its looping memory for up to 18 months. An external activation device is used at the time of symptoms. The device stores ECG data 20 min before and 4 min after activation. However, a small proportion of patients are unable to activate the device after a spontaneous event. In a study, it has been reported that the use of these devices established a symptom–arrhythmia correlation in 42% of the 85 patients who had recurrence of symptoms within 3 months of implant.

Invasive Electrophysiological Studies Invasive electrophysiological studies allow the measurement of conduction times between specific cardiac sites. They provide information about sinus node function, atrio-ventricular conduction, and ventricular conduction, thus determining the predisposition to abnormalities of cardiac conduction. Use of electrical extrastimuli coupled to normal sinus rhythm or paced rhythms can be used to evaluate the propensity for developing tachyarrhythmias and allow analysis of the mechanism of arrhythmias. The yield of electrophysiological tests depends on whether there is heart disease; the results are more likely to be positive in the patients with structural heart disease, especially those with an ejection fraction less than 40%. Generally, electrophysiological studies have poor sensitivity and specificity in patients with bradyarrhythmias associated with syncope. Loop monitoring is the test of choice when bradyarrhythmia is a consideration. Syncope can be attributed more confidently to abnormalities of His-Purkinje conduction. Syncope associated with induced or spontaneous ventricular tachyarrhythmias on electrophysiological testing is accompanied by a high risk of death. Induction of sustained monomorphic ventricular tachycardia (lasting > 30 s) in a patient who has experienced syncope makes this arrhythmia the likely cause of the syncopal episode. A negative stimulation response does not exclude a ventricular arrhythmia as the cause of the patient's previous symptoms. Cardiac arrest survivors with poor left ventricular function and negative electrophysiological studies have rates of sudden death of up to 30% at 1 year.

Tilt Table Testing Tilt table testing, also named head-up tilt table testing, is a non-invasive provocative test used to determine a patient's susceptibility to neurally mediated syncope. As demonstrated by a large prospective study including 1096 subjects aged 60 to 74 and 873 aged 75 and older, tilt table testing is a safe and well-tolerated investigation in older people with one cardiovascular and no neurological complications.

Tilt table testing is best considered for patients with suspected neurally mediated syncope but in whom the cause is not obvious or in patients with syncope of otherwise unknown origin with no evidence of structural heart disease. Because the symptoms, the hemodynamic responses, and the release of catecholamines during tilt table testing are similar to those during spontaneous vasovagal syncope, tilt table testing is believed to provoke vasovagal syncope in susceptible persons.

During the test, the patient should be in a fasting state, blood pressure and electrocardiographic monitoring should be continuous, and resuscitative equipment should be available. The head of the table is tilted upward to an angle of 60 to 80°, with 70° most commonly used. The test is continued for 30 to 45 min unless hemodynamic collapse occurs earlier. If the drug-free test is negative, a provocative agent such as nitroglycerin or isoproterenol is administered, and tilting is continued for another 10 to 15 min. Sublingual nitroglycerine use with tilt table testing seems to be simpler and better tolerated, especially in the elderly and in those with coronary artery disease.

The result is considered positive for vasovagal syncope if the original symptoms are reproduced with objective evidence of an abrupt blood pressure decrease or bradycardia (or both). Patients with a dysautonomic response to tilt table testing demonstrate a gradual and progressive decrease in blood pressure with only a small or no significant change in heart rate.

Most studies suggest that such testing discriminates relatively well between symptomatic patients and asymptomatic control subjects. However, 10 to 15% of asymptomatic subjects have false-positive test results. Sensitivity of tilt table testing is more difficult to evaluate because there is no accepted diagnostic gold standard. It has been calculated at between 20 and 75%. Pharmacological provocation

increases the sensitivity of the test while the specificity decreases a little.

Neurological Investigations and Laboratory Tests In the absence of focal neurological deficits, and symptoms or a history suggestive of transient cerebral ischemia or seizure, computed tomographic scans of the head, electroencephalography, and carotid echo-Doppler have very low yield and should not be performed in patients with syncope.

Baseline laboratory tests (for electrolytes, renal function, blood sugar, and hemoglobin) rarely lead to an assignment of cause (in 2 to 3% of patients) but may reveal predisposing factors for various causes of syncope such as anemia or hypokaliemia.

Conclusion

Syncope and presyncope are great diagnostic challenges in geriatrics. Potential causes are multiple and the symptoms may result from a benign condition or from a serious cardiac disease that poses an imminent threat to life. Patients with a cardiac cause of syncope are at far greater risk of dying in the first year following the syncope than individuals with a non-cardiac cause. That is why the presence of a known or suspected heart disease helps to categorize patients into those with a high likelihood of cardiac syncope and those with a low likelihood. Cardiac evaluation is recommended in those patients with heart disease. In any case, a well-defined diagnostic strategy, in which the initial clinical evaluation is crucial, is needed to unmask the cause.

T

Telomeres

D M Baird, Cardiff University, Cardiff, UK

Glossary

Hayflick Limit – The number of cell divisions that define a cell's replicative capacity.

Replicative Senescence – A deleterious cellular phenotype acquired at the end of a cell's replicative capacity.

Telomerase – A ribonucleoprotein complex that displays reverse transcriptase activity that is capable of extending telomeres via the addition of telomere repeat units.

Telomere – Genetic elements located at the ends of linear eukaryotic chromosomes, composed of a repetitive DNA sequence and associated protein complexes.

Introduction

Telomeres are essential chromosomal structures that cap the ends of linear eukaryotic chromosomes. Incomplete DNA replication every time cells divide results in a gradual loss of telomeric sequences in human somatic tissues. Telomere erosion ultimately results in the loss of telomeric function, which in turn triggers the cells to enter a non-dividing but biochemically active state termed replicative senescence. Telomere-dependent replicative senescence is considered to have evolved as a tumor suppressive mechanism; indeed, 85% of human malignancies express the enzyme telomerase that synthesizes telomere repeat sequences, preventing telomere loss and facilitating unlimited cell division. Senescent cells have the potential to interfere with the tissue microenvironment, and the accumulation of senescent cells is considered to contribute to age-related tissue deterioration and disease. Consistent with this hypothesis, telomere loss is observed as a function of age in human tissue, and this loss has been linked to specific disease phenotypes.

Replicative Senescence and Aging

The observation that normal human fibroblast cells display a limited life span in culture was first described by Hayflick in the 1960s. This phenomenon appeared to result from an intrinsic ability of the cell to count not chronological time, but the number of cell divisions they have undergone. Indeed, quiescent or frozen cells, once allowed to resume growth, still undertake the same number of divisions as if they had been grown continuously, i.e., they appear to remember the number of divisions they had undergone prior to freezing. After a number of cell divisions specific to each strain, referred to as the Hayflick limit, the cells enter a state of irreversible growth arrest referred to as replicative senescence. Typically around 50–100 population doublings, the Hayflick limit varies between different individuals and biopsy sites. Despite this variation, there appears to be a general trend toward a decrease in the limit as a function of age, which may reflect the replicative history of the cells *in vivo*. Since the initial observations in fibroblast strains, many other human somatic cell types, including lymphocytes, astrocytes, endothelial cells, epithelial cells, and myocytes, have been shown to undergo replicative senescence. Senescent cells remain biologically active but display a change in their gene expression profile to a more catabolic and pro-inflammatory phenotype. For example, senescent cells upregulate specific matrix metalloproteinases (such as collagenase) and downregulate their corresponding tissue inhibitors; such a phenotype has been demonstrated to actively degrade the tissue microenvironment. Furthermore, senescent stromal fibroblasts can specifically stimulate the proliferation of premalignant epithelial cells in a manner similar to that described for carcinoma-associated fibroblasts. Thus, in addition to the simple cessation of cell division, an age-related accumulation of senescent cells has the potential to disrupt tissue homeostasis and

underlie age-related disease and cancer (*see* Cellular Aging: Growth Factors and Cellular Senescence).

Telomeric Functions and Structure

In the 1920s Herman Muller observed that after X-irradiation, *Drosophila* chromosomes have various types of internal rearrangements, including translocations, inversions, and deletions; however, no rearrangements that involved the ends of chromosomes were detected. Thus, he proposed the existence of an essential structure at the ends of chromosomes that was necessary to maintain chromosomal integrity. He named these structures telomeres, meaning end parts. In the 1930s, Barbara McClintock, working on chromosomes in the endosperm of maize, observed the effects of losing telomeric functions; dicentric chromosomes were observed to undergo anaphase bridging, resulting in chromosome breakage and further cycles of fusion, bridge, and breakage. However, these cycles did not continue indefinitely, as in embryonic tissue she described chromosome healing whereby the broken ends were no longer fusagenic and behaved like natural chromosome ends. Thus, telomeres were demonstrated to be specialized structures that cap the ends of chromosomes and prevent end-to-end fusion. The molecular structure of telomeres was not established until 1978 when Elizabeth Blackburn was sequencing the rRNA genes in *Tetrahymena*. The genome of *Tetrahymena* contains tens of thousands of linear DNA molecules containing amplified genes; Blackburn discovered that the rRNA genes terminated in tandem arrays of the hexameric sequence TTGGGG. Within 10 years of this discovery, related simple sequence elements were discovered at the chromosome ends of the majority of eukaryotes. In 1988 the human telomeric sequence was established to be TTAGGG reiterated into arrays of 5–20 kb.

After the mechanisms of DNA replication had been elucidated, a potential additional role for telomeres was proposed by Alexey Olovnikov in 1971 and independently by Watson in 1972. Olovnikov pointed out a problem that would arise when linear DNA was replicated by semiconservative replication initiated from RNA primers. When the replication fork reaches the end of the chromosome, the continuous strand will be synthesized 5′ to 3′ of the end of the molecule, creating a fully replicated chromosome. However, the discontinuous or lagging strand that is synthesized in discrete units (Okazaki fragments) each initiated from an RNA primer could not be fully replicated. Even if the last RNA primer was located at the end of the molecule, once removed there would a gap at least as long as an RNA primer and potentially up to the length of an Okazaki fragment (**Figure 1**). The outcome of this would be a gradual shortening of the telomere with each round of replication. Showing remarkable insight, Olovnikov pointed out that this could create a cell division counting mechanism that had the potential to account for replicative senescence.

The answer to Olovnikov's end replication problem came again from *Tetrahymena*. It had been noted that plasmids containing *Tetrahymena* telomere repeats could function as telomeres in yeast via the addition of yeast telomere repeats onto the end of the *Tetrahymena* repeats. Thus, the existence of a terminal transferase activity was postulated, and the abundant telomeres of *Tetrahymena* rendered this organism a good source of this activity, which was subsequently purified by Greider and Blackburn in 1985. Further work established that this activity was a reverse transcriptase with a RNA component that templated the addition of telomere repeats on to the 3′-OH of the terminus; the enzyme complex was termed telomerase.

In humans the G-rich telomeric DNA strand is orientated 5′ to 3′ toward the terminus, and the terminus is composed of a 3′ overhang of several hundred bases in length. It is now established that human telomeres are composed of a nucleoprotein complex that folds back on itself to form a lariat structure termed a T loop that may be facilitated in part by strand invasion of the 3′ overhang into the beginning of the telomere repeat array. This T loop may mediate some of the functions of telomeres by sequestering away the terminus such that it is not available for fusion. A complex set of proteins have been identified that together form functional telomeres. These proteins are assembled to two major complexes formed around the telomere repeat binding factors TRF1 and TRF2 that in dimeric form directly bind TTAGGG repeats. Numerous proteins have been identified on the basis of their interaction with these two proteins. A key role of the TRF1 complex is in the regulation of telomere length via a telomere repeat counting mechanism that regulates the access of telomerase to the terminus, thus creating a negative feedback loop. Consistent with this concept, the overexpression of TRF1 in telomerase-expressing cells results in telomere shortening, whereas a dominant negative TRF1 that inhibited the binding of endogenous TRF1 resulted in telomere elongation. Components of the TRF1 complex are involved in functions in addition to telomere length regulation; for example, the TRF1 regulating protein TANK1 is required for sister chromatid separation at the telomeres during mitosis. The TRF2 complex plays a key role in the end protection function of

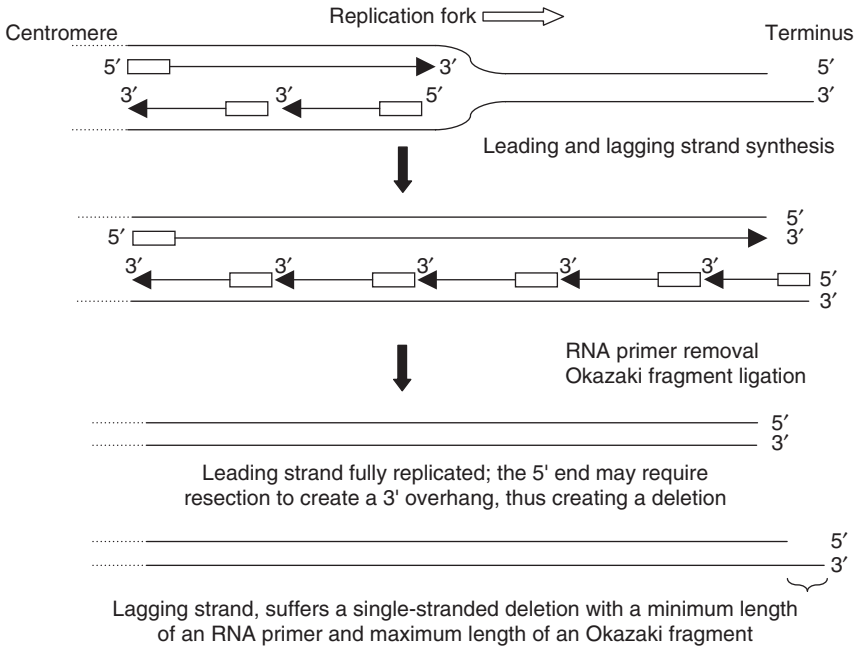

Figure 1 A schematic showing the end replication problem. When a DNA replication fork reaches the terminus of a linear DNA molecule, the leading strand (continuous) is fully synthesized. If the RNA primer (box) of the last Okazaki fragment of the lagging strand (discontinuous) is placed at the terminus, the strand will suffer a single-stranded deletion of the size of the RNA primer. Additional bases will be lost if the primer is not placed at the terminus. The 3′ overhang is required for telomere structure and function and as a substrate for telomerase-mediated lengthening. Thus, there may be a requirement for the leading strand to be resected to create a 3′ overhang; such an activity would result in an additional loss of telomeric sequences. When the daughter strands are subsequently replicated, the single-stranded deletion will be converted into a double-stranded deletion. In the absence of telomerase, the measured rates of telomere loss in human cells due to the end replication problem (plus the putative resecting activity) are between 50 and 120 bp/cell division.

telomeres; dominant negative TRF2 induces end-to-end telomeric fusions that are independent of telomere length. Interestingly, various proteins involved in DNA repair localize to telomeres via their interactions with TRF2 to form the TRF2 complex. Conversely, TRF2 and telomerase have been shown to localize to non-telomeric double-strand breaks. The details of the complex interplay between telomeric proteins and the DNA damage apparatus remain to be elucidated.

The Dynamics of Telomere Loss

The majority of human somatic cells display no detectable telomerase activity, the activity in humans being restricted to the stem cell compartments of actively proliferating tissues and at least 85% of malignancies. Both the human telomerase components have been cloned and characterized; the RNA component (hTERC) is expressed in all cell types, and the limiting component of telomerase activity is the expression of the catalytic component (hTERT). Recent reports have demonstrated that transient telomerase activity can be detected during S phase (in cells that were previously considered not to express hTERT). The function of this activity is currently unclear, but it could be capable of creating the terminal 3′ overhang that is important for end protection.

As Olonikov predicted, the expression pattern of telomerase means that in the majority of cell types, telomeres shorten every time the cells divide. This was first observed in 1990 by Harley and co-workers, whose analysis of telomere length in human fibroblast cells cultured *in vitro* revealed a gradual loss of telomeric sequences with ongoing cell division. Later, Allsopp and co-workers, in a study of cells obtained from donors aged between 0 and 93, observed a relatively weak correlation between replicative capacity and donor age, but, strikingly, a strong correlation was demonstrated between the proliferative capacities of cell cultures and the telomere length of the starting cell population. These observations made it clear that telomere length was a biomarker of cellular aging and led to the hypothesis that telomere erosion could account for the cell division counter that determined the Hayflick limit. Conclusive proof of this came after the cloning of hTERT and when it was ectopically expressed in mortal telomerase negative cell cultures (**Figure 2**). These cultures were shown to have stabilized the length of their telomeres and continued to proliferate well beyond their respective Hayflick limits.

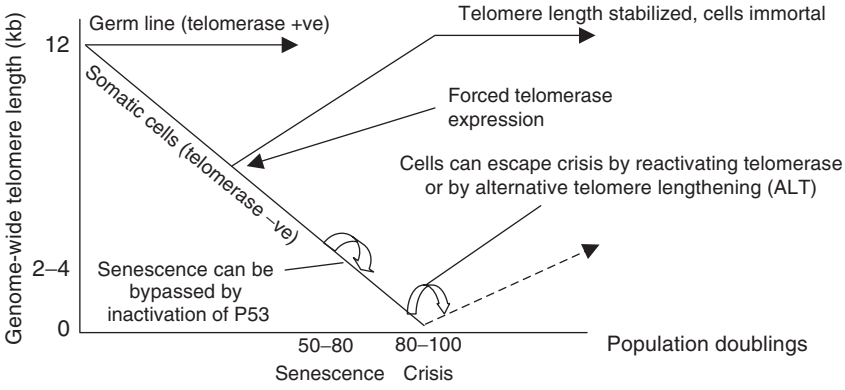

Figure 2 The relationship between telomere loss and replicative senescence. Telomerase expression in the germ line maintains telomere length for subsequent generations (germ line immortality). The majority of cells from somatic tissues do not express telomerase and therefore exhibit telomere erosion with ongoing cell division. Ultimately, the loss of telomeric function triggers a P53-dependent checkpoint known as replicative senescence. The forced expression of telomerase prior to senescence re-lengthens the telomeres and prevents the onset of replicative senescence; these cells are immortal. Replicative senescence can be bypassed by the abrogation of P53; for example, with HPV oncoproteins E6/E7, the cells continue to divide and lose telomeric sequences until a point termed crisis, which is characterized by extensive genomic instability and cell death. At a very low frequency in human cells, crisis can be overcome via the reactivation of telomerase or alternative telomere lengthening (ATL).

Importantly, however, other than their apparent immortality, these cell cultures did not demonstrate any of the characteristics of transformed cells; for example, they maintained their karyotypes, contact inhibition, and responses to serum deprivation. Replicative senescence is triggered when telomeres have eroded to a length at which telomeric functions can no longer be maintained. Neither the number of telomeres nor the critical telomere length at which senescence is triggered has yet been defined, but the minimum telomere length in senescent cells currently stands at around 1 kb. The loss of telomeric function triggers a double-strand DNA damage response triggering a p53-dependent G1/S cell cycle checkpoint. The abrogation of this checkpoint, for example, with the viral oncoproteins HPV E6/E7, leads to continued cell division and telomere erosion (**Figure 2**). This ultimately leads to a second proliferative life span barrier known as crisis that is characterized by genomic instability that probably arises as a result of extensive loss of telomeric function. In this situation there is a strong selective pressure for cells to stabilize their genome; thus, the cells that escape crisis have reactivated telomerase activity or found alternative routes to maintain telomere length.

The concept that the erosion of telomeres accounted for the Hayflick limit created an intense interest in the role that telomere biology may play in the human aging process. Telomere length is maintained in the germ line at its maximum length (10–20 kb) for subsequent generations by the expression of telomerase. However, in somatic tissues and cells, where telomerase is repressed in the majority of cells, telomere length is extremely heterogeneous, and this can confound the interpretation of telomere length data. This heterogeneity arises from multiple processes that influence cellular telomere length. The end replication problem is intrinsically heterogeneous (**Figure 1**), with each daughter cell receiving telomeric molecules of different lengths. Furthermore, the rate of loss observed in humans, typically 50–120 bp/population doubling, is less that that predicted by end replication losses alone and is less than observed in lower eukaryotes that have been engineered to not express telomerase. This suggests that human telomeres may be subjected to additional processing that causes more DNA to be lost from the terminus. Such activity has yet to be identified, but it could include C-strand resecting to create the 3′ overhang; clearly, such an activity would contribute to the overall heterogeneity of end replication losses. High-resolution telomere length analysis methods such as single telomere length analysis (STELA) are now available; these have revealed that in addition to the end replication losses, telomeres suffer sudden large-scale deletion events. Such events may be mechanistically similar to telomere rapid deletion observed in yeast and would contribute significantly to the overall heterogeneity of telomere length. In addition, there is some evidence to suggest that when compared to other genomic loci, telomeres may be more sensitive to oxidative damage. Indeed, telomeres were referred to by von Zglinicki in 2002 as sentinels for genomic damage. Oxidative damage contributes to rates of telomere erosion and telomere length heterogeneity in cultured human cells; the mechanisms are currently unclear, but they may include the induction of

telomere rapid deletion. The majority of our understanding of human telomere dynamics has been gained from cells grown in culture, and the kinetics of cell division of cultured cells can indirectly influence the measured rates of telomere loss. An extreme example of this is observed with Werner syndrome fibroblasts (a segmental progeroid syndrome) (*see* Premature Aging), these cells have an extremely attenuated replicative capacity. The majority of growth in the culture is accounted for by a small number of clones that are capable of growth; these eventually exhaust their replicative capacity and can be replaced by newly dividing clones. In this situation, the growth of the culture (measured as population doublings) does not equal the cell division of the proliferating clones. Thus, when telomere erosion is expressed as a function of population doublings it will appear to be elevated, when at a single cell level the rate is within the normal range. Thus, the kinetics of cell division both *in vitro* and *in vivo* will contribute to telomere length heterogeneity. In addition, as telomerase activity elongates the shortest telomeres in preference to the longest and adds heterogeneous amounts of telomere repeats, this will contribute significantly to telomeric heterogeneity, particularly in a tissue biopsy containing telomerase-expressing cells.

Implications for Human Aging

Despite the potential problems associated with the detection of significant correlations with such a heterogeneous system, information has been gained regarding telomere length and age in humans. Numerous cross-sectional surveys of telomere length in various human tissues have been undertaken. The key points from these studies are that telomere loss has been observed in human tissues, the extent of which varies between tissues and appears to correlate with levels of cellular turnover. For example, cerebral cortex and myocardium display negligible cell turnover and display no apparent telomere loss with age, whereas tissues such as the liver, kidney, lymphocytes, endothelium, and the epidermis all display varying degrees of telomere loss (**Table 1**). Furthermore, several datasets, particularly those obtained from peripheral blood cells, reveal that the majority of telomere erosion occurs during early life, appearing to stabilize during adulthood with further erosion in the later years. This could be explained by the increase in cellularity during early life; however, in tissues such as the immune system, skin, and gastrointestinal mucosa, whose function is supported by significant cellular turnover, telomere lengths may be stabilized by telomerase activity in stem cells. The

Table 1 Telomere dynamics and telomerase immortalization of human cells

Cell type	*Telomere loss*		*Telomerase activity*	*hTERT immortalization?*[a]
	In vivo (age)	*In vitro (population doublings [PD])*		
Bone marrow stromal cells	na	✓	Negative	Immortal
Chrondrocyte	✓	✓	Negative	Life span extension in low O_2
Corneal keratocytes	na	✓	Negative	Immortal
Endometrial stromal	na	✓	Negative	Immortal
Epithelial[b]	✓	✓	Negative	Immortal
Fibroblast[b]	✓	✓	Negative	Immortal
Hepatic stellate	na	✓	Negative	Immortal
Hematopoietic progenitor cells (CD34+)	na	na	Positive	No life span extension, enhanced survival
Hepatocytes	✓	✓	Negative	Immortal
Keratinocytes	✓	✓	Negative	Immortal only on feeder layers
Lymphocytes[b]	✓	✓	Transiently (following activation)	Life span extension
Myoblasts	✓ (in muscular dystrophies)	✓	Negative	Life span extension, not immortalized
Neural progenitor	na	✓	Negative	Immortal (>168 PD)
Osteoblasts	na	✓	Negative	Life span extension (>30 PD)
Retinal pigment epithelial	na	✓	Negative	Immortal
Retinal microvascular endothelial	na	✓	Negative	Life span extension (>100 PD)
Smooth muscle	na	✓	Negative	Life span extension (>100 PD)

[a] Several cell types require abrogation of p53 to facilitate hTERT immortalization; these were not included in this list.
[b] Similar results have been observed with the same cell types from several different tissues or in the case of lymphocytes in specific differentiated subsets.

majority of these cross-sectional telomere length studies were undertaken using terminal restriction fragment (TRF) analysis; this has several limitations, most notably its inability to detect the shortest telomeres that are likely to trigger replicative senescence. The correlations of telomere loss as a function of age are often weak and the telomere loss rates appear small. However, the problems with TRF analysis coupled with the inherent heterogeneity of telomeres may be masking more significant rates of erosion.

The hematopoietic system has been extensively studied for telomere dynamics and aging. It is becoming clear that, while the upregulation of telomerase activity in proliferating lymphocyte clones maintains telomere length in the early rounds of clonal expansion in response to specific antigens, this activity diminishes with repeated stimulation. Therefore, with successive clonal expansions, telomere erosion may limit the proliferative capacity of lymphocytes. Consequently, there is considerable interest in determining whether telomere-dependent replicative senescence may account for age-related immunosenescence.

More recently studies have been undertaken that utilize new developments in telomere length analysis and appropriate sampling to limit heterogeneity. These studies are revealing significant correlations of telomere length with age-related diseases and lifestyles. High-throughput quantitative PCR methods for telomere length determination have revealed correlations between short telomeres and psychological stress and that short telomeres in the blood increased the risk of mortality from heart disease 3.2-fold and from infection 8.5-fold in individuals over the age of 60; however, this risk was not significant in individuals over 75 years of age. Twin studies using TRF analysis revealed shorter telomeres in smokers and obese individuals. Telomere shortening in blood has been correlated with atherosclerosis, and quantitative trait linkage analysis using TRF data has revealed genomic loci that may contain telomere length regulators. While it is clear that telomere loss triggers replicative senescence and telomere loss occurs with age and can be modulated by lifestyle, a direct biological link between telomeres and human aging is tantalizing, but as yet not proven. However, the potential consequences of telomere loss in aging human tissues are becoming clear from both mouse models and human genetic diseases. Mice have long telomeres, and both cellular and organismal aging are not considered to be telomere driven in this organism. Consistent with this, telomerase knockout mice showed no phenotype in the first few generations. However, after four to six generations there had been sufficient cell turnover for the long mouse telomeres to have shortened sufficiently for the mice to exhibit specific phenotypes, some of which resembled age-related tissue deterioration and disease in humans. In addition to a reduction in longevity, these phenotypes included immunosenescence, with the mice showing a compromised reactivity of the germinal centers and a reduced replicative capacity of both T and B lymphocytes; age-related cutaneous phenotypes such as an impaired wound healing response and an earlier onset of skin ulcerations, hair graying, and alopecia; increased cancer incidence, which may have been a consequence of an increase in chromosomal fusions and aneuploidy; and weight loss due to a disruption of the villous architecture of the intestine. These phenotypes represent an extreme example of telomere loss and may not accurately model the gradual loss of telomeric sequences in long-lived organisms causing a progressive increase in the proportion of senescent cells over long periods. Nevertheless, they reveal the consequences of a loss of telomere function causing proliferative defects in tissues subjected to high levels of cellular turnover. Further insights into telomere biology and aging have come from human genetic disorders that result from mutations that affect telomerase activity. X-linked recessive dyskeratosis congenita (DKC) originates from mutations in the dyskerin gene (DKC1), a small nucleolar ribonucleoprotein (snoRNP) thought to be a pseudouridine synthase that may play a role in RNA processing. A second form of DKC results in the autosomal dominant form, which is a consequence of mutations in the RNA component of telomerase. The functional association of DKC1 with hTERC led to the realization that DKC is a telomerase deficiency disorder and that the DKC1 protein may be required for stability of the telomerase complex. Indeed, DKC individuals are haploinsufficient for the expression of hTERC, which results in lower levels of telomerase activity and shorter telomeres. Furthermore, like the telomerase knockout mice, DKC pedigrees display disease anticipation in which the age of onset and severity of the condition increases between generations, and this is associated with progressive telomere shortening from one generation to the next. DKC results in symptoms that show similarity to the phenotypes of the telomerase knockout mice; indeed, it has been described as a disease of premature aging. The defects primarily arise in proliferative tissues, the most profound of which are bone marrow failure or aplastic anemia, which is the most prevalent cause of death in DKC patients. The condition results in cancer predisposition and mucocutaneous features including leucoplakia of tongue, abnormal skin pigmentation, nail dystrophy, alopecia, and premature graying of hair. Thus, it is clear that telomere defects in humans

result in severe phenotypes, some of which resemble normal human aging. An understanding of the nature of the telomeric signal that triggers replicative senescence, for example, how many telomeres and how short they have to be, coupled with further work utilizing the new generation of high-resolution telomere length analysis technologies, will allow us to come to an understanding of the extent of telomere loss as a function of age in humans. In particular, documenting the accumulation of severely shortened telomeres that are capable of triggering replicative senescence will allow us to assess the functional significance in terms of age-related disease and tissue deterioration.

What about potential telomere-based therapeutics for age-related disease? As explained earlier, the key experiment that defined the role of telomere loss in triggering replicative senescence and accounting for the Hayflick limit was the bypassing of the senescence checkpoints by the forced expression of telomerase. By adjusting the culture conditions to minimize the impact of additional cell cycle checkpoints such as that mediated via p16, for example, by using physiological oxygen tensions and feeder layers, telomerase expression has resulted in an extension of replicative life span and often immortalization in numerous cell types (**Table 1**). These cells maintain their differentiated status and do not exhibit the characteristics of transformed cells. Importantly, these experiments have allowed us to understand that telomere-dependent senescence is widespread in human tissues. Furthermore, the understanding that many of these cell types exhibit age-related telomere loss *in vivo* led to the conclusion that telomere loss in these tissues is at least theoretically capable of triggering replicative senescence, and indeed that this can be prevented by telomeric stabilization via reactivation of telomerase. Some lines of evidence have emerged from animal models to support the concept that telomerase reactivation could have therapeutic potential. These include a mouse model in which *in vitro* aged dermal fibroblasts were incorporated into reconstituted human skin, which resulted in fragility and subepidermal blistering reminiscent of aged human skin, whereas the forced expression of hTERT in the same aged fibroblasts restored the phenotype. In addition, human bone marrow stromal cells ectopically expressing telomerase appeared immortal yet maintained their differentiated status and osteoblastic markers. Upon implantation into mice, these cells displayed an enhanced ability to produce bone compared to normal cells. In the telomerase knockout mice, experimentally induced liver cirrhosis was associated with telomere dysfunction; this was successfully treated by adenoviral delivery of the mouse telomerase RNA component to reconstitute telomerase activity.

The telomere barrier to unlimited replication imposed in most human somatic cells by a combination of telomerase inactivation and species-specific telomere lengths is considered to have evolved as a tumor suppressive mechanism. Thus, the reactivation of telomerase for therapeutic purposes would have to be carefully controlled, and the ideal therapy would use small molecule activators of the endogenous catalytic component of telomerase, the key advantages being that the reactivation of telomerase could be more carefully controlled, with perhaps a transient reactivation to re-lengthen telomeres and restore proliferative capacity. This work will be facilitated by a greater understanding of the genetics of control of the hTERT gene; currently it is known that estradiol can transactivate hTERT via the estrogen response elements in the *hTERT* promoter and that the oncogene c-Myc induces hTERT expression potentially via c-MYC binding sites (E boxes) in the hTERT promoter. Thus, the potential for small molecule activators of telomerase looks promising. In the absence of small molecule telomerase activators, alternative therapeutic strategies could be envisaged, the most promising of which could be the *ex vivo* manipulation of telomere length with hTERT expressing constructs, before being reintroduced into diseased tissue.

Telomeres and Cancer

Genetic instability is a hallmark of neoplastic transformation in humans; such instability is manifested by mutations at the DNA level or by gross chromosomal rearrangements. These rearrangements are required for epithelial carcinogenesis, occurring early in tumor development typically by the carcinoma *in situ* stage, after which the genome appears to stabilize with advancing malignancy. The apparent cessation of genomic instability appears to correlate with the activation of telomerase. Hence, there is considerable interest in the concept of telomerase inhibition as a potential chemotherapeutic agent for cancer. The later-generation telomerase knockout mice show telomere loss and genomic instability, which leads to both a lower age of onset and higher rates of tumor formation. Furthermore, mTERC$^{-/-}$ P53$^{+/-}$ compound heterozygous mice displayed a changed tumor spectrum from soft tissue sarcomas and lymphomas (observed in p53$^{+/-}$ mice) to carcinomas (observed in mTERC$^{-/-}$ p53$^{+/-}$ mice), demonstrating that an alteration in telomere length dynamics can cause a radical shift in tumor spectrum. Cytogenetic analysis

of tumors derived from late-generation telomerase knockout mice revealed high frequencies of chromosomes lacking telomeric signals, anaphase bridges, non-reciprocal translocations, and end-to-end fusions. These events were consistent with a loss of telomeric function resulting in genomic instability via cycles of bridge breakage and fusion driving early-stage neoplasia; this was in contrast to the analysis of tumors from early generation mice (with intact telomere function), which displayed no such events. Anaphase bridging can also result in complete chromosomal loss and the failure of cytokinesis, which can result in tetraploidization. These events, in particular non-reciprocal translocations, are observed in adult carcinomas but not pediatric cancer, in which reciprocal translocations are more common. Furthermore, an analysis of human pancreatic carcinomas revealed a negative correlation of terminal breakpoint frequency and telomere length. These data indicate a model whereby the loss of telomeric sequences with ongoing division during life in self-renewing tissues, most notably epithelium, results in telomere dysfunction. In the absence of a functional double-strand DNA break response, the ensuing genomic instability creates the appropriate rearrangements that may initiate tumor formation and facilitate the development to malignancy. The reactivation of telomerase re-establishes telomeric function and stabilizes the genome, allowing further tumor development. Thus, telomere loss as a function of age in self-renewing tissues may account for the age-related increase in carcinoma.

This model appears to contrast with the known expression profiles of telomerase in human somatic tissues, it being expressed only in the stem compartments of actively regenerating tissues. For example, proliferating keratinocytes at the basal layer of the skin epidermis exhibit high levels of telomerase activity, an activity that is absent in the more superficial layers. However, despite this activity a weak negative correlation of telomere length with age in DNA derived from skin has been documented. The mechanisms and cellular compartments that are responsible for this loss are currently unclear; however, it may be that the levels of telomerase are insufficient to fully counteract telomere loss or the additional mutational mechanisms other than end replication losses; for example, telomere rapid deletion may operate to create telomere loss even in the presence of telomerase. Thus, the stem cell compartments of highly proliferative tissues may be subjected to telomere loss, and the ensuing loss of genomic stability may underlie the age-related increase in cancer, particularly carcinoma.

Summary

The key role of telomere loss in the determination of proliferative life span of many human cell types has now been established. Telomere loss as a function of age has been documented in numerous human tissues and correlations observed with telomere length and age-related disease and stresses. Mouse models and human genetic diseases have clearly revealed the disorders of proliferative tissues associated with telomere shortening. *In vitro* studies have shown that it is possible to prevent telomere loss and the subsequent onset of replicative senescence, and rodent models have shown that it is possible to ameliorate some conditions with telomerase-expressing cells. This has opened up the real possibility of telomerase-based therapeutics for age-related and degenerative disease.

Theories of Aging: Biological

F E Yates, The John Douglas French Alzheimer's Foundation, Los Angeles, CA, USA

Glossary

Aging – Any time-dependent change in an object or system. The change may be good, bad, or indifferent as judged by an observer.

Biomarkers (of Aging) – Hoped for but so far fictitious age-related changes that predict remaining life span. No age-related changes are predictors of life span in humans. Even in colonies of inbred animals under laboratory conditions efforts using physical, chemical, or biological measures have so far failed to predict individual life spans in any species.

Component Failure Death – Failure of a complex system of many nodes and connections and levels when some local or particular part or region ceases to have the dynamic range required for its contribution to the stability of the whole system. In medical and pathological terms, one says, for example, that the patient died of renal failure.

Degrees of Freedom (Dynamical) – The statistical meaning of this term is not relevant here. A system has one degree of freedom for every variable whose value must be specified to define the state of the system. It is the number of independent variables in a system. A simple physical example is the gas law $PV = nRT$. R and n are parameters (constant in any particular instance); P, V, and T are variables. Degrees of freedom equal the number of variables (here three) minus the number of laws of rules that bind the variables (here one) – thus two. When any pair of P, V, and T is specified, the remaining variable is no longer free, but is determined by the rule. In a complex system, when structures are added they act like rule constraints and reduce degrees of freedom. Paradoxically, the behavior of the system may be enriched. A gasoline spill burning in air has many degrees of freedom, but little behavior. When that burning is confined by the geometrical constraints of engine blocks and valves, torque can be applied to roadways through wheels and the possibilities enlarge. When structural genetic constraints bear on carbon chemistry degrees of freedom are drastically reduced, but system behavior enlarges.

Maximum Life Span Potential – A statistical extreme value for a population of members of the same species and birth cohort, under similar circumstances, that estimates the duration of life of the last to die. It is a random variable, not precisely determined by genotype or phenotype. (Caution: the statistics of extreme values is underdeveloped.)

Mortality Rate, $m(t)$ – As a function of age, $m(t)dt$ is the fraction of the surviving population that dies between t and $t + dt$.

Mortality Rate Doubling Time – In preference to the constant hazard term in the exponent of the Gompertz equation, which varies inversely with life span potential, the doubling time is a more natural unit for mortality rate acceleration because it is in the same direction as the life span and is measured in the same units of time. It is given by $ln2/C$, where C is the Gompertz exponent constant.

Negentropic Process – Any process occurring in a system not at equilibrium, which leads to a local increase in order (decrease in entropy), usually manifested as the appearance of a new structure. (The risk of confounding entropy and information is great, and is invited by the similarity between the Shannon formulation for selective information and Boltzmann's statistical entropy. That confusion will not be dealt with here.)

Process – Any time-dependent series of changes. The current condition may or may not depend on past conditions, depending on the type of process.

Senescence – Progressive loss of stability arising from the cumulative effects of by-products of otherwise normal, salubrious processes that increase the probability of system failure. It may be accelerated by interaction with or addition of other processes that are deleterious (e.g., smoking).

Specific Metabolism – Total energy conversion rate (a unit of power) per unit of mass of the active tissues and organs. In the case of mammals, for example, connective tissue, bone, and fat are often excluded, and the residue, a virtual lean body mass is used as reference total mass.

System Death – Failure of a complex system when all its parts, though compromised, are individually still within viable limits or specifications. A loss of connectivity is often involved.

Introduction

This article begins by setting a background for evaluating putative theories of aging. It contrasts physical and biological views of time, and regards senescence as a progressive loss with time of the competence of forms and functions. Senescence is the subject of interest. (The term 'aging' is neutral, encompassing any change, good, bad, or indifferent. However, in gerontology, aging and senescence are assumed for convenience to be synonyms, and so the simpler term 'aging' is used here also.) Next, facts, conjectures, hypotheses, and theories are contrasted, and some requirements for a comprehensive theory of aging are enumerated. It is shown by an example how biological 'facts' can be inflated into a (pseudo-) theory that addresses only an aspect of aging. Prior attempts to catalogue theories of aging have been inadequate, failing to neutralize George Sacher's strenuous complaint against mere 'aspect' theories. A selection of salient facts, that a synoptic theory of aging seemingly ought to accommodate and explain, follows. Finally, the article concludes with comments on several robust and general theories of aging.

Time: Biological versus Physical Time

Dynamic, biological time flows from a past through a present into a future, and is irreversible. It is anisotropic and has a direction. In contrast, physical time, as it appears in the great theories of Newtonian mechanics, relativity (special or general), or quantum field theory, is exactly or very nearly time invariant (i.e., time is isotropic, reversible). As the physicist David Mermin has remarked, in modern physical perspectives clocks do not measure some pre-existing thing called 'time' – the concept of time is just a convenient way to abstract the common behavior of things we call clocks. To the physicist, it is remarkably liberating to realize that time itself does not exist. The discovery that there is no time – only clocks – has deep and surprising consequences. There is no 'flowing' physical time.

Any attempt to reconcile biology and physics strategically will have to resolve this conflict about time. Until then our awareness that, barring accidents, illness, or catastrophic circumstances, we all grow old and die assures us that the metaphor of a unidirectional flowing time underlies any biological theory of aging.

Prior Attempts to Specify Theories of Aging

In 1990 Z. A. Medvedev made a heroic attempt at a rational classification of theories of aging. More than 300 so-called theories were grouped thematically, but the effort failed to escape Sacher's criticism that they were 'aspect' theories whose pluralism distracts from the development of a comprehensive, theoretical structure for gerontology. Aspect theories arise because specialized investigators with different disciplinary backgrounds perceive many diverse growing points for the development of theories about senescence. Unfortunately, there is a tendency for each aspect theory to become transformed from a fact or conjecture about an aspect of aging into a general, all-comprehending theory of senescence.

Example of the Invention of an Aspect Theory

First, select a set of experimental facts, such as the following:

- Fact: In eukaryotic cells the histone octamer, which comprises the protein core of the nucleosome (repetitive subunit of chromatin), forms a fiber that compacts DNA into a chromosome.
- Fact: Acetylations, methylations, and chaperones are involved in establishing and maintaining chromatin integrity and functions. (These structures and processes have been thought of as being part of an 'epigenome.')
- Fact: Core histones can be modified post-translationally by interacting through their protruding tails with many nuclear factors, thus acquiring the potential to serve as regulatory agents, especially

by modifications of highly conserved Lys, Arg, and Ser residues. (Conjecture: In this way histone modifications play a major role in the epigenetic integration of nuclear events. M. Esteller and colleagues advanced a histone code hypothesis based on these facts. The histone code hypothesis proposes that the combinatorial and/or sequential post-translational modifications of histone residues can be read by nuclear factors to promote different processes and determine specific states.)
- Fact: Identical twins, as they grow older, differ increasingly in their epigenomes. For example, chromosome 1 looks identical in monozygotic twins 1 year old. In such twins at age 50, there are striking differences between their chromosomes 1.

Now generalize the following: therefore aging is primarily a chromosomal, epigenetic phenomenon, brought about by non-genetic influences, systematic or random, such as growth factors, cytokines, stresses, pharmacological agents, and internal as well as external environmental fluctuations.

One sees in the preceding a mix of facts, conjectures, and hypotheses – all aggrandized into yet another aspect theory of aging. **Table 1** lists ten of the processes that sustain the life of multicellular organisms, each item inviting the invention of an aspect theory of aging.

Facts, Conjectures, Hypotheses, and Theories

- A biological fact is an observation or measurement, ultimately macroscopic (i.e., so a human being can recognize and interpret the datum), usually contaminated by 'noise' (any unwanted feature of the data, systematic or random) that may require removal by filtering. Facts are not theories, but as Darwin remarked in a letter to a friend, surely every fact is for or against some theory.

Table 1 Ten requirements to sustain the life of a eukaryotic, metazoan organism[a]

1. Maintain differentiated specialization of genes
2. Assure faithful replication of DNA
3. Preserve chromosomal integrity (but allow for telomeric shortening with normal cell divisions)
4. Remove, sequester, or repair defective proteins
5. Quench free radicals not required for essential reactions
6. Detoxify noxious agents
7. Defend 'self' against alien materials
8. Protect against environmental shocks
9. Heal or replace worn or missing parts
10. Defend *milieu interieur* by means of regulations and controls

[a] There is at least one aspect theory of aging addressing each of these desiderata. (Of course, to sustain a species, replication or reproduction must be added.)

- A conjecture is a conclusion or supposition deduced by surmise or guesswork, or inferred from defective or presumptive evidence.
- A hypothesis is a tentative assumption or model made in order to draw out or test its logical or empirical consequences.
- A theory is a plausible, scientifically acceptable general principle or set of principles offered to explain phenomena such as a set of facts in their relation to one another. (In a formal theory, the general principle is expressed mathematically.)

P. Suppes has illuminated the procedures for theorizing in mature physical sciences. To develop a model on theory, an idea is expressed in text as generally as seems appropriate. If possible, the text is then formalized as a mathematical model, still very general. The model is then specified for a particular application by ancillary constraints. This constrained model on theory is then compared to an empirical model of data, generated by observations and measurements, filtered to remove noise, and then treated statistically by curve-fitting or other procedures. The two models are compared and tested for logical isomorphisms. Unfortunately, the greatest theory of the life sciences – some version of Darwinian evolution – does not fit comfortably into this scheme, emphasizing as it does chronicles rather than dynamics.

A Random Selection of Salient Facts That a Satisfying Theory of Aging Might Accommodate

A valid fundamental theory of aging is not required to explain all available facts in all members of one species and among all species. George Martin usefully emphasized that in light of evolutionary theories, a fundamental process of aging need not create a universality of phenotypes. Some mechanisms may indeed be 'public,' but others can be 'private' (i.e., "they may reflect patterns of decline in structure and function that are idiosyncratic…").

A typical life span (as framed genetically for each mortal species) may be thought of as consisting of three epochs: (1) development to onset of reproductive capability, (2) maturity, constituting a 'health span' during which the organism can explore its behavioral repertoire without limitation, and (3) a senescent decline to death. The length of the life span is not as important as the health span. Does evolution optimize anything other than reproduction? Is there a 'drift toward smarts'? This is a contentious issue. What do we want from a fundamental theory of aging? What are the facts that most need an

explanation from such a theory? The following list presents 16 candidates. Facts that are contended are marked with an asterisk.

1. Among all the species of living organisms (the number of species being variously estimated to be from 10 million to 30 million, with only a small fraction identified so far), there are some species whose individual organisms will always die, even if they escape accidents or predation or catastrophic environmental change, i.e., members of such species are mortal. In contrast, some coelenterates and all prokaryotes do not express any life span limitation. Some trees have vegetative reproduction and do not age.

There are some ambiguities to this fact, however: (1) Many living forms have complicated life cycles (e.g., insects that go through the stages of egg, larva, pupa, imago, and egg again) that confound attempts to define the organism. Each stage is limited in time, but the cycle may endure indefinitely. (2) The slime mold *Dictyostelium discoideum* has a stage of free-swimming, single-celled amoebae that can aggregate to become one multicellular organism with differentiated parts. (3) The Portuguese man-of-war presents as a single organism but is actually a colony of four different types of polyps, one of which serves reproductive functions by sexual and asexual methods, leading to free-swimming larvae that can generate a new colony with differentiated parts.

2. For species whose members are mortal, population data can generate survival curves for a cohort. The shapes of these curves should be rationalized by a theory of aging. These curves are non-linear, and they have two strong parameters, the median life span and mortality rate doubling time (MRDT), and one weaker parameter, the maximum life span. The maximum life span is by definition an extremum, and there is no agreed-upon statistical approach for it. Jeanne Calment, for example, lived 122 years, 5 months, and 14 days; her life currently sets the documented extremum for human maximum life span. (But someday a person with a documented birth date may be found to have lived longer.)

3. The median life span for successive cohorts of a species can undergo substantial changes over time periods much too short for there to have been a genetic basis for the changes. For example, the median life span for human cohorts born in the United States increased more than 30 years during the twentieth century, largely because of improvements in medicine and public health, leading to decreased infant mortality.

4. *Normal eukaryotic cells with mitotic potential do not continue to divide indefinitely when cultured under special, idealized laboratory conditions (unless they become transformed into cancer cells). However, there are a few studies in which the phenomenon of clonal senescence has not been observed.

5. In all mortal species tested so far, some degree of caloric restriction (usually a reduction by about 30 to 40% of the *ad libitum* intake under the laboratory conditions) will lead to an appreciable increase in median (sometimes also maximum) life spans of a sheltered population.

6. Certain single-gene (point) mutations in some organisms favored for genetic research in this field (e.g., daf-2 or age-1 in the worm *Caenorhabditis elegans*, RAS_1 in budding yeast *Saccharomyces cerevisiae*) can lead to increased life spans (but usually with reduced fertility) under laboratory conditions.

7. The non-linearity of human population survival curves can be approximated by the famous Makeham-Gompertz model for mortality rates:

$$\mathrm{m}(t) = A + B\ \exp C(x - 30)\ (30 \leqslant x \leqslant 80), \quad [1]$$

where $\mathrm{m}(t)$ is observed mortality rate, A is an age-independent but environmentally dependent mortality rate, B is an intrinsic, initial, age-independent but slightly environmentally dependent mortality rate, and C is the Gompertz hazard parameter. It can be interpreted as an 'aging rate' expressed as a mortality rate doubling time (MRDT). MRDT has a value of about 8 years for humans, 3 months for mice, and 10 days for fruit flies. It is age independent over the human age range from 30 to 80 years, after which MRDT may (counter-intuitively) spontaneously increase. It is almost environmentally independent, except that under special conditions of partial caloric intake restriction in our laboratory, MRDT can be increased so that lifespan is prolonged.

8. *In spite of the Gompertz non-linearity for mortality of populations, cross-sectional data from healthy human beings living in developed countries manifest a kinetics of senescence (rates of the progressive losses of individual forms and functions) that are roughly quasilinear between ages 30 and 70 years, with a median slope of –0.5% per year loss rate from the initial condition (100% reference) at age 30 years:

$$y_x = -r(x - x_\mathrm{o}) + 1\ (30 \leqslant x \leqslant 70), \quad [2]$$

where $x_\mathrm{o} = 30$ years, $x =$ chronological age rounded to nearest year ($30 \leqslant x \leqslant 70$), y_x is the fraction of capacity at age 30 that is left at age x (capacity at age 30 is 1.0), and r is the fractional change per year (a loss rate via the negative sign; $r \approx 0.005$).

Whether or not these kinetics extracted from cross-sectional data are indicative of what happens

to the population of parts and processes within an individual remains to be seen. A formal model has been developed that shows that for population data there is no contradiction between a set of averaged linear loss rates and an exponential hazard function, provided that there is a dispersion or variance associated with the set of linear losses.

9. Under laboratory conditions, repetitively selecting for survival and maturation eggs only from the oldest fruit flies ultimately leads to generations of longer-lived flies. This result was anticipated by the assumption that because of antagonistic pleiotropy, a strong artificial selection rewarding females capable of late reproduction should select against those pleiotropic traits that are most antagonistic to long-term survival.

10. Transplantation of a nucleus from a mature, adult, differentiated mammalian cell into an enucleated mammalian ovum (e.g., cloning) can, under special circumstances (so far with low probability), support the complete set of processes of implantation, embryogenesis, fetal growth, birth, and development of a new young animal. The life span potential of such creatures is still uncertain. Dolly, the first mammal cloned by nuclear transfer of a cell from an adult (6 years old) was born on July 5, 1996. Her expected life span, were she actually a young newborn lamb, was 11 or 12 years. However, she soon became arthritic and suffered progressive lung disease – afflictions typical of very old sheep. Mercifully, her caretakers put her down before she was 7 years old.

11. *Hybridizations of young and old cells indicate that the senescent condition dominates the result.

12. The median life spans for populations of different species in the same taxonomic class (e.g., class Mammalia) cover a wide range (several orders of magnitude for mammals, whose body weight range for the placental terrestrials covers six orders of magnitude from shrews to elephants). Linearized, allometric (log-log) scaling plots for the model $y = a(x)^b$ of selected morphological or physiological features (y) vs. body weight (x), where y includes life span, heart rate, surface area, and metabolic rate, typically have positive slopes (b) of 0.20 (life span) to 0.75 (metabolic rate). The exact values are in dispute, and some entries lie far off the general line. Nevertheless, there is a strong tendency for the life span of different mammalian species to increase with size across species. Within a species this trend need not hold – large dogs, for example, do not live as long as small dogs.

S. Austad refined the size-longevity relation by defining a new term, longevity quotient (LQ), obtained for a species by measuring the departure in longevity from the value expected for a specific body size according to allometric scaling rules. An LQ of 2 means that an animal lives twice as long as expected from size alone. The LQs are not immutable: opossums living in an environment without predators have evolved a pattern of reduced litter size, longer lives, and slowed aging rate compared to opossums living in areas where predation is a major risk.

Among the mammals (some kept in zoos) that Austad considered, giraffes, African lions, and African elephants had LQs of about 1.0. The LQs of white-eared possum, Asian house shrew, and Asiatic wild dog were low, about 0.4, and those for various bats (African collared fruit bat, vampire bat, greater horseshoe bat, little brown bat) were all high, 3.1 to 5.8. (The little brown bat is smaller than a mouse, but even in the wild it lives ten times as long as does a mouse in a protected laboratory environment.) Humans come in at 4.2. That means that according to conventional allometric scaling, given our size we should live only about 25 years. A comprehensive theory of aging should account for the general allometric scaling approximation and for the departures from it.

13. Older organisms lose homeodynamic competence, including the ability to resist stresses and produce heat shock proteins.

14. *All the cells in adult *C. elegans* are postmitotic except the gametes. If a mutant delays maturation, the life span of the worm will be increased, but the span after maturity is reached is not changed.

15. Canaries and mice are about the same size. However, canaries have higher body temperatures, faster heat rates, and blood glucose levels twice as high – so high that such levels in mammals would lead irreversibly (via the Maillard reaction) to advanced glycosylated end products (AGEs) and separately to sorbitol – substances not cleared from cells. Yet in protected environments, canaries live ten times as long as mice.

16. Women live longer than men in all cultures (except those in which girls and women are treated badly compared to males). Human females are definitely the hardier sex biologically, yet their aging rate (mortality rate doubling time) is the same as that for males. They simply die at a lower rate at all ages. Longevity itself is not a marker for any supposed universal, fundamental aging process.

This list is just a sampler; there are many other plausible facts eligible for attention by a comprehensive theory of aging. However, those shown here are indicative of their variety.

Major Classes of Current Theories of Aging

Because of the prevalence of age-associated diseases it might be supposed that senescence itself is a disease (for which a cure might be found). But because (by definition) mortal organisms that have avoided diseases, accidents, or predation and survived any overwhelming environmental changes and challenges all grow old and die, it is plausible to adopt a first assumption that there is an underlying cause (to be discovered) that inevitably leads to senescence, frailty, vulnerability, and death – whatever the circumstances. The manifestation of this process is the mortality rate doubling time, not longevity itself.

Exactly when senescence begins during a life span is not known. However, for human beings a second assumption is that up to (about) 30 years, growth and development dominate the life trajectories, and the fundamental process causing senescence begins right after their completion, exerting effects even during the health span of mature middle life and continuing to the end. (But see the reliability theory discussion of initial and early defects that set up later aging events.)

Table 2 lists a sample of theories that have been widely and seriously considered. Some have been proven false and were rejected or reinterpreted. Two durable ideas remain as dominant classes of comprehensive theories of senescence: (1) evolutionary theories and (2) free radical theories, originating in 1956 and 1952, respectively.

Ernst Mayr has insisted that biology is unique among the sciences, and should not and cannot be 'physicalized.' If so, then there is little to be gained from applying the strict requirements of theory building in physics to developing biological theories of aging. Indeed, given the stupendous diversity of living creatures (none being exactly alike, whereas all electrons are alike), it may be that no overarching theory of aging can ever be achieved. However, the search may not be hopeless – recall the comments of George Martin cited earlier. Perhaps there are many different ways that mortal organisms living under favorable conditions, and with good luck, grow old and die even under the agency of some universal aging process. The biosphere is supremely rich in possibilities.

It would be a high price to pay if gerontologists abandoned the demanding (Popperian) requirement for validating hypotheses and theories in the physical sciences; deductions or inferences from them, under constraints, must lead to specific protocols for empirical tests that could (at least in principle) falsify them. Were we to abandon that criterion for validity, theorizing in gerontology would consist merely of collecting Kiplingesque 'just so' stories. (Ironically, it is not yet clear that the string, M, and loop quantum gravity theories at the forefront of theorizing in physics today can ever be tested empirically.)

Evolutionary Theories of Aging: Some Highlights

When one invokes natural selection as a causal basis for phenomena in biology, as the evolutionary

Table 2 Theories of aging[a]

- **Error catastrophe** (Leslie Orgel – who later withdrew the claim when it was disproved. However, reinterpretations based on new data justify reconsideration.)
- **For-the-good-of-the-species theory** (once rejected, but now being reconsidered)
- **Evolutionary theories of aging (Peter Medawar)**
  - Disposable soma theory (Tom Kirkwood)
  - Antagonistic pleiotropy (George Williams, Michael Rose)
  - Late-acting genes (J. B. S. Haldane)
  - Longevity versus early reproduction trade-off (Maynard Smith, Steven Austad)

    Though their reasons differ somewhat, these views all hold that natural selection will be ineffective in purging genes that exert deleterious effects only late in life, after reproduction has already occurred (artificial selection for late reproduction can delay their effects). Senescence and mortality are caused by the expressions of such genes, many of which are 'normal,' in that they serve early to support life during growth, development, and reproductive maturation.

Wear-and-tear theories
  - Thermodynamic (Eugene Yates)
  - Free radical (Denham Harman)
  - Rate-of-living, also known as metabolic rate theory (Max Rubner; Raymond Pearl) (disproved)
- **Limited cell division theories** (telomere shortening, replicative senescence) (Now rejected as an essence of aging, but still regarded as an important, normal biological phenomenon.) (Leonard Hayflick)
- **Reliability theory** (Leonid Gavrilov and Natalia Gavrilova)

[a] This table contains a selection of some of the major themes that have been frequently invoked as theories of aging. When the origin of a proto-theory is associated with particular scientists, those names are given. Some of the theories are stochastic in nature, and others are programmatic/deterministic. (The listing is not in chronological order.)

theories all do, especially with regard to reproductive behaviors, the assignment of energy budgets, and longevity, one risks making anthropomorphic projections onto the data and seeing adaptations where there may be only by-products of other causes not comprehended.

Evolutionary theories apply only to reproducing systems exposed to a natural selection characterized as a 'force' that diminishes with age. For example, assume a dominant, dangerous gene effective in single copy, with delayed expression, that reveals its lethal mischief only after the host carrying it has already matured and had offspring. Such a deleterious gene will be propagated and cannot be eliminated from a population by natural selection. An example is the gene for Huntington's disease in humans. Generalizing, there may be other genes, persistent in a population, whose late expression will limit life spans.

Because the force of natural selection diminishes with age, the force of mortality, i.e., probability of dying, increases with age. A variation on the above scheme would be the assumption that there are normal genes (to be identified) that act beneficially during growth and development, but act detrimentally later under the changed context provided by differentiation and maturity, at which time they cause senescence, i.e., they exhibit antagonistic pleiotropy. (A single pleiotropic gene has multiple effects involving multiple changes in expression of other genes. In aging research, loosely, a gene is pleiotropic if it produces different effects at different stages of a life span as physiological contexts change.) The continued expression of such genes eventually weakens the organism. They cannot be eliminated by natural selection because normal offspring would have already been produced. Actions of many such genes could be common, non-threatening, and 'invisible' in short-lived species, but produce morbid 'gerontogene' effects in long-lived species.

If there are gerontogenes, they need to be better characterized. Which ones are they? (Genes for insulin-like growth factor receptor type 1 [IGF-1R] are considered to be a putative 'public' candidate operating in many species. If their expression is decreased, life span may increase.) How big is the set? How widely distributed are they? What do they do or fail to do, alone or in concert?

It is often stated that the costs in resources and energy of reproduction may diminish the means available to meet the maintenance requirements listed in **Table 1**, but there is no physical law or biological rule that says this has to be so. Nevertheless, from an evolutionary point of view, the need for high quality of cells in the germline surely outranks that for a 'perfect' soma, and quality is usually expensive. Some experiments indicate that delaying the onset of reproductive capability will extend life span. But, as noted previously, the actual aging rate of *C. elegans* so treated is unaltered once maturity is reached after the delay.

Another plausible evolutionary argument (the disposable soma theory) supposes that organisms, especially small ones, living in dangerous environments should mature rapidly and get on with reproduction, and not invest heavily in long-term maintenance processes, as this would seem to make evolutionary sense. But examining the time budgets for energy expenditures of such creatures (e.g., mammals) reveals that they mainly (1) eat to move, (2) move to eat, (3) repair and maintain form and housekeeping functions, (4) sleep to refresh, and (5) play. They spend little time in reproduction (although when they are in the reproductive mode, as when a female mammal is in heat or estrus, and males are responding or carrying out courtship rituals, including fighting, there is a concentration of energy expenditures on those processes, and there may be frenzied motor activity and no eating until they are over).

To support this version of the evolutionary story, it would help to demonstrate that the total lifetime energy budget of small, ground-based, short-lived mammals (for example) assigns a much greater portion to reproductive behavior and pregnancies than on the other processes listed previously, compared to bats (for example) of the same size who suffer less from predation and live longer. Until that is done, this evolutionary story remains seductive but not absolutely compelling. However, Tom Kirkwood, the inventor and champion of the disposable soma theory, which insists on the evolutionary benefits of a trade-off in the use of resources that favors reproduction over maintenance (within limits), stoutly rejects the criticism that resources are typically sufficiently abundant so there need be no such trade-off.

Regardless of the merits of the evolutionary argument from partitioning of resources, from a game-theoretic perspective it is indeed the case that in dangerous environments small animals that mature and reproduce early will necessarily change gene frequencies in favor of those very characteristics as time goes by, whether or not they underinvest in maintenance. Slow developers and less fecund animals in competition are naturally eliminated eventually.

Books have been devoted to various evolutionary theories of aging, and the preceding short selection of highlights can not do them justice. Some version of evolutionary theorizing is currently very popular among gerontologists and strongly advocated by many experts who believe that it is the theory of

aging. But demographic studies of normal strains of fruit flies show that the well-documented slowing of the mortality rate at advanced ages seems to start at the end of reproduction. If late-occurring expression and deleterious effects of genes that normally favor reproduction over sustained maintenance cause senescence, then the rate of aging might be expected to continue to increase at advanced ages, contrary to fact. (There is necessarily a survivor bias in data from old organisms that confounds predictions for heterogeneous populations, but the slowing is also seen in the more homogeneous highly inbred strains.)

Wear-and-Tear Theories

There is intuitive appeal to the idea that mortal living things eventually simply wear out, as do automobiles, following requirements of the second law of thermodynamics. A problem with this notion is that, in contrast to automobiles, living things are self-organizing and self-repairing, without requiring the services of a *deus ex machina*. Therefore, there is no obvious reason that they should inevitably become senescent and die, if they avoid accidents, sustained stresses, and changes in their environment that challenge them beyond their capacity to adjust and adapt.

Wear-and-tear theories invoke entropic consequences to organisms of the normal dynamics of their daily rounds. At maturity their processes that use or transform the Gibbs free energy required for maintenance and for operations (movements, syntheses, material turnover, charging cell membranes, propagating nerve impulses, etc.) necessarily occur away from, and do not lead to, equilibria. (No useful work can be accomplished at an equilibrium.) Instead, near-steady states appear.

In the last half of the twentieth century, Ilya Prigogine developed non-equilibrium thermodynamics and illuminated its potential for explaining creative chemistries that support the sudden appearance of structures in previously homogeneous media. He and many others extended the concepts mathematically, using bifurcation theories, fractals, criticality conditions, phase change theories, chaos, non-linearities, irreversibility, and dissipative processes, to establish a modern non-linear mechanics sufficiently rich to attack the mysteries associated with all self-organizing systems. Recently, E. Schneider and D. Sagan have dramatically shown how creative the second law can be in open systems.

F. E. Yates and L.A. Benton have applied some of these themes to the problem of explaining senescence. It is necessary to go beyond classical thermodynamics, which is a completed science that best deals with equilibrium states and quasi-static, linear trends toward equilibrium, from initial conditions not at equilibrium, in isolated systems that cannot exchange energy or matter (or information) with an environment. (Equilibrium is a state that applies separately to individual processes, but not to systems globally. Thus, there are separate mechanical, electrical, chemical, thermal, etc., equilibria to be considered in systems analyses.) The familiar, established features of natural processes in isolated systems, according to classical thermodynamics (i.e.., as they move toward an equilibrium state specified by the constrained conditions, Gibbs free energy decreases and entropy increases) do not suffice to explain or predict the rich behavioral potentials of open systems. Open systems, by definition, interact with environments and can obtain or replenish free energy supplies as well as eliminate products of molar entropy higher than that of those taken in. E. Schrödinger noted that, in this way, thermodynamically open, living systems can be said to feed on 'negentropy,' thus maintaining their internal order and preventing degradation. But Schrödinger's attractive notion fails to set up an explanation of senescence. Unfortunately, because the thermodynamics of open systems is a science still under development, any attempt to remedy its deficiencies may require new conjectures or hypotheses.

Senescence from the Perspective of Thermodynamics of Open Systems

An explanation for senescence, based on a view of open-system thermodynamics, might well begin with the observation that metabolism operates through many cyclic processes. Each metabolic cycle, as a natural process, necessarily (second law) generates an internal gain in entropy (ΔS_i) with destructive potential. The fundamental question for gerontology then becomes the following: can exchanges of matter and energy across the boundary of an organism compensate fully for the positive ΔS_i leaving no net entropic gain internally? That is, can the following two statements both be true?

$$\Delta S_{i\ (\text{metabolism})} - \Delta \hat{S}_{i\ (\text{compensation})} = 0$$
$$(\text{i.e., maintenance is perfect})$$

where $-\Delta \hat{S}_{(\text{compensation})}$ is a negentropic effect, and

$$\Delta S_{i\ (\text{metabolism})} - \Delta \hat{S}_{i\ (\text{compensation})} + \Delta S_{(\text{environment})} = \Delta S_{\Sigma} > 0 (\text{i.e., second law satisfied}).$$

With respect to an open system such as an organism, with many active transport systems at its boundary, it might be supposed that during or after each metabolic cycle, the following could be true: negentropic $\Delta\hat{S}_{(\text{compensation})} \geqslant$ positive $\Delta S_{(\text{metabolism})}$ internally. If so, it would permit perfect maintenance and defy senescence. However, there is a difficulty, because whatever constitutes negentropic $\Delta\hat{S}_{(\text{compensation})}$ internally has to be the result of a natural process itself, and therefore also a generator of some positive ΔS_i, even as it supplies a (lesser) negentropic benefit to some local internal region. Therefore, it is postulated that metabolic processes in open systems always tend toward a net accumulation of entropy internally, especially in cells that cannot divide. That accumulation universally drives senescence. During cell divisions, such as those that occur during growth and development, the internal states perhaps can be reset or renormalized so daughter cells do not necessarily inherit all the entropic accumulations of the parent cell. But after differentiations there are many tissues and organs with postmitotic cells, and those conspicuously do senesce.

Consequences of Freezing Out Degrees of Freedom during Development

Another physical reason for the inevitability of senescence has to do with a universal property of self-organizing systems: they are self-scaling in time, space, and energy. For example, a human being at maturity is scaled to operate with a daily energy budget of about 2000–3000 kcal/day. (Transiently, this budget can be increased to more than 6000 kcal/day, as in Tour de France cyclists, but at a cost of material breakdowns that will end the effort.) During growth and development, stages with many negentropic features, by definition, the specific-energy budget (energy per unit mass) is substantially increased by the costs of construction, including differentiations. Construction requires that dynamic degrees of freedom be available for creation of new parts. While that condition is met, the net effect of energetic transactions can be negentropic internally. At maturity, those degrees of freedom have been frozen out by the structures made, which provide new constraints on dynamics. As a result, all further energy transformations must then follow the preceding scenario, in which a net accumulation of destructive internal entropy is inevitable, manifested as eroded constraints and weakened couplings and connections. This is a central, general thermodynamic cause of senescence in mortal metazoans. Starting as soon as maturity is reached, the net internal entropic accumulation begins to displace a living system from its normal optimal operating point. Details will vary within and across species, but controls and regulations will always breakdown.

Prominent agents of the destructive effects of the internal entropy increases arising as by-products of metabolism are free radicals.

Free Radical Theory of Aging

The free radical theory of aging proposes that free radical oxidants produced during aerobic respiration play a major role in the disintegrations of aging. Especially potent are products associated with energy consumption by mitochondria that generates the leading oxidants $O_2^{-\bullet}$ (which can also be a reductant), H_2O_2, and $^{\bullet}OH$ (the most destructive to biomolecules). For convenience they are often referred to together as reactive oxygen species (ROS). ROS, as noted previously, are postulated to be particular agents of the entopic residues of metabolism (ΔS_i) required by the general thermodynamic theory.

A substantial literature is now available addressing three important questions, among others: (1) Do ROS play a role in degenerative senescence? (2) Do they determine mortality rates of different species? (3) Are mitochondria particularly vulnerable to age-associated pathology?

The discovery that respiring cells have numerous agents that can quench free radical metabolic 'sparks' and afford damage control lends credence to this theory. Beckman and Ames have assembled an impressive database that identifies these agents and supports the general claims of the theory. For example, transgenic fruit flies with enhanced antioxidant defenses show extended mean and maximum life spans, and large deletions of mitochondrial DNA have been found in older organisms of many species. Yet mysteries remain. Why does oxidative dysregulation take so much longer in humans than in mice? And why does caloric restriction so powerfully extend life spans when it has little or no effect on specific metabolic rates? However, even considering these questions, the free radical theory of aging is doing very well.

Reliability Theory

All the theories discussed previously have existed for many years. Reliability theory, however, is an original, new theory that, among its many virtues, can even be formalized. The need for a new theory is illustrated by the circular reasoning that explains aging at the level of the organism by aging changes at

the molecular and cellular levels, leaving aging still a mystery. (Stable isotopes of atoms do not age.) But, at higher levels of organization, components may fail at random, with a constant risk of failure independent of age. Furthermore, complex systems in general can have failure modes peculiar to their global organization – this is system failure, as opposed to component failure.

Gavrilov and Gavrilova argued that gerontology needs a general theory of systems failure, known as reliability theory. This class of theories was developed to describe failure rates observed in electronic equipment, but it has a very general applicability. Reliability is described by the function $S(x)$, which is the probability that a system or component will continue to operate properly according to a standard of merit:

$$S(x) = P(X > x) + 1 - P(X \leqslant x) = 1 - F(x),$$

where x is time, X is time to failure, P is the probability that failure time X is beyond time x, and $F(x)$ is a standard cumulative distribution function in probability theory.

From that starting point, Gavrilov and Gavrilova brilliantly developed their theory and proved that the phenomena of the mortality increase with age and subsequent leveling-off are theoretically predicted to be inevitable features of all reliability models that consider aging as a progressive accumulation of random damage. They next demonstrated the importance of redundancies and parallel structure in protecting complex systems by establishing damage tolerance. However, as time goes by, the redundancy in the number of elements decreases, so fragility increases. Finally, they formally introduced the hypothesis of high initial damage load. As modeled, this hypothesis predicts that even a small advance in optimizing early developmental processes can potentially prevent the occurrence of many diseases later in life. Furthermore, it has the capacity to postpone aging-related morbidity and mortality. These features of their theory are especially welcome now that the epoch of intense genetic reductionism in biology has been replaced by the more mature understanding that between the genome and the global phenotype lie many aleatory, epigenetic, developmental events.

The reliability theory of Gavrilov and Gavrilova has the power to address an astonishing range of phenomena of interest to gerontologists, and substantial data sets are offered in its defense. It has no rival for its predictive and explanatory power. It is not possible to show its rich details here, but the references cited provide the substance and beauty of the theory.

Theories of Aging: Psychology

J J F Schroots, Free University Amsterdam, Amsterdam, The Netherlands

Glossary

Chaos Theory – States that fluctuations of far-from-equilibrium systems can create order out of chaos through a process of self-organization.

Gerodynamics – Dynamic systems theory of aging, based on general systems theory and chaos theory.

Gerotranscendence – Shift in meta-perspective from a materialistic and rational vision to a more cosmic and transcendent one.

Gompertz' Law – States that there is regular acceleration in the rate of death with age from about age 10 to the end of the usual life span.

Psychology of Age – Study of age differences in behavior.

Psychology of Aging – Study of behavioral patterns of change with age.

Psychology of the Aged – Study of problematic and non-problematic behavior in the elderly.

Introduction

Research in the psychology of aging has been guided by a diverse collection of theories. Historically, there are three approaches: the aged, age, and aging. The psychology of the aged focuses on the behavior of older people. Grounded in a stages-of-life perspective, most studies of the aged demonstrate a thematic approach and little coherence, e.g., studies of Alzheimer's disease, retirement, widowhood, etc. The psychology of age studies age differences in behavior by comparing groups of people of different ages in cross-sectional research. Productive research focuses on identifying the causes and consequences of the processes responsible for age-related differences, e.g., processing speed, attentional capacity. The psychology of aging studies behavioral patterns of change with age, integrating both the psychology of age and the aged in longitudinal research. In this article, major but diverse psychological theories of aging are presented chronologically, beginning with early nineteenth century theorizing on processes of aging.

History

Early Roots

The roots of psychological theories of aging lie in the European soil of nineteenth century science. The intellectual climate fostered a strong conviction that the scientific method could be applied to all natural phenomena and that all matters could be examined by research and reduced to lawful generalizations, including the subject matter of aging. In 1825, the English actuary Benjamin Gompertz published his classic paper on the force of mortality, which expresses a lawful relationship between death rates and age within a given population. He noted the regular acceleration in the rate of death with age from about age 10 to the end of the usual life span. The regularity of this observation has led to much research into the genetic and biological basis of aging and the causes of death.

While scientific effort was devoted to identifying specific relationships such as Gompertz' law, the Belgian mathematician and astronomer Quetelet attempted to demonstrate that all facets of the changes in human behavior across the life span were lawful. In 1835, he published his book on man and the development of his faculties. In addition to information about differences in mortality rates, he included material about physical and behavioral characteristics of people according to age. As a mathematician, Quetelet emphasized observations of many individuals that would lead to the characterization of the average man around whom observations are distributed. His commitment to studying the lawfulness of the life span is seen in the following statement: "It will first be necessary to determine the period at which memory, imagination, and judgment commence, and the stages through which they necessarily pass in their progress to maturity: thus having established the maximum point, we may extend our inquiries to the law of their decline." Quetelet's thinking represented the breadth of nineteenth century scientists, who aimed for theories encompassing the total organism.

Pioneers

Little systematic work was conducted on the processes of aging during the latter part of the nineteenth century and the beginning of the twentieth century, the years in which psychology became established as a separate discipline. In addition, the subdiscipline of developmental psychology turned out to be child

psychology. However, a few early pioneers in the study of child development did turn their attention to the psychology of aging later in their careers. Among these were G. S. Hall, Charlotte Bühler, Carl Jung, and Walter Miles.

In 1922, Hall published *Senescence: The Second Half of Life*. He summarized what was known about aging in several scholarly fields, but it can be looked upon as the beginning of a focus on the psychology of aging. *Senescence* was a broadly conceived book in which Hall reviewed the evidence about aging from all contemporary sciences and the general literature at the time (e.g., physiology, medicine, anatomy, philosophy) and something of the humanistic content about the psychology of the aging adult, in particular, the psychological issues of death. For Hall, the experience of aging was a matter of walking up the hill of life toward maturity and then walking carefully down the other side toward old age.

Charlotte Bühler began publishing articles on child developmental psychology during the 1920s and produced her original book on the course of human life in German in 1933. Relying upon diverse material (biological and psychological studies, production and performance records, biographical and autobiographical material), she laid the foundation of what later has been called life span developmental psychology. While Buhler emphasized the psychological processes of development and aging, she considered them in conjunction with the biological life cycle. The underlying biological structure of life provided a ground plan of growth, maintenance, and decline as the basis of psychological expansion (development) and restriction (aging).

From the beginning, psychoanalytic theory has been a developmental theory only for childhood and adolescence. Yet there was an exception in Swiss clinician Carl G. Jung, who in 1933 described stages of development in adulthood, assuming maturational processes of the adult person to account for stage change. Jung's focus was on exploring the self over the life span. He noted a transformative shift from extraversion to introversion in middle and later life: the later years are not a simple addition to youth, but have their own purpose and significance. Due to this perspective, Jung accepted older patients for psychotherapy as well.

The first laboratory of psychology devoted to the study of aging was founded in 1927 at Stanford University. At that time a good amount of research had already been completed on age differences in psychomotor skills and sensory capacities. By 1931 Walter Miles was able to publish a review on the psychology of aging, *Measures of Certain Human Abilities throughout the Life Span*, and in 1933 he followed it with a longer paper on life span changes. Miles directed most of his attention to psychomotor functions and was led to distinguish motility, i.e., the speed of motor movements, from the speed of simple reaction. For historical reasons, the research at Stanford was not continued when Miles left in 1933 for Yale University.

Concepts of Aging

Theory, Model, and Metaphor

Before reviewing specific psychological theories of aging during the time period following World War II, it is instructive to elaborate on a few theoretical concepts. Recall the classic dictum that there is nothing so practical as a good theory. A theoretical framework helps the scientist to accumulate and integrate data into a body of knowledge, as well as to provide directions for new research. Recently, several researchers in gerontology came to the conclusion that the psychology of aging is data rich, but theory poor. This conclusion, of course, depends at least partially on the definition of the term theory.

Under the influence of logical positivism, it has been assumed that proper theory development is identical with theory formalization in terms of logically linked mathematical propositions. From this view, attempts to develop formal (i.e., rigorous, precise, and at least potentially quantitative) theories in the psychology of aging have not been very successful. Almost imperceptibly, the attention of researchers turned to the formalization of models, which – generally speaking – are regarded as more simple and quantifiable than theories, but which also focus on limited aspects of aging.

Formalization in terms of quantitative models (or theories, for that matter) ignores the constructivist view that science is in an essential way metaphorical or characteristically employs metaphors. In fact, models are extended and systematic metaphors. For instance, before World War II, most researchers in intellectual abilities adopted the model of decline with age, i.e., intellectual abilities declined just as functions of the physical body declined with increasing age. This model is based on the so-called hill metaphor, introduced by G. S. Hall in 1922, describing development going uphill and aging going downhill.

The hill metaphor is still alive to this day, and so are many other metaphors, hidden in the disguise of some model or theory. This explains why the terms theory, model, and metaphor are often used interchangeably in the literature. Briefly summarized, the relative significance of these terms can be phrased as

follows: the metaphor drives the theory in the psychology of aging in the first place, and the model functions as a more general, extended, or systematic kind of metaphor, which connects theory with empirical research. In the following, the term theory should be understood in the broadest sense of the word.

Psychology of the Aged

Research in the psychology of aging has been guided by a somewhat diverse collection of theories, models, and metaphors. Historically, there have been three approaches in this field: the aged, age, and aging. The psychology of the aged focuses on older people and later life. Grounded in a stages-of-life perspective, most studies of the aged demonstrate a thematic, descriptive approach and little coherence. In the research literature, at least 70 different themes can be distinguished, varying from Alzheimer's disease, life satisfaction, widowhood, and retirement to cognition, death, and dying. Most research findings consist essentially of descriptive statements about the organization of behavior in the aged and their social-medical problems. Given the wide variety of themes and findings, the psychology of the aged may be broadly defined as the study of problematic and nonproblematic behavior in the elderly.

The lack of gerontological theory in psychological studies of the aged results from the traditional stability orientation to adulthood, i.e., ordered changes are restricted to childhood and adolescence, while further developments in adulthood are not assumed. It has been shown that the psychological study of the aged is heavily infested with biomedical conceptions of aging as a disease or a result of some deteriorative process. For instance, cognitive processes at older age are often described in terms of failure, loss, insufficiency, inadequacy, impoverishment, decrement, inefficiency, or impaired performance. These biomedical conceptions of aging reflect the dominant metaphor that aging is a biological or medical problem and that the elderly make up a problem group in society.

Psychology of Age

The second approach in psychogerontology is the psychology of age, which focuses on age differences. Most research according to this approach has been cross-sectional, describing and comparing groups of people of different ages measured at the same time. The central research question concerns the relation between age as the primary independent variable and some other variable of interest as the primary dependent variable, e.g., mortality, morbidity, autonomy, quality of life, mental abilities, or productivity. The derived research question often concerns the extent to which intervening variables, such as sociodemographic, environmental, psychosocial, biophysiologic, or lifestyle factors, are related to the observed differences with age.

Cross-sectional age differences are frequently misinterpreted in terms of age changes, aging, or changes in behavior over time. Over the last three decades, however, researchers gradually realized that age differences do not equal age changes, or – to put it differently – that chronological age used as the independent variable does not help to explain, or at most only partially explains, the aging process. In 1965, K. Warner Schaie was one of the first to realize that cohort and period of time may have more productive explanatory properties than age, and, accordingly, he designed the age-period-cohort (APC) general developmental model. However, due to the dependency of these three time parameters upon calendar time (both dependent and independent variables are expressed in terms of the same calendar time), there is always the problem of time confounds, regardless of how data are collected or statistically analyzed.

Another point of view regarding the age variable is based on the conception of age as an index variable that is in need of further explanation in terms of aging processes. Most researchers use chronological age implicitly as a dummy variable or index that stands not for a single underlying aging process, but for a host of processes that independently and in concert bring about changes we recognize as aging. From an experimental perspective, this means that fruitful research will focus on identifying the causes and consequences of the processes responsible for age-related differences. This type of cross-sectional experiments is particularly found in the field of cognitive aging, though longitudinal information is needed to reach more definitive conclusions about the hypothesized aging processes.

Psychology of Aging

The third approach in psychogerontology is the psychology of aging, which, briefly summarized, studies the regular changes in behavior after young adulthood. In order to study changes over time, it is necessary to carry out longitudinal research, which essentially means that the performance of a group of subjects from a single cohort is compared with that group's own performance at other periods in time. In this context, the term aging is often used both as a label for an independent variable to explain other phenomena (e.g., mortality, productivity, health,

competence) and as a dependent variable that is explained by other processes (e.g., wear and tear, genetics).

It should be noted in the preceding definition that the adjective regular in the phrase regular changes in behavior refers to the orderly or typical changes in behavior – or so-called behavioral patterns of change with age – as found in longitudinal research on aging. In the cognitive domain, for example, a general pattern of average declines with advancing age has been reliably established. Within this pattern, however, another classic pattern of cognitive aging can be distinguished, i.e., the relative increase of verbal information with age compared with decline in spatial-perceptual performance.

It is important to note also the implications of the phrase after young adulthood in the preceding definition. Thus defined, the psychology of aging is grounded in the perspective of two stages of life, development and aging, which are usually described as two successive processes of change in time, with the transition point or apex at maturity. As noted before, the classic metaphor for the two stages of age-related change in life is the hill metaphor, which is based on biological conceptions of growth and decline, particularly the so-called mortality curve. Mortality rates are high for infants, regularly decline to a minimum at about age 10, and then rise progressively throughout the remainder of the life span (Gompertz' law). Psychological processes of change, however, do not necessarily parallel biological changes along the life span. For example, fluid abilities such as speed of information processing reflect genetic-biological determinants and tend to decline with age. Crystallized abilities, on the other hand, represent cultural-social influences, e.g., on general world knowledge, and may display some growth with age. This cognitive phenomenon raises the as-yet-unsolved problem of to what extent psychological processes of development and aging are different from each other, as both processes refer to age-related changes.

Classical Theories

Developmental Tasks/Activity Theory

In 1948, Robert J. Havighurst published his much-reprinted book on the concept of developmental tasks in a life span perspective. A developmental task arises at a certain period in the life of the individual, successful achievement of which leads to the individual's happiness and success with later tasks, whereas failure leads to unhappiness, disapproval from society, and difficulty with later tasks. All of these tasks have biological (physical maturation), psychological (aspirations or values), and cultural (expectations of society) bases. Havighurst described the following six developmental stages or age periods, each with its own developmental tasks: infancy and early childhood, middle childhood, adolescence, early adulthood, middle age, and later maturity (beyond age 60). The developmental tasks of later maturity, for instance, can be summarized as follows: (1) coping with the physical changes of aging, (2) redirecting energy to new roles and activities such as grandparenting, retirement, and widowhood, (3) accepting one's own life, and (4) developing a point of view about death. Later on, the central organizing concept of age-related developmental tasks was named activity theory, as opposed to disengagement theory.

Psychosocial Theory of Personality Development

With the publication of *Childhood and Society* in 1950, Erik Erikson made a major contribution to the understanding of personality development across the life span. Erikson formulated a psychosocial theory of eight stages of life, each with its own characteristic crisis that arises out of the conflict between two opposite tendencies. The developmental task of each age period is to resolve its conflict, which requires the integration of personal needs with the demands of society. The successful resolution of each conflict leads to developmental strength in terms of a new virtue. Failure to deal adequately with a task during its period of ascendancy, however, is damaging to personality development. For example, the last stage of life, old age, refers to the opposite tendencies of integrity versus despair. At this point an individual's life either makes sense because of some cross-cultural, human principles or is marked by a sense of despair, because it seems meaningless. The successful achievement of integrity might lead, eventually, to the virtue of wisdom.

Erikson's life stages and their respective age periods, opposing trends (crises), and potential virtues are as follows:

1. Infancy: 0–1 years, basic trust vs. basic mistrust, hope
2. Early childhood: 1–6 years, autonomy vs. doubt and shame, will
3. Play age: 6–10 years, initiative vs. guilt, purpose
4. School age: 10–14 years, industry vs. inferiority, competence
5. Adolescence: 14–20 years, identity vs. role confusion, fidelity
6. Young adulthood: 20–35 years, intimacy vs. isolation, love

7. Maturity: 35–65 years, generativity vs. stagnation, care
8. Old age: 65 + years, integrity vs. despair, wisdom.

Erikson sees development as a function of both individual and cultural factors, hence the description of his theory as a psychosocial theory of personality development. In each stage of life, the social world widens, so that the infant whose society began with a dim image of the first caregiver at last becomes an elder whose view of the world encompasses humanity. It should be noted that – in spite of the seemingly accurate age division – Erikson's stages of life are not tied closely to specific age periods or age-related changes. The early stages are defined in much more detail than the later ones: postadolescence, for example, includes about three-quarters of the life span, but only three of the eight stages. This division reflects the increase in psychosocial variability with age: the developmental tasks of an infant are relatively universal, but the tasks in later life are dependent as much on personal experiences as on general principles.

Counterpart Theory

In 1960, James E. Birren, the nestor of American gerontology, presented a general theory of aging as a counterpart of development. The use of the metaphor counterpart is meant to express the idea that there are latent structures of behavior (emotions, cognitions, and motivations) carried forward from earlier experience that interact with present situations. Aging is viewed as a transformation of the biological and behavioral development of the organism expressed in a counterpart manner in variable ecological contexts.

Observations of old persons suggested that there is a pattern to the changes that occur in late life, which are not merely due to happenstance or chance. In explanation of these late-life patterns of change, Birren noticed that natural selection as an explanatory mechanism was not very obvious since some of the patterns or features in old persons (organisms) do not appear until long after the age of reproduction has passed. He concluded, therefore, that these regularly appearing features (including longevity) must be a consequence of traits that were selected for at the time of reproduction. Briefly summarized, Birren's counterpart theory states that any biologically based order in late-life characteristics must arise in association from counterpart characteristics of development that were subject to pressures of selection.

Birren pointed out that behavioral factors can be involved in the counterpart process, that is, patterning of late-life events could arise via natural selection of long-lived and intelligent persons. For example, although individual differences in longevity do not appear until long after reproduction has been completed, intelligent, long-lived parents are able to provide an environment in terms of food and protection that is favorable for their young to survive. In other words, counterpart theory advocates indirect selection for positive late-life characteristics that embrace a wide range of complex biological (e.g., potential for a long life) and behavioral (e.g., intelligence) characteristics. As such, counterpart theory expanded the classical hill metaphor of development and aging to include questions about their relationships and how behavior comes to be organized over the adult years of life, if not over the whole life span.

Disengagement Theory/Activity Theory

The term disengagement refers to the withdrawal of people from previous roles or activities. Starting from the assumption that people turn inward from middle age on, Cumming and Henry theorized in 1961 that this primary mental process produces (1) a natural and normal withdrawal from social roles and activities, and (2) an increasing preoccupation with self and decreasing emotional involvement with others. In positing the universality and normality of withdrawal, disengagement theory has been criticized for being neither natural nor inevitable. While the theory professes to explain general psychological and social processes of aging, it offers only a one-sided view of the aged, given the significant proportion of older people who do not lose interest in life and do not withdraw from society.

Disengagement theory encouraged the development of an opposing theory of the aged, activity theory, which is based on the concept of development tasks. According to its main proponent, Robert J. Havighurst, activity theory states that in order to maintain a positive sense of self, elderly persons must substitute new roles for those lost in old age. As such, activity theory presents a broader view of older people.

Personality Theory of Age and Aging

In 1968, Bernice L. Neugarten published her classic book of readings, *Middle Age and Aging,* from a life cycle perspective. Starting from a series of studies begun in the 1950s, Neugarten and her associates described the life cycle in terms of two theoretical emphases. The first area of emphasis is the study of timing of transitional events in the lives and roles of individuals. Life events, such as marriage, parenthood, occupational achievement, or retirement, are

normatively scheduled; that is, they are expected to occur within certain ages and in a certain sequence. As such, they lead to changes in self-concept and identity. In metaphorical terms, individuals have internalized a social clock, and age norms act as prods and brakes upon behavior over the life span. However, unexpected events (such as automobile accidents) or age-normative events that occur off time (such as early widowhood) may have negative developmental consequences (e.g., life crises).

The second area of emphasis is the study of personality type as a predictor for successful aging. Aging persons have differing capacities for coping with life stresses and for coming to terms with their changing life situations. Eight different personality types of aging have been distinguished, which Neugarten named the reorganizers, the focused, the disengaged, the holding-on, the constricted, the succorance-seeking, the apathetic, and the disorganized. Briefly summarized, aging is viewed as a process of adaptation in which personality is the key element. The aging individual plays an active role not only in adapting to the biological and social changes that occur with the passage of time but also in creating patterns of life that will give him or her greatest ego involvement and life satisfaction.

Cognitive Theory of Personality and Aging

In 1970, Hans Thomae described briefly a cognitive theory of the aging personality, intended to integrate various biological, sociological, and interactionist perspectives while at the same time focusing upon the psychodynamics of aging. Central concepts in his theory are perception, perceived situation, and perceived self. Thomae postulates, for example, that perceived change rather than objective change is related to behavioral change and that change is perceived and evaluated in terms of the aging person's dominant concerns and expectations. Successful adaptation to age-related changes, then, relates to the maintenance and restructuring of the balance between cognitive and motivational systems, e.g., the balance between acceptance of oneself as old or rejection of this perception, which is one of the developmental tasks of aging persons.

Modern Theories

Life Span Development and Aging

Since the beginning of the 1980s, Paul B. Baltes and his associates have conducted a series of studies on psychological processes of development and aging from a life span perspective. In line with the tradition of life span developmental psychology, development and aging are conceived as synonyms for behavioral changes across the life span. Starting from these studies, Baltes has developed a theoretical framework of seven propositions about the nature of human aging from a psychological point of view: (1) there are major differences between normal, pathological, and optimal aging, the latter defined as aging under development-enhancing and age-friendly environmental conditions, (2) the course of aging shows much interindividual variability (heterogeneity), (3) there is much latent reserve capacity in old age, (4) there is aging loss in the range of reserve capacity or adaptivity, (5) individual and social knowledge (crystallized intelligence) enrich the mind and can compensate for age-related decline in fluid intelligence (aging losses), (6) with age, the balance between gains and losses becomes increasingly negative, and (7) the self in old age remains a resilient system of coping and maintaining integrity.

Based on this framework of propositions, a psychological model of successful aging has been devised, named selective optimization with compensation. The central focus of this model is the management of the dynamics between gains and losses, i.e., a general process of adaptation, consisting of three interacting elements. First, there is the element of selection, which refers to an increasing restriction of one's life world to fewer domains of functioning because of an aging-related loss in the range of adaptive potential. The second element, optimization, reflects the view that people engage in behaviors to enrich and augment their general reserves and to maximize their chosen life courses (and associated forms of behavior) with regard to quantity and quality. The third element, compensation, like selection, results from restrictions in the range of adaptive potential. It becomes operative when specific behavioral capacities are lost or are reduced below a standard required for adequate functioning.

The lifelong process of selective optimization with compensation allows people to age successfully, i.e., to engage in life tasks that are important to them despite a reduction in energy. For instance, the pianist Rubinstein remarked in a television interview that he conquers weaknesses of aging (adaptation) in his piano playing in the following manner. First, he reduces his repertoire and plays a smaller number of pieces (selection); second, he practices these more often (optimization); and third, he slows down his speed of playing prior to fast movements, thereby producing a contrast that enhances the impression of speed in the fast movements (compensation).

Reduced Processing Resources

For some time it has generally been accepted that there is an average age-related decline in cognitive performance. Researchers have advanced several explanations for this aging phenomenon, but so far only the resource-reduction view has found wide support. In this view, aging leads to a reduction in the quantity of one or more processing resources, such as attentional capacity, working memory capacity, or speed of processing. According to Timothy A. Salthouse, a typical exponent of this view since the 1980s, processing resources are characterized by three properties: (1) they are limited in quantity, with a measurable aspect such as quantity or effectiveness of allocation increasing until maturity and then decreasing across the adult years, (2) they enable or enhance cognitive processing such that performance in many cognitive tasks is improved when greater amounts of the resources are available, and (3) they are not local or specific in the sense that they are restricted to a small number of highly similar cognitive tasks, but instead are relevant to a broad range of cognitive processes.

These three properties of processing resources have generated a number of specific theories. They can be classified into three categories, based on the dominant metaphor used in theorizing on resource-reduction: space, energy, and/or time. That is, space limitations correspond to restrictions on the size of the computational or working memory region available for processing; energy limitations correspond to attentional capacity restrictions; and time limitations refer to restrictions imposed by tradeoffs between the rate at which information can be processed and the rate at which it becomes unavailable through decay, interference, or some other mechanism.

In a series of experimental studies, Salthouse and his associates focused on the time metaphor of processing speed as an explanatory construct of cognitive aging. Their findings indicate that processing speed is a fundamental construct in human cognition, linked to explicit changes in neural structure and functioning on the one hand and to higher-order cognitive processes such as reasoning and abstraction on the other. As such, Salthouse hypothesizes that processing speed may well provide the cornerstone for integrative theories of cognitive aging. It should be noted, however, that the resource-reduction view leaves unanswered the fundamental questions of why the reduction in resources occurs, and how that reduction results in lower levels of cognitive performance.

Personality and Aging

Studies of personality and aging reflect the concept of personality, here defined as the set of characteristic dispositions that determine emotional, interpersonal, experiential, attitudinal, and motivational styles. Generally speaking, two theoretical traditions can be distinguished in this field, trait and developmental stage models. In both traditions, the central issue concerns the extent and nature of personality stability and change over the life span, or, to put it differently, the extent to which aging processes per se are responsible for personality change.

Overall, longitudinal studies of personality traits have consistently found structural invariance of personality over time, i.e., a marked pattern of similarity in factor structure across instruments, cohorts, and types and times of measurement. According to Paul Costa and Robert McCrae, typical proponents of the trait model, the same five major factors (neuroticism, extraversion, openness to experience, agreeableness, and conscientiousness) have emerged from longitudinal studies using somewhat different approaches. In conclusion of the evidence, they state that people stay much the same in their basic dispositions and show a high degree of stability of personality, particularly during the latter half of their life course.

More recent extensions of the trait model pertain to personality-linked constructs such as locus of control and self-concept. Generalizations about stability and change are limited by the relatively small number of studies available, the large majority of which are cross-sectional in design. However, there is growing consensus that personality traits tend to be stable with age, whereas key aspects of self such as goals, values, coping styles, and control beliefs are more amenable to change.

Theoretical models of adult personality development represent the second tradition in the personality and aging field. Two theories, developed by Erik Erikson and Daniel Levinson, respectively, offer developmental stages beyond the period of early adulthood. As discussed previously, Erikson's eight stages, extending from infancy to old age, were formulated more than 55 years ago. From this perspective, it is surprising that only limited empirical evidence has been collected for the maturity and old-age stages, i.e., generativity vs. stagnation and integrity vs. despair. There are no longitudinal studies, for example, that ask whether the achievement of generativity in midlife is a necessary precursor for the achievement of integrity in the later years. Erikson's theory deserves more critical attention from gerontologists.

In Levinson's theory of personality development (based on a series of in-depth interviews with 40 men), each man's life structure goes through an orderly sequence of periods that alternate between stable phases and transitional phases, which are generally crucial turning points in life. Beginning with a transition out of adolescence (17 to 22 years), there are three major periods: early adulthood (ages 17 to 45), middle adulthood (ages 40 to 65), and late adulthood (past age 60). The periods overlap because each is bridged by a 5-year transition that is part of both periods. The timing and length of each period and the development that takes place within it vary from man to man depending on the biological, psychological, and social conditions of his life. Nevertheless, a close linkage of periods with age intervals is suggested. Levinson's theory can be severely criticized on many grounds, of which the impossibility of replicating the in-depth interviews poses the most serious problem.

Behavioral Genetics and Aging

Behavioral geneticists of aging are concerned with the extent to which hereditary factors influence age-related changes over the life span of the individual. Here, heritability is defined as a descriptive statistic referring to the portion of observed, phenotypic variation in the population that can be accounted for by genetic differences among individuals; the rest of the variation, the non-genetic portion, is called environmental. Thus, change in heritability over the life span indicates that the relative roles of genetic and environmental influences can change with age in terms of their effects on biological and behavioral differences among individuals in the population.

With regard to the issue of stability and change, Nancy L. Pedersen and Robert Plomin, two leading researchers since the 1980s, make a distinction between phenotypic and structural stability. Phenotypic stability, as expressed in the familiar correlation between the same measures on successive occasions, refers to the stability of both genetic and environmental components. Structural stability, on the other hand, refers to either genetic or environmental invariance (stability) throughout the life span. Given this distinction, Pedersen states that theories of aging that rely on the demonstration of genetic variance only as support for claims of phenotypic stability need to be modified to incorporate findings of both genetic and environmental involvement in stability. For example, early predictions of cognitive performance with age suggest that changes in phenotypic variance would reflect changes in environmental variance only, while assuming implicitly genetic stability. However, as the Swedish Adoption/Twin Study of Aging (SATSA) has shown, no simple explanation exists for changes in variance of cognitive performance with age: increases in phenotypic (total) variance resulted from increases in environmental experiences, whereas decreases in total variance were distributed equally among genetic and environmental components.

Theory formation in gerontological behavioral genetics is still in its infancy. On the basis of recent analyses, however, Pedersen comes to the following tentative conclusions: (1) the relative importance of genetic and environmental effects on individual differences in the elderly is phenotype specific. Heritability is low to moderate for personality traits and measures of well-being, moderate for health-related phenotypes, and greater for cognitive abilities, whereas heritability for memory is lower than that for verbal and spatial abilities or perceptual speed. (2) There are age differences in heritability, the pattern of which is phenotype dependent. For some measures, particularly health-related characteristics, the relative importance of genetic effects appears to decrease across age groups. For others, heritability is stable, increases, or reflects an inverted L-shaped function. Variance changes may reflect an increase of either environmental or genetic influences, depending on the phenotype. More often, environmental effects account for the increase in variability in health-related phenotypes. (3) Across short spans of time, genetic effects are more stable than environmental effects for personality and cognition. Environmental effects of importance for individual differences late in life are changing. Nevertheless, environmental influences are at least as important for phenotypic stability across short (3–6-year) spans of time.

New Theories

Gerotranscendence

In 1989, Lars Tornstam suggested that human aging, the very process of living into old age, encompasses a general potential toward gerotranscendence, i.e., a shift in meta-perspective from a materialistic and rational vision to a more cosmic and transcendent one, normally followed by an increase in life satisfaction. On the basis of qualitative and quantitative studies, Tornstam developed the theoretical concept of gerotranscendence at three levels of age-related, ontological change: (1) the cosmic level, for example, changes in the perception of time, space, and objects, increase of affinity with past and coming generations, changes in the perception of life, disappearing fear of death, acceptance of the mystery dimension in life, and increase of cosmic communion

with the spirit of the universe, (2) self, for example, discovery of hidden – both good and bad – aspects of the self, decrease of self-centeredness, self-transcendence from egoism to altruism, rediscovery of the child within, and ego integrity, (3) social and individual relations, for example, less interest in superficial relations, increasing need for solitude, more understanding of the difference between self and role, decreasing interest in material things, and increase of reflection.

The new theory of gerotranscendence is reminiscent of the classical concepts of disengagement (Cumming and Henry) and integrity (Erikson), but differs qualitatively in some aspects. For example, gerotranscendence implies a redefinition of reality, while disengagement is restricted to turning inward; also, gerotranscendence is connected with social activity and a need for solitary philosophizing at the same time, while disengagement encompasses social withdrawal only. Next, gerotranscendence refers to offensive, multicoping strategies, while disengagement implies defensive coping strategies and social breakdown, and, finally, Erikson's integrity refers primarily to the integration of elements in life that has passed, while gerotranscendence implies more of a forward or outward direction, including the redefinition of reality. In summary, even though Tomstam's theory of gerotranscendence is based on limited empirical evidence, it nevertheless makes a promising attempt to integrate and further develop some classical and modern psychosocial theories of aging.

Branching Theory

In 1995, Johannes J. F. Schroots presented a brief outline of a dynamic systems theory of aging, called gerodynamics. This comprehensive theory *in statu nascendi* is based on general systems theory, notably the second law of thermodynamics, and dynamic systems theory (chaos theory). The second law states that there is an increase of entropy or disorder with age in living systems, resulting in the system's death. Chaos theory postulates that internal or external fluctuations of dynamic, far-from-equilibrium systems can pass a critical point – the transformation point – and create order out of disorder through a process of self-organization, that is, a process by which a structure or pattern of change emerges with the passage of time. From this meta-theoretical viewpoint, the aging of living systems can be conceived as a non-linear series of transformations into higher- and/or lower- order structures or processes, showing a progressive trend toward more disorder than order over the life span, and resulting in the system's death.

Gerodynamics lies at the root of a new aspect theory of aging, called branching theory. The basic principle of this theory is the bifurcation or branching behavior of the individual at the biological, psychological, or social level of functioning. Metaphorically speaking, bifurcation means that the fluctuating individual (organism) passes a critical point – the bifurcation, branching, or transformation point – and can branch off into higher- and/or lower- order structures or processes. Higher- and lower- order structures can be translated in terms of mortality (probability of dying, life expectancy), morbidity (disease, disorder, disability, or dysfunction), and quality of life (well-being, life satisfaction). For example, traumatic life events and a healthy lifestyle may result in lower- and higher- order structures, respectively, and consequently in higher- and lower-probabilities of dying. It should be noted, however, that lower- order bifurcations at the biological or psychological level of functioning (e.g., illness or divorce) do not always result in lower- order branching behavior, that is, some people are strengthened by illness, and divorce may have a positive rather than a negative effect on mental health in terms of life expectancy and quality of life. Briefly summarized, branching theory requires the study of determinants and patterns of branching behavior across the life span. It remains to be seen how empirical research lends support to its theoretical claims.

Life Course Dynamics

As noted previously, development and aging are traditionally thought of as two successive processes of change, with development conceived as an incremental process like biological growth, and aging as a decremental process like senescence. The old-fashioned calendars of life, with people of all ages arranged in order of age on a platform, are an excellent illustration of the hill or pyramid metaphor, with rising and declining steps. Essentially, this metaphor views the human life course as a single-peaked function with the apex varying across the life span, dependent on the biological or psychological function in question.

The notion has been growing that psychological processes of change do not necessarily closely parallel biological changes along the life span. The differential course of fluid and crystallized mental abilities may serve as an example. The life span patterns of both abilities show a rapid rise until early adulthood, followed by a period of relative stability for the crystallized abilities until the age of 60 years, but a slow decline of the fluid abilities after early adulthood. The as-yet-unsolved problem in the

psychology of aging, then, concerns the diachronic (successive) and synchronic (simultaneous) relations of development and aging.

Recently, a dual process theory of life course dynamics has been developed that might help to explain the differential decline of fluid and crystallized abilities in terms of varied sensitivities for neural processes of growth and senescing. Generally, the growth of the central nervous system (CNS) comes to a stop in early adulthood, while the aging of the system or neural slowing continues increasingly. As crystallized intelligence is primarily based on the full-grown storage capacity of the CNS, which has enormous reserves, crystallized abilities are less dependent on neural slowing than fluid abilities, which are primarily related to speed of information processing or neural slowing, rather than to informational capacity. In other words, the life span patterns of crystallized and fluid abilities are minimally determined by two fundamental, synchronic forces, growth (development) and decline (aging), which produce – in combination and with varying rates – the differential course of fluid and crystallized abilities. Computer simulation studies might show that the simultaneous forces of growth and decline explain the course of other psychological functions and abilities as well.

Prospects

Psychological theories of aging deal with one of the most complex issues science can face, that is, how behavior becomes organized over the course of an individual's life. A theory of aging that integrates changes in cognitive and personality functions awaits development. From dynamic systems theory, it has become clear that adaptive self-stabilization and maintenance with age in the face of environmental challenges calls for increases in complexity of organization and that such complexity carries a price: the more complex the adaptive process, the less stable the individual and the more energy it must disperse in order to stabilize and maintain its complexity. The overall picture, then, is that aging both causes and reflects the increasing variability of individual functioning.

As clarity emerges about what is being explained of complex behavior, it becomes evident that chronological age as a causal or explanatory variable needs to be replaced and/or supplemented by other variables more sensitive to intra- and interindividual differences. Recent studies of development and aging show that the combination of chronological age with variables reflecting directly or indirectly the length of life or the residual life span offers a promising perspective for theoretical progress.

Human individuals have similar and different genetic backgrounds; they also grow up and grow old in similar and different social and physical environments. Consequently, the general and unique features of the psychological pathways of life call for concepts and theories to identify the causal factors determining the length, context, and personal interpretations of life. In other words, future theories ask for a frame of reference that includes both the organismic and the ecological perspective on life. In this respect, it should be noted that the relative dominance of biological, psychological, or social variables over the life span changes with age; this applies also to their interactions. In the final analysis, there will be an increasing need for theories of aging that are more integrated and inclusive. Dynamic systems theory and computer simulation might offer tools to deal with the issues of complexity and integration.

Glossary

Age Stratification Perspective – A theoretical approach that focuses on the progression of birth cohorts through the age strata of a society and that views the age stratification system as changing in response to cohort characteristics and other social phenomena.

Disengagement Theory – Theory arguing that successful aging involves a mutual withdrawal of the aging individual and society. This is seen as functional for society and beneficial, normal, typical, and ideally voluntary on the part of the individual.

Interpretive Theory – Theory that assumes that individuals have significant freedom of action or choice and that emphasizes that humans are capable of creating and using symbols.

Modernization Theory – Theory arguing that as societies modernize, industrialization, urbanization, new technology, improved health, and longevity contribute to a decline in the social status of the aged.

Political Economy Perspectives – A range of theoretical viewpoints that emphasize the importance of power and economic forces in the structuring of society and the life chances of individuals.

Introduction

Social gerontology draws on a broad array of theoretical perspectives and social theories from several disciplines, but rarely has it developed its own interdisciplinary theories or theoretical perspectives. By theoretical perspective, we refer to an articulated set of concepts held to be important for the understanding of a social phenomenon. In essence, a perspective says, 'look at this,' whereas theories provide a meaningful interpretation and a background of assumptions about the way the social world works, grounding the individual concepts and their postulated linkages.

There is not, and probably should never be, an overarching theory of aging. Aging is living, and it is doubtful that any attempt to construct such a theory would be capable of capturing all the dynamics of all aspects of life. Rather, there are theories in aging. There have been some attempts to systematically and logically relate hypotheses, based on precise conceptualization, to understand specific phenomena in relation to aging. Such phenomena cover a wide range of specific areas, including work and retirement behavior, economic security, changes in health and health-care utilization, family life, and social integration. Questions about theory in this sense have to do with the empirical validity of theories in aging or, more often, with the empirical validity of models that are not well theorized. In contrast, most theorizing is directed to the articulation of theoretical perspectives and their applicability to social processes of aging, the social status of the aged, and the ways in which social institutions are shaped by, adaptive to, or reactive to changes in the age structure of societies. There would be little to say if we were to confine attention to formal theories. The first section of this article therefore presents a framework to describe different theoretical perspectives that are or have been used in social gerontology. This framework will allow us to contextualize major developments in the history of theorizing in social gerontology, as well as current theoretical approaches. A final section considers major challenges for social theorizing in gerontology.

A Framework to Classify Theory

Explicit discussions of theory in social gerontology have taken many forms. Most commonly, scholars contrast two different approaches, such as structural-functionalist versus political economy approaches or feminist versus masculinist theorizing. More comprehensive classifications of social theories of aging have taken several approaches. Bengtson *et al*. describe social science theories used in aging as rooted intellectually in symbolic interactionism, structural functionalism, Marxism, economic rationalism, hermeneutics, and postmodernism. Their gerontological applications include activity theory, disengagement theory, modernization theory, subculture theory, continuity theory, social breakdown/labeling theory, exchange theory, political economy of aging, social constructionism, life course and feminist theories, and critical gerontology. Other classifications have a similar list but describe the temporal relationship among theoretical perspectives differently. That is, they tell different stories about how theory developed in social gerontology.

Our approach is loosely narrative, distinguishing early and emergent theorizing, but it rests on a typology articulated by Marshall that distinguishes two major axes of social theory: the normative-interpretive dimension and the micro-macro dimension. The micro-macro dimension describes whether the theoretical approach focuses on social psychological processes at the level of the individual in social interaction, focuses on social institutions or large-scale aspects of social structure, or tries to link individual and small-scale social interaction in the context of social structure and macro-level social processes. The normative-interpretive dimension classifies approaches ranging from those that give little attention to human autonomy and meaning-construction to those that view the individual as a voluntaristic actor who at least attempts to exercise choice. Theoretical perspectives (and the rare actual theories in the field) can be classified along these two dimensions.

The Legacy of Early Theorizing

Early theorizing in social gerontology attended to both micro- and macro-level concerns, but primarily from a normative or deterministic perspective. From the beginnings of serious social theorizing around 1940, there was a concern for an alleged decline in the extent to which older people were integrated into society. This concern was expressed principally by structural functionalist sociologists, who view role as the key building block of society. Social integration was defined as embeddedness in role relations, and large-scale social changes were thought to cause declines in social integration with aging. From its origins, social gerontology thus took as problematic the 'fit' between the aging individual and society, but it failed to adequately describe the structuring of life experience by class, gender, and similar structural properties, let alone age structure. These early attempts were predominantly normative. Theorists developed interpretive approaches to understand aging, in part, as a reaction against the earlier normative approaches.

The Early Focus on Adjustment

The history of social gerontology has until recently been largely an American history and has been influenced by America's ideology of individualism. As Shanas (1971: 159) has noted of early social gerontology, "Current American sociological interest in the aged …. can be traced directly to the efforts of Ernest W. Burgess as a member of the Committee on Social Adjustment of the Social Sciences Research Council". For Burgess, the modernization of society had led to the loss of many significant roles for the elderly to play, leading to the so-called 'role-less role of the aged.' This phenomenon was subsequently addressed through functionalist role theory investigating the adjustment of the aging individual to changing social roles or the loss of roles, with the dependent variable being some form of adjustment. Burgess saw this as a problem of a lack of fit between the individual and society that could be remedied either by societal change or by individual adjustment, but the field primarily focused on the latter. The Committee on Social Adjustment report was published in 1948 under the title, 'Social Adjustment in Old Age.' The program of work funded by the council supported activities at the Institute for Human Adjustment at the University of Michigan (from which derived the field-defining handbook edited by Tibbitts in 1960 and the work of Cavan and associates at Chicago, leading to the landmark, *Personal Adjustment in Old Age*, published in 1949).

Modernization Theory

Early research pursuing this theme of adjustment at the macro level dealt with modernization and its allegedly detrimental effects on the social status of the aged person. Both society and the individual were poorly theorized in most of this work – the individual was largely ignored in this macro-sociological research area, and critical scholarship eventually showed that work in the area failed to adequately place societies within a world socioeconomic system and failed to recognize the complexities of societal modernization processes. While Burgess presented specific statements about the relationship between modernization and the social status of older people, Cowgill progressed from an initial list of 22 independent propositional statements to a logically related set of four causal pathways through which modernization acted to reduce the social status of the aged. The major aspects of modernization, in his theory, were advances in health technology, economic technology, urbanization, and education. The theory suggested that each led, through intervening variables, to lower status of the aged. For example, urbanization led to migration of the younger generation, neolocal marriage, and residential segregation, which removed the younger generation from the authority of their parents, leading to lower social status.

Problems with the approach include its assumption that modernization is a uniform process, empirical problems with timing (for example, there are many historical cases in which retirement emerged prior to economic modernization), the assumption that older people historically had higher status in premodern

societies or that they have it in contemporary societies that have not modernized, and an unclear conceptualization of social status. For example, if government allocation of resources to the aged is a sign of status, then clearly the modern industrialized welfare states accord historically unprecedented status to the aged.

Through Cowgill's efforts at formal theory construction, the theory of aging and modernization served as a useful reference point for researchers precisely because it could be tested, and this led to extensive qualification and substantial rejection of the theory. To a great extent the theory served as a foil, stimulating a reactive development of theorizing in the political economy tradition.

Role Theory, Disengagement Theory, and Activity Theory

The modernization and aging theory is one of two major formal social theories of aging. We now consider disengagement theory, the most important formal theoretical approach at the micro or social psychological level, although it did have a social structural component and was explicitly formulated as a theory about the link between the individual and society. Its formalization included nine postulates and several explicit corollary statements. Its major premise was that, with aging, there was a mutual severing of the ties between the individual and society, and that this was a good thing for both. Social structural change is defined as disengagement if it involves "a thinning out of the number of members in the social structure surrounding the individual, a diminishing of interactions with these members, and a restructuring of the goals of the system" (Cumming and Henry, 1961: 37). Engagement is measured by a count of social role occupancy, a subjective rating of the amount of time spent in normatively governed interaction with others, and an actual count of the number of interactions. Social structure in this structural-functionalist view is conceptualized as a complex system of interlocking status positions, to which role expectations correspond. Social integration during this period of theorizing was equated with adaptation of the older person to society, and adaptation in turn was considered to be indexed by life satisfaction, morale, or happiness. The structural-functional theoretical foundations of this work saw the individual as nothing other than a bundle of roles, spiced with some need dispositions and personality characteristics. In this conceptualization the individual was largely reactive – either to societal demands or to presumably inevitable and universal pressures of physiological and psychological development.

In the general research program from which the disengagement theory was developed, and the subsequent social psychological emphasis on adjustment, the major independent variables entered into models to predict variability in life satisfaction were dispositional or personality factors, or were largely restricted to three domains: health, income security, and social integration. These, in turn, were largely unexamined variables. Few scholars theorized about the causes of variability in health, wealth, or social integration, and no one studied this topic from a life course perspective. To do so would have shifted attention away from the social psychological level toward a social structural level of analysis and required people working with cross-sectional data to think longitudinally. Moreover, to do so would have been a stretch away from the overall individualistic bias of the social sciences in North America.

Activity theory was invented by Cumming and Henry as a foil for their presentation of disengagement theory. They asserted that it was an implicit theory. The response to disengagement theory led to more formal explication of the activity theory by Havighurst *et al.* using data from the Kansas City studies and by Maddox and other scholars using data from the Duke Longitudinal Survey of Aging. The debate was joined by other American social gerontologists and dominated gerontology conferences and publications for many years. More developed theoretical formalization and testing was conducted by Lemon *et al.* and by Longino and Kart. The results, overall, favored activity theory in that life satisfaction was more often found to be associated with higher levels of social integration (measured by a role count) than not. Personality factors were found to be in play. The most damning critiques of disengagement theory argued that much disengagement from social roles was involuntary, occurring, for example, through widowhood and retirement. For all its faults, disengagement theory at least tried to be a theory, but it was not precisely conceptualized, making it difficult to test.

We have grouped activity and disengagement theory into the category of role theories because a structural-functionalist conceptualization of role is common to both. Other scholars, without entering this specific debate, used the same conceptualization of roles. Irving Rosow, the most prominent theorist to do so, spent most of his career articulating a functionalist understanding of aging in terms of role occupancy and argued that socialization for role occupancy in old age was problematic for several reasons, including low motivation to learn the role and a dearth of formal teachers or role models.

The Age Stratification Perspective

An attempt to focus gerontological research more squarely on social structure resulted in the development of the age stratification perspective by Riley and a number of colleagues. What is rarely recognized is that this perspective also postulated an explicit link between the individual and society, through the processes of socialization and role allocation.

The main thrust of the age stratification perspective is precisely to develop a conceptualization of age as structure, a social organization of age statuses through which either cohorts or individuals flow as they age. Each stratum in an age stratification system has its own sets of expectations for behavior and rewards for fulfilling these expectations. There are two components to social structure: people (forming the population structure) and roles. The conceptualization is structural-functionalist. Age is seen not just as providing criteria for entry into or relinquishment of roles. Age-related acts are also viewed in terms of the contributions they make to society, and analytic attention can focus on "either the total system of age-related roles, on the complex of roles appropriate to a given age (stratum), or on particular roles as parts either of the total system or of the complex" (Riley *et al*., 1972: 8).

Role allocation refers to "a set of mechanisms for the continual assignment and reassignment of individuals of given ages to the appropriate roles" (Riley *et al*., 1972: 11). Role allocation as a concept has the potential to describe social structure dynamically, but the treatment of this concept is schematic. The age structure is not static but can be changed by cohorts flowing through it. How this change occurs is not well developed within the perspective, which may be because of the general assumptions found in structural functionalism that social systems tend toward equilibrium.

Socialization is a process that "serves to teach individuals at each stage of the life course how to perform new roles, how to adjust to changing roles, and how to relinquish old ones" (Riley *et al*., 1972: 11). In structural-functionalist theory, societal equilibrium is maintained largely through highly efficient socialization, which teaches people to do (and to want to do) what they must do if the social system is to survive. For the most part, early social psychological concerns had seen the individual not in terms of the self but in terms of either personality or need dispositions, or as bundles of roles. And the individual has mostly been viewed as passive or reactive – being socialized, for example, to more or less unwittingly live up to the scripts for behavior that are found in the general culture and transmitted through socialization. Although much of the social psychology emanated explicitly or implicitly from a Parsonian version of structural functionalism, and Parsons expounded a 'general theory of action,' there is little real action in this approach, as others have noted. Insofar as this approach touches on the self at all, it treats the self as object – the 'self concept,' rather than the self as process.

The age stratification perspective is not a theory but rather a loosely structured set of assumptions to guide research. This looseness perhaps increased its survivability, because testing through falsification was never an issue. Rather, the perspective played an important role in directing gerontologists' attention to social structure. Although its conceptualization of social structure may have been too rooted in structural-functionalist thinking to adequately address structured social inequality, it was at least a step in the right direction.

The age stratification perspective survives among some social gerontologists as the 'age and society paradigm,' which represents only a slight modification in emphasis to the age stratification perspective. As Riley noted (1994: 436), "Earlier, we had called it 'age stratification,' but then abandoned that term as overly static, failing as it did to reflect the dynamic aspects of both lives and structures." The evolution of the age stratification perspective into the age and society paradigm encompassed Riley's move to a life course perspective, discussed later in this article.

To summarize our brief historical overview, early theorizing in social gerontology did deal with micro- and macro-level approaches, but largely through the analytic lens of functionalist sociological theory. Early theorizing thus falls well into the normative spectrum on the normative-interpretive dimension. The link between the social structure and the individual is the role, the set of expectations for the behavior of the occupant of a specific status position. Socialization prepares people for role occupancy and enactment, and it is usually assumed that it is successful. (Rosow was an exception, stressing reasons why socialization for old age was rarely successful.) Social structure in this view is nothing but a complex interweave of social roles. As such, this perspective fails to find a place for social structure that would allow it to be seen as constraining or enabling individual behavior, and it fails to give the individual much say as to role performance. Subsequent theorizing has been largely reactive to these problems and has sought to develop a conceptualization of social structure that can deal with macro-level social relations of power, domination, and allocation of opportunities and resources, while at the same time avoiding the fallacy of reification that treats social

structure as if it exists independently of the actions of human beings.

Current Theoretical Approaches

The set of theoretical perspectives currently in use by social gerontologists consists of a mix of some remnants of the early theoretical approaches and others that can be seen largely as reactive to the early approaches. These approaches have been taken at the micro and macro levels but often seek to bridge those levels.

Political Economy Approaches

Since the 1980s, a number of theorists have been elaborating theory under the rubric of the political economy perspective to understand the social circumstances of the aged. The term 'political economy' has come to be used in different ways. Walker's 1981 paper, 'Towards a political economy of old age,' and Townsend's 1981 'The structured dependence of the elderly: a creation of social policy in the twentieth century' were two of the earliest defining statements for the perspective's application in the field of aging. Walker (2005: 816) describes "the origins of the political economy of ageing as an explicit attempt to counteract the then prevailing functionalist paradigm in social gerontology…." A Marxian emphasis on the importance of social class and classlike differences between age groups that experience structurally different life chances is linked to an emphasis on the moral economy, which recognizes that social movements, the political process, and economic processes are shaped by cultural conceptions of legitimacy, equity or fairness, citizens' rights, and moral contracts between the generations (*see* Politics of Aging). The link to processes of aging is made by viewing the life course as socially constructed in light of such economic and moral concerns; this aspect of the perspective draws on Weber's assertion that sociology's task is to understand meaningful patterns of social interaction. For example, political economists might view the category 'old age' as defined by retirement, and retirement as a humanly invented social institution reflecting trade-offs between different parties with at least potentially conflicting interests: workers seeking a citizen's wage, owners seeking ways to exercise more control over their workers, and the state seeking to provide for the welfare of its citizens. Townsend (1981: 9) sets out the domain:

> … society creates the framework of institutions and rules within which the general problems of the elderly emerge and, indeed, are manufactured. Decisions are being taken every day, in the management of the economy and in the maintenance and development of social institutions, which govern the position which the elderly occupy in national life, and these also contribute powerfully to the public consciousness of different meanings of ageing and old age. These are decisions … about the commitment of public expenditure which directly govern the services and benefits of older people. Then there are decisions about employment, wages and taxation, transport, urban planning and housing which have a powerful indirect effect on the situation and standard of living of the elderly.

The contrast with the earlier theoretical perspectives is stark. Note the emphasis on the social construction of the social problems of the aged, and also how these concerns focus more on the material conditions of life than on people's feelings of life satisfaction or their social status. Walker makes a similar argument and suggests that the starting point for a political economy of aging should be the relationship between age and the labor market. Myles also calls attention to what Townsend called 'indirect' effects, suggesting that the impact of public policy on the aged is more of a latent function or unintended consequence than something deliberately intended to marginalize the aged. Guillemard points to the importance of ideology and argues that the state fosters ideologies (such as the ideology of '*le troisieme age*') as a means of social control.

We mentioned earlier that much political economy theorizing was reactive to the modernization theory of aging. Aboderin has brought political economy principles to bear in her systematic critique of the modernization theory of aging, during the course of which she may well have given it new life. In a series of papers, she has critically reviewed the literature as it focuses on declines associated with modernization in the extent of kin support provided to the aged. While the modernization and aging theory would suggest that modernization leads to declines in adherence to norms of filial obligation and these in turn lead to declines in material support for the aged, Aboderin's multigenerational research in Ghana supports a much more textured argument that emphasizes materialist (and thus political economy) causes of declining support, but interwoven with factors already considered in the earlier modernization literature (2004b: S136):

> … the identified processes of change clearly suggest that it is the alteration in families' material circumstances that has been the dominant driver of the shifts in support norms and patterns. However, a wholly materialistic explanation is not enough: Changes in broader societal values and ideas have played a role. They have interacted with deteriorating material conditions and serve to exacerbate their effect…. The value that younger and older generations now place on self-reliance, away from

> support by children or kin, is, above all, a response to the worsening economic situation. The principle, it seems, is that if material conditions change to such an extent that fulfillment of a particular family norm becomes harmful to the younger generation, it is no longer tenable and must change.

As Walker notes, the approach furthers our understanding of social structure, which acts to either enable or constrain agency. Agency is not denied, but rather is placed in a context that allows one to theorize the relationships between action and structure or self and society. Walker (2005: 833) makes a persuasive case that the major shortcoming of political economy theorists so far has been to neglect the importance of globalization: "An international political economy of ageing is needed to understand current national and global responses to ageing; to highlight the roles of transnational corporations and IGOs; to critically evaluate globalization and responses to it as they affect older people; to counteract the ideology of the ageing crisis; and to combine agendas that have existed for too long in separate pigeon-holes: human rights, development and ageing."

Walker (2005: 815) states that "The political economy perspective quickly became the key paradigm in social gerontology." But this is surely not so, as any examination of the major social gerontology journals will attest. While most articles found in such journals are atheoretical, those that invoke theory are much more likely to invoke social constructionist, life course, and exchange perspectives than the political economy approach. Walker's view may be shaped by his embeddedness in European gerontology, in which political economy approaches are much more commonly used. Nevertheless, the political economy perspective is increasingly used not only by European social gerontologists but also by those in North America in contemporary research on income security, health care, and a number of other issues (*see* Politics of Aging). In addition, the political economy perspective is so strongly foundational to the newly fashionable critical theory perspective in social gerontology that it is hard to tell the difference.

Critical Theory Approaches

Critical theory has been an important strand of general social theory for almost a century, but it has gained currency in social gerontology only since the 1980s. It builds upon and beyond political economy approaches, drawing on "a number of feminist, discursive, and micropolitical issues typically neglected in formal political economy treatments" (Katz, in press; see also Phillipson and Walker, 1987). Critical theorists critique positivism and strive for reflexivity, an awareness of the social conditions of their theorizing. The leading contemporary critical theorist Jurgen Habermas emphasizes the importance of free communication and forms of practical and emancipatory discourse that are distinct from the rationality of technical discourse. In gerontology, Moody calls for a hermeneutic gerontology, drawing on the humanities as a resource, but he also sees the need for emancipatory knowledge to ensure that our hard-gained technical and practical knowledge will not be misused for domination and exploitation. It is thus important to recognize that critical theorists advocate theorizing for emancipation, not simply for understanding. This political commitment is distinct from most theorizing in social gerontology, which is motivated by the quest for understanding alone, and also from most atheoretical research in the field, which is primarily concerned not with emancipation or understanding, but rather prediction.

Some scholars see 'the new critical gerontology' as the political economy perspective carried to its logical extensions, with the inclusion of feminist theory and cultural studies. Minkler sees critical gerontology as bringing together the political economy of aging and a more 'humanistic path.' These distinctions are not clear and are not accepted by all political economists. We argue that the political economy perspective has room for the emancipatory project of critical theory. Critical theory, like the political economy perspective, is in a sense Marxism in disguise. The early critical theorists were Marxists preoccupied with the development of the class structure and its impact on individual psychology who brought to their theorizing perspectives on human nature and individual behavior from the phenomenologist Heidegger, the psychoanalyst Freud, and others. Later critical theorists in the Frankfurt school turned to pragmatism and symbolic interactionist thinking. They drew on the cultural sciences to further understand the cultural conditions under which people accepted capitalism, and the alienation of the individual resulting from the 'civilization process' and the application of 'instrumental rationality.' It is not at all surprising that some of the political economy theorists, such as Minkler, Phillipson, and Walker, at least sometimes invoke 'critical theory' to describe what they are now doing.

Interpretive Sociology: Social Constructionism, Symbolic Interactionism, and Phenomenology

Even during the early period of social gerontology research, a number of researchers drew explicitly on strands of interpretive theory rooted in symbolic

interactionist and phenomenological sociology as well as symbolic and cultural anthropology to understand aging and the life course. These approaches emphasize that the human being is a symbol-creating and symbol-using creature who actively seeks meaning and seeks to develop lines of actions in order to realize individual interests or motivations. Human behavior, in this view, is seen as constrained, but not fully determined, by biological or social structural factors. Structural-functionalist equilibrium assumptions are rejected, as is strong determinism. This view is wholly compatible with the political economy perspective. The challenge is to theorize the ways in which people struggle to make their lives.

Chappell and Orbach systematically explore the symbolic interactionism of Mead and its applicability to guide research in aging. They highlight the importance of Mead's conceptualization of temporality, his concept of the 'problematic situation,' and his focus on the uniqueness of the individual. We live in the present, but our present influences the ways in which we construct both our past and our future. Mead's perspective stresses constant change, novelty, and emergence in response to problematic situations. The self is not an object or thing, but a process. Chappell and Orbach emphasize that this view of the self is quite at odds with that of many other sociologists who have dealt with aging, including Riley and Rosow.

Continuity theory was developed in a series of works by Atchley. In his most elaborated formalization, he articulated nine specific assumptions and five propositions. The key proposition is perhaps that "Continuity of general patterns of thought, behavior, and relationship is the first strategy people usually attempt to use to achieve their goals or adapt to changing circumstances" (Atchley, 1999: 101). Atchley states that the theory, while a "feedback systems theory," is constructionist, and his description is a good general portrait of the social constructionist perspective (1999: 98):

> It assumes that in response to their life experiences, people actively develop individualized personal constructs…. ideas of what is going on in the world and why…. Continuity theory posits that our personal constructs are influenced by the social construction of reality we learn from those around us and from the mass media, but are not determined by them. No matter how strongly society's efforts to influence personal constructs, individuals ultimately are free to decide for themselves how to construe their personal reality. An important implication of this aspect of the theory is that subjective perceptions of continuity become more theoretically relevant than researchers' perceptions of objective continuity.

Gubrium has made a sustained contribution to the interpretive perspective on aging with his phenomenological and narrative theorizing. His approach can be illustrated from the distinction he makes between the life history and the life narrative: "… the life history is an objective record of the person's past, while the life narrative is the subjectively constructed life" (Gubrium, 1993: 178). When narratives are generated through interviewing, they are viewed as joint constructions or narrative collaborations between respondent and interviewer. In his study of life in the nursing home, Gubrium sees residents as acting the 'resident role' within their individualized horizons of meaning, constructing 'worlds of their own' within organizational parameters and constraints.

Running through this account of social theories of aging is a concern to adequately theorize the relationship between the micro and macro levels of analysis. Interpretive sociologists view the micro-macro linkage in terms of the relationship between self and society, and they see this link as resting on negotiation. Most theorizing in this area has been inductive and based on ethnographic or otherwise qualitative data analysis, which focuses on individuals negotiating a number of transitions in the aging process, such as transitions into age-homogenous environments, chronic illness, widowhood, or impending death. Marshall has presented a set of 13 propositional statements rooted in the interpretive perspective to move toward a theory of aging and dying, but in general there is little formal theorizing within the interpretive perspective at the micro level. This is also true when the perspective is employed to interpret macro-level social structural or institutional processes, as in much of the political economy and critical theorizing discussed previously.

The Life Course Perspective

The life course perspective, in its own varied manifestations, encompasses many of the perspectives previously discussed. There are several different, albeit related, approaches within the life course perspective, and there are also many researchers who describe their work as 'life course' when it does not incorporate some of the key assumptions of that loosely defined perspective. In North America, scholars draw most heavily on the systematic articulation of 'principles of the life course perspective' by Elder, Jr., who has done more than any single scholar internationally to develop the perspective and apply it empirically in aging research, but he acknowledges several precursors, and other exemplars in North

America and beyond take a somewhat different approach.

The North American version of the life course perspective is generally more confined to social psychological rather than social structural domains, or dealing with the linkage between self and society. There has been progressive theoretical formalization since Mills established an imagery for the perspective, arguing that the sociological imagination seeks connections between personal troubles and public issues, or biography and history. Cain, Jr. (1964: 273) sought "to identify, isolate, and systematize a life course, or age status, frame of reference" in an extensive essay, 'Life course and social structure,' published in 1964. However, Riley crystallized what she called the 'emerging life course perspective' in 1979 under 'four central premises,' in which she argued that aging is a lifelong process that starts at birth, really three interacting sets of processes at the biological, psychological, and social levels, and that people's lives affect the social structure of the life course just as that structure influences their lives. In many publications, Elder subsequently codified the perspective in five principles, going beyond Riley to stress the importance of timing of life transitions in relation to historical events, as well as the principle of 'linked lives,' which insists that we view people's lives as interdependent. Finally, Elder gave more importance than Riley to a principle of 'human agency,' asserting that individuals construct their own life course through their own choices and actions, although in the context of opportunities and constraints of history and their social circumstances.

A few North American life course researchers have paid more attention to social institutions and the way they structure the life course in the area of family and work and variability in economic security. However, a significant body of theorizing about the life course at the macro or social structural level is found principally in Europe. European scholars in the life course perspective systematically analyze how the state functions, along with other social institutions such as industry, to create a life course structure in which age is one basis of social inequality interacting with gender and social class. The role of the state is almost completely ignored by North American life course and aging scholars, who have also underconceptualized social structure; however, in Canada there is an ongoing significant attempt by a consortium of government agencies to articulate a life course perspective that will support public policy development.

Both European and North American life course and aging scholars have attended to micro-level phenomena, but in North America this has meant largely specific empirical studies of individual life courses, or types of life courses, examined in terms of the theory of cumulative advantage (perhaps the only formal theory rooted in the life course perspective), which suggests that initial differences in socioeconomic advantage increase over the life course, or the question of orderliness in transitions. In contrast, European life course researchers have generally painted with a broad brush while describing the meaning of biography and career under conditions of social change.

Challenges for Social Theory in Gerontology

We identify three major challenges (of a much larger set) for social theory in gerontology. These are (1) to develop ways to understand the dynamics of self and society and the linkages between micro and macro phenomena; (2) to establish a richer dialogue with general social theory; and (3) theorizing diversity.

Theorizing Self–Society Linkages

The call to achieve a better understanding of the self–society linkage has long been voiced. For example, Marshall and Tindale (1978–9: 169–170) made such a call in a paper, 'Notes for a radical gerontology,' castigating the field for its individualism and neglect of social structure and asserting the following:

> … we believe future research in gerontology has to relate the realities of constituents' lives to the social structure in which they live…. Research moving in this direction takes gerontology away form the focus on personality. We are not arguing against the social psychological concerns of gerontology. Aging is an individual as well as a collective phenomenon. What is needed, we feel, is more research on interpersonal interaction in face-to-face situations, but cast in processual terms, and situating the individual in terms relating to an environment historically understood. Also needed are more studies of the political economy of aging, which will restore a sense of context to our understanding of the lives of today's aged, and especially inform us concerning the socio-economic forces influencing the psychological processes of aging.

Marshall and Tindale were here influenced very much by Mills' reminder, in *The Sociological Imagination* (1959: 3) that "The facts of contemporary history are also facts about the success and the failure of individual men and women," and that "Neither the life of an individual nor the history of a society can be understood without understanding both". Much progress has been made in linking self and society in aging research, especially by life course

theorists. However, to advance the field, North American social gerontologists will have to continue to struggle with the conceptualization of social structure. Moreover, this is not a challenge for theorists of aging only. Rather, it is probably the leading theoretical challenge for the social sciences in general.

Greater Dialogue with General Social Theory

In an insightful essay of 1988, the time when theorizing was moving beyond the early stage to what we are terming more recent work, Martin Kohli argued that while the sociology of aging has often borrowed from general sociology, it has rarely returned much to general sociology. This remains largely true today. He suggested that one major avenue to do that would be by theorizing what society will look like when smaller proportions of the population, at any one time, have their lives structured by work. With great fluctuations in age patterns of labor force participation since Kohli made this suggestion, it still remains an area in which aging theorists have much to contribute. This theorizing will probably draw heavily on the life course perspective, which aging research in the area of work has already helped to refine, but it will also draw on, and hopefully contribute to, the political economy perspective and to critical theory.

If theoretical development in social gerontology is to flourish, it will be due to the openness of social gerontologists to working with existing general social theory. For example, the notable social theorist Giddens (who is not, however, identified as a gerontologist) has theoretically articulated a view of trajectories of the self in the risk society of late modernity that may be helpful to social gerontologists in the life course perspective, particularly those who actively seek to link the micro and macro dimension from an interpretive perspective. As a second example, drawing on Foucault, Bourdieu, and other major sociological theorists who are definitely not gerontologists, Katz has developed a cogent historical sociology of how gerontological knowledge develops as a discipline while co-constituting the aged as a social group. As a third example, many social gerontologists have made creative use of exchange theory and related micro-economic theories that assume people make rational calculations and strive, in their social relationships, to maximize utility (the rewards minus the costs) of the actions. Ideally, greater openness of social gerontology to general social theory will result in an increased two-way flow of knowledge.

Theorizing Diversity

Another challenge for theorizing in social gerontology is to better grasp diversity. The call for this has taken different forms in the history of the field, from Neugarten's distinction between the 'young-old' and 'old-old,' to Dannefer's plea for a 'differential gerontology,' to the life course theorists' recognition of the principle of cumulative advantage. Additional theoretical gains may come from refinements in feminist theorizing.

We take the position that feminist theory is distinguished from sophisticated general social theory only by the commitment of the theorist to use theory in certain ways as a critique of mainstream gerontological research for its neglect of the gendered nature of work life, family life, and social stratification. Much feminist theorizing in social gerontology draws heavily on the political economy approach, and some such theorists label themselves as 'social feminists' or 'Marxist feminists.' McMullin (2000: 517) stresses the importance of placing gender analyses in a broader conceptual framework and suggests that feminist theory is superior to the age stratification and political economy perspectives: "… for a theory to be well suited for diversity research at least two criteria must be met. First, class, age, gender, and ethnicity/race must be conceptualized as power relations, and second, they must come together as an interlocking hierarchy of power rather than as separate systems." Feminist aging scholars such as Calasanti, McMullin, and Estes are contributing to a better understanding of the interplay of different aspects of diversity, of which gender is only one.

Facing these challenges will also call for a recognition that the aging experience of individuals and cohorts has to do with much more than the two domains that currently characterize the field of social gerontology: health and family. Aging does occur in the context of a life course, and life courses occur in the context of social structures that act as either opportunity structures or structures of constraint. At a structural level, life course and aging takes on global aspects in an increasingly interdependent world. To adequately understand individual processes of aging, scholars have to find a way to understand the dynamic relationships that link self and society. We anticipate that productive research will continue to occur at both the social psychological and the social structural levels, but the real payoff will come when theorists succeed in this linkage. Finally, research in the social aspects of aging too often leaves us asking, 'what does all this mean for the individuals involved?' The current structures of research funding and publication

favor normative rather than interpretive research, and it is no surprise that we have more research in the normative than in the interpretive tradition of the social sciences. We need both. Social theory in aging has yet to adequately address these issues.

Thirst and Hydration

M-M G Wilson, St. Louis University Health Sciences Center, St. Louis, MO, USA

Glossary

Anosmia – Absence of the sense of smell.

Dehydration – Excessive loss of body water, usually resulting from a negative balance between fluid intake and output.

Dipsogenic – Thirst provoking.

Dysgeusia – Distortion of the sense of taste.

Homeostasis – Tendency to maintain stability or constancy of the internal physiological environment.

Hypodipsia – Physiological condition resulting in delayed initiation of drinking.

Osmoreceptor – Central nervous system receptor that responds to changes in plasma osmotic pressure.

Thirst – A strong, uncomfortable desire or craving to drink liquid.

Introduction

Franz Grillparzer, a nineteenth-century Austrian classical dramatist and lyric poet, captured the essence of the impact of age-related hypodipsia in one of his writings: "Drink and be thankful to the host! What seems insignificant when you have it, is important when you need it." (Sauer A (ed.) *Complete works of Franz Grillparzer*, 5th edn. Stuttgart, 1892–93).

Table 1 Thirst regulation in older adults: Homeostatic and non-homeostatic factors

Homeostatic
Plasma hyperosmolarity
Hypovolemia
Plasma renin activity
Peripheral and central vasopressin levels
Oropharyngeal metering
Non-homeostatic
Hedonic qualities of fluid
Palatability of drink
Fluid preference
Availability
Sociocultural influences
Lifestyle habits
Social isolation
Functional status
Associated comorbidity

Thirst is perceived as an uncomfortable sensation that exerts a motivational effect on drinking behavior and resolves with fluid consumption. In humans, the perception of thirst is subject to a complex interplay between physiological homeostatic mechanisms and behavioral influences that trigger drinking under a variety of circumstances. Under stressful conditions, physiological thirst mechanisms are ultimately responsible for the maintenance of fluid balance. However, in the healthy adult, under non-stressful conditions, thirst and subsequent fluid consumption are modulated primarily by non-regulatory and behavioral factors. Thirst may therefore be classified as either homeostatic or non-homeostatic (**Table 1**).

Thirst and Homeostasis

Hyperosmolarity and hypovolemia are the two major pathophysiological mechanisms that influence thirst. Specialized osmoreceptor cells function as tonicity sensors responding to changes in plasma osmolality. Although the precise neuroanatomic site of these osmoreceptors is unknown, animal studies suggest a location in the hypothalamus within the organum vasculosum and the subfornical organ of the lamina terminalis. Afferent neural input arising from these osmoreceptors is conveyed within the nucleus tractus solitarius. The latter nucleus also contains fibers arising from peripheral baroreceptors located within the aortic arch, carotid sinus, and left atrium. Subsequently, fibers from the nucleus tractus solitarius converge on the supra-optic and paraventricular nuclei, from where axons travel via the median eminence to the postpituitary gland, thereby modulating vasopressin release. In addition, other fibers from the nucleus tractus solitarius converge on the lateral pre-optic area of the hypothalamus that is responsible for stimulation of the thirst sensation and drinking. Thus, plasma hypertonicity, and to a lesser extent, hypotension and volume depletion, increase vasopressin release and elicit a homeostatic dipsogenic response.

Maintenance of fluid homeostasis is also facilitated by modulation of the renin-angiotensin system. Intravascular volume depletion increases plasma renin levels and consequently elevates angiotensin and aldosterone levels. Subsequently, the potent dipsogenic effect of renin and angiotensin I and II encourages drinking. Intraventricular administration of angiotensin II also stimulates vasopressin release, in addition to stimulating thirst. Available evidence also indicates the presence of an independent central renin-angiotensin axis that may exert a central modulatory effect on thirst and vasopressin release.

Of mounting interest is an additional, though poorly understood, thirst regulatory mechanism described as oropharyngeal metering. Evidence suggests that the act of swallowing is the afferent limb of a conceptual pathway that regulates the volume of fluid ingested in response to dipsogenic stimuli. Although the exact pathophysiology is unclear, this pathway is thought to account for the rapid assuaging of thirst following drinking, even prior to the restoration of euvolemia and normal tonicity. Additionally, this regulatory mechanism may also be involved in the dampening of vasopressin secretion that occurs during drinking. It is likely that the teleological role of the oropharyngeal reflex is to bar the excessive ingestion of water.

Drinking is a voluntary and highly coordinated function indicating involvement of multiple complex neural pathways. However, neural pathways responsible for the cortical control of drinking and dipsogenesis remain poorly defined. This is likely due to the confounding effect of multiple psychosocial and behavioral influences on drinking habits.

Thirst and Aging: Homeostatic Regulation

Older adults are more likely to develop hyperosmolar dehydration following water deprivation. Reasons for the increased risk of dehydration in older adults include a reduction in total body water with aging and age-related impairment in renal tubular concentrating ability. Dipsogenic influences therefore assume increased significance in fluid homeostasis in older adults.

Age-related hypodipsia is well recognized. Additionally, compensatory dipsogenic fluid repletion, following a period of water deprivation, proceeds at a much slower rate in older adults. However, available

evidence indicates that fluid deficits are eventually fully replaced. Experimental data obtained from human studies of hypertonic saline infusion reveal comparatively lower levels of thirst and less water intake in older adults compared with younger adults. These findings support the theory of age-related blunting of osmoreceptor sensitivity. Hypertonic saline infusion in older adults results in increased vasopressin release, suggesting an age-related increase in the sensitivity of central vasopressin neuroreceptors. Thus, it is plausible that age-related attenuation of the thirst response is more likely due to altered circulating vasopressin levels. Indeed, there is a loss of circadian rhythm resulting in nocturnal peaking of vasopressin secretion in older adults. However, studies have yielded conflicting results regarding age-related changes in circulating baseline and diurnal vasopressin levels.

Several other hormones have been implicated in the etiology of age-related hypodipsia. Intravenous infusion of pharmacological levels of atrial natriuretic peptide has been shown to inhibit osmotically induced dipsogenesis and vasopressin secretion. Likewise, data relating the relatively higher levels of circulating norepinephrine (NE) levels to the known antidipsogenic effect of NE suggest a possible role for NE in the genesis of age-related hypodipsia.

Altered opioid sensitivity may play a causal role in age-related physiological hypodipsia. Administration of naloxone has been shown to suppress fluid intake after overnight water deprivation in younger subjects. However, the antidipsogenic effect of naloxone is far less pronounced in older adults, raising the possibility of reduced opioid receptor sensitivity with aging.

Available data from animal studies also suggest that aging results in an attenuated rise in plasma osmolality in response to thermal dehydration. Additional evidence also supports an age-related reduction in salt appetite responses to regulatory challenges. Animal studies comparing the response of young and older rats to captopril-adulterated drinking water show that young rats significantly increase daily ingestion of 0.3 M NaCl when provided as an alternative to water. In the absence of a saline drinking solution, young rats simply increase daily water intake. Older rats fail to exhibit a similar differential response when offered both saline drinking solution and water.

Age-related changes in oropharyngeal metering have not been described. Pharyngeal dysphagia, resulting from esophageal dysmotility, is a recognized complication of presbyesophagus. However, the effect of this condition on oropharyngeal metering as a fluid homeostatic mechanism requires exploration. Similarly, other age-related oropharyngeal responses are ill defined. Traditionally, taste and tactile sensations are considered the primary sensory modalities perceived by the oral and lingual surface. However, degrees of moistness are perceived within the oral cavity. It is plausible that persons with age-related dysgeusia might also exhibit an attenuated response to dryness of the oral mucosa. Further research is needed in this area.

Thirst and Aging: Nonhomeostatic Regulation

Much of the research on thirst focuses on homeostatic responses to fluid deprivation and altered plasma tonicity, possibly because fluid balance in the younger, healthy adult is notably threatened only under conditions that overtly disrupt homeostatic regulation. In contrast, older adults not only are subject to the effects of physiological attenuation of fluid homeostasis, but also face the threat of compromised non-homeostatic dipsogenic influences. Available evidence indicates that approximately 15% of adults over the age of 65 years and 25% over the age of 85 years drink insufficient amounts of fluid for a variety of inappropriate attitudinal reasons. The most prominent reasons identified for limiting fluid intake were lack of thirst and fluid restriction to combat urinary incontinence or nocturia.

The significance of non-homeostatic factors is highlighted by studies of ad lib fluid intake, which indicate that physiological regulation of fluid intake rarely comes into play in free-living healthy individuals, regardless of age. When fluid is available, data indicate that in both young and old adults, thirst results in fluid intake well before hypovolemic or hypertonic deficits occur. Dipsogenic triggering events are undoubtedly complex and intricate. Multiple non-homeostatic dipsogenic factors include hedonic influences such as appearance, ambience, fluid preferences, and palatability. Thus, age-related sensory impairments such as dysgeusia, anosmia, and impaired vision might detract notably from the hedonic qualities of fluids. Psychological influences, sociocultural expectations, health awareness, and lifestyle habits also affect the type and quantity of fluid consumed. Most importantly, data indicate a positive correlation between food intake and fluid intake, introducing age-related and pathological anorexia as additional factors in threatening fluid balance in older adults. Increased isolation and impaired functional status may further restrict access to fluid. Acute illness and chronic disease have a notable, albeit variable, effect on fluid balance in older adults. An added variable that threatens fluid balance is

the effect of medication and polypharmacy on fluid balance.

Dehydration in the Elderly: Clinical Overview

Dehydration is highly prevalent among older adults, occurring in more than one million elders admitted to acute care facilities each year in the United States. Annually, health-care expenditure on dehydration among persons older than 65 years exceeds 1.2 billion dollars. Complications of dehydration are myriad, including delirium, falls, and incontinence (**Table 2**). Associated mortality rates approach 50%. Multiple clinical factors predispose the older adult to dehydration. Although an exhaustive review of the clinical causes, diagnosis, and treatment of dehydration is beyond the scope of this article, it is pertinent to note that most of the causes of dehydration are avoidable and easily reversible. Prompt clinical detection, however, depends on increased awareness of the risk of dehydration in geriatric patients. Reliance on clinical diagnosis of dehydration is confounded by the poor predictive value of traditional clinical indices of dehydration. Poor skin turgor and lack of axillary sweating correlate poorly with dehydration in older persons. Similarly, dry oral mucous membranes are insensitive signs of dehydration in older patients, as adverse effects of medication and mouth breathing may produce identical changes. Furthermore, available data show that orthostatic hypotension in older patients does not reflect dehydration severity, as medications, age-related changes, and prolonged bed rest may also result in orthostasis via autonomic dysfunction. So far, selected laboratory indices of dehydration, namely, serum osmolarity >300, blood urea nitrogen >20, or BUN:creatinine ratio >20, are the most reliable indices of dehydration.

Table 2 Complications of dehydration in the elderly

Cardiopulmonary
Fatigue
Reduced exercise tolerance
Hypotension
Gastrointestinal
Constipation
Dysgeusia
Anorexia
Dental caries
Weight loss
Neuromuscular
Delirium
Cognitive impairment
Thrombotic cerebrovascular disease
Falls
Dermatological
Pressure ulcers
Recurrent skin infections
Renal
Hypernatremia
Nephrolithiasis
Urinary incontinence
Dysuria
Renal failure
Increased risk of uro-epithelial malignancies

Ultimately, prevention of dehydration is the most cost-effective method of thwarting this potentially fatal, yet easily treatable, condition. Dietary guidelines for older Americans recommend consumption of at least 2 liters of fluid daily. However, there is limited evidence to support this arbitrary figure. Available evidence-based data support the benefits of ingestion of at least 1.5 liters of fluid daily. Currently, it is unclear as to whether regular consumption of fluids in excess of this amount may result in dilutional hyponatremia and other consequences of water overload. Treatment of dehydration mandates due attention to restoration of normal plasma tonicity and correction of the fluid deficit. Older persons who are unable to ingest fluids orally may require parenteral fluid administration. Intravenous administration is the traditional method. However, health professionals should be aware of the utility of alternative routes, such as percutaneous gastrostomy, that may be preferred in older adults with co-existing anorexia or dysphagia. Subcutaneous fluid infusion (hypodermoclysis) is a convenient, simple, relatively safe, and cost-effective method that is particularly effective in older patients in subacute or long-term care.

Effective management of dehydration in the older adult mandates meticulous attention to pathophysiological stressors in the context of pre-existing hypodipsia. Ultimately, the ideal therapeutic goal is the development of an individualized fluid maintenance and hydration intervention strategy for all older adults, healthy or otherwise.

Time: Perceptions and Concepts

J J F Schroots, Free University Amsterdam, Amsterdam, The Netherlands

Glossary

Biological Clock – Generic term for biological processes that show periodic behavior and are clock-like in their rhythmicity.

Biological Time – A species-dependent unit of physical time required to complete a species-independent biological event or process.

Physical Time – Generic term for solar, calendar, clock, objective, historical, dialectical, and social time.

Social Clock – Metaphor for the timing of social events and age-appropriate behavior.

Time Confound – Interdependency of seemingly independent time parameters.

Time Perception – Generic term for the experience of time, subjective judgment, and/or the amount of elapsed time.

Time Perspective – The totality of the individual's views of his or her psychological future and his or her psychological past existing at a given time.

Introduction

Time is a symbol for a connection made by a group of beings with the capacity for memory and synthesis between two or more continua of changes, one of which is used by them as a frame of reference or standard for measuring the other or others. Relations of time are therefore connections between at least three continua: between people who bring about connections and two continua of changes, to one of which they give the function of standard continuum, a frame of reference for the other. In modern society, physical time – also called solar, calendar, or clock time – plays the role of standard continuum, a frame of reference for the other continua of changes such as biological, psychological, and intrinsic time. In this context, social time is conceived as a tautology for physical time. In this article, distinctions between major concepts of time are presented, as well as their corresponding clocks and age scales, to begin with physical time in relation to calendar (days, months, years), clock (hours, minutes, seconds), and chronological age.

Physical Time

History

In Western antiquity, time was conceived in two ways, as a cycle and as a line. *Cyclic* time is the oldest concept, as the image of the cycle best applies to natural phenomena like the revolution of the planets,

the succession of the seasons, night and day, sleeping and waking, growth and decay. *Linear* time, however, is not a product of observables; it is an abstraction, developed successively by the Greek philosophers Pythagoras (the nature of things is number), Plato (time equals the number of revolutions of the planets), and his pupil Aristotle (384–322 BC), who defined times as "number of motion in respect of before and after." In brief, the classical concept of time is an aspect of motion that makes possible the enumeration of successive states linearly by dividing up cycles (of planets) into units. This concept lasted in science for almost 20 centuries, when, at the end of the seventeenth century, it was displaced by physicist Sir Isaac Newton (1642–1727).

Newton conceived of time as something *absolute*, an immaterial, fixed property of the universe by which motion or change can be measured. Thus, in classical physics, time is an absolute standard or measuring scale. In this view, time is not only *linear*, but also *reversible*, for nothing changes when t is replaced by $-t$ in physical equations. Because the Newtonian concept of time is not a product of the perceiving subject, absolute time is often called objective time. This concept has become equated more and more with its measure, the mechanical clock. Consequently, time has become transformed and reified into *objective*, *mechanical*, *calendar*, or *clock* time. Objective time is basic to seemingly different time variables, such as period or historical time, chronological or calendar age, cohort or time of birth, calendar time, and clock time. They all can be reduced to the same, basic concept of classical-physical time.

Concept of Physical Time

Newton's physical time does not have intrinsic direction; there is no difference between its past orientation $(t-)$ and its future orientation $(t+)$. This concept of time violates generally accepted natural laws. Natural phenomena are described by the second law of thermodynamics, which states that chaos or disorder will increase irreversibly with energetic processes. Thus, the direction of physical time is defined by the irreversible destruction of macroscopic order, or the increase of *entropy*. In twentieth-century physics, time is no longer reversible but irreversible, at least at the macroscopic level.

It should be noted that the modern concept of *physical* time as *linear* and *irreversible* did not change the conception of chronological age as additive, that is, a quantity that can be added, subtracted, multiplied, and divided regardless of the age of the organism. The implication is that all possible calendar ages of the organism are equal. For instance, the first 20 years of life are equal to the middle or last 20 years of life. This, however, makes sense only from a purely clock or calendar time perspective.

Biological Time

Biological Clocks

Many biological processes show periodic behavior and are clocklike in their rhythmicity, in particular biological processes on a 24-h basis, the so-called *circadian* rhythms. These rhythms, as well as the progressive reification of time in terms of mechanical clocks, encouraged the search for biological instead of mechanical clocks. The major anatomical clock for numerous physiological (blood pressure, hormones, body temperature) and behavioral (attention, reaction time) processes with circadian variation has been located in the *suprachiasmatic nucleus* at the base of the brain. The circadian rhythm of this clock differs slightly from the earth's rotation cycle of 24 h, and from one individual to another (e.g., 24.5 or 25.5 h periods instead of 24 h). Because the internal period deviates somewhat from 24 h, it has to be reset daily to retain synchrony with the external light–dark cycle. This process is called *entrainment* or synchronization. In brief, daily synchronization is reached under the external influence of physical and social timers like the light–dark cycle and the well-structured 8-h working day.

Another major class of so-called *metabolic* clocks is based on *energy transformations* or metabolically related processes and functions in the organism, Metabolic clocks are inferred from the rhythmic activity of, for example, heart, lungs, and intestines, on the basis of the allometric power law $M^{0.25}$. This law says that the length of time between consecutive heart beats increases as a linear function of about the 0.25 power of body mass (M) in mammals. The *basal metabolic rate* (BMR), or the time needed to process one joule per gram, also increases with $M^{0.25}$. Corrected for weight, all mammals use an equivalent amount of joules per heart beat, per generation, or per life span. This suggests that metabolic clocks, as time measures of numerous periodic phenomena in the human organism, are closely associated with the rate of living. Also, positive or negative events influence biological-periodic phenomena, modulate metabolic clock rate, and thereby increase or decrease the *rate of living* within limits.

Using the clock metaphor, the human organism can be viewed as a clock shop with two master clocks – circadian and metabolic clocks – and many entrained

slave clocks. Aging of the organism may involve *desynchronization* of the clock shop, in which the various master and slave clocks that are normally in synchrony are put out of phase; amplitude and period may be changed as well. There is more and more evidence for a strong relationship between the temporal organization of organisms with age and the occurrence of mortality and morbidity patterns (sleeping disorder, reduced thermoregulatory capacity, depression, and Alzheimer's disease). As such, measures of the degree of synchronization in the elderly might function as predictors of nearness of death.

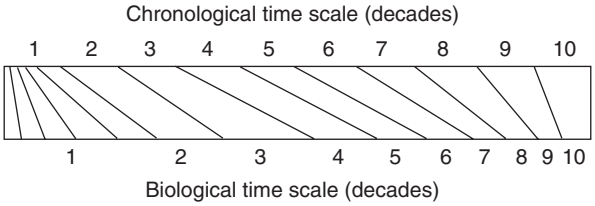

Figure 1 Schematic comparison of chronological and biological time scales. Much more biological activity (e.g., metabolic activity) can be packed into the first decades of biological time than into those of later life; hence the length of that part of the biological measuring rod appears to be longer in the early period of life than a comparable portion of the chronological measuring rod. At the other extreme of life the opposite relationship applies.

Concept of Biological Time

The individual human life might be viewed as governed by a single biological clock or individual life cycle with one period. The length of this period, that is, *length of life* or life span, reflects the rate of biological aging and is one of the most significant characteristics of biological time. Length of life as a variable, however, raises two serious problems. First, it is virtually impossible to construct a time scale for the measurement of biological time on the basis of a single clock with one period. To solve this problem, biologists have looked for an alternative length-of-life variable at the population level and have focused on the *probability of dying*. Second, biological time must be defined with reference to a specified biological process. The probability of dying is not a biological process but a statistical concept, and the length-of-life variable reflects at most an undetermined biological process.

Given the foregoing, biological time can be defined as a species-dependent unit of physical time required to complete a species-independent biological event or process. In other words, a biological time scale for a specified biological process can be constructed by transforming a chronological time scale so that the rate of change of the process becomes time invariant in biological time. Recently, several physiologists have pointed out that the metabolism of the organism over the life span might be that biological process. It should be noted that *biological* time is not only *irreversible*, but also *non-linearly* related to physical (objective) time or chronological (calendar, clock) time. **Figure 1** shows how chronological and biological time scales might be related.

Psychological Time

Time Perception

On a clock in Chester cathedral (UK) the following inscription can be read "For when I was a babe and wept and slept, Time crept/When I was a boy and laughed and talked, Time walked/Then when the years saw me a man, Time ran/But as I older grew, Time flew." Put in this verse is the phenomenological view that time passes faster with age. This view refers to the perception, awareness and/or the experience of (the passage of) time. *Time perception* is used here as the generic term for the experience of time, subjective judgment and/or estimation of the duration of events or the amount of elapsed time. Since the publication of Paul Janet's study in 1877, several studies have sought to quantify the acceleration of time as a function of chronological age. Broadly speaking, three approaches can be distinguished.

First, classical psychophysical studies based on the metaphor of *temporal modality*. This metaphor implies a sensory receptor system for time, so that Weber's law (we perceive not the difference between sensations, but the ratio of this difference to the magnitude of the sensations compared) can be put to the test for differences in duration between various time intervals. It has been suggested that subjective duration varies inversely with the square root of chronological age, but too many exceptions to the rule have been found in practice. In the final analysis, the psychophysical approach did not prove to be very productive.

Second, by analogy with biological clocks an *internal psychological clock* has been hypothesized. The slowing of this clock can occur with advanced age, decreased metabolic activity, lower body temperature, and use of alcohol, barbiturates, and other drugs. External clock time by comparison seems to be going faster – time seems to fly like magic – and clock time will be underestimated. The reverse also holds: when a person's internal clock is going fast, then clock time by comparison seems to be going slow. This occurs when metabolic rate is increased, with higher body temperature (e.g., fever), and by the use of stimulants such as caffeine and psychedelic drugs. In general, the greater frequency of internal

changes per unit of clock time makes clock time seem to be longer (and the other way around). The internal clock metaphor also explains to some degree why the days seem to pass slowly for children, but rush past faster and faster with increasing age: children have a slightly higher metabolic rare, and consequently a higher body temperature than the elderly.

Third, Ornstein introduced in 1969 the *temporal information-processing* approach in cognitive psychology, which relates the faster passage of time to the fact that with advancing age there are less novel events in life worthy of being stored in memory. For children, everything is new, whereas old age brings fewer surprises. The cognitive approach of time perception is a highly specialized area: models of time estimation are formulated in terms of event-related attributes rather than in terms of clocks, and the models used are only fit for the perception of brief durations in the 100 ms to 10 s range.

Summarizing part of the results of both long-term and short-term memory research on the subjective experience of time, it might be said that unpleasant emotions are associated with a feeling of time urgency, making (external) clock time by comparison seem to pass slowly. During pleasant emotions, however, there is less time urgency and, therefore, clock time by comparison appears to go quickly.

Time Perspective

According to St. Augustine's *Confessions* (ca. 400) there are three times: a present of past things, a present of present things, and a present of future things. Together they form the basic elements of what has been called *time perspective*, which Kurt Lewin defined as the totality of the individual's views of his psychological future and his psychological past existing at a given time; in other words, the individual span of awareness extending into the past or future. This raises the question of the subjective duration of the present.

According to William James (1890), the *mental now*, classically known as the specious present, has a certain duration: It is no knife edge, but a saddle, with a certain breadth of its own on which one sits perched, and from which one looks in two directions into time. Some authors report 20–200 ms as minimum duration of the mental now, whereas others mention 4–7 s; the latter figures are more consistent with modern research data. Another characteristic of the individual present is its temporal *intentionality*; that is, the mental now is directed at the past, the private world of memories, as well as the future, with its individual expectations. How the past, present, and future temporal realms interrelate with one another can be stated as follows: both past and future are hypothetical reconstructions interpreted from and bound together through the mental now. In other words, the psychological past and future are *constructions*, experienced as a series of presents.

In research on time perspective several dimensions of significance can be identified. The basic dimension of *time orientation* refers to the relative dominance of the past, present, and future in an individual's thinking. Most often dealt with is the dimension of *extension*, which is based on reported life events and their estimated ages of occurrence, which can be defined as the length of past, present, future, or total life time considered by the individual. In this context, the question arises whether the individual's future extension diminishes with advancing age. The answer on the basis of research evidence is that advancing age does not necessarily lead to a loss of futurity. The empirical studies of time perspective instead point to increasing individual differences with age as well as an increasing complexity of the individual's time perspective.

Finally, most research on time perspective is based on explicit reports or implicit expectations of (1) life events, and (2) their estimated ages of occurrence. This type of operationalization is notorious for methodological problems with the analysis, coding, and interpretation of the data, with the result that the outcomes of time perspective studies are difficult to replicate.

Concept of Psychological Time

Time perception and time perspective might be conceived as the two basic dimensions of psychological time, crossing each other in the mental now of the individual's temporal awareness, However, the concept of psychological time is extremely complex and embraces more than the temporal dimensions of perception and perspective. For example, *psychological time* might be simply defined – by analogy with biological time – as the unit of chronological time required to complete a psychological event. Next, this simple definition might be extended with the following characteristics or aspects: (1) psychological time may pass in a non-linear fashion; (2) its flow may be perturbed by either internal or external influences; (3) it may become detached from the past, affirming persistence within the present; and (4) it may function in a manner unrelated to causality. To cut a long story short, a definition of psychological time can be given only in terms of temporal dimensions, characteristics, and/or aspects.

In the final analysis, however, the following conception of a psychological time scale comes closest to

the ideal definition of psychological time, i.e., in which each psychological event has its own unique place on the absolute time scale of personal history and future, which defines a conscious present, a privileged now, but also beginnings and endings.

Social Time

Concept of Social Time

Concepts of physical, biological, and psychological time refer to corresponding time scales with specific features. It is difficult, perhaps even impossible, to delineate the features of a social time scale, which is identifiable with the concept of social time. Definitions, or even cues for possible definitions of social time, are not presented in the social sciences. At best, *social time* might be defined as the unit of chronological time required to complete a social event.

It should be noted that the term social time is used very frequently, but also improperly in social science. What sociologists and other social scientists mean, if they refer to social time, is not essentially different from the calendar or clock time of social phenomena. In other words, the term social time, as well as the related term *dialectical time*, is simply another disguise of the basic concept of physical time.

Social Clocks

In the social sciences, various age-related concepts have been introduced. Anthropologists were the first to introduce the concept of *age grading*. Age-graded systems are expressions of the fact that all societies divide time into socially relevant units, thus supposedly transforming calendar time into social time, although clustering rather than transforming calendar time into (chronological) age grades would be more to the point of the physical time scale used.

Another age-related concept is *age stratification*, i.e., chronological age strata function as an organizing principle in society. Because age-related roles may change under the influence of history-normative events, society will change as new birth cohorts replace older ones. The concept of age stratification emphasizes that there are significant variations in older people depending on the characteristics of their birth cohort. A second important feature of age stratification is the emphasis on the relations of cohorts within the age structure of society; this makes possible the analytical distinction between developmental age changes and cohort historical differences.

Age grading and age stratification lie at the root of the idea that every society has a system of social *expectations for age-appropriate behavior*, and that all members of that society internalize these expectations or so-called age norms as they grow up and move from one age stratum to the next. In brief, age norms constitute a script, timetable, calendar, or time schedule for the life course, and function therefore as social controls. In this context, social gerontologist Bernice Neugarten found widespread consensus regarding the timing of events, that is, the appropriate age when individuals are expected to go to school, to marry, to start a career, and so on. People know whether they are 'on time' or 'off time' as if they have a *social clock*; furthermore, they feel good about themselves when they are on time, but they feel bad if they have been either early or late.

The lack of fit between the individual timing of events and social clocks is called desynchronization. In general, the greater the degree of individual temporal desynchronization, the greater will be the sense of stress. Recently, a *social entrainment model* has been developed, which emphasizes that various temporal rhythms underlie a wide range of social behavior and that synchronizations among them (or the lack of such synchronizations) have widespread and crucial implications for human cognition, social interaction, task performance, and role behavior, and therefore for human health and well-being. The basis for the model lies in the notion of *entrainment* as introduced in the section on biological clocks. Viewed from a social perspective, entraining cycles correspond with Neugarten's social clocks or prescriptive timetables, for example, but they may also refer to conversational behavior, group interaction, or task performance. Summarizing, the social entrainment model provides a framework for describing the operation of biological, psychological, and social clocks, their coupling to one another and potentially to outside pacers (signals), and the temporal patterns of behavior resulting from these clocks and rhythms of human behavior.

Time Confounds

The concepts of age grading, age norms, age strata, social clocks, and social time are all aspects of the same time scale, calendar time, or physical time, of which chronological age (or calendar age) is still the most popular, though much abused, index. Chronological age is usually introduced in developmental and aging research as an *independent* or *explanatory variable*. However, chronological age does not have much explanatory power by itself, which is not surprising after all, as both independent and dependent variables are expressed in terms of the same calendar time, the source of most time confounds. Precisely because of the problem of confounded time parameters, K. Warner Schaie proposed in 1965 a

general developmental model with three interdependent, objective time parameters. This so-called *APC model* is based on the formula that age = period (or time-of-measurement) – cohort (birth), and has served to separate statistically age, period, and cohort effects. However, regardless of how data are collected, there is a triple confound. In later studies, it has been noted that the triangular confound is not unique to developmental or aging research, but even more important is the observation that a strictly statistical solution to the APC problem, or any other triangular confound for that matter, is not possible.

A radical solution to the problem of time confounds is to get rid of time itself by redefining its meaning. In research practice, psychological and social phenomena are inferred from the calendar or clock. By identifying the meaning attributed to various time parameters, it should be possible to unlock some of the confounds. Schaie made an attempt to solve the APC problem by conceptually separating historical time (time of measurement or period) and cohort effects from calendar time. Essentially, he redefined cohort as a selection variable that characterizes the common point of entry for a group of individuals into a given environment. Period, on the other hand, is translated into a measure of event density, Thus, Schaie was able to remove calendar age as a confound for cohort or period.

Intrinsic Time

Age Scales

James E. Birren has repeatedly observed that chronological age or the elapsed physical time in days, months, and years since birth is one of the most useful single items of information about an individual if not the most useful. Nevertheless, the useful, though rough index of *chronological age* is not very sensitive to individual differences. For that reason, Birren introduced three new age scales and contrasted them to chronological age. The first scale, *biological age*, can be defined as an estimate of the individual's present position with respect to his or her potential life span. Such a measure of biological age should be able to predict the residual life span of the individual with a smaller error than that based on chronological age alone. The second scale, *psychological age*, refers to the age-related adaptive capacities of the individual, such as perception, learning, and memory. Just as one may be older or younger than one's chronological age in a biological sense, one may also be older or younger psychologically. Presumably, a measure of psychological age would correlate highly with chronological age and also with environment. The third scale, *social age*, refers to acquired social habits and status, to the individual's filling the many social roles or expectancies of a person of his or her age in his or her culture and social group. An individual may be older or younger depending on the extent to which he or she shows the age-graded behavior expected by a particular society or culture. A measure of social age presumably would also be related to chronological age, somewhat to psychological age, and to a lesser degree to biological age.

Due to its popularity in industrial organizations, as well as its close affinity to biological, psychological, and social age scales, the functional age scale needs to be explained. *Functional age* can be defined as a dimension in which individuals could be younger or older than their chronological years in their ability to adapt to their environments. The individual's level of capacities for daily life functioning in society could be compared to other individuals of the same age by a series of measurements comprising operationalizations of biological, psychological, and social ages, respectively. Functional age scales have been severely critiqued for several reasons. First, there are different meanings of the terms *function* or *functional*, as they refer to occupational functional age, biomedical functional age, or to the structural organization of human functioning. Second, functional age researchers vary to the extent that they hypothesize a unitary aging process on the one hand, or prefer to assume multiple aging processes and various combinations of variables, each of which may be optimally employed for different situations or against different criteria. Third, two criteria have been put forward: chronological age and length of life (residual life span). The most common approach is to employ multiple-regression techniques to predict chronological age or length of life. If the ultimate criterion is chronological age, then the functional age measure does not make much sense, as chronological age can be assessed much easier (just ask for it). The second criterion, length of life, residual life span, or the person's time until death is more promising, although no conclusive studies have been conducted yet. For the time being, chronological age is the best general index to the residual life span of healthy individuals.

Concept of Intrinsic Time

In the foregoing discussion, various concepts of time and age were introduced from a physical, biological, psychological, and social perspective. The question arises whether these different concepts can be integrated in a general concept of time and age, valid for all (levels of) living systems. A tentative

answer has been given by theoretical biologist Robert Rosen, who assumed that any given dynamics of any system will generate its own intrinsic time; that is, *intrinsic time* is created by physical, biological, psychological, or social processes as an emergent property of their *non-linear dynamics* (energy transformations). In plain words, *intrinsic time* depends on the number of transformations or changes, intrinsic to the dynamics of the system. As such, intrinsic time is a *dependent variable*.

From the above it follows that intrinsic time is scaled by the system from which it emerges. As any dynamic process can serve as a clock, intrinsic time is measured by monitoring one of the state variables undergoing change. The dimensional unit of this intrinsic time is simply the unit of the state variable chosen for observation. For example, consider the primitive clock made by notching a candle at 1-inch intervals along its length. With a fresh candle as the initial condition, time is given as the length L of candle burned. The unit of time intrinsic to this particular dynamical system is inches. Mathematically this is expressed by $t = L$, where t is intrinsic time. This time is well defined and will serve for many purposes. However, it is particular and intrinsic – and thus is absolute. A metric is needed to calculate the relative relationship of the intrinsic times of two candles having different constitutive parameters. Such comparisons are made by the promotion of one time-keeping device to the status of the standard clock with clock time t.

Rosen has developed an *entropic time metric*, based on the second law of thermodynamics, which states that there is an increase of entropy in energetic systems (entropy is defined here as the degree to which relationships between the components of any system are mixed up, undifferentiated, or random). The entropic time metric scales the passage of intrinsic time to standard clock time. Given this metric, the *intrinsic age* of any system might be assessed. Intrinsic age as an intrinsic, directed measure of the state of a particular system should be distinguished from chronological age, which is extrinsic, universal, and reversible. For instance, two systems are in temporal corresponding states, that is, at the same intrinsic age, at equal instants of intrinsic time. However, although they are at the same intrinsic age, they may have traversed different periods of extrinsic clock time and are, then, of different chronological age.

Intrinsic Age Scales

Generally speaking, the transformation rules between intrinsic time and other times (biological, psychological, and social) are not known. However, in biological systems the entropic time metric is probably associated with the metabolism of the organism, which relates to entropy production. Given the known relationship between total rate of change of entropy or metabolic rate of an individual and his or her chronological age, it is feasible to define a metabolic or *intrinsic biological age* scale for human subjects. The definition of an intrinsic age scale at the psychological system level is less obvious, but nevertheless feasible. To start with, all psychological events should be formulated in entropic terms. Normally speaking, psychological events are formulated in informational terms. Given however the concept of *negentropy*, which is a measure of negative entropy or information, it should be possible to compute the *intrinsic psychological age* of individuals by feeding the external entropy flow rate, as calculated from informational data, into the entropy equation for living systems. Similarly, the *intrinsic social age* of social systems might be computed, based on Bailey's social entropy theory. By means of these three *intrinsic age* scales, it should no longer be difficult to develop an *intrinsic functional age* scale for human individuals, which is a better predictor of length of life than chronological age, and replaces chronological age as an independent and dependent variable.

Touch and Proprioception

J M Weisenberger, Ohio State University, Columbus, OH, USA

Glossary

Cutaneous – Term used in reference to receptors and stimulation that produce sensations of touch or pressure.

Glabrous Skin – Hairless skin found on the palms of the hands and the soles of the feet.

Kinesthesia – Term used to describe sense of movement of limbs.

Mechanoreceptor – Cutaneous receptor that mediates aspects of touch or pressure sensations.

Nociceptor – Cutaneous receptor that mediates pain sensitivity.

Proprioception – Term used to describe sense of the position of limbs in space.

Somatosensory – Term used to describe the receptors, afferent pathways, and cortical areas devoted to the senses of touch, temperature, and pain.

Thermoreceptor – Cutaneous receptor that mediates temperature sensitivity.

Introduction

The sense of **touch** is the encompassing term for a complex variety of sensations, including pressure, arising from mechanical deformation of the skin surface; temperature, arising from thermal stimulation of the skin; and pain, arising from potentially damaging application of mechanical, thermal, chemical, or electrical stimulation. Considered by many researchers as a separate sense is **proprioception**, the awareness of the position and movement of body and limbs in space. Both of these senses are mediated by a number of physiological receptive structures and central pathways, and both can be influenced by inputs from other sensory modalities, such as the visual and vestibular systems. And, like other sensory systems, the senses of touch and proprioception are vulnerable to the effects of aging. This article summarizes the state of knowledge in the psychophysics and physiology of touch and proprioception, together with research on how these senses change in aging individuals.

Touch

Physiology

The skin surface constitutes the largest sensory organ in the body, with a surface area of some 1.7 m^2 in the adult. The skin actually consists of numerous layers of tissue, which can be divided into two main sections, the epidermis, or outer layer, and the dermis, or inner layer. On the body surface are three kinds of skin: hairy skin, characterized by the presence of hair; glabrous skin, a hairless surface found on the palm and sole; and mucocutaneous skin, found at the entrance to various body cavities at the junction with mucous membrane. Although these skin types differ in the density and distribution of sensory receptors they contain, there are some general features that characterize most areas.

There are a number of structures believed to serve as receptors for transducing tactile stimulation. Variations in the density and distribution of receptors at different body sites influence responsiveness to a stimulus. For sensations of touch, pressure, and vibration, four different structures have been investigated as putative mechanoreceptors. These include the Pacinian corpuscle (PC), Meissner corpuscle (MEI), Merkel disk (MRK), and Ruffini cylinder (RU), all shown in **Figure 1**. It should be noted that in many cases the structure of these receptors makes it difficult to record activity directly at the receptor; instead, the probable role of a mechanoreceptive structure is

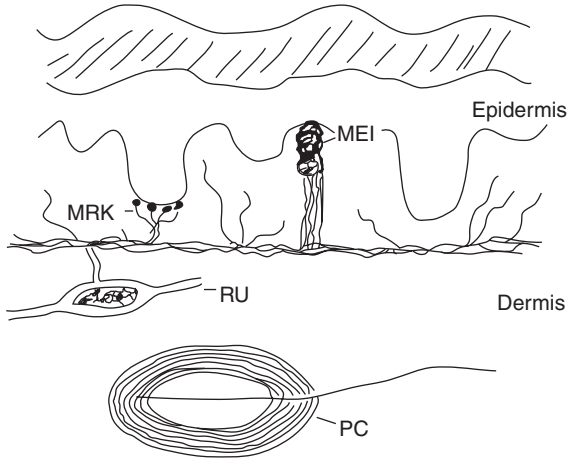

Figure 1 Schematic drawings of four mechanoreceptors. Shown are the Pacinian corpuscle (PC), Meissner corpuscle (MEI), Merkel disk (MRK), and Ruffini cylinder (RU).

inferred from activity measured in primary afferent fibers innervating the structure. Recent studies have addressed the relationship between end receptor and primary afferent response via microneurography, a technique in which activity is recorded by percutaneous microelectrodes from primary afferent fibers in awake human subjects, who can report sensations based on stimuli delivered to the skin at the same time as afferent activity is measured. This technique permits some confidence in assigning mechanoreceptive roles to particular cutaneous end organs.

The primary afferent responses measured for mechanical indentation are of two types: (1) slowly adapting (SA), indicating a response at stimulus onset that continues for the duration of the stimulation; and (2) rapidly adapting (RA), indicating a vigorous onset response, and perhaps an offset response, but no sustained response to a prolonged stimulus. Each of these two types of afferent response can be subdivided, based on the size of the receptive field (skin surface area) that excites a particular afferent fiber. Thus, afferent responses fall into four categories: SA types I and II, and RA types I and II.

The relationship between afferent response and end organ is best understood for the PC. The PC is a relatively large receptor, which in the adult has numerous layers (lamellae) that produce an onion-like appearance. PCs are located rather deep in the dermis, as well as in joints. Each PC is innervated by a single afferent, and thus it is straightforward to assume that transduction for a fiber takes place at the PC at the fiber's termination. Based on this relationship, it has been determined that the PC is RA and has a large receptive field. The distribution and placement of MEI, located at the junction of epidermis and dermis in the dermal papillae, suggests that they serve as the other RA mechanoreceptor. MEI are surrounded by an elastic capsule that is attached to the epidermis above and to the dermis below, and are supplied by 2–6 afferent fibers. Receptive field size for the MEI is small, particularly in comparison to the large field of the PC. Identification of the mechanoreceptors for the two SA fiber types is even more tentative. However, likely candidates for these endings are the MRK for the small receptive-field SA I fibers, and the RU for the larger receptive field SA II fibers. The MRK is a disk-shaped terminal located on certain basal epidermal cells, and the RU is a spindle-shaped capsule-like structure found in the upper layers of the dermis, although in many cases it is considered too loosely organized to reflect true encapsulation. Although these pairings are presently rather speculative, advances in microrecording techniques should permit more certain identification in the future.

The situation for thermoreceptors is even less certain than that for mechanoreceptors. A variety of receptive structures at various levels in the skin show a response to thermal stimulation; however, many of these also respond to other kinds of stimulation, such as mechanical. For example, the response of the PC is quite affected by changes in skin temperature, but the PC is thought to be primarily mechanoreceptive in function, rather than thermoreceptive. Some researchers have suggested a role for the Krause end bulb, but others have been less willing to speculate about the identity of individual thermoreceptors. As for the mechanoreceptors, the main source of information about the system has been the response profiles of individual primary afferent fibers, which appear to change their firing rates in response to either temperature increases or temperature decreases, but not both. Thus, one can speak of cold fibers and warm fibers. Some mechanoreceptors, as mentioned, modulate their response behavior in the face of temperature changes, but are not primarily considered to be thermoreceptors.

For sensations of pain, there appear to be several classes of receptors responding to excessive heat, excessive cold, or extreme mechanical deformation. Some also respond in the presence of chemical irritation. The fibers delivering information about noxious stimulation appear to terminate in free nerve endings scattered throughout the epidermis and dermis. A common feature of the pain receptors, or nociceptors, is their high thresholds for stimulation. In the case of pressure, the threshold for a pain receptor may be as much as 1000 times the displacement needed to detect pressure for a low-threshold mechanoreceptor. Similarly, thermal nociceptors may have thresholds of 45°C or higher for heat, or 15°C or lower for cold. Overall, it appears that the stimulus for these nociceptors must be intense enough to cause actual or potential damage to skin tissues (*see* Pain and Presbyalgos).

All of these receptors, whether mechanical, thermal, or pain, pass information via primary afferent fibers from the periphery to more central structures via the spinal cord. Cell bodies for these afferents are located in the dorsal root ganglia. Within the spinal cord, a functional division of fibers takes place, with larger-diameter fibers (carrying mainly mechanoreceptive information) forming the lemniscal bundle, and smaller-diameter fibers (carrying mainly thermoreceptive and nocioceptive information) forming the spinothalamic bundle. The lemniscal fibers ascend to the medulla, where they cross to the contralateral side before continuing on to the ventral posterolateral nucleus of the thalamus. Projection from the thalamus terminates in the somatosensory

cortex, located in the parietal lobe of the brain on the postcentral gyrus. Representation of different areas of the body in somatosensory cortex is somatotropic, that is, different parts of cortex are devoted to inputs from particular areas of the body. It is important to note that sensations of touch or pressure are mediated by cortical areas on the side of the brain opposite to the side of the body on which they occur, in contrast to projections from the visual and auditory systems, which are both ipsilateral and contralateral. In the spinothalamic pathway, neurons actually cross contralaterally while still in the spinal cord, synapsing in the dorsal horn, and ascend to the ventrobasal portions of the thalamus, from which they project to somatosensory cortex. The cortex itself is organized into two general areas, SI and SII, both of which may contain complete representations of all body areas.

Psychophysics

In characterizing the response of the tactile system to input stimuli, it is important to understand the impact of changes in various parameters of the physical stimulus, specifically, changes in spatial, intensive, and temporal aspects. In this section research into these stimulus aspects is summarized.

Spatial sensitivity in touch has been studied rather extensively, primarily using techniques such as two-point discrimination (in which the observer determines whether one or two points have touched the skin, at different point separations) and error of localization (in which the observer indicates the place where the skin was touched). More recently, tactile acuity for grating stimuli with varying separations impressed onto the skin has been measured. These measurements indicate that spatial acuity for tactile stimuli varies substantially across body sites. Areas such as the fingertips, tongue, and lips show excellent spatial sensitivity, whereas areas such as the abdomen and back are far less acute. At the fingertip, stimuli separated by as little as 0.5 mm can be discriminated, whereas on the abdomen, resolution is closer to 40 mm. Recent research has pointed to the MRK as the primary receptor for spatial sensitivity, based on its distribution across body sites. The MRK is most numerous at sites having the greatest spatial acuity. A secondary role in spatial sensitivity may be played by the MEI, which is also relatively dense in highly sensitive areas. Both of these receptors evidence small receptive fields, making them good candidates for spatial acuity mediation.

For the slowly adapting mechanoreceptive channels, SA I and SA II, punctate indentation is an adequate stimulus for excitation. However, to obtain consistent responding from the PC and RA channels, simple pressure is not sufficient. For these channels, it is necessary to provide a stimulus that has repeated onsets and offsets; vibration has proved to be an ideal stimulus for this purpose. The tactile response to vibration has been extensively investigated, and it has been determined that response to vibration in different frequency ranges is most likely mediated by different mechanoreceptors. **Figure 2** shows tactile sensitivity to vibration, as a function of vibration frequency. Current models of vibrotactile response postulate that the PC is responsible for the U-shaped portion of this curve, covering frequencies above about 40 Hz. Maximum sensitivity to vibration is seen at around 250 Hz. Threshold measures in the middle-frequency range (from about 10–40 Hz) are

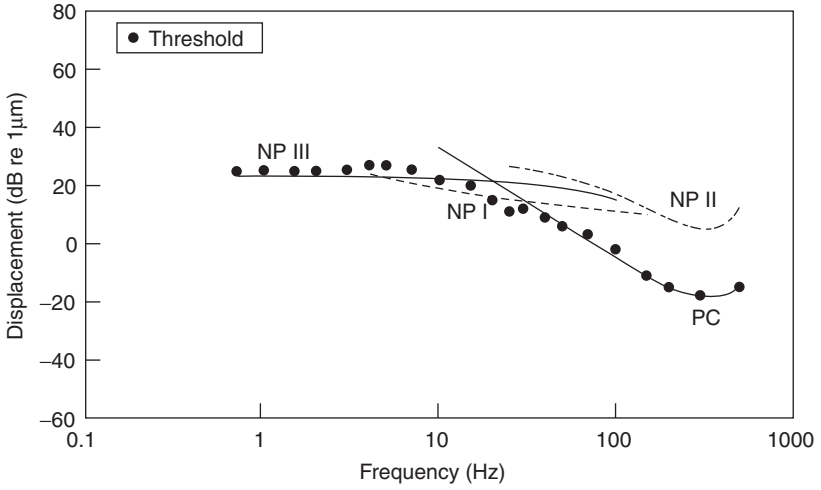

Figure 2 Threshold for detection of a vibratory stimulus applied to the thenar eminence (palm), for different frequencies of vibration. PC, Pacinian corpuscle; NP, non-Pacinian. Reprinted with permission from Bolanowski SJ, Gescheider GA, Verrillo RT and Checkosky CM (1988) Four channels mediate the mechanical aspects of touch. *Journal of the Acoustical Society of America* 84: 1680–1694, © 1988, Acoustical Society of America.

thought to be mediated by the MEI (labeled NP I, or non-Pacinian I, on the figure). The lowest frequency portion, labeled NP III, is assumed to be the MRK, and the high-frequency, high-amplitude curve labeled NP II may be the RU, serving the SA II afferent fibers.

Measures of intensity response indicate that the tactile system has a dynamic range, or range between threshold and uncomfortable stimulation, of 40–50 dB. Current physiological studies suggest that firing rate in the primary afferents may be the primary code for intensity perception. Temporal sensitivity measures produce varied results, depending on the task employed. In the best case, temporal resolution on the order of 3–5 ms has been observed.

In response to thermal stimulation, the tactile system again shows variation in sensitivity depending on the area and location stimulated. In measuring temperature sensitivity, the typical task involves detecting a change in the temperature of an area of skin from its previous temperature. Under the best circumstances, changes in skin temperature of as little as 0.003°C have been measured. The detection of a temperature change, however, depends on the initial temperature of the skin. Over a range of temperatures, between approximately 28 and 37°C, the body adapts to the skin's temperature, such that it is perceived to be neutral. This neutrality is referred to as physiological zero. Thus, detection of temperature changes from an initial neutral point may vary considerably, depending on the neutral temperature.

Measurement of pain responsiveness is much more complex. Individuals vary widely in their sensitivity to pain, as well as in their willingness to report it. In addition, pain produced by stimulation in the laboratory (laboratory pain) evokes a very different response from pain produced by disease or injury (clinical pain). Furthermore, long-term or chronic pain may be perceived very differently from short-term or acute pain. The additional factors involved may be psychological, in that pain has emotional or affective components of anxiety, unpleasantness, or depression. Furthermore, if the pain results from a serious illness or injury that debilitates physical condition, the response to it may be different from short-term pain experienced by a healthy individual. One current theory of pain perception posits three aspects of pain: sensory or discriminative, motivational or affective, and cognitive or evaluative. As a result, the measurement of pain requires considerable resourcefulness on the part of the researcher. One technique that has yielded promising results in the evaluation of pain perception is signal-detection analysis, in which it is possible to separate sensitivity effects from response bias effects. Other approaches often focus on adjectival scales and questionnaires to get information about pain perception beyond simple detection. These scales involve sets of adjectives that fall into sensory, affective, and evaluative categories.

Changes in Tactile Response over the Life Span

The most comprehensive study of the effects of aging on peripheral receptor anatomy was that of Cauna in 1965, who examined changes across the entire life span in a group of some 200 persons ranging in age from birth to 95 years. He reported observations for PC, MEI, MRK, and free nerve endings.

PCs, according to this report, begin development in the fourth fetal month, and are fully formed before birth. In infants, PCs are numerous and oval in shape, with a length of 500–700 μm. During the course of life, the number of PCs decreases steadily, and the receptors themselves change in size and appearance. Increases in size with age are accompanied by the addition of lamellae, or layers, that give the corpuscle an irregular shape and an onion-like appearance. The spaces between lamellae contain collagen, free cells, and blood vessels. The result of these added lamellae is the extension of the axon's myelin sheath inside the cell. The receptor segment of the nerve fiber also increases in length. By late in life, there are far fewer PCs than were present in the infant or even the young adult, and those that remain are large and irregular in shape.

The MEIs, which are found in the dermal papillae, have a spherical shape in the infant, and are some 25 μm in diameter. In young children they are relatively numerous, with a density of up to 70 per mm^2, and begin to assume a cylindrical shape, with a firm attachment to the epidermis. At this point in life, the nerve endings are neurofibrillar networks. In young adults who do not engage in heavy manual work, these networks are maintained. However, in individuals with a history of manual labor, the nerve endings develop into long, winding terminals of much larger diameter. With aging, the epidermal attachment is reduced, and the corpuscles take on a radically different appearance. Continued longitudinal growth over the life span results in a coiling of the receptor and a disarrangement of the nerve endings. Taking all coils into account, an individual MEI can reach a length of up to 1 mm. These changes are easily observable by middle age. With advanced age, some corpuscles undergo atrophy and are lost, with density reports as low as 4 per mm^2. Up to 90% of MEI receptors can be lost in very old individuals. The remaining corpuscles show terminal nerve fibers that branch repeatedly, producing long, winding filaments with an irregular organization. It is possible

that this ramification of nerve fibers is the result of inactivity in old age.

MRKs are also very numerous during late fetal life and can cover almost the entire epidermal undersurface. In infants, they become restricted to the undersurface of the intermediate ridge of glabrous skin. MRKs undergo relatively little change in structure over the course of life, remaining relatively densely distributed even in old age. However, some disks can enlarge in an uneven fashion, resulting in an altered appearance compared to the circular disk shape of infancy and young adulthood.

The free nerve endings, arising from medium-size myelinated fibers, undergo the least change over the life span. In elderly individuals, their appearance, number, and distribution are very similar to that of younger persons. However, changes in psychophysical measures thought to be mediated by free nerve endings do show some changes with aging, so the lack of obvious difference in appearance may not indicate functional changes in the activity of free nerve endings with age.

Psychophysical studies of tactile response as a function of age have not been pursued as actively as might be desired; thus, there is still a considerable amount of research needed to specify in detail the changes in tactile function with aging. Early reports indicated a decrease in sensitivity to light touch with increasing age. More recently, a series of studies has focused on changes in vibrotactile sensitivity across the life span. Measurements of vibratory threshold indicate a systematic decrease in sensitivity with age, starting quite early in life. Elevations in threshold have been observed even between 10- and 20-year olds, in both longitudinal and cross-sectional studies. By the age of 65, thresholds at 250 Hz, the frequency at which the tactile system is most sensitive, can change by as much as 20–25 dB. **Figure 3** shows the systematic change in vibrotactile thresholds by decade. As can be seen, the greatest loss of sensitivity occurs for higher frequencies, which are thought to be mediated by the PC. As mentioned, PCs decrease substantially in number in aging individuals, and those remaining assume a large and irregular shape. The loss of PCs most likely underlies the changes in vibrotactile sensitivity that are observed for frequencies above 40 Hz. At first it was believed that there was not a similar elevation in threshold with age in the lower frequency range, but recent results suggest that sensitivity also declines for these frequencies, just not as dramatically as for the higher frequencies. An additional consideration here is the fact that PCs have been shown to modify their response when skin temperature is altered. PCs show maximum sensitivity at fairly warm temperatures and have elevated detection thresholds when skin is cooled. Many aging individuals have lower body temperatures, and it is possible that this could affect the response of the remaining PC population. The MEI corpuscle does not show great sensitivity to temperature variation, however.

A number of hypotheses have been proposed to account for decreased sensitivity to vibration with aging. In addition to changes in the number of receptors, as mentioned above, other possibilities include altered receptor morphology, decreases in the number of spinal root fibers, dietary deficiencies in older persons, decreases in circulation, decreases in nerve conduction velocity, and general changes in the aging nervous system.

Magnitude estimation of the perceived loudness of suprathreshold vibratory stimuli indicates that older

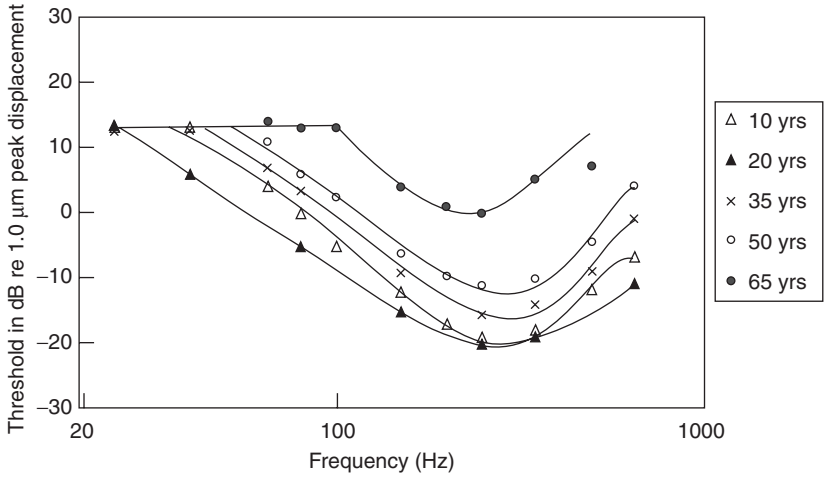

Figure 3 Changes in threshold detection of vibration, across age groups. Reprinted from Verrillo RT (1979) Change in vibrotactile thresholds as a function of age. *Sensory Processes* 3: 49–59, with permission from Elsevier.

individuals have simply shifted their entire dynamic range (i.e., both threshold and suprathreshold stimuli are perceived less acutely). Although results are mixed, it is generally believed that most individuals do not exhibit a phenomenon similar to that of auditory recruitment in which the dynamic range of the system is much smaller than would be predicted based on the threshold elevation.

Temporal resolution is also affected by aging. Measures of persistence, which is the duration over which a stimulus has an effect on perception, are longer in older persons. This result has been interpreted as indicating that the activity of aging neurons to a stimulus lasts longer than for neurons in younger persons. This result is supported by data from studies of temporal masking, a paradigm in which a previously presented stimulus interferes with the detection of another, target stimulus (forward masking), or in which a stimulus presented after the target interferes with target detection (backward masking). Both kinds of temporal masking are greater in older persons, again suggesting greater persistence of neural activity in response to both the target and masking stimuli. This effect, like those of detection, is more pronounced at high frequencies.

Far less is known about changes in sensitivity to temperature with aging. Some studies have shown changes in the ability to detect a thermal stimulus, but others have not. One report indicates a decrease in the ability to distinguish between two temperatures in older persons, but overall, results are inconclusive. It is possible that differences in stimulus delivery methods, or in subject criterion, may have great effects on the obtained measures. For example, one study reported that older subjects were poorer at detecting a radiant-heat stimulus than younger subjects. The radiant stimulus does not actually touch the skin surface, eliminating mechanoreceptive cues that might be used by older persons to supplement thermal perception *per se*. Criterion effects are a consideration in all studies of older persons. Results from a variety of studies indicate that old persons tend to set a very conservative response criterion, and are reluctant to report the presence of a stimulus until they are very sure that it is there. This tendency could lead to the assumption that older persons simply have reduced sensitivity to the stimulus.

In measurements of pain sensitivity, two types of tasks have been evaluated: detection of onset of a painful stimulus, and the tolerance limit for pain. In older subjects, threshold for detecting the onset of a painful stimulus is not particularly affected by age, but mixed results are obtained in studies of tolerance limits for pain. In fact, some studies show that older persons are more tolerant of pain, and others show that older persons are less tolerant of pain. Furthermore, there are some indications that the effectiveness of analgesic drugs is greater in older persons. As mentioned, pain sensitivity is postulated to be controlled by free nerve endings, which do not show great changes in either number or morphology with age. Thus, the lack of difference in the detection of pain onset between older and younger persons is not surprising. The mixed findings regarding tolerance for pain are most likely affected by the same emotional and cognitive considerations as are inherent in any pain research, and at present no definitive statement about pain sensitivity and aging can be made.

Proprioception

Physiology

Sensations generated by the body that give rise to a knowledge of the location and movement of limbs in space are the province of proprioception. Technically, the appropriate term for the sensation of movement is kinesthesia, whereas proprioception is reserved for the knowledge of static limb position. In practice, however, researchers use the two terms interchangeably. Sensations of body location and movement are mediated by specialized sensory receptors, that convey information about joint angles, muscle length, muscle tension, and the rate at which each of these changes during movement. Historically, the physiologist Sherrington referred to proprioception as muscle sense.

Over the years, researchers in kinesthesis have ascribed to differing notions of which receptors actually provide the necessary information. At various times, the field has held that the crucial receptors are in the muscles, or in the joints, or both, or neither. The current position is that the most important receptors are indeed located in the muscles, with joint receptors playing a minor part.

In considering the information that is provided to the central nervous system from the receptors, two classes of input would be required for accurate sensing. First, information about the position of limbs, or their displacement, could be coded in joint angle. Second, movement cues could be coded in transient responses signaling rate or acceleration.

Possible receptors that have been examined as participants in the coding of kinesthetic or proprioceptive information have included mechanoreceptors in the skin, receptors in the ligaments or capsules of the joints, and receptors in muscle. In skin, the RU, which has been implicated in the SA II mechanoreceptive response, seems to respond also to

skin stretch, and to change its discharge rate in response to changes in joint position. However, RU density in most areas of skin is not great enough to provide detailed information about position, and activation of RUs in isolation does not produce any conscious sensation of position or movement. It is possible that they do contribute to position sense, but perhaps only in conjunction with other receptors. Furthermore, they may play a more important role at body sites that have a high density of RU innervation, such as the tongue or fingers. Studies where topical anesthetic has inactivated mechanoreceptor response in the fingers indicate that movement of the affected areas is also inhibited. This result suggests that the mechanoreceptors may contribute to kinesthetic sensibility, but only at certain body sites, since in some areas (e.g., the knee), topical anesthesia does not inhibit movement or kinesthetic awareness. An additional consideration is that tactile input from pressure mechanoreceptors, such as the MRK, can enhance the sense of position of a body part. For example, placing the fingertips on a table improves the salience of perceived location of the fingertips.

In the joints, ligament and capsule structures are well innervated with SA mechanoreceptors that show responses to stretch of the joint or to stretching or bending of the capsule. In ligaments, Golgi-type endings, which have a dense branching of nerve terminals, show a strong response to stretch when stimulated in isolation. However, in the intact preparation, these endings tend to fire only at the extremes of movement, rather than to any movement. This tendency has led researchers to postulate that the Golgi joint receptors may serve a protective function, to indicate when a limb has been moved too far. In the capsule, SA responses from Ruffini receptors occur to stretching or bending, and could signal some aspects of joint position. It should be noted that local anesthesia of joint receptors, delivered by injection, does not impair the performance of motor tasks.

In muscles, there are two candidate receptors for proprioceptive sensation. First, the Golgi tendon organ, which is a thinly encapsulated bundle of fascicles with a spindle-like shape, may signal information about muscle tension. This receptor is shown in **Figure 4**. Because the Golgi tendon has low compliance, it could in fact respond to muscle tension. It is clear that this information is of great importance for regulating muscle contraction, but not as clear that it signals position *per se*. However, it is possible that muscle tension information is fed to other receptors, to correct their position judgments.

The most likely candidate receptor for mediation of kinesthetic and proprioceptive sensation is the muscle spindle receptor, also shown in **Figure 4**. Muscle spindles consist of a bundle of 2–12 intrafusal muscle fibers in a fluid-filled capsule. These spindles receive both sensory and motor innervation, and in fact a substantial amount of motor control outflow from the CNS is directed to the muscle spindles, for regulation of muscle contraction. The number of spindles found in a muscle varies greatly, depending on the size of the muscle, from 4 or 5 spindles to over 500. Smaller muscles show a greater density of spindles. These spindles lie parallel to the main, or extrafusal, fibers. There are two kinds of intrafusal spindle fibers: the nuclear bag and nuclear chain fibers, distinguished by the arrangement of cellular nuclei. Sensory innervation of these spindles terminates in the center region, and stretch here activates potentials in the receptor endings. Contraction of the end regions of the muscle spindles changes the sensory function of the fiber but does not appear to add to overall muscle tension. Instead, these changes are used to signal length and rate of change of length information to the CNS. Two different kinds of spindle endings have been discriminated. These include primary endings, located at the middle of the spindle, and secondary endings, located just off the middle. The primary endings show strong responses to velocity of movement, as well as to muscle length, suggesting that they can signal both position

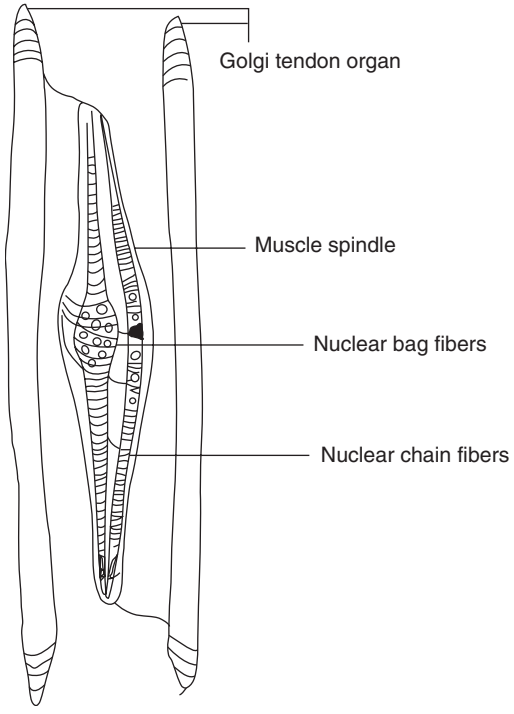

Figure 4 Schematic drawings of muscle receptors involved in proprioception, the Golgi tendon organ and the muscle spindle.

and movement. Secondary endings, on the other hand, provide primarily length responses. For both, the optimal stimulus falls between 0.1 and 2 Hz; it is important to note that few voluntary movements occur at rates higher than this. The fact that primary fibers show a temperature dependence in their responses but the secondary fibers do not, and that the secondary fiber firing rate is dependent on spontaneous rate but the primary fiber rate is not, suggest that the two kinds of fibers employ different encoding mechanisms. To some degree, differences in the contractile properties of the nuclear bag and nuclear chain fibers can account for observed response patterns in the muscle spindle afferents. In any case, it has been demonstrated that impulses from muscle spindles reach both sensory and motor cortex areas, reinforcing the notion that they may be the primary encoders for proprioceptive information.

Studies in which passive movement of joints is performed and the output of muscle spindles recorded indicate that muscle receptors signal movement over virtually the entire range of a joint's movement. The range appears to be about equally divided between the agonist and antagonist muscles governing the movement. Vibration of muscle tendons, which would activate spindle receptors, gives rise to a sensation that the joint is being moved, and further reinforces the notion that these receptors play a major role in kinesthesia.

Yet another putative source of information about joint and limb position and movement could be provided by motor commands that control voluntary movement. These commands, called corollary discharges, could provide information about the planned position of joints and limbs after the movement occurs. It is assumed that such corollary discharges, if present, arise at high levels in the CNS, at least above the cerebellum, which controls involuntary movements. There is some disagreement regarding the exact location of corollary discharges, but it is agreed that such discharges may be particularly important in the sense of effort that accompanies voluntary movement (*see* Motor Control).

At the CNS, a number of different possible codes have been considered as the primary input for proprioceptive sensibility. Rate-dependent discharges in the peripheral afferents, including differences in primary and secondary receptor activity, could signal directional information. It has been observed that primary receptors have a greater firing rate during muscle lengthening, whereas secondary fibers show a greater response to shortening. Although it is generally agreed that kinesthetic information is coded in firing rate, some difficulties have not yet been resolved, such as the fact that firing rate will increase with movement rate as well as direction and extent (*see* Neuromuscular System).

Psychophysics

In measuring the behavioral response of an observer to static position or movement, several kinds of information can be obtained. These include movement rate, direction, and extent, as well as the awareness of static limb position, the perceived amount of weight supported by a limb, the force produced by muscular contraction, and the sense of effort necessary to contract a muscle. Much of this work has focused on non-voluntary movements and placements of limbs. For example, in studies of passive limb extension, subjects can typically sense that movement has occurred before they can determine the direction of the movement. The dependent variable in such studies is often the displacement of the limb required for reliable detection of movement, at a particular movement velocity. Velocity is an important control, in that subjects tend to perceive very fast movements as having larger displacements than they do. However, errors are also more prevalent in very slow movements, and subjects show the greatest sensitivity to movement when velocity approximates the range in which most voluntary movements occur (in the vicinity of 5 m/s, for the hand). Accuracy is also dependent on the starting and ending position of the limb, and for different limbs, sensitivity may be better for movement in one direction than in another.

In general, proximal joints, those closer to the body, have greater sensitivity to movement than more distal ones, those at the extremities. This may be because in real movement, operation of the lever principle means that proximal joints move less than do distal ones. The poorest sensitivity to movement is seen for the finger, if displacement is the value measured. However, if responses are evaluated in terms of muscle stretch, different joints appear more similar in response, suggesting that the CNS may monitor muscle stretch rather than displacement per se.

Another measure of perceived movement is obtained via joint rotation. Minimum values for detection of passive joint rotation range from 0.2° for the hip to 0.7° for the first metatarsal phalange (big toe). These values, obtained from young adults, generally are higher by 0.1 to 0.2° in older persons. However, joint rotation detection is also rate dependent, and the range of movement necessary for detection of movement may be as high as 6°, depending on rate.

It is also possible to measure a more purely proprioceptive sensation, that of judged limb position, rather than movement. This measurement is more complex, of course, because responses to limb

movement necessary to change limb position could influence responding. Thus, rather than asking whether the limb has changed position following passive movement by the experimenter, some studies have employed a technique in which the subject is instructed to move the limb to a particular position, or to point to a position after a limb has been passively moved there. Results of such studies indicate that errors are greatest when the limb is passively moved and held there by the experimenter, and lowest when the subject actively moves the limb and actively maintains its position. Variability in positioning accuracy increases as the distance to be moved increases, and in general, subjects tend to overestimate short movement distances and underestimate long ones.

A major consideration in measuring proprioceptive sensation is the necessity of eliminating additional sources of information that might be used to signal limb position or movement. Two important sources of such information are visual and cutaneous inputs. Studies suggest that when vision is permitted, it dominates kinesthesis, even when the visual information is misleading, as when a distorted visual image is provided. In this case, position errors are made consistently, even though the kinesthetic information is maintained. At first, when vision and kinesthesis are decoupled in such a manner, they feel separated, but subjects quickly adapt to the changed visual environment, and the two modalities again feel congruent. In any event, measurement of proprioceptive feedback requires the elimination of visual cues, typically accomplished by blindfolding the subject. Elimination of cutaneous feedback from mechanoreceptors in response to passive movement of limbs has been approached in a number of creative ways. The most successful involve the use of air-bladder splints, which produce minimal cutaneous sensation, and topical ischemia, or reduction of circulation to a particular limb, which eliminates cutaneous sensations and induces a feeling of numbness in the limb after about 20 min. The need to eliminate these cues suggests that in normal activity, their inputs contribute to position sense.

Other studies have found that human subjects are surprisingly good at remembering previous limb positions, over remarkable periods of time. Up to 24 h later, subjects can indicate the position in which a limb was previously placed. This aspect of kinesthetic memory is of considerable interest, particularly given that most subjects are poor at verbal encoding of movement and position, and given the notion that verbal encoding of stimuli permits them to be retained in longer term memory.

Furthermore, it appears that individuals are better at judgments involving relative limb position (i.e., how one position is different from another) than those involving absolute limb position. This may be related to phenomena of postural persistence, the persistence of sensations related to a particular limb position. In any case, results indicate that judgments of the current position of a limb are influenced by its prior position, particularly if that prior position has been held for some period of time.

Researchers have also investigated the perceptual aspects of the sense of effort, or force, required to perform particular activities. There are two possible mechanisms for estimating effort: monitoring sensory inputs from Golgi tendon organ receptors in muscles; or monitoring motor command signals generated in the CNS (the corollary discharges discussed above). However, judgments of the heaviness of weights, for example, depend not only on the actual weight of the object, but also on the condition of the muscles involved in lifting it. Intervening muscle exertion that induces fatigue will make a lifted object seem heavier than before the exertion. Interestingly, the same phenomenon occurs for the perceived weakness of muscles following stroke, when peripheral muscle processes may in fact be unaffected. This result suggests that there is a central component in the estimation of weight, such that CNS signals generated during voluntary movement are also input to sensory areas, where they can influence perception. In addition, adaptation of heaviness occurs, for example, in situations in which light weights seem even lighter after heavier weights are lifted. And as for other proprioceptive functions, in the fingers cutaneous receptors may play a role; results indicate that anesthesia of cutaneous mechanoreceptors in the fingers also affects perceived heaviness.

Involved in the perception of effort is the sensation of muscle tension. Vibrating a muscle that facilitates or opposes the lifting of a weight will influence the perceived heaviness and thus the perceived effort of lifting. However, subjects do appear to be able to distinguish muscle tension from overall effort. If subjects are instructed to keep effort constant, the exerted force of muscle will vary with the object to be lifted. However, if subjects are instructed to keep tension constant, the exerted muscle force does not change. Weakening of muscles with injected curare will cause an increase in perceived effort.

In summary, humans seem to have good ability to sense limb position and limb movement, as well as judge the degree of effort required in task completion. Under normal circumstances, these sensations are influenced by visual and/or cutaneous inputs, at least at some body sites. In measuring the integrity of

kinesthetic sensibility after injury or disease, a number of tasks have been employed. Some of these are also used in assessing the effects of aging on proprioceptive sensation, and will be discussed in the next section.

Effects of Aging on Proprioception

It has been well documented that motor performance becomes slower and less accurate with age. However, opinion is divided on why this occurs. One hypothesis is that a decline in the quality of sensory input associated with movement results in a deterioration of motor performance. Thus, researchers have taken an active interest in changes in proprioceptive and kinesthetic sensation associated with aging.

Studies of the effects of aging on kinesthesis indicate that passive movement thresholds for the knee, hip, and ankle were as much as twice as high for older subjects (over 50 years) as those for younger subjects (under 40 years). However, little difference in sensitivity was observed for upper extremities (hands, fingers). These differences between upper and lower extremities may be partially attributable to the fact that the ankle and knee are weight-bearing joints that may be more susceptible to aging effects. Other results indicate that older subjects have higher thresholds for detection of joint movements when movement rate is slow. For higher rates of movement, differences due to age are less apparent. In examining the tasks used in such studies, it can be noted that some tasks are more memory intensive than others. Specific evaluation of the effects of memory load on kinesthetic perception shows that when the memory demands are low, differences between older and younger subjects are minimal, but when memory load is increased, elderly subjects exhibit worse performance (*see* Memory).

Nonetheless, even relatively simple tasks, such as reproducing a passive movement, were found in some studies to be more difficult for older subjects. The problem with movement reproduction studies is that the subject must store the proprioceptive input from the first movement in order to complete the matching movement. Some researchers have argued that immediate reproduction of a movement of one limb with the opposite limb reduces the memory requirements of the task.

One study investigated differences in performance of younger and older subjects on two different tasks, one involving constrained movement and one involving preselected movement. In the constrained movement condition, subjects were instructed to match a passive movement controlled by the experimenter, and in the preselected movement condition, subjects could select a movement that they wished to match. Results indicated that older subjects were much worse than younger ones in the constrained movement condition, showing many errors in matching experimenter-controlled passive movement. In the preselected movement condition, however, older and younger subjects performed similarly. Interpretation of these data was based on the notion that preselected movements can benefit from the corollary discharges that accompany voluntary movements, but passive movements cannot. If the older subjects' proprioceptive sensibility were reduced, performance in the constrained movement condition would be impaired, but the ability to use corollary discharge information in the preselected movement condition could compensate for any decreases in proprioceptive afferent function, such that performance would not necessarily suffer. In younger subjects, such corollary discharge facilitation is not needed, because proprioceptive input is sufficient for performance.

Many studies of aging and proprioception have focused on changes in the ability to maintain balance, or postural control. Numerous experiments have demonstrated that older subjects exhibit increased postural sway, and increased tendency to lose balance when stress is placed on the system, due to a slower initiation of balance control movements. One difficulty with such studies is the need to separate the effects of aging per se from the effects of decondition of muscles associated with reduced activity and possible subclinical pathologies in elderly individuals.

Postural control, under normal circumstances, involves the coordination of inputs from several systems, both motor and sensory. The strength and condition of effector muscles involved in balance, as well as the range of motion of knee, hip, and ankle joints will affect postural control. In addition, sensory inputs from kinesthetic, visual, cutaneous, and vestibular systems may play a role in the maintenance of balance. A number of studies have investigated the interactions of visual and vestibular factors in postural control, by selectively eliminating factors in tasks where balance is challenged by perturbation of a platform on which subjects stood. In general, it appears that in the average adult, the influence of visual cues was most evident at low perturbation frequencies, less than 0.1 Hz. Vestibular function is divided in its effects: the otolith organs respond maximally below 0.1 Hz for postural sway, but the semicircular canals, which mediate angular acceleration, are most responsive above that range. Cutaneous inputs could respond well above 1 Hz.

Results for younger adults indicate that postural sway increases by about 50% when the eyes are

closed, as compared to open. Postural sway is also increased when the head is placed in an odd orientation, affecting vestibular inputs. Lower extremity ischemia, induced by applying a blood pressure cuff at the ankle, eliminated cutaneous sensation, and also resulted in increased postural sway. These data indicate that all of these systems could contribute to postural control. However, researchers argue that if any two of the systems are intact in the young adult, balance can be maintained. Reflexive responses appear not to be affected by these other modality inputs, but instead seem to be organized in advance based on past experience, and are not flexible in implementation. A more continuous monitoring mode seems to be more dependent on visual, vestibular, and proprioceptive input for the ongoing maintenance of balance.

Studies comparing performance of younger and older subjects in postural control tasks show that older subjects can maintain balance as well as younger ones when conditions were not stressful, but that under stressful conditions, such as a greater degree of platform perturbation, older subjects were more likely to lose balance. In addition, although all subjects showed some deficits when inputs from other sensory modalities were limited, older subjects showed greater impairment of balance control. Modifications of vestibular or cutaneous inputs via the methods described above were very disturbing to older subjects. Both younger and older subjects were most affected by elimination of visual inputs. Furthermore, when two sensory input sources were disturbed simultaneously, older subjects showed severe deterioration of postural control, far greater than was seen for younger subjects. The implications of these results are that older individuals rely more heavily on input from additional sources, such as visual and vestibular modalities, to maintain balance, in the face of decreased proprioceptive sensibility. When these additional sources are eliminated, balance fails (*see* Balance, Posture and Gait).

Interestingly, attempts to correlate decreases in proprioceptive, visual, cutaneous, and vestibular function with postural sway measures have not indicated strong relationships. For example, visual acuity was not associated with degree of postural sway, except to the degree that both show decreases with age. Vibration detection by cutaneous receptors was related to postural sway, but did not correlate with proprioceptive measures. Finally, vestibular functioning was only weakly related to postural sway. The lack of strong correlations here should not be misinterpreted, however. It is possible that the detection measures used here would not show deficits correlated to postural sway, but this does not mean that declines in sensory ability at suprathreshold levels might not contribute to increases in postural sway. Furthermore, some investigators believe that decreases in postural control with aging are mediated more centrally, at some point where peripheral inputs are integrated. This notion is reinforced by the finding that in many cases, the longer-latency, voluntary corrections to balance are more affected in older persons than are short-term, monosynaptic reflex corrections.

Summary

Overall, results indicate that both touch and proprioception are susceptible to the effects of aging, and that declines in function can be observed for many tasks. For touch, sensitivity to vibration shows a systematic decline with age, and the perceived intensity of vibratory stimuli is also reduced at suprathreshold levels. Some reports also indicate reduced sensitivity to thermal stimulation, together with a general decrease in body temperature in older persons. In addition, pain sensitivity in older persons also appears to differ from that of younger persons, although differences in response criterion may underlie some of this difference. In many cases, these psychophysical changes are accompanied by decreases in number and density, and changes in morphology, of cutaneous receptors, particularly the PC and MEI.

Proprioceptive and kinesthetic function also appears to decline in older persons, although care must be taken to rule out declines in muscle condition due to inactivity. Threshold for detection of limb movement and the ability to reproduce changes in limb position seem to be worse for older persons, particularly in situations in which proprioceptive memory load is high. Postural control, an important consequence of proprioceptive sensibility, is also impaired in older persons, especially when balance is challenged. It appears that older individuals maintain postural control by relying more heavily on inputs from multiple sensory modalities, including visual, vestibular, and cutaneous sensations, to compensate for reductions in proprioceptive input, and that when these sensations are eliminated, postural control is more strongly affected than in younger persons.

There is a pressing need for further research into the physiological mechanisms and behavioral function of the senses of touch and proprioception, both in younger adults and in older adults. A better understanding of how these modalities are affected by age could lead to strategies to remediate or avoid these deficits, improving quality of life for older persons.

Glossary

Acuity – Ability to resolve fine detail, usually in stationary, high-contrast targets.

Age-Related Maculopathy (ARM) – A visual disorder involving atrophy of the photoreceptors and neurons within the central retina; also known as age-related macular degeneration.

Contrast Sensitivity – Ability to detect luminance differences, usually between spatially contiguous surfaces.

Dark Adaptation – Increase in the visual system's light sensitivity in low illumination.

Glaucoma – An age-related visual disorder involving the loss of peripheral vision due to excessive pressure within the eye.

Optic Media – Transparent anterior components of the eye responsible for focusing images on the retina.

Presbyopia – Age-related loss of the ability to alter the refractive power of the lens to focus objects at varying distances.

Retina – Sensorineural structure in the posterior of the eye that contains the photoreceptors (rods and cones) and neural elements that transform retinal images into neural code.

Saccades – High-velocity, largely ballistic eye movements used to fixate different objects in visual scenes.

Useful Field of View – Visual area over which targets can be recognized and localized without eye or head movements.

Introduction

The normal, progressive changes that occur in vision as we age can make it more difficult to perform everyday visual tasks, especially those that have to be carried out under demanding viewing conditions such as dim lighting or low contrast. Some of the changes are due to age-related alterations in the optic media of the eye, others to sensorineural changes in the retina, visual pathways, and brain. The effects of the latter, however, are likely to be observed later in age (45 to 55 or so) than the former.

Although far less common than the visual changes experienced as a normal aspect of aging, serious visual disorders that can degrade well-being and mobility are also more prevalent in old age. Disorders such as these presumably account for research showing that vision loss is a commonly reported fear of aging.

The Aging Visual System

Optical Changes and the Retinal Image

A curved, transparent continuation of the sclera, the cornea at the front of the eye provides approximately two-thirds of the optical power needed to focus an image on the retina. Age-related changes in the cornea are usually moderate in extent. There tends to be some increase in corneal curvature and thus refractive power, primarily along the horizontal axis, and some increase in the cornea's tendency to scatter light.

The primary purpose of the pupil is to maximize the eye's depth of focus by maintaining the minimum size needed for ambient light levels. It also plays a secondary role in adjusting the level of light admitted into the eye. As we age, the diameter of the pupil decreases, a change referred to as pupillary or senile meiosis. As a result, the older eye admits less light than its younger counterpart under comparable illumination conditions. Because the difference in pupil size is more pronounced under dim light than bright light, older observers are especially prone to be disadvantaged by reduced lighting relative to their younger counterparts. A smaller pupil, however, also

enhances retinal image quality in the older eye by reducing light scatter and optical aberration and by increasing depth of focus.

By changing its sphericity via the ciliary muscle, the lens of the eye is able to adjust its refractive power to focus on closer or more distant objects. This adjustment process, known as accommodation, is steadily eroded with age by age-related hardening of the lens (lenticular sclerosis). Whereas a young child may be able to adjust the eye's focus by 18 to 20 diopters, by age 60, virtually all accommodative power is lost. Unless the observer was already quite near-sighted (i.e., myopic), the associated recession of the near point of vision (presbyopia) will demand added focusing power in the form of reading glasses, bifocals, or trifocals for near tasks. The lens also yellows and becomes less transparent with age, especially so for short wavelength light (i.e., blues and greens).

Around age 60, the average retina receives only about one-third as much light as it did at age 20. About two-thirds of this loss appears to be due to the older eye's smaller pupil, and about one-third to the increased opacity of the lens. Lens changes also increase light scatter markedly, an effect that makes older observers more sensitive to glare from strong light sources such as the headlights of oncoming vehicles at night.

Optically correctable errors in image formation, in particular far-sightedness (i.e., hyperopia) and astigmatism, are increasingly likely with age and contribute to the prevalent use of corrective lenses in older observers. Hyperopia results when the optic media are weak relative to eyeball length, making it difficult to focus on nearby objects. Large-scale epidemiological studies show that the prevalence of hyperopia increases with age; some also report the increase to be greater among women than men. Conversely, the prevalence of myopia or nearsightedness tends to decline with age.

In astigmatism, the eye's focus is irregular, usually because the refractive power of the cornea is greater for one orientation (i.e., axis) than another. Astigmatism is labeled depending on the orientation along which the eye has its greatest refractive power and clearest vision. If the eye has more power at vertical orientations it is termed with-the-rule astigmatism; if power is greater along the horizontal plane, it is termed against-the-rule astigmatism. Eyes with greatest focusing power between the vertical and horizontal are said to manifest oblique astigmatism. Epidemiological studies indicate an increase in the prevalence and severity of astigmatism among both men and women in the later years. There also appears to be a fairly consistent change toward greater rates of against-the-rule and oblique astigmatisms and a reduced likelihood of with-the-rule astigmatism. These changes likely reflect the age-related increase in the cornea's horizontal curvature. Without an appropriate cylindrical lens correction, older observers will have difficulty seeing vertically oriented target elements clearly.

The Aging Retina and Response to Light

Aging is associated with a pronounced loss of rods, the photoreceptors that predominate in the peripheral retina and are responsible for low-light (scotopic) sensitivity. Cones, the receptors that mediate fine detail vision and color perception at high ambient light (photopic) levels, are concentrated in the central area (macula) of the retina. Their density appears to be much less affected by aging than that of rods. Consistent with the loss of rods and their supporting retinal structures, scotopic sensitivity declines with aging about twice as fast as photopic sensitivity. Dark adaptation, the increase in visual sensitivity with falling light level due to the regeneration of cone and rod photopigments, also appears to progress more slowly in the older eye.

Photoreceptor response is processed initially in a retinal neural network of bipolar, amacrine, and horizontal cells and then is passed on to the retinal ganglion cells that compose the optic nerve for transmission to the brain. Several studies have reported significant age-related reductions in the number of retinal ganglion cells serving the macular region of the retina, and also in the number of axons in the optic nerve. These neuroanatomical changes appear to be accompanied by corresponding reductions in the retina's electrophysiological response.

The Visual Pathways and Brain

The optic nerve carries the neural information from the retina on to the lateral geniculate nucleus (LGN), the relay station for visual information in the thalamus. From there, it is conveyed to the primary visual cortex (V1). In the healthy older brain, there seems to be relatively little change in the density or size of LGN and V1 neurons. There is some evidence of functional deficits, however. These include slowing in visual transmission, reduced capacity to track rapidly changing stimuli, and in cortical cells, reduced selectivity for stimulus orientation and direction. Alterations in the neurochemical characteristics, synaptic organization, diminished intracortical inhibition, and/or demyelinization in the visual pathways have been suggested to explain these deficits. Such neural changes may also contribute to a functional decline in the extrastriate areas responsible for

higher-level visual functions. Even when no cell loss is apparent, imaging research reveals a tendency toward reduced efficiency and less specialization in the extrastriate cortical areas responsible for higher-level visual processing.

Color Vision

Although color vision losses can be severe in the presence of an eye disease (e.g. cataract, age-related maculopathy), a moderate linear increase in errors on color discrimination tests is characteristic of the healthy aging eye. Such errors tend to occur along the so-called blue-yellow rather than the red-green axis. This means that the typical older observer is most likely to experience difficulty distinguishing between colors that contain trace levels of blue or yellow, especially under conditions of low illumination. Much of this loss appears to be due to yellowing and darkening of the crystalline lens. Senescent changes in each of the three cone types (red, green, and blue) also appear to contribute to the age-related decline in color discrimination.

Age-related color vision changes are often sufficient to affect everyday visual tasks. Older observers report colors as less colorful or saturated, and tasks that depend on color coding (e.g., discriminating medicine bottles) can be more difficult for older observers, particularly in dim lighting.

Eye Movements

Three sets of extraocular muscles allow us to move our eyes to optimize different aspects of visual function, including fixation and acuity, balance, and the allocation of attention. Some eye movements are reflexive, while others are the result of goal-directed intent. Two generally voluntary eye movements that have been investigated in the elderly are smooth pursuit and saccades. Smooth pursuit movements, as the name implies, are those fluid movements made to track a moving object. Saccades are quasiballistic, high-velocity movements made to change the direction of gaze and attention. Smooth pursuit eye movements are slower in the elderly, with the result that there is more retinal blur for quickly moving objects. Saccadic eye movements are slowed in onset latency and are less accurate, at least when distractors are present and upward movements are required. What follows is a more detailed discussion of recent work in saccadic behavior.

Saccadic eye movements are readily executed in response to a peripheral onset (e.g., a flash of light) that elicits a prosaccade. In what is called an antisaccade task, observers are asked to move their eyes in the direction opposite this peripheral onset. This requires inhibition of the reflexive prosaccade. Some studies have found that the elderly make more errors and have slower correct responses in the antisaccade task. There is continuing examination of whether this reflects a lack of inhibitory control or a failure to hold in working memory the parameters for the correct eye movement.

In what is known as oculomotor capture, saccades are made to a unique stimulus, even when observers know that they are irrelevant to the task. The most robust capture obtains for rapid peripheral onsets. Older and younger adults show equivalent oculomotor capture when a single onset distractor is presented during visual search.

It is not only unique items that interfere with the accurate execution of saccadic eye movements. Saccadic averaging, also known as the center-of-gravity effect, occurs when saccades to an intended target are pulled toward neighboring objects. Older adults demonstrate greater saccadic averaging, with the result that they will need to program a second, smaller-amplitude eye movement in order to fixate a target. Thus, if rapid and accurate saccades are needed, visual clutter should be reduced.

Aspects of Visual Function

Spatial Vision

One of the more frequently studied aspects of spatial vision is acuity, the smallest detail that can be reliably resolved, usually in a high-contrast target or optotype. Under ideal viewing conditions, the best acuity for a human observer can be as low as 0.5 minutes of arc; under normal conditions, acuity averages 1 minarc in younger people. This corresponds to 20/20 vision. Older adults who are wearing appropriate optical correction for the test distance (this is not the usual case) can typically obtain 20/20 vision until their 60s, at which point detail vision deteriorates. Age differences in acuity are magnified at near distances because of the lack of accommodation. Additionally, acuity in older adults is relatively worse when the stimuli are of lower luminance contrast.

A more comprehensive index of spatial vision involves measuring an individual's contrast sensitivity function, sensitivity to small differences in luminance for coarse, intermediate, and fine detail (i.e., spatial frequency). For humans, contrast sensitivity is at a maximum between approximately three and five cycles per degree of visual angle under daylight viewing conditions. The high frequency cutoff under these same conditions, corresponding to acuity, is about 30 cycles per degree.

Older adults, even those wearing their best optical corrections for the viewing distance, show systematic

declines in contrast sensitivity (CS) that are more pronounced for intermediate and higher spatial frequencies. In low luminance conditions, age deficits emerge at low spatial frequencies as well. Age-related changes in contrast sensitivity do not appear to be caused by optical aberrations. Instead, they are related to changes in retinal illuminance and neural integrity. Interestingly, recent research shows that age-related losses in CS are predictive of later acuity decline.

Another facet of spatial vision is depth perception, which is critical for a variety of actions including walking, grasping, and collision avoidance. There are a myriad of cues, both environmental (e.g., texture gradient) and physiological (e.g., stereopsis), that mediate depth perception. Several studies suggest that the elderly are less able to make use of binocular disparity to judge depth at near distances, but there has been little additional work in this area.

Human spatial vision has evolved so that details are seen best when they are imaged on the foveal (i.e., central) portions of the retina. However, a great deal of important visual information is obtained from peripheral vision. This information is used to guide eye movements and attention, to facilitate the perception of depth and motion, and to maintain balance and postural stability. Traditional measures of peripheral function often assess a person's visual field when the stimulus is a small target (e.g., a light onset) presented in an otherwise empty field. Static visual fields are diminished from approximately 180 to 140 degrees, but this may be an artifact of low luminance in the perimeter. Perhaps more important functionally are age-related differences in the useful field of view (UFOV), the area over which peripheral processing occurs in cluttered scenes, often when attention is divided over more than one task. The UFOV is quite task dependent, often very small relative to classically measured visual fields, and can predict performance on everyday tasks such as driving. Current research centers on whether age-related declines in the UFOV are best described as a general loss in sensitivity or one that is exacerbated as targets are presented more peripherally.

Hyperacuity is a term applied to a range of visual tasks involving the discrimination of relative location, motion, or shape that produce thresholds as low as a few seconds of arc. Exceeding the optical resolution of the eye as well as the limits of cone size and density, such precision is attributable to the neural pooling of photoreceptor information at higher levels of the visual system. Thus, hyperacuity tasks can be useful for measuring the effects of age-related sensorineural change separate from those due to optical losses.

Age differences on static hyperacuity (e.g., vernier acuity) tend to be small relative to those seen for dynamic tasks (e.g., oscillatory motion discrimination). Vernier hyperacuity refers to the judgment of the alignment of two or more clearly visible targets; when the targets are separated rather than abutting, the task is also referred to as extrapolation acuity. Everyday examples include reading a thermometer or aligning a ruler with an edge. Although most studies have reported that aging has little or no effect on Vernier or extrapolation tasks, some recent studies have reported an age deficit.

There is no such conflict in the findings from studies of age differences on dynamic hyperacuity tasks. They show that the minimum displacement of a target needed to discriminate it from a stationary stimulus is increased among older observers, even when no age difference is seen on a static version of the same type of task.

Processing Visual Events: Sensitivity to Time and Motion

The traditional technique for measuring the ability of visual system to track rapidly changing visual events is to measure the critical flicker frequency (CFF), the minimum frequency at which a bright pulsating light patch appears to be on steadily rather than flickering. The CFF threshold declines gradually to about age 60 and more rapidly thereafter. A large part of this loss appears to be due to reduced retinal illumination associated with normal age changes in the optic media and pupil. Indicative of reduced temporal resolution in the senescent visual system, however, changes in the visual nervous system also contribute to the age-related deficit on the CFF task.

Because it provides a more comprehensive assessment of the visual system's temporal sensitivity than the CFF task, more recent studies measure the effects of aging on flicker sensitivity using the temporal contrast sensitivity function (tCSF). The temporal analog of the spatial CSF, the tCSF task varies the depth of luminance change (i.e., contrast) of a small (2–5 degrees) target sinusoidally around a mean baseline luminance level over a wide range of frequencies. Initial research on age effects on the tCSF reported that the age deficit increased with flicker rate. There was also a leftward shift of the overall function toward lower flicker rates, suggestive of a decline in the speed of visual functioning. Subsequent research, however, provided evidence that this shift is explained by reduced retinal illumination. When this was controlled for, most of the age difference was eliminated; the remainder has been attributed to reduced sensitivity in the temporal visual channels.

Older adults are less capable of detecting the onset of motion, the direction of motion, and motion-defined surfaces as well as discriminating differences in speed under near-threshold conditions. However, for stimuli well above contrast thresholds, there appear to be no meaningful age differences in detecting the direction of a single, directional 'jump.' Additionally, estimates of subjective speed appear to be age invariant for suprathreshold speeds, at least under relatively simple viewing conditions.

Responses to moving stimuli can be primed by prior exposure. In contrast to directionally sensitive motion phenomena such as the waterfall illusion, visual motion priming is an enhancement of perception in which the primed stimulus is more likely to be seen as moving in the same direction as that of the priming stimulus. Older adults show less two-dimensional (2D) and three-dimensional (3D) visual motion priming than the young, and it has been suggested on the basis of psychophysical and imaging studies that this deficit reflects changes in temporal sensitivity in middle temporal regions of visual cortex.

Motion parallax refers to the fact that when we fixate on a particular distance while moving through a stationary world, retinal image velocity is inversely related to the distance of an object from fixation. Parallax is a powerful monocular cue to depth and also plays a critical role in the perception of 3D shape. While older adults are able to use parallax to mediate depth perception, they exhibit deficits in detecting the presence of 3D surfaces and identifying 3D shape via parallax.

Signals arising from several sources (e.g., the extraocular muscles and the brain) help us to maintain the veridical perception of a motion. However, there are circumstances in which these mechanisms fail. The Filehne illusion refers to the observation that stationary objects appear to move opposite to an eye movement. The Aubert-Fleischl phenomenon occurs when objects appear to move more slowly when we smoothly pursue them. Older adults appear to show the same Aubert-Fleischl effect as the young, at least for low image speeds at which age differences in pursuit gain would not be a factor. However, at least for stimuli of short duration, the aged demonstrate a reduced Filehne illusion. The reason for this deficit is unclear.

Biological motion refers to the motion pattern that unfolds as people engage in activities such as walking and running. Although relatively little work has been done in this area, it appears that older adults can accurately perceive biological motion associated with gross activities such as walking, even at durations of only 0.25s and when the moving object is occasionally occluded.

Another ecologically important type of motion perception involves time to contact (TTC), a subjective estimate of the time remaining before two objects in relative motion would cross paths. Clearly, TTC judgments are important for avoiding collisions while driving. Several studies indicate that the elderly consistently underestimate TTC, a difference that should put them at less risk for accidents. However, it also appears that the elderly are less accurate in judging whether a collision will occur. It is unclear how these two trends interact to influence safety.

Finally, there are practical reasons for asking whether aging affects the ability to perceive detail in motion. Conventionally, research involving dynamic visual acuity has found that the elderly age differences in acuity increase at high rates of target motion. Dynamic contrast sensitivity is also negatively correlated with age, particularly for higher spatial frequencies. While age differences in smooth pursuit gain could account for these findings, the observation that age deficits are minimal under high contrast/luminance conditions suggests that the problem lies within the optic media.

Attention

Attention can be thought of as the deployment of processing resources to task-relevant objects, locations, or subtasks. It can be stimulus driven, as when we orient to a loud sound, or goal directed, as when we selectively attend to signage because we are trying to locate an office building. Short-lived attentional demands are common. Generally, we attend to the contents of our clothes closet for only a moment or two in order to pick out a shirt to wear. On other occasions – over-the-road driving is one example – we must maintain an attentive state for long, dull periods of time.

One of the most frequently employed tasks for investigating age differences in selective attention is visual search, which is often executed in complex and cluttered scenes containing a great amount of distraction. For many search tasks, performance slows and becomes more error prone as the number of distractors increases – the display size effect. In some instances, however, search is relatively independent of the number of items in the display. This occurs when targets are defined by only one salient feature or when people have been provided with a great deal of practice.

A substantial body of research, anecdotal, experimental, and applied, documents the difficulties that older adults experience with visual search. These problems tend to increase with display size, particularly when the object being sought is visually complex

and similar to the distractors. They are also exacerbated when there is limited time to search the scene, when targets are presented in the periphery, and when other tasks must be performed simultaneously. Aging effects under these conditions are manifested often as a proportionate increase in reaction time, consistent with generalized slowing.

There are numerous ways in which the use of attention appears to be age invariant. Older adults have little difficulty attending selectively to simple features like orientation, color, direction of motion, and depth. They also make as much or more use of advance information about where to search. Additionally, they seem to learn simple search tasks at the same rate as their younger counterparts and seem to be relatively flexible in modulating the features to which they attend, as long as some higher-order rule can be used to guide search.

Most attention tasks demand that observers allocate processing resources over relatively short periods of time when targets occur regularly and frequently. In contrast, vigilance, or sustained attention, demands a longer duration of attentional allocation when signals are uncommon. Most of the gerontological research on vigilance indicates that there are no age differences in overall vigilance performance or the vigilance decrement, the decline on performance with increased time on task. There is some indication that the elderly are more prone to vigilance problems when event rates are high and visual quality is low, but this is not a consistent finding. A few recent studies suggest that age differences in vigilance may emerge in ecologically valid tasks such as driving. There are no data on inhibitory control, goal maintenance, or task-switching in sustained attention tasks.

Age-Related Visual Disorders

As we age, the likelihood of a disabling visual disorder increases, dramatically so after age 65 or so. Two levels of visual disability are generally distinguished: low vision and legal blindness. Low vision refers to a vision loss of sufficient severity to interfere with the ability to carry out everyday tasks and is often defined as a best corrected acuity level between 20/40 and 20/200. Legal blindness is defined as a corrected acuity of 20/200 or worse in the better eye and/or a visual field smaller than 20 degrees. Epidemiological studies indicate that low vision or blindness affects more than 3 million adults aged 40 and over in the United States alone and that the future prevalence of such disabling losses will increase markedly as the proportion of elderly people rises. Age-related losses of sight can result from a primary eye disease or can occur as the secondary consequence of some other age-related illness. The four disorders that most commonly threaten sight in old age are cataract, age-related maculopathy (ARM), glaucoma, and diabetic retinopathy.

Cataract or opacification of the lens is the leading cause of visual impairment among older adults. Cataracts appear to be a near-universal outcome of old age; close to 70% of adults in the United States exhibit clinically significant cataracts by age 80. By absorbing and scattering light, cataracts reduce image luminance and contrast. This in turn impairs acuity, color discrimination, and contrast sensitivity and increases susceptibility to glare. Risk factors for cataract in addition to age include exposure to sunlight, steroid use, previous intraocular surgery, smoking, and diabetes. Fortunately, cataracts are readily treated by the replacement of the natural lens with an artificial version (i.e., an intraocular lens [IOL]).

Age-related macular degeneration (ARMD), the leading cause of irreversible visual blindness among the elderly in developed countries, causes a loss of central vision. Although the specific cause is not known, it results from the loss of photoreceptors associated with changes in the underlying retinal pigment epithelium (RPE) and Bruch's membrane that support their metabolic needs. The 'dry' or early form of ARMD leads to some impairment of acuity; the late form causes severe acuity loss. When the late form of ARMD is accompanied by a proliferation of fragile and often leaky new retinal blood vessels, it is referred to as the exudative or 'wet' form of the disease. While laser photocoagulation, photodynamic, and/or antioxidant treatment may slow the neovascularization, they cannot reverse the vision loss. The severe loss of acuity, color perception, and contrast sensitivity with ARMD can impair the patient's ability to carry out even the most basic tasks of everyday life.

Glaucoma is a progressive loss of peripheral vision due to damage to the optic nerve where it exits the eye. Although there are marked individual differences, glaucoma usually occurs in association with elevated intraocular pressure. There are two types of the disease, both of them associated with a buildup of aqueous humor that is produced continuously by the ciliary body. In open angle glaucoma, the aqueous humor is prevented from exiting the anterior chamber of the eye via the canal of Schlemm. In closed angle glaucoma, the prolapse of the iris against the lens prevents aqueous humor from circulating from the ciliary to the front of the eye. The patient is often unaware of the presence of glaucoma until quite late in its progression. In addition to a narrowing of the visual field, or 'tunnel vision,'

glaucoma can cause loss of contrast sensitivity, night vision, motion perception, and color vision. Regions of blindness (scotoma) can accumulate and eventually may lead to complete blindness. Tasks needing effective peripheral vision such as walking, obstacle avoidance, and driving can be impaired early in the disease. Moderate glaucoma often responds well to drugs that reduce aqueous production or enhance its outflow; closed angle glaucoma is also sometimes treated by creating a small hole in the iris (an iridectomy) to equalize pressure on either side of the iris.

Diabetic retinopathy (DR), the fourth leading cause of legal blindness in adults over 65 in the United States, is caused by diabetes-induced changes in the retinal vasculature. In its common initial form, DR is associated with a swelling and some leakage from the retinal capillaries, which impair vision. For a minority, these changes can progress to rapid retinal neovascularization with bleeding into the vitreous humor, retinal scarring, and even retinal detachment. This outcome is more likely for those who need to take insulin. The loss of acuity, color, and contrast sensitivity, scotoma, and reduced visual fields that can result from DR can make everyday tasks difficult. In addition to management of the underlying diabetes, lasers can be used to anneal leaking blood vessels. If necessary, panretinal photocoagulation can be used to reduce neovascularization by lowering the overall metabolic demands of the retina.

Low vision and blindness can make it exceedingly difficult to carry out such instrumental activities of daily living (IADLs) such as handling money, shopping, or taking medication and can even affect the basic ADLs such as bathing, feeding, or dressing. In assisting low-vision patients it is important to address both their visual loss and their adaptation to that loss. For example, visual functioning may be improved through the use of low-vision optical aids, good lighting, large-print materials, and simplified floor plans and marking the edges of stairs with high-contrast strips. Social service interventions that foster peer and family support in combination with psychosocial and rehabilitation programs can help to reduce social isolation and enhance overall quality of life.

Vision in Everyday Life

Age-related visual pathologies such as glaucoma and ARMD often have a profound impact on a person's ability to participate in important activities such as walking, reading, driving, and engaging in a variety of work-related and leisurely activities. Even in the absence of pathology, the elderly report visual problems with everyday tasks such as driving and use of the World Wide Web. Their self-reports are often highly insightful and generally consistent with the findings from lab and clinical studies.

Surveys conducted over the past two decades have asked healthy older people about the visual problems they experience in common tasks such as driving. The difficulties that emerge are consistently related to events occurring too quickly vis-à-vis their ability to respond, search, and deal with unexpected events, light sensitivity (e.g., dim displays and glare), and near vision. The self-reports of older drivers are consistent with changes in their driving habits. For example, older adults reduce driving distances generally and are particularly reluctant to drive at night, in poor weather, during high-volume times of day, and along higher-speed roadways and unfamiliar routes. The self-reports are also consistent with the accident profile of older drivers, in which merging, yielding right of way, and negotiating intersections weigh heavily. Certainly, many of the changes in visual function that have been summarized previously should be related to driving performance. These include dynamic acuity and contrast sensitivity, glare recovery, peripheral vision, motion and depth perception and visual attention. Unfortunately, with relatively few exceptions such as in studies of the UFOV (*see* Driving Behavior), attempts to use measures of visual function to predict accident involvement in the aged have not met with much success, and so the critical issue of licensure for at-risk older drivers remains a research and policy challenge.

Older adults represent the fastest-growing group of users of the Internet and World Wide Web. They use these resources to communicate with family and friends, plan activities, develop and maintain interests, obtain health information, and find psychosocial support. Several studies have suggested that access to the Internet and web can enhance self-efficacy, build social support, and reduce depression and isolation. Still, even a cursory examination of websites leads to the conclusion that usability issues abound and that age-related declines in visual function can interact with poor web design to render usage error prone and frustrating. A small but growing literature indicates that the elderly have difficulties with font size and style, color usage, clutter and crowding, finding links, recovering from 'broken links,' and navigation in general. There are a few empirical studies linking web performance with visual function, and guidelines have been proposed by various agencies to reduce visual demands of web resources so as to make them more accessible to the elderly. It will be important in future years to evaluate the usefulness of these guidelines and to build a

stronger empirical base for directly testing the influence of individual difference variables and design features on elder use of these important tools.

Volunteer Activity by Older Adults ☆

R A Harootyan, American Association of Retired Persons, Washington, DC, USA

Glossary

Formal Volunteering – Any activity intended to help others that is freely provided through a charitable, religious, civic, or similar organization and for which no pay or other type of material compensation is received.

Independent Sector – A non-profit coalition of over 800 foundation, corporate, and voluntary organization members with interests in philanthropy and voluntary action.

Informal Volunteering – Any activity intended to help others that is freely provided on an ad hoc basis by an individual and for which no pay or other material reward is received.

Intensity of Volunteering – Hours spent per week or per month in either formal or informal volunteer activity.

Volunteer Participation Rate – Incidence of volunteer activity within a specified population or group.

Introduction

Volunteer activity is generally defined as any activity intended to help others that is provided without obligation and for which the volunteer does not receive pay or other material compensation. Volunteers usually provide such assistance through a religious, charitable, or civic organization, but their assistance also can be given on an ad hoc or non-organizational basis. This article uses the broader definition of volunteer activity that includes assistance to others (except immediate family members or relatives), which is either organized and formal or episodic and informal in nature. Because there is no standard definition of what constitutes volunteer activity, it is somewhat difficult to provide a precise picture of trends in volunteerism in the United States. I use data from national surveys as well as information from studies on various aspects of volunteering to provide some general trends and findings about volunteerism and the older population in recent decades. The article concludes by looking to prospects for expanded volunteerism among older Americans in the future.

☆ Any views expressed in this article are those of the author and do not necessarily represent formal policies of the American Association of Retired Persons.

Trends in the Prevalence of Volunteering

Although they use somewhat different definitions of volunteering, national surveys conducted during the last two decades in the United States indicate that the prevalence of volunteering increased steadily during the late 1970s and throughout the 1980s, but declined slightly since 1990. At the same time, the composition of the volunteer population has changed – a reflection of wider trends in society as a whole. One of the more noteworthy trends is a recent increase in the incidence of volunteering among older Americans.

A series of national surveys conducted in 1988, 1990, 1992, and 1994 by Independent Sector (IS) provides the most consistent set of data measuring volunteer activity among adult (aged 18 and over) Americans. The IS biennial surveys explicitly define volunteer activity as "not just belonging to a service organization, but actually working in some way to help others for no monetary pay." This definition, which includes both formal and informal volunteering, is the most common way that volunteerism is measured and discussed.

As shown in **Table 1**, the prevalence of volunteer activity increased during the 1980s, reaching a peak of 54% in 1989–90. Since then, however, overall rates of volunteerism decreased to 48% in 1993–94. (The IS surveys, conducted in March, ask about volunteer work "during the previous 12 months"; resulting in data covering most of the previous year and the first-quarter of the year in which the survey was taken.)

Also shown in **Table 1** are volunteerism data for 1973–74, based on a national survey conducted by the Census Bureau for ACTION, the federal agency for volunteer service. It is important to note, however, that the ACTION survey restricted its data only to "unpaid volunteer work for a group ... or ... any other type of organization" that regularly uses volunteers – a distinctly more restricted definition than in the IS surveys. Although **Table 1** includes these earlier data, the rates are not directly comparable to those for the later years. I include them because they indicate the prevalence of formal volunteering in 1973–74. An analysis by Susan Chambre of the recent IS survey data showed that less than 10% of the respondents who say they volunteered did so solely on an informal basis. Applying this difference to the 1973–74 survey results would adjust upward the rates of overall volunteerism at that time. But even after this adjustment, it appears that volunteerism – both formal and informal – was less prevalent before the 1980s.

Factors Related to the Likelihood of Volunteering

Definitive explanations for these changing rates of volunteerism are elusive. There are few in-depth national studies on the complex aspects of volunteering. Most studies are descriptive in nature and confined to small populations of specific programs, making it difficult to generalize about volunteerism in the United States during the past three decades.

Table 1 Volunteer participation rates by annual income, employment status, and educational attainment (%): United States 1973–94[a]

	1993–94	*1991–92*	*1989–90*	*1987–88*	*1973–74*
Total	48	51	54	45	24

Although there is no clear 'model' that consistently predicts rates of volunteering, who volunteers, or what motivates volunteer activity, enough information is available from both national surveys and case studies to indicate which factors are most commonly associated with volunteerism.

Some researchers believe that volunteer activity increases during periods when the economy is growing or steady, but decreases during periods of economic sluggishness or recessions. This theory is based on the assumption that people are more likely to seek out opportunities to help others when they themselves feel economically and emotionally secure. The IS survey data in **Table 1** provide limited support for this thesis. The incidence of volunteer activity in the United States increased from 45% to 54% of all adults during the last half of the 1980s – a period of steady economic growth – and began declining during the recessionary period of 1991–92 (51%). But the most recent survey indicates further declines in these rates (down to 48% in 1993–94) even though the economy was growing once again.

This anomaly may be related to the type of volunteering that has declined. Although not shown in **Table 1**, the latest decline in the proportion who volunteer is largely due to lower incidence of informal volunteering. The proportion of respondents who gave assistance to individuals or organizations on an ad hoc or informal basis declined from 23% in 1991–92 to 17% in 1993–94. In contrast, rates of formal volunteerism remained steady during the same period. The surveys also indicate that those who are members of various organizations – religious, civic, charitable, educational – are significantly more likely to do formal volunteering than those who do not belong to such organizations.

Organizational membership is the bedrock of volunteering, providing a relatively steady stream of formal volunteers. In contrast, informal volunteering is less consistent and more prone to variation over time. This type of volunteer work is more sensitive to economic conditions, or, more precisely, people's perceptions of their economic well-being. National opinion polls in recent years indicate that a large proportion of Americans feel insecure about their economic well-being and uncertain of their future security, despite the relative health of the economy. Those perceptions may reflect economic realities that are not evident in standard macroeconomic measures. Recent studies indicate that during the 1990s real wages and income were stagnant for most middle-income Americans, declined for those in the lowest income quintile, and increased for those in the highest income quintile. These economic trends and a growing sense of insecurity among many Americans coincide with the recent downturns in volunteerism (*see* Economics: Society).

The link between volunteerism and economic factors is supported in many studies indicating that income and education are strongly related to likelihood of volunteering. **Table 1** shows that the highest rates of volunteering are among those who are better educated, wealthier, and employed. These persons are also most likely to be members of communal organizations through which most formal volunteering occurs. Multivariate analysis by Robert Harootyan and Robert Vorek of national survey data on volunteerism found that education and income are the two strongest predictors of volunteering. Their model also shows that – all else being equal – volunteerism is determined by (in descending order of influence) altruistic attitudes (e.g., belief in sharing one's benefits with those who are less fortunate), having positive perceptions of the contributions that others make to society, being aged 35–44, being satisfied with one's quality of life, having a larger household, and being married (the latter is reflected in **Table 2**).

Their findings stress the simultaneous influence of socioeconomic and attitudinal factors on volunteerism. In addition, being married, having a large household, and/or being in a child-rearing age group suggests that the presence of a spouse, children, or

Table 2 Volunteer participation rates by gender and marital status (%) and average hours per week in volunteer activity: United States 1973–94[a]

other family member increases the likelihood of volunteer activity. These characteristics are likely to generate greater awareness and more opportunities for volunteering, especially through educational, religious, and civic or charitable organizations. Such opportunities may be due to a family member's awareness of or involvement in community-based organizations. A child's school-related activities or participation in extracurricular or recreational programs often leads to parental involvement as volunteers, which may be truly voluntary or the result of implicit expectations or explicit requests for volunteer assistance.

The relevance of household size is also related to findings from the IS and other surveys, which indicate that simply being asked to volunteer greatly increases the likelihood that persons will do so. This is especially true when persons are asked by relatives, close friends, or co-workers. Being a member of a large household naturally increases the chance that individuals will not only hear about volunteer opportunities but be asked to do volunteer work. The IS studies indicate that more than four out of five persons (82%) who are asked to volunteer do so. In contrast, only one out of five persons (21%) who are not asked to volunteer actually do so.

Not only is volunteerism induced by family circumstances and employment, it is also strongly related to involvement in educational and religious organizations. By far the most frequently mentioned vehicle for volunteer activity is a religious organization. Most studies show that 45–50% of all volunteers donate some or all of their time through a synagogue or church. The second most prevalent vehicle for volunteerism is educational organizations, which are mentioned by one-fourth to one-third of all volunteers. Other types of organizations – hospitals, civic groups, and charitable organizations – are less common avenues for volunteerism (*see* Religion and Spirituality).

To summarize, volunteers are most likely to be better educated, financially comfortable, employed, satisfied with the quality of their life, concerned about the welfare of others, younger adults, married, and living in relatively large households (probably comprising two or three generations). These findings indicate the complex manner by which socioeconomic, attitudinal, and structural factors influence volunteerism in contemporary American society. Those who are most integrated into the social fabric and the economic structure of society are most likely to be volunteers.

Trends in Volunteerism in the Older Population

The findings about volunteerism in general also help to describe and explain age-specific and age-related trends in volunteer behavior. Elderly persons (aged 65–74 and 75+) and those who are retired are less likely than non-elderly persons and those who are employed to be volunteers (see **Table 3**). The data are consistent with the general thesis associating volunteerism with socioeconomic status, household size, and degree of involvement in communal life. Until recently, aging and old age were often viewed negatively and characterized by the loss of important roles such as parent and paid worker. Old age usually brings lower income upon retirement. Households headed by older persons tend to be small. The older population's average level of educational attainment has been significantly lower than for persons under age 65. For many older persons mobility becomes restricted and community activities decrease (*see* Retirement).

We are not surprised, then, that elderly persons are less likely to volunteer than non-elderly persons. Yet some observers have suggested that old age should be a time of increased volunteer activity precisely

Table 3 Volunteer participation rates by age (%): United States 1973–94[a]

because of the role losses that occur. This perspective assumes that volunteer activity is a key way for older persons to fill an assumed void in their lives. But numerous studies indicate that role loss is unlikely to induce volunteerism among the elderly. In a comprehensive examination of the potential for 'unpaid productive roles' (i.e., volunteerism) by older Americans in the future, the Committee for an Aging Society concluded in 1986 that unpaid work does not appear to be a substitute for paid work. The report emphasized that societal values and the meanings attached to paid and unpaid work are notably different. One does not take the place of the other. The committee's conclusions are consistent with the findings that volunteerism is strongly associated with being employed rather than unemployed or retired. Chambre's thorough analysis of volunteerism and the elderly reached the same conclusion. Volunteer activity is supplemental to and intrinsically different from paid work.

Moreover, the IS surveys and a 1991 national survey on senior volunteerism sponsored by Marriott Senior Living Services indicate that neither loneliness, lack of activity, extra time, nor desire for socialization is a strong motivator for volunteerism. Rather, the desire to help others – altruism – and to make a real difference in the well-being of the community – a sense of accomplishment or self-fulfillment – are significant determinants (along with income and education) of who volunteers. In addition, positive perceptions of the importance of charitable and civic organizations, as well as active involvement in religious institutions are highly likely to influence who volunteers, whether old, middle-aged, or young.

For older persons, however, volunteerism can be restricted by social and physical barriers. Poor health is most often cited by older persons as the reason for not volunteering. Health problems, combined with limited economic resources (lack of reimbursement for costs associated with volunteering affects lower-income persons the most), lower educational levels, and transportation difficulties all serve as barriers to volunteering by older persons. The Committee on an Aging Society also stressed that biases against older people, especially when combined with negative orientations towards some type of volunteer work, serve to thwart elder volunteerism.

Finally, a life-course perspective is necessary to fully understand the relationship between age and volunteerism. People do not suddenly become 'old' at age of 65 or 70. Nor do values, attitudes, ethical standards, political philosophies, and general personality traits change significantly with age. Similarly, people who have not been active volunteers during most of their lives or those who have not had positive role models of volunteer behavior in their youth are unlikely to become volunteers when their parental responsibilities end, when they retire, or when they reach age 65. As with other characteristics, volunteerism tends to be a lifelong activity that begins in youth and continues in old age.

Viewed from the life-course perspective, volunteerism among younger age groups in earlier decades becomes important for understanding volunteerism among today's older population. The attitudes, experiences, and behaviors of specific birth cohorts provide clues to volunteerism in the future. Although the data are limited, most surveys show that volunteering in general was less prevalent before the 1980s, regardless of educational level, income, marital status, or age (see **Tables 1, 2** and **3**). Thus, the lower incidence of volunteering among those who were aged 35–54 in the 1970s is reflected in the lower proportions of volunteers among those aged 55–64 and 65 and over today. The life-course perspective, when combined with knowledge of the key predictors of volunteering, provides a basis for projecting changes in the volunteer activity of older Americans (*see* Life Course).

Implication for Future Volunteerism by Older Americans

Will significant age differences in volunteer activity persist in the future? I think not. As discussed above, birth cohort differences help explain the lower rates of volunteerism among retirees and persons aged 65 and over through the early 1990s. But differences by age and employment status in volunteer participation rates appear to be lessening. As seen in **Table 1**, between 1987 and 1992 the difference between the volunteer participation rates of employed and retired persons increased from 14 percentage points to 25 percentage points. By 1993–94, however, the difference declined to its lowest level – 11 percentage points – during the years covered by the IS surveys.

More significantly, the direction of the changes within these groups has reversed. Since 1991–92, the volunteer participation rate among employed persons declined from 59 to 52% in 1993–94. For retired persons, however, the participation rate during this time increased from a low of 34% to a high of 41%. It is premature to suggest that this short-term change will continue as a long-term trend, but the degree of change in the rates of volunteering among retired Americans is very large. And because this change occurred in just 2 years, the possible influence of the trend toward lower average retirement age is not a factor, as shown by the age-specific data for those years.

The same pattern emerges in the age-specific rates of volunteerism. Since 1991–92, the proportion of volunteers decreased in each age group under 65, while the incidence of volunteering among those aged 65–74 increased one percentage point, reaching 43% in 1993–94. More dramatic was the increase from 27 to 36% for those aged 75 and over – the highest rate recorded for this age group in any national survey (the Marriott survey recorded 39% among those aged 75–79 and 27% among those aged 80 and over).

Although the volunteer participation rate of Americans aged 65–74 is still lower than for some younger age groups, it now approaches the rates of those aged 18–24 and 25–34. These trends cannot be explained simply by the aging of the US population. More complex processes influence the growing involvement of older persons in volunteering – processes that exemplify the 'coming of age' of today's older population and those who will soon reach their 65th birthday. This emerging trend reflects the changing characteristics of older Americans – characteristics that tend to make them more similar than dissimilar to the rest of the population.

I have emphasized that retirement does not induce volunteering and that employment is a predictor of it. It seems ironic, then, that the increasing labor force participation rates of women have constrained their level of volunteerism. The IS surveys indicate that, as with other population subgroups, volunteer participation rates have declined since 1990 for both women and married persons. Also, the number of hours that can be devoted to volunteer work has been constricted for those who traditionally have been the most active volunteers – women aged 35–64, especially married women. Among all women, the labor force participation rate surpassed 57% in 1993, compared to less than 50% in 1970. Most significant are the changes since 1970 in the employment rates for married women in this age range. Among those aged 35–44, the rate increased from 47% in 1970 to 75% in 1993. For married women aged 45–64, labor force participation grew from 44 to 60% during this period. These employment trends have reduced the incidence of volunteerism and the amount of time spent by those who do volunteer (especially for informal volunteering), except among those aged 65 and over (*see* Work and Employment: Individual).

Indeed, older Americans are in part making up for the reduced incidence and 'intensity' (hours spent per week or month) of volunteering by young-adult and middle-aged persons in recent years. The two trends may be serendipitous and not causally related, but the pattern is clear.

Other forces also have influenced the growing incidence of volunteerism by older persons. Significant changes in birth cohort characteristics that span less than two decades are the most likely reasons for the increasing rates of elder volunteerism in the 1990s. Amendments to the Social Security Act that introduced automatic annual cost-of-living adjustments for retiree benefits in 1975 have reduced the poverty rate among the elderly. Also, more than 40% receive some type of private or public pension payment. Similarly, the 30-year-old Medicare program has helped reduce a major fear of older persons – the potentially high burden of health-care costs. Thus, older Americans in general feel more economically secure today than in previous decades. But it is unclear if this sense of security will last. Older Americans now pay a higher proportion of their average income out-of-pocket for their health-care expenses than 30 years ago (22 versus 15%, respectively). Congressional proposals to dramatically reduce federal spending on Medicare are raising concerns among many elders.

As discussed earlier concerning Americans in general, perceptions of economic well-being and a sense of security allow persons to look beyond themselves and reach out to help others. Older Americans are no different in that regard. Altruism and a sense of accomplishment are important inducements to volunteering among all age groups. So, too, are socioeconomic characteristics other than income or perceived economic security. Among older persons themselves, those who are employed (whether full-time or part-time), married, and better educated are more likely to volunteer than are other older persons. Labor force participation rates have declined steadily for males and risen only slightly for females aged 55 and older during the last 20 years. The overall effect is to reduce their likelihood of volunteering. In contrast, a slightly higher proportion of older Americans are married than in previous decades, which increases their likelihood of volunteerism.

But the most significant and rapid change in birth cohort characteristics of older Americans has been educational attainment, which is the most influential predictor of volunteerism in the regression and discriminant analyses by Harootyan and Vorek. As recently as 1980, 43% of all persons aged 65 and over had less than 8 years of schooling, compared to 24% in 1993. Less than one-fourth (24%) had completed high school in 1980, but by 1993 more than one-third (34%) had done so. And in 1980, 17% had some college education or beyond, rising to 26% in 1993. This minor 'revolution' in the educational attainment of older Americans in less than 15 years promises to continue as new cohorts with higher

average years of schooling reach age 65 during ensuing decades.

The implications of this upward trend in educational attainment are highly significant for future volunteerism by older Americans. As the most influential predictor of volunteerism, educational attainment will foster new levels of volunteerism among older persons. Multivariate analysis indicates that after controlling for other factors, older persons with at least some college education are almost three times more likely to volunteer than those with a high school education or less. The educational trend also bodes well for increased volunteer activity by older persons that focuses on young people. Harootyan and Vorek found that disproportionately high percentages of elders with college degrees (37%) and education beyond college (28%) volunteer in programs benefiting youth, compared to 22% with a high school degree and 8% of elders with less than a high school education. An additional benefit from higher educational attainment among older Americans is its positive relationship to health status. New cohorts of older Americans who are both better educated and healthier than their predecessors will 'double' the likelihood of increased volunteerism.

Another factor is especially important regarding future prospects of elder volunteerism – the influence of religious organizations. Studies such as the IS surveys consistently point to religious affiliation and activity as important determinants of volunteerism. Harootyan and Vorek showed that volunteer activity through a religious organization increases with age, rising from 38% among those aged 18–34 to 54% among those aged 65 and over. As the average age of religious congregations continues to rise, so too will the concentration of older volunteers.

It is also possible that new cohorts of older Americans will not only be members of religious organizations but also more likely than their current age peers to be members of secular organizations. For reasons that are not clear, the typical older American today is less likely to be a member of secular organizations in the community. But middle-aged Americans have relatively high incidence of such memberships, which are expected to be maintained over their life courses. Should this pattern continue, the likelihood of increased formal volunteering by elders in the future is quite strong.

A 'hidden' indicator of the potential impact of more older volunteers is the multiplier effect of the time they devote to such activity (the intensity of volunteer time). The data from various national surveys during the last decade indicate that the average volunteer gives about 4 hours per week. The Harootyan and Vorek survey showed wide variation by age in average hours volunteered per month. The monthly average for all volunteers is 17 hours, compared to 26 hours for those aged 65–74. Even the oldest volunteers – those aged 75 and over – average 14 hours per month, the same amount as volunteers aged 35–44. Although elder volunteer participation rates are lower than most other age groups, the intensity of their volunteer time is the highest.

Past attempts to increase the number and proportion of older volunteers also may prove beneficial in the future. The federal government has administered a number of voluntary action programs to foster the availability of older Americans as a community resource. They are currently administered under the umbrella of the National Senior Volunteer Corps. Some of these programs have a second purpose – to provide a modest stipend for low-income older persons who would otherwise be unable or unlikely to volunteer. They also focus the volunteer effort on populations with special needs. The Foster Grandparent Program is targeted to children with special needs, whereas the Senior Companion Program promotes volunteer activity that assists elders who are isolated. The largest federal elder volunteer program is the Retired and Senior Volunteer Program, which accounts for almost 500 000 volunteers aged 55 and over who serve all age groups in communities throughout the nation.

Taken together, however, these government efforts provide only a fraction of the potential volunteer force within the older population. And cutbacks in federal spending are likely to constrict the growth of these programs. Helping to fill the void are new nationally oriented volunteer service programs. Most notable among them is the National Retiree Volunteer Center, which fosters the development of corporate and educational retiree programs that have the potential to recruit hundreds of thousands of new volunteers among the retired.

The effects of private non-profit initiatives, whether in a local community or on a national scale, can be profound. The potential resource they can tap within the older population is greater than most realize. Already, the American Red Cross notes that more than half of its volunteers are aged 55 and over. The Committee on an Aging Society reported that for every five older volunteers, there are another two older Americans who are willing to volunteer but do not. National surveys, such as the 1991 Marriott study, since then support that estimate.

The barriers to elder volunteerism discussed above provide some of the reasons why those elders are not volunteers. Embedded in one of those barriers – ageism – is a key element to promoting more volunteerism by older Americans. I already alluded to this

simple yet historically overlooked factor: people are far more likely to volunteer if they are asked (e.g., being in a larger household). Ageism, perhaps abetted by negative self-images, has kept many older persons who might otherwise volunteer from doing so. However, the changing socioeconomic characteristics of older Americans will increase their propensity to volunteer. Tapping that propensity may be no more difficult than simply asking them to help.

Widowhood and Widowerhood

A Martin-Matthews, University of British Columbia, Vancouver, BC, Canada
K Davidson, University of Surrey, Surrey, UK

Glossary

Anticipatory Socialization – In the process of anticipatory socialization to the role of widowed person, individuals who are not yet widowed engage in behaviors or have experiences typical of widowhood. The extent to which this occurs varies with age and the expectedness of widowhood, the duration of the spouse's fatal illness, and the forewarning of death.

Bereavement – The actual process of experiencing grief, mourning, and re-organization of one's life. Although some argue that bereavement cannot be assigned a specific amount of time, clinicians and researchers generally suggest that the process can take a full 2 years; some suggest even longer.

Social Support – That set of personal contacts through which the individual maintains social identity and lifestyle. Supports may be economic, tangible, or emotional in nature.

Introduction

Widowhood or widowerhood is both a status and a process. The status of widowhood is given to an individual who has not remarried following the death of his or her spouse. Widowhood is also a process of transition, progressing from the illness of the spouse (which may vary from lengthy to very short term) to the death of the spouse and related events involving burial and mourning, grieving, and reconstruction of one's social world.

Women who have experienced the death of their husbands are referred to as widows, and men who have been widowed are referred to as widowers. The experience of widowhood takes place within a variety of contexts: spatially (from one culture to another), temporally (within any one culture over historical time), and longitudinally (over the course of an individual's life time). Furthermore, the experience is defined differently according to subcultural definitions such as gender, ethnicity, age, and class. Other factors that influence the experience of widow- and widowerhood include the nature of the marital relationship prior to bereavement and the status of women in society. Variations from one society to another, and within societies, often reflect social and cultural norms surrounding death, mourning, and remarriage.

The focus on the female experience of widowhood has been so predominant that only comparatively recently has the word 'widowerhood' been included in some, but not all, English dictionaries. Indeed, in all societies, women are more likely to be widowed than are men, and the differential increases substantially with age.

The Changing Profile of Widowhood

In many countries, the proportion of the population aged 15 and over who are widowed is approximately 6%. Two factors typically characterize the incidence of widowhood in the population: its sex selectivity and its age-related nature.

Half of all marriages end with the death of the husband, but only one-fifth with the death of the wife. Among women aged 65 and over, almost 70% are widowed; the comparable figure among men is 22%. Because of this demographic reality, discussions of widowhood generally focus on women (*see* Demography). In the developed world, nearly half of women aged 65 and over are widowed, and this proportion rises to four-fifths of those aged 85 and over. On the other hand, fewer than one in five men is widowed at 65, although almost half of men aged 85 and over are widowed.

The discrepancy in age and incidence can be explained by three principal factors: biological, cultural, and social. First, in all societies men tend to die earlier on average than do women. Second, in most cultures, women tend to marry men who are several years older than they are (this is sometimes referred

to as the 'mating gradient'). These two factors combined mean that the likelihood of widowhood increases with old age and being female. However, the third explanation for the imbalance in gendered widowhood statistics is the social acceptance, and to some extent expectation, that a widowed man will remarry and will do so within 2 years of his loss. Not only are men far less likely than women to become widowed, they are also less likely than women to remain widowed. It is estimated than fewer than one in five widowers and one in ten widows do eventually remarry. It can be argued, therefore, that statistics on men's marriage status do not offer the complete picture since even in longitudinal studies, a man might be registered as married at each survey point but may have been widowed between waves of data collection. Research has shown that the older the widower, the less likely he is to re-partner, hence the apparently dramatic increase in the proportion of widowed men in the oldest-old age group. However, even among elderly persons, widowed men have remarriage rates over eight times higher those of elderly women.

Since the 1970s the average age at widowhood has steadily increased in many countries. Thus, widowhood is associated not only with women but also with old people. Almost three-quarters of the widows in North America are over the age of 65. The average age of the widowed population is 75 for both men and women.

The increased average age at widowhood is not a global phenomenon, however. The epidemic of HIV/AIDS in sub-Saharan Africa has meant a reduction in the average age of widowhood for both men and women. However, in these circumstances widowhood is more likely to be of short duration, partly as a result of remarriage patterns among younger generations. Also, when both partners are infected, as is frequently the situation, the period of survivorship is truncated.

Even in the developed world, life expectancy and average age at widowhood can vary widely among gender, ethnic, and socio-economic groupings. For men, but less so for women, there is a strong correlation between wealth and low morbidity (illness) and mortality rates. Men with higher incomes and high educational attainment live longer, healthier lives than low-income, poorly educated men. As a consequence, the experience of a surviving spouse, whether male or female, can be vastly different in widowhood, especially in relation to financial security. These findings must be interpreted with caution, however. A widow left with a large family house, reduced income, and altered standard of living can become what is termed 'equity rich, income poor,' inasmuch as she has valuable property but is unable to afford its maintenance and may be discouraged by adult children from selling their 'inheritance.'

Ethnic and cultural differences also mediate the experience of bereavement, not only in terms of age and pension poverty. Within some cultures, such as parts of the rural Indian subcontinent, for example, widows face a life of poverty and societal rejection.

Two other features characterize the experience of widowhood: the expectability of widowhood as a life event and the relative duration of widowhood in the lives of elderly people. Because most individuals in society marry, the experience of widowhood has been an 'expectable' life event of later life for most people; however, there is some evidence that this pattern is changing. Recent trends in North America and Europe indicate that growing proportions of older populations are married, declining proportions are widowed, and the percentage of older people who are divorced or separated is small but rising precipitously. Because of increases in the proportions of the population who are entering old age outside of marriage (because of having remained single or through separation and divorce without remarriage), the likelihood of being widowed in later life is in decline. Indeed, there is some suggestion that widowhood will, in proportional terms, become a less normative life event among future cohorts of women.

Because of the mating gradient referred to earlier, and the longer life expectancy of women, the average length of widowhood for women is considerably longer than for men. In many countries in the developed world, the average duration of widowhood is 6 years for men and approximately 15 years for women. However, there are recent changes in these long-term trends in differences in life expectancy between men and women. In many countries, the gender mortality gap is closing, because men's mortality rates are decreasing as a result of better standards of living and health promotion strategies. Nevertheless, with the aging of the baby boom generation and associated anticipated increases in the absolute numbers of widowed persons in the population, the careful attention of policy makers will be required to address the needs of many elderly widowed persons, and widows in particular.

Widowhood as a Relative Life Event

Widowhood is considered one of the most stressful of life events and role transitions. Although research findings are somewhat equivocal, the timing of widowhood in the life course and the duration of the spouse's final illness contribute significantly to the experience of bereavement. The experience of widowhood as 'on time' or 'off time' affects individuals in terms of their psychological preparedness, their opportunities for anticipatory socialization, and the

societal resources and supports available to them. The age at which a person experiences the death of the spouse is a very important feature of the experience of widowhood because of the way in which the person's life is embedded in other social roles at that point in time. Similarly, the duration of a spouse's final illness also influences opportunities for anticipatory socialization to the role of widowed person. However, this relationship appears to be stronger for the case of early, off-time widowhood than for widowhood in later life.

Many individuals take 2 to 4 years to adjust to the loss of their spouse (*see* Bereavement and Loss). Although the early period of bereavement is typically associated with profound psychological disorganization and feelings of status loss, widowhood also provides opportunities for personal growth and independence, and, for some, release from an unhappy union. Qualitative studies and narrative accounts of widowhood confirm that widowhood fundamentally involves a renegotiation of aspects of daily life and, as reported for women in particular, a reconfiguration of one's sense of self and relationship to others.

Research on the relationship between widowhood and morbidity and mortality is fraught with contradictory findings. Although there is evidence of short-term decreases in health status and perceived health following widowhood, long-term health appears largely unaffected. Despite early research findings of high mortality rates among widowers, more current epidemiological studies have found no significant relationship between bereavement and mortality. Findings of the long-term impact of widowhood on mental health are similarly equivocal, although the early bereavement period is generally associated with depression, mood alterations, disrupted sleep patterns, obsessive thoughts of the deceased, and disorientation. Nevertheless, the degree of disorganization produced by widowhood is influenced by many factors, especially by the degree of dependence upon a social network associated with the role of husband or wife and upon the level of commitment to that role (*see* Bereavement and Loss).

Despite the view of widowhood as a particularly stressful life event, most individuals adapt well over time, although the process of reconstruction of a new life and social order is for some a long and painful one. Many women, in particular, fare well in widowhood and underscore the point that widowhood is not necessarily a state of deprivation or deficit. For many people, widowhood represents a crisis not in the sense of a threat of catastrophe but rather a turning point, a crucial period of increased vulnerability and heightened potential. Many realize that potential, although as they advance in age and grow increasingly frail, the threat of becoming dependent looms large in their lives (*see* Life Course; Life Events).

Social Supports in Widowhood

The meaning and nature of social support has been extensively examined in the gerontological literature. There is strong evidence of a positive relationship between social support and health. The need for support in widowhood is by no means fixed. Thus, the types and sources of support beneficial at one point in the process of widowhood may not necessarily be appropriate at a later point in the transition. Researchers have also questioned the assumption of the inherent value of social support. Loose, low-density networks, rather than tightly bound, all-embracing networks, may be most appropriate in enabling widowed men and women to develop new social roles consistent with their new status.

Research findings indicate the predominant role of family ties in informal helping networks following widowhood. However, as many as one in five widowed persons report not having a single living relative to whom they feel particularly close. Clearly, there are many sources of variability in the experience of widowhood, all of which will influence the patterns of access to available social supports and their perceived benefit.

Adult children provide much of the assistance received by older widowed parents. But patterns of contact between widowed individuals and their adult children are not necessarily uniform, either among children or in terms of the duration of widowhood. Most contact is with daughters, and although the support of adult children is crucial during acute grief, it may become less salient over time as friends increase in importance.

Sibling relations hold a unique place in support networks in terms of their longer duration in comparison with other family ties and their essentially egalitarian nature. Research suggests generally strong patterns of emotional support between widowed persons and their siblings, especially sisters, although frequency of contact and exchange of aid may be comparatively low. Other extended family members, such as nieces and nephews, also act as viable members of the support networks of widowed people, especially in terms of emotional support. Research has also found that the memory of a deceased spouse can provide a form of support in widowhood.

Friendship relations change substantially with widowhood. Not distinguished by the feelings of obligation that characterize family relations, friendships – especially those with members of a married

couple – may not survive widowhood. The ability to make new friendships may indeed be an important indicator of how an individual is coping with the loss of a spouse. Self-help and mutual support groups represent particular kinds of peer relationships. Although typically utilized by only a minority of widowed people, such groups have been demonstrated to effectively reduce the distress of widowed people in intervention groups. However, formal organizational support groups are consistently underutilized by widows and are rarely used by widowers.

In relation to all these sources of support, the redefined personal resources and identity of a widowed person strongly influence the utilization of potential social supports. Recent research has documented the experience among some widowed people of what are called 'identifying moments,' the widows' sudden conscious awareness of their new status and the fact that their identity has changed. In any study of changes in patterns of social support in widowhood, the possibility of change in widowed individuals themselves as an influencing factor is an important consideration (*see* Social Networks, Support, and Integration).

Diversity in the Experience of Widowhood

Many factors distinguish the experience of widowhood for men and for women. The greater 'expectability' of widowhood as a life course event for women frequently leads to a mental rehearsal or anticipation of circumstances associated with being 'unattached' in later life. Although considerable research has debated whether the loss of a spouse is more difficult for men than for women, the meaning and consequences of death and widowhood for men and women under varying sets of circumstances remain little understood. The challenge of analyzing the effects of gender is complicated by the demography of widowhood, such that studies of widowed persons often result in samples in which only 13% are men.

Despite these research difficulties, studies have identified overall differences between widows and widowers in attitudes toward remarriage and in the issues that are most problematic to them in widowhood. Loneliness is a major problem for both men and women; financial resources are much more typically a concern for widows. Widows are far more likely than widowers to be poor in old age. Feelings of competency in the completion of household tasks and issues involving sexuality are more often reported as major areas of concern for widowers, although this may reflect cohort effects for older men in general (*see* Loneliness).

There are also points of contrast between widows and widowers on measures of social support. Overall, widowers report smaller support networks and less involvement with friends and family than widows. In negotiating their social worlds, widowers rely almost exclusively on themselves or their children. Many widows, by contrast, have much more extensive and diverse social networks. Overall, then, widowers appear comparatively disadvantaged in their ties to family and in their domestic skills, but both these patterns may be cohort specific.

Social isolation is a typical feature of life for elderly men who are 'unattached' in old age due to either widowhood or divorce. Research shows that older divorced men are even more likely to be socially isolated from family and friends and engage in more risky health behaviors, such as smoking and harmful alcohol consumption, than other groups of older men. In some Western countries, such as the United Kingdom, more men in their late 60s are divorced or separated (9%) than widowed (7%).

Until comparatively recently, less attention has been paid to men who are widowed. Research on widowers has principally focused on the health outcomes and psychological disorientation caused by an unanticipated disjunction: a husband does not expect to predecease his wife. There is a continuing debate on 'who suffers more,' widowers or widows. Research in Canada, the Netherlands, the United Kingdom, and the United States has examined the well-being and living conditions of older widows and widowers in order to establish gender differences in adaptation to conjugal loss. Remarkable similarities in the reported well-being of elderly widowed people have been noted. Availability of resources such as income, education, and freedom from limiting disability advantaged the widowers, but widows benefited from the support of close female friends and neighbors as well as adult children. Few significant differences were found in the reported personal relationship needs, although the relational patterns were different: the women tended to have more 'emotionally intimate' female friends. The men were content with male friends for 'sociability,' but also wished for a cross-gender romantic relationship. The men derived satisfaction from the presence of new partners or partner-like relationships and tended to depend more on adult children than the widows. While widowed women were disadvantaged regarding income, education, and health resources, they reported a degree of life satisfaction similar to the widowed men. It was concluded that this was because women had been socialized to greater flexibility and adaptability over the life course. This helped them with the major change brought about by widowhood and mediated the instrumental disadvantages.

An increasing number of widowed persons live alone, many of them residing in the same community and the same housing unit for many years. Although home ownership may be an important source of economic security for a widowed person, high housing-related costs may seriously undermine the financial benefits of ownership. In addition, long residential tenure, often for reasons of sentimental attachment to home as well as inertia at the prospect of relocation, may confine widowed men and women to homes whose physical characteristics are no longer appropriate to their needs and to a neighborhood that is no longer able to provide a supportive environment.

Widowed persons living in rural areas have marginally stronger supportive relationships with family and friends but often lack the economic resources and access to transportation available to the urban widowed. When relocation finally comes for those widowed in later life, it may be into an institutional setting. Although comparatively few elderly people are institutionalized, widowed individuals are proportionally overrepresented among those who seek institutional care in later life.

Childlessness does not appear to exacerbate the transition to widowhood. However, some studies note the distinctive experience of widowhood from a marriage that involved stepchildren. The challenges experienced by some of these widows in maintaining relationships with stepchildren can be an additional source of strain in the period following bereavement.

Competing demands associated with the performance of other roles or the experience of simultaneous transitions may also have an impact on the experience of widowhood in later life. Although the experience of retirement from the paid labor force is rarely coincident with widowhood, the loss of ongoing contact with work associates exacerbates the loneliness of widowhood for some individuals. Responsibilities involving providing care to dependent adult children or disabled parents may also complicate the transition to widowhood.

There is also little empirical support for the popular assumption of more extended networks and more involvement in those networks by widows and widowers with strong ethnic group identification. However, comparatively little is known about how societal norms and expectations of bereavement and widowhood shape the experience in non-Western societies. An exception is the well-known but long-banned traditional Indian practice of suttee (the expectation that widows would immolate themselves on their husband's funeral pyre). While this practice is no longer carried out, an Indian widow does undergo a form of 'social suttee' whereby she is considered 'as good as dead' and must endure crippling poverty and destitution, especially if she is without sons. In Botswana, the practice of 'seantlo' requires that a widow marry her dead husband's brother and that a widower marry his dead wife's sister. This practice mirrors the ancient Israeli custom of 'Levarite marriage,' in which if a man died leaving no sons, his nearest male relative was to marry his widow. While these practices have traditionally applied only to widowed men and women of childbearing age, they do reflect cultural norms involving widowhood and widowerhood and societal expectations of the behavior of widowed persons.

Research Limitations and Future Directions

Although the aging of the population is well documented and widely acknowledged, the implications of old age for the experience of widowhood is, surprisingly, not well recognized. Most studies have focused on younger populations, despite the fact that widowhood is age related and is a characteristic feature of later life, particularly of late old age and especially so for women. Relatively few studies extensively examine issues specific to elderly widowed persons.

Most studies of widowhood do not include comparison groups of those who have not experienced the loss of their spouse, or of those who have experienced other kinds of losses. As a result, conclusions that any observed patterns are, in fact, due exclusively to widowhood may be questionable.

Several recent qualitative studies focus on the narrative accounts of older widowed women and challenge the dominant public narrative of misery and decline, pointing instead to a complexity of experience that is rooted in personal biography and the female life course rather than in later-life widowhood itself.

Although in some countries (such as Canada) social policies have been developed to address issues of particular concern to the widowed (such as income supplementation), few such policies exist worldwide. Where they are present, social programs will need to be as flexible as possible. Today's widowed elderly people have characteristics – in terms of social roles and expectations, availability of family members, labor force history, education, and financial resources – that are quite different from the attributes of the elderly widows and widowers of tomorrow.

Wisdom

U M Staudinger and J Dörner, International University Bremen, Bremen, Germany

Glossary

Wisdom – The ideal of human knowledge and character, representing a well-balanced coordination of emotions, motivation, and thought, with good judgment and the ability to offer advice in difficult and uncertain matters of life.

Introduction

Wisdom is a phenomenon characterized by a rich cultural history and complex associations. Across cultures and history, wisdom has been discussed as the ideal of human knowledge and character. Starting from the dictionary definition of wisdom as good judgment and advice in difficult and uncertain matters of life, psychologists have described wisdom as the search for the moderate course between extremes, a dynamic between knowledge and doubt, a sufficient detachment from the problem at hand, and a well-balanced coordination of emotion, motivation, and thought. Within psychological research on wisdom, two kinds of approaches can be distinguished. One is the study of lay conceptions of wisdom, and the other is the attempt to measure behavioral expressions of wisdom. With regard to behavioral expressions, a personal and a general form of wisdom need to be distinguished. Age trajectories and antecedents of general and personal wisdom are discussed.

Historical Background

Since the beginnings of human culture, wisdom has been viewed as the ideal endpoint of human development. Indeed, the idea of wisdom as one of the highest forms of knowledge and skill is evident in the definition of the historical grand master of all scholarship, philosophy: the love/pursuit of wisdom. Historically, wisdom was conceptualized in terms of

a state of idealized being (such as Lady Wisdom), as a process of perfect knowing and judgment, as in King Solomon's judgments, or as an oral or written product such as wisdom-related proverbs and the so-called wisdom literature. Important to recognize is that the identification of wisdom with individuals (such as wise persons), the predominant approach in psychology, is but one of the ways by which wisdom is instantiated. In fact, in the historical literature on wisdom, the identification of wisdom with the mind and character of individuals is not the preferred mode of analysis. Wisdom is considered an ideal that is difficult to be fully represented in the isolated individual.

Throughout history, interest in the topic of wisdom has waxed and waned. In general, two main lines of argument were pivotal in the historical evolution of the concept of wisdom: the distinction between philosophical and practical wisdom – often attributed to Aristotle's differentiation between *sophia* and *phronesis* – and the question of whether wisdom is divine or human. In the Western world, these two issues (philosophical vs. practical; divine vs. human) were at the center of heated discourse during the Renaissance. An initial conclusion of the debate was reached during the later phases of the Enlightenment. Wisdom was still critical, for instance, to the thinking of Kant and Hegel. Both understood wisdom as being based on the coordination of the world of science and the practical world of humankind. However, the eighteenth century French encyclopedia of Diderot (and others), despite its more than 50 volumes, barely mentioned the topic. During the Enlightenment and the process of secularization, wisdom lost its salience as one of the fundamental categories guiding human thought and conduct.

Nevertheless, from time to time, scholars in such fields as philosophy, political science, theology, and cultural anthropology continued to attend to wisdom, although less in a cumulative sense of theory building than in rejuvenating and revisiting its meaning, historical roots, and implications for raising human awareness about the complexities and uncertainties of life. During the past decade, for example, some philosophers have struggled with the definition of wisdom, including the polarization between practical and philosophical wisdom, the integration of different forms of knowledge into one overarching whole, and the search for orientation in life. The latter issue has gained special importance in relation to the advent of postmodernity. Finally, there is the archeological-cultural work dealing with the origins of religious and secular bodies of wisdom-related texts in China, India, Egypt, Old Mesopotamia, and other sites of ancient civilizations. The degree of cultural and historical invariance of wisdom-related proverbs and tales found in this research context is impressive and gives rise to the assumption that concepts such as wisdom, with its related body of knowledge and skills, have been culturally selected because of their adaptive value for humankind.

Among one of the major reasons for the emergence of the psychological study of wisdom in the late 1970s and early 1980s was the search for the potential of aging or, more specifically, the search for domains or types of intellectual functioning that would not show age-related decline. Life experience and wisdom as well as professional expertise, everyday problem solving, or practical intelligence were selected as topics of investigation.

Psychological Approaches to the Definition of Wisdom

A first approach to the definition of wisdom from a psychological perspective is its treatment in dictionaries. The major German historical dictionary, for instance, defined wisdom as "insight and knowledge about oneself and the world … and sound judgment in the case of difficult life problems." Similarly, the *Oxford Dictionary* includes in its definition of wisdom "Good judgment and advice in difficult and uncertain matters of life."

When psychologists approach the definition of wisdom, like philosophers, they are confronted with the need to specify the content and formal properties of wisdom-related thought, judgment, and advice in terms of psychological categories, and also to describe the characteristics of persons who have approached a state of wisdom and who are capable of transmitting wisdom to others. These initial efforts by psychologists for the most part were theoretical and speculative. In his pioneering piece on senescence, G. Stanley Hall, for example, associated wisdom with the emergence of a meditative attitude, philosophic calmness, impartiality, and the desire to draw moral lessons that emerge in later adulthood. Furthermore, other writers have emphasized that wisdom involves the search for the moderate course between extremes, a dynamic between knowledge and doubt, a sufficient detachment from the problem at hand, and a well-balanced coordination of emotion, motivation, and thought. In line with dictionary definitions, writings by psychologists typically refer to wisdom as knowledge about the human condition at its frontier, knowledge about the most difficult questions of the meaning and conduct of life, and

knowledge about the uncertainties of life, about what cannot be known, and how to deal with that limited knowledge.

Implicit (Subjective) Theories about Wisdom

Most empirical research on wisdom in psychology so far has focused on further elaboration of the definition of wisdom. Moving beyond the dictionary definitions of wisdom, research explored the nature of everyday beliefs, folk conceptions, or implicit (subjective) theories of wisdom. The pursuit of answers to questions such as what is wisdom?, how is wisdom different from other forms of intelligence?, which situations require wisdom?, what is a wise act?, and what are the characteristics of wise people? have been at the center of psychological wisdom research during the 1980s. These studies in principle built on research initiated by Clayton and colleagues in 1975, whose methodology to identify lay conceptions of wisdom has become fairly common among wisdom researchers. First, a sample of lay persons or experts (e.g., professors from different fields) are asked to generate a list of wisdom-related characteristics or vignettes. The resulting pool of items – or, at least, a subgroup of items that is left after terms have been screened for synonyms and redundancies – in turn, is rated by another group of individuals in terms of its wisdom-relatedness or -typicality. Subsequently, factor analytical procedures are frequently used to identify underlying dimensions of items. In Clayton and Birren's study, this procedure yielded three dimensions found to be prototypical of wise people: (1) affective characteristics such as empathy and compassion, (2) reflective processes such as intuition and introspection, and (3) cognitive capacities such as experience and intelligence. The dimensions found by Clayton and Birren still pertain today. Recently, new dimensions have been added, and characteristics have been ordered differently (see **Table 1**). For example, Bluck and Glück in their review of implicit measures drew more heavily on the distinction between real-world skills and interpersonal skills (concern for others) as opposed to capacities with a less interactive emphasis, such as cognitive ability, insight, and reflective attitude. Furthermore, results of studies on implicit notions of wisdom are heavily influenced by the initial pool of items. For example, a study by Hershey and Farrell, comprising also characteristics assumed not to be associated with wisdom, yielded one dimension labeled egotism comprising only attributes deemed as unwise. In the same vein, another study including items referring to protection of the environment or religion resulted in two additional factors that had not been identified by previous studies (see **Table 1**).

Additional dimensions of a contextual and interactive nature emerge when individuals are asked about their own experiences with wisdom (rather than describing a wise person in general), as is the case, for example, in studies on wisdom nominees. In these studies, typically, individuals are asked to name persons they consider as being wise, and potential commonalities are identified among the nominees. The most general finding of these studies is that most wisdom nominees are relatively old (i.e., around 60 years). Further criteria ascribed to wise people emerging from the nominee approach – next to those mentioned previously – were, most commonly, guidance and moral principles.

Finally one may ask the question, what is the purpose of wisdom in everyday life? Drawing on autobiographical memories and structured interviews, three forms of wisdom were identified: empathy and support, self-determination and assertion, and knowledge and flexibility. Self-determination and assertion, as opposed to the other two facets, may be recognized as an aspect of wisdom primarily when people are asked about their own life, that is, when interviewees have also access to their inner thoughts, feelings, and motivations. A similar result, that is, a focus on inner motives or the relationship between intentions and external circumstances, was found when analyzing wise acts. According to studies by Oser and colleagues, wise acts seem to be characterized by the following seven features: (1) paradoxical, unexpected; (2) morally upright; (3) selfless; (4) overcoming internal and external dictates; (5) striving toward equilibrium; (6) implying a risk; (7) striving toward improving the human condition. Hence, different approaches to the study of implicit notions of wisdom yield findings that supplement and enrich the results from other studies.

From this research on implicit theories of wisdom and wise persons, it is evident that people in Western samples hold fairly clear-cut images of the nature of wisdom. What about other cultures? Do similar conceptions of wisdom arise when investigating participants in non-Western cultures? Along these lines, Takahashi and Bordia compared implicit definitions of wisdom among young adults from the United States, Australia, India, and Japan. They interpreted their findings to mean that the association between wisdom and cognitive variables pervasive to findings collected in Western samples is perceived as less important in East Asian cultures, in which characteristics such as aged, experienced, and discreet are perceived as pivotal for wisdom. Additionally, the

Table 1 Implicit theories of wisdom: a comparison of findings from five studies with sample items[a]

Clayton (1976)	*Sternberg (1986)*	*Holliday and Chandler (1986)*	*Hershey and Farrell (1997)*	*Jason et al. (2001)*
Affective (1) Empathy Compassion	Sagacity (2) Concern for others Considers advice Perspicacity (6) Intuition Offers right and true solutions	Interpersonal skills (4) Sensitive Sociable Judgment and communication skills (2) Is a good source of advice Understands life	Egotism, inverse (2) Extravagant Presumptuous Perceptive judgment (1) Sincere Fair Thoughtful	Warmth (2) Compassion and warmth for others Kindness
Reflective (2) Intuition Introspection	Judgment (4) Acts within own limitations Is sensible	Social unobtrusiveness (5) Discreet Non-judgmental	Basic temperament (3) Withdrawn Reflective	Harmony (1) Good judgment Experiences an underlying unity in life
	Learning from ideas and environment (3) Perceptive Learns from mistakes	Exceptional understanding as based on ordinary experience (1) Has learned from experience Sees things in a larger context		
Cognitive (3) Experience Intelligence	Reasoning ability (1) Good problem-solving ability Logical mind Expeditious use of information (5) Experienced Seeks out information	General competence (3) Intelligent Educated		Intelligence (3) Intelligence Problem-solving ability
				Connecting to nature (4) Reverence for nature Childlike wonder and awe Spirituality (5) Feels love, fellowship, or union with god Living a spiritual life

[a] Sequence of factors or dimensions obtained in original research is given in parentheses. Studies are based on different methodologies (factor analysis, multidimensional scaling).

association of wisdom with experience and practical knowledge was found to be stronger in Asian than in Western samples.

When summarizing findings on how people across different cultures view wisdom, wise people, and wise acts, five findings seem especially noteworthy. First, in the minds of people, wisdom seems to be closely related to wise persons and their acts as carriers of wisdom. Second, wise people are expected to combine features of mind and character and to balance multiple interests and choices. Third, wisdom carries a very strong interpersonal and social aspect with regard both to its application (advice) and the consensual recognition of its occurrence. Fourth, wisdom exhibits overlap with other related concepts, such as intelligence, but in aspects like sagacity, prudence, and the integration of cognition, emotion, and motivation, it also carries unique variance. Fifth, it seems to make a difference whether one conceives of one's own wisdom or describes that of another prototypical person.

Explicit Theories and the Assessment of Wisdom

A more recent line of empirical psychological inquiry on wisdom addresses the question of how to measure

behavioral expressions of wisdom. Although wisdom frequently is considered to defy any attempts of scientific identification, research on explicit theories of wisdom has shown that it is possible to measure wisdom in terms of personality characteristics (standardized or open-ended), characteristics of adult thought, and performance (judgment, advice) on difficult life tasks.

The various lines of work can be subsumed under two main headings, namely, personal wisdom and general wisdom. This distinction is loosely related to the philosophical separation between the ontology of the first and the third person. The ontology of the first person indicates insight into life based on personal experience. In contrast, the ontology of the third person refers to the view of life that is based on an observer's perspective. In loose analogy to Searle's first-person perspective, personal wisdom refers to a person's insight into his or her own life: what does a person know about him- or herself, his or her life? Analogous to the third-person perspective, general wisdom is concerned with insights into life in general. What does an individual know about life from an observer's point of view, that is, when she or he is not personally concerned? For instance, your general wisdom is tapped if a friend comes to you because his or her marriage is in a deep crisis and he or she is considering divorce. But it takes your personal wisdom if you are searching for a solution because your own marriage is in a deep crisis and you are considering divorce.

The distinction between personal and general wisdom might be helpful when trying to settle some of the ongoing debates in the field of wisdom research. For heuristic purposes, **Table 2** assigns many of the extant approaches in research on wisdom to either a personal wisdom or a general wisdom perspective. Note that this categorization is sometimes difficult to make because the original authors do not describe their notion of wisdom along the distinction between personal and general wisdom. Consequently, the assignment is based on inferences on the authors' behalf and is made according to the relative emphasis placed on either personal or general wisdom.

The two types of wisdom are usually related to different research traditions. The approaches primarily geared toward personal wisdom are usually based in the tradition of personality research and personality development. Wisdom in this perspective describes the mature personality or the endpoint of personality growth (e.g., Erikson or Ryff). Thinking about wisdom from this vantage point clearly reveals a close link to research on coping. The approaches primarily investigating general wisdom typically have a stronger connection with the historical wisdom literature (i.e., wisdom as sound advice) and an expertise approach to the study of wisdom (e.g., Berlin wisdom paradigm, Sternberg's balance theory of wisdom).

The distinction between personal and general wisdom also is relevant when exploring the ontogenesis of wisdom. First, there is reason to assume that it is the dynamic between personal and general life insight that is at the heart of eventually attaining wisdom. Decades of research on self-regulation as well as research on the therapeutical process have demonstrated that it is much more difficult to obtain insight into one's own life than into the difficulties and problems of others. Thus, general wisdom might be less difficult to attain than personal wisdom, and therefore the final attainment of the former may precede that of the latter in ontogenesis. Certainly, in the course of ontogeny, that is, in working toward general and/or personal wisdom, both types may alternate in taking the lead. We do know, however, from research on the development of the self-concept that the infant appropriates general knowledge about the world before she or he is able to acknowledge the self. From research on the self later in ontogeny, we have learned that self-related information is processed differently than general information, showing, for example, in a biased processing of

self-referent information, which indeed may hinder the development of personal wisdom. Furthermore, it is conceivable that individuals who have attained personal wisdom do not have the ability and/or the motivation to think about life problems beyond their own specific circumstances or are lacking the ability to give advice. As a consequence, we expect that finding both personal and general wisdom in one person is a very rare event. As a prerequesite, however, to test the coincidence and different trajectories of the two types of wisdom, they need to be conceptualized and measured independently of each other.

Approaches to General Wisdom

Various approaches to general wisdom can be distinguished, one of which is the cultural-historical analysis of wisdom mentioned previously. Cultural-historical work concerning the origins of religious and secular bodies of wisdom-related texts has revealed a common core of defining features of wisdom that seems to reflect the notion of general wisdom more than that of personal wisdom. According to this analysis conducted by Paul Baltes, the common core of wisdom is the following: (1) wisdom comprises knowledge with extraordinary scope, depth, measure, and balance; (2) it addresses important and difficult questions and strategies about the conduct and meaning of life; (3) it includes knowledge about the limits of knowledge and the uncertainties of the world; (4) it represents a truly superior level of knowledge, judgment, and advice; and (5) it is easily recognized when manifested, though difficult to achieve and to specify. Note that in this analysis personality characteristics are not mentioned as a defining feature common to wisdom across cultures and historical time.

Within psychology, different approaches to general wisdom are distinguished, such as wisdom as postformal thought in the Neopiagetian tradition, Sternberg's balance theory of wisdom, and the notion of wisdom as expert knowledge in the Berlin wisdom paradigm. In the following, these conceptions of wisdom are discussed in more detail.

Informed by the Piagetian tradition of studying cognitive development, several investigators have proposed a postformal stage of adult thinking and related this stage to mature thought or wisdom. In theories of postformal thought, wisdom is conceptualized as increasingly complex and dialectic thinking. Criteria of postformal thinking include awareness of multiple causes and solutions, awareness of paradoxes and contradictions, and the ability to deal with uncertainty, inconsistency, imperfection, and compromise. Pivotal for postformal thinking is the transcendence of the universal truth criterion that characterizes formal logic – a tolerance of ambiguity created by an acceptance of multiple truths. In this approach, little attention has been paid to the need for bounded relativity.

Empirical research in the field of Neopiagetian conceptions of wisdom has addressed, for example, the relationship of postformal stages of development with social cognition. For example, postformal thinkers demonstrated a tendency to show less of an actor-observer effect (i.e., situational causes are held responsible for one's own behavior and dispositional factors for others' behavior) and higher levels of moral reasoning than non-postformal thinkers. It was also found that positive mood induction and relaxation improved postformal operations, whereas focusing attention had detrimental effects. In sum, it might be concluded that wise thinking in the Neopiagetian sense is related to a tolerant and open-minded attitude, which is also characteristic of one of the big five personality dimensions, that is, openness to experience. Plus, it seems easier to think wisely when being relaxed and in a positive mood.

In Sternberg's approach, wisdom is related to both practical and academic intelligence. Academic intelligence provides a necessary but by no means sufficient basis to wisdom-related functioning. But wisdom also involves the application of tacit knowledge, which is the key aspect of practical intelligence. Tacit knowledge is action-oriented (procedural) knowledge that is usually acquired without direct help from others (rather by role modeling) and that allows individuals to achieve goals that they personally value. In contrast to practical intelligence, however, wisdom by definition is oriented toward a balance between self-interest, the interests of others, and other contextual interests to achieve a common good. This balancing is the key aspect of Sternberg's theory of wisdom. The output of wisdom typically is a piece of advice. Wisdom is assessed by presenting people with problems that involve solutions that maximize a variety of intrapersonal, interpersonal, and extrapersonal interests.

A wise person in this sense is comfortable with ambiguity, in contrast to a conventionally intelligent person, who considers ambiguity as something to be resolved, and in contrast to a creative person, who can tolerate ambiguity but is uncomfortable with it. Also, when managing obstacles, the wise person tries to understand the problem and its implications for self and others. The wise person endorses a judicial thinking style, that is, she or he always

tries to understand why, rather than judging whether something is good or bad. Also related to the area of personality is the assumption that a wise person is highly motivated to seek the common good.

In the Berlin wisdom paradigm, wisdom is defined as expertise in the fundamental pragmatics of life. The fundamental pragmatics of life refer to deep knowledge and sound judgment about the essence of the human condition and the ways and means of planning, managing, and understanding a good life. Expert knowledge in fundamental pragmatics of life can be described according to five criteria. The first criterion, factual knowledge, concerns knowledge about such topics as human nature, life span development, variations in developmental processes and outcomes, interpersonal relations, and social norms. The second criterion, procedural knowledge, involves strategies and heuristics for dealing with the meaning and conduct of life, for example, heuristics for giving advice and ways to handle life conflicts. Additionally, a wise person should show life span contextualism, that is, consider life problems in relation to the domains of life (e.g., education, family, work, friends, leisure, the public good of society) and their interrelations and to put these in a lifetime perspective (i.e., past, present, future). Relativism of values and life priorities is another criterion of wisdom. This means to acknowledge and tolerate interindividual differences in values, as long as they are geared toward optimizing and balancing the individual and the common good. The last criterion, the recognition and management of uncertainty, is based on the idea that human beings can never know everything that is necessary to determine the best decision in the present, to perfectly predict the future, or to be 100% sure about why things happened the way they did in the past. A wise person is aware of this uncertainty and has developed ways to manage it.

To elicit and measure wisdom-related knowledge and skills, the Berlin group of wisdom researchers has presented participants with difficult life dilemmas such as the following: imagine a good friend of yours calls you up and tells you that she can't go on anymore and has decided to commit suicide. What would you be thinking about, how would you deal with this situation? Participants are then asked to think aloud about the dilemma. Their responses are recorded on tape and later transcribed. To quantify performance quality, a select panel of judges, who are extensively trained and calibrated, evaluates the protocols of the respondents in light of the five wisdom-related criteria using seven-point scales. The obtained scores are reliable and provide an approximation of the quantity and quality of wisdom-related knowledge and skills of a given person. When using this wisdom paradigm to study people who were nominated as wise according to nominators' subjective beliefs about wisdom, wisdom nominees received higher wisdom scores than comparable control samples of various ages and professional backgrounds.

Part of the Berlin paradigm also is a general framework outlining the conditions for the development of wisdom as it is instantiated in persons. The model presents a set of factors and processes that need to cooperate for wisdom to develop. First, there are general individual characteristics, such as intelligence and personality. Second, the model presumes that the development of wisdom is advanced by certain expertise-specific factors, such as a strong motivation to find out about life, practice with difficult life situations, and being guided by a mentor. Third, the model implies the operation of macro-level facilitative experiential contexts. For instance, certain professions and historical periods are more facilitative than others. Further, certain social-cognitive processes (life planning, life management, and life review) are assumed to be critical for the development of wisdom-related knowledge and judgment.

The empirical work based on this ontogenetic model and the measurement paradigm produced outcomes consistent with expectations. Contrary to work on the fluid mechanics of cognitive aging, older adults perform as well as younger adults. It seems that wisdom-related knowledge and judgment emerges between the ages of 14 and 25 years. Furthermore, when age has been combined with wisdom-related experiential contexts, such as professional specialization specifically involving training and experience in matters of life (e.g., clinical psychology), higher levels of performance were observed. In line with the historical wisdom literature, which portrays wisdom as the ideal combination of mind and virtue, it was found that wisdom-related performance is best predicted by measures located at the interface of cognition and personality, such as a judicious cognitive style, creativity, and moral reasoning. Neither intelligence nor personality independently of each other made a significant contribution to wisdom-related knowledge and judgment. When it comes to emotional experiences, general wisdom as measured according to the Berlin wisdom paradigm has been shown to be negatively related to both positive (e.g., happy, cheerful) and negative affect (e.g., angry, afraid) but positively with affective involvement (e.g., interested, inspired). This relational pattern suggests that wisdom might go along with a more realistic, less self-enhancing, and less positively biased view on life but at the same time

with better skills of coping with negative emotions. Furthermore, in line with implicit notions of wisdom, wisdom-related performance is positively related to the endorsement of values referring to personal growth, life insight, societal engagement, the well-being of friends, and ecological protection. Wisdom-related knowledge and judgment have also been found to demonstrate plasticity. In two intervention studies, Staudinger and co-workers found that either by providing for a certain type of social performance context or by teaching a specific knowledge search strategy, wisdom-related performance was significantly increased.

Approaches to Personal wisdom

When we turn from conceptions of general wisdom to those of personal wisdom, two other notions come to mind: maturity and personal growth. Influential conceptions of personal wisdom can be found in clinical, personality, and developmental psychology. However, only a selection can be discussed here, namely, some approaches in the tradition of wisdom as a personality characteristic (e.g., Webster), Loevinger's concept of ego development, and Labouvie-Vief's dichotomy of affect complexity and affect optimization, along with a conception of personal wisdom that has been designed in analogy to the Berlin wisdom paradigm and an operationalization of personality growth that is based on the maturity of the self-concept.

In the attempt to capture the characteristics of wise persons rather than those of wise thought and knowledge, Webster developed the self-assessment wisdom scale (SAWS), which assesses five dimensions of wise individuals: emotional regulation, reminiscence and reflectiveness, openness to experience, humor, and experience. In line with expectations, the SAWS scores have been shown to correlate with measures of generativity and ego integrity. Furthermore, no significant age differences were found. Preliminary evidence on the convergent validity of the SAWS seems to indicate that the scale measures something like personal wisdom. However, it remains unclear whether these predictive relationships are mediated by standard measures of personality and intelligence and to which degree the results of the SAWS are distorted by social desirability.

It was Loevinger's ambition to capture character development in a stage model following the Piagetian model of cognitive development. Loevinger conceived the stages of ego development as a successive progression toward psychological maturity, unfolding along the four dimensions of impulse control, interpersonal style, conscious preoccupations, and cognitive styles. The model comprises eight stages (impulsive, self-protective, conformist, self-aware, conscientious, individualistic, autonomous, integrated) that are characterized by increasingly mature forms of those four dimensions. Most people are categorized to be in the third to fifth stages, that is the conformist, self-aware, and conscientious stages. The eighth stage, the integrated stage, is rarely observed in random samples. Ego development is measured by a sentence completion task.

With regard to predictive validity, ego level has been found to be positively related with ego resiliency, interpersonal integrity, and regulation of needs, or mastery of socioemotional tasks and impulse control, as well as indicators of mental health. Interestingly, ego level is also positively correlated with number of lifetime psychiatric visits and regular psychotherapeutic sessions. It is unclear, however, whether psychotherapy helped subjects to advance developmentally or whether later-stage capacity to see ambiguities in life increased their willingness to seek psychotherapy. The latter interpretation is in line with the positive quadratic relation between neuroticism and ego level (i.e., higher neuroticism at low and high ego levels) and a negative quadratic relation between conscientiousness and ego level (i.e., lower conscientiousness at low and high ego levels). Openness to experience, extraversion, and agreeableness show positive linear relations with ego level. Finally, chronological age is unrelated to ego development.

In sum, this pattern of results revolving around Loevinger's measure of ego development suggests that moving beyond the given, seeing reality more clearly, and transcending extant social norms, central features of wisdom, do not come without costs. It seems that being faced with the complexities of one's own life in the way it is true for a person at high levels of ego development does not always lead to greater happiness but also to greater concern and doubt, as well as to the insight that further self-development is needed (I know that I don't know).

Combining the cognitive theory of Piaget with psychoanalytic notions and ideas from adult attachment theory, Labouvie-Vief designed developmental models of self as well as emotional understanding. Building on this earlier work, Gisela Labouvie-Vief in her most recent publications has focused on the development and/or maturation of self- and affect regulation. In this latest approach, she has developed a notion of growth or maturity that combines affect optimization (AO), "the tendency to constrain affect to positive values," with affect complexity (AC), "the amplification of affect in the search for

differentiation and objectivity" (Lebouvie-Vief and Medler 2002:571). In this notion of maturity, it is crucial that the search for complexity and differentiation is combined with or better constrained by a search for optimizing positive affect in any given situation. At the same time, the search for positive affect is guarded by the ability to experience events and other persons in an open and differentiated fashion. Combining the two (dichotomized) dimensions of AC and AO results in four personality types.

Labouvie-Vief and Medler could show that these four types are related in a predictable and systematic manner to a variety of indicators of psychological functioning and chronological age. For example, those with high levels on both AC and AO are characterized by high ego levels, high intelligence, and adaptive coping patterns, excluding repressive or regressive strategies. In contrast, across the different indicators, such as intelligence, affect regulation, coping, and personality, those individuals with low levels on both dimensions demonstrate the lowest levels of functioning.

Another method to measure personal wisdom has been developed along the lines of the Berlin general wisdom paradigm. Five criteria have been defined to index personal wisdom that are based on the literature on personality development. The first criterion is rich self-knowledge, that is, deep insight into oneself. A self-wise person should be aware of his or her own competencies, emotions, and goals and have a sense of meaning in life. The second criterion requires of a self-wise person to have available heuristics for growth and self-regulation (e.g., how to express and regulate emotions or how to develop and maintain deep social relations). Humor is an example of an important heuristic that helps one cope with various difficult and challenging situations. Interrelating the self, the third criterion, refers to the ability to reflect on and have insight into the possible causes of one's behavior and/or feelings. The fourth criterion is called self-relativism. People high in self-relativism are able to evaluate themselves as well as others with a distanced view. They critically appraise their own behavior but at the same time display a basic acceptance of themselves. They also show tolerance for others' values and lifestyles – as long as they are not damaging to self or others. Finally, tolerance of ambiguity involves the ability to recognize and manage the uncertainties in one's own life and one's own development. Personal wisdom is measured by first using a thinking-aloud and subsequently a rating procedure.

In a first study, the new measure of personal wisdom showed good convergent validity. It was positively correlated with other measures of personality growth, such as Ryff's personal growth and purpose in life and Loevinger's ego development, as well as with benevolent values. With regard to discriminant validity, it was demonstrated that personal wisdom, as to be expected for a measure of personal maturity, was uncorrelated with notions of well-being and adjustment, such as life satisfaction, negative or positive emotions, and adaptive motives such as power, achievement, and hedonism. Also, personal wisdom is not preempted by knowing a person's intelligence. As far as the relationship with personality variables is concerned, openness to experience was the most important predictor – of the other big five variables, none showed significant correlations with personal wisdom. Psychological mindedness, a concept measuring interest in thoughts and feelings of other people, however, was positively correlated with personal wisdom.

As a theoretical background for the construction of yet another measure of personal wisdom, the literature on the self-concept as well as on personality growth was reviewed. Five self-concept facets were identified as theoretically meaningful indicators of personal wisdom, namely, complexity of content, self-concept integration, affect balance, self-esteem, and value orientation. It was hypothesized that only by combining these five components could one arrive at an appropriate operationalization of personal wisdom. That is, a profile of the five self-concept facets was established that should serve as a prototype of a mature personality as reflected in the self-concept or self-concept maturity (SCM). As hypothesized, SCM correlated strongly and significantly with other measures of personal wisdom, especially with Loevinger's ego development and the newly developed personal wisdom task presented previously, whereas no significant associations existed with chronological age.

Conclusion and Future Directions

The concept of wisdom represents a fruitful topic for psychological research: the study of wisdom emphasizes the search for continued optimization and the further evolution of the human condition, and in a prototypical fashion, it allows for the study of collaboration between cognitive, emotional, and motivational processes. We expect that future research on wisdom will be expanded in at least three ways: (1) the further identification of social and personality factors and life processes relevant for the ontogeny of wisdom, (2) the exploration of wisdom as a meta-heuristic aimed at orchestrating mind and

virtue toward human excellence, and (3) the differentiation between personal and general wisdom outlined in this article might contribute to building a psychological art of life.

Work and Employment: Individual

J N Cleveland, The Pennsylvania State University, PA, USA
L M Shore, San Diego State University, San Diego, CA, USA

Glossary

Age Discrimination in Employment Act (ADEA) – US Congressional legislation passed in 1967 and amended in 1978 and 1986 that protects workers age 40 years and older from unfair discrimination at work.

Age Stereotypes – Generalized beliefs about the characteristics of older people.

Downsizing – The systematic reduction of employees and possibly occupational areas within an organization.

Equal Employment Opportunity Commission (EEOC) – A regulatory agency with the responsibility of enforcing discrimination laws concerning the workplace.

Functional Age – Performance-based measures of age that are based on the premise that there is great individual variability in abilities and functioning at all ages.

Psychosocial Age – Measures of age based on social perceptions of the individual including perceptions of the characteristics of the individual and self-perceptions of age.

Introduction

Today's workforce differs substantially from that of the past. The workforce is more diverse, with more women, more ethnic and racial representation, and more older workers. In the United States, as in other

countries, four forces combine to cause an aging workforce. First, there are a large number of older employees in society and in the workplace reflecting the baby boomer generation. Second, the incoming generation of younger work cohorts (labeled the baby bust generation) is few in number. Third, the proportion of older workers delaying retirement has been increasing since the mid-1990s due to a loss of retirement security and mandatory retirement age. Finally, due to an increase in concerns about age discrimination, especially within the United States, more organizations focus on retraining and retaining older workers rather than trying to outsource them.

Researchers increasingly have investigated the relationships among worker age and important work processes and outcomes, including unemployment, hiring, performance appraisal, work attitudes, career characteristics, turnover, absence and terminations, and discrimination. This article examines issues concerning older workers as they seek employment, secure employment within the organization, work within the organization, and exit the paid employment domain. Before these employment issues are explored, however, a brief discussion is presented on the meaning and measurement of age in work-related research. This discussion is important because the information accumulated on older workers is based on research using chronological age, yet chronological age is only one assessment of how 'old' a person is. Finally, the article presents a brief overview of the theoretical developments in this area.

Conceptions of Age

The study of aging and work, specifically, industrial gerontology, examines issues concerning the employment and retirement of middle-aged and older workers. A continuing problem in the field of industrial gerontology is the lack of an agreed-upon definition for mature and older workers. One reason for the difficulty in securing an adequate definition is that aging is a multidimensional process that is difficult to embrace in a single definition or measure. This section discusses four approaches to defining the older worker's age: (1) chronological or legal, (2) functional, (3) psychosocial, and (4) organizational. It is important to keep in mind, however, that each of these approaches to conceptualizing age can be categorized into two general groups: person-based measures and context-based measures of age. Person-based measures focus chiefly on the age characteristics of the individual, whereas context-based measures incorporate aspects of the work situation and often reflect comparisons among persons in the situation.

Chronological or Legal Age

Chronological or legal age is the most widely used person-based measure in research on older workers. The US Age Discrimination in Employment Act (ADEA) of 1967 and amended in 1978 and 1986 protects workers over the age of 40, reflecting the fact that job openings may be disproportionately barred to applicants 40–45 years, and more so for applicants over 55. Two individuals with the same chronological age may vary in terms of the subjective meaning that age has for them. For example, an individual's interpretation of his or her age may reflect perceptions of health, appearance, energy, and so forth.

Functional Age

Another largely person-based age measure is functional age. Functional age is a performance-based definition of age that is based on the premise that there is great individual variation in abilities and functioning at all ages. As chronological age increases, individuals change both biologically and psychologically, including declines in abilities and increases in experience and judgment. The concept of functional age has been criticized on a number of grounds, with a major limitation being the use of a single index and the assumption of decline with increasing chronological years. Even when there are measurable age-related functional changes, these changes may not translate to performance decrements in any particular job.

Psychosocial and Organizational

Psychosocial definitions of older workers are based on social perceptions of the individual, including stereotypic perceptions of older workers and self-perceptions of age. These perceptions may depend in part on the age type of the job that one holds or the age composition of the work group. These approaches are discussed together because both include largely context-based definitions of age; they vary perhaps in terms of unit of focus (i.e., the psychosocial approach is a more individual unit of analysis, whereas the organizational approach may use the group or organization as the unit of analysis).

Industrial gerontologists have suggested that the older worker should be examined in relation to the work context. The work context includes characteristics of the group, age perceptions of self compared to work group members, age perceptions of self compared to one's supervisor, and age perceptions of self compared with typical ages within a given occupation or career path.

There is evidence that context-bound measures of age can predict such work outcomes as self- and manager-rated performance, manager-rated promotability, perceptions of organizational support, and self- and manager-rated on-the-job training. Furthermore, differences in the ages of supervisors and subordinates have been used to predict work outcomes. The similarity-attraction model has been used to conceptualize the impact of differences in age between the supervisor and the subordinate. Although empirical studies provide little support for this paradigm (e.g., similarity of supervisor and subordinate age had no effect on performance ratings, manager's liking of the subordinate, employee attitudes, or propensity to quit), others have argued that age differences between the supervisor and subordinate are most important when they defy social norms (e.g., when the subordinate is older than the manager). Furthermore, support for age as defined by the specific organizational context has been found in research on age norms. For example, performance ratings are higher for managers who are viewed as younger than the perceived typical ages of individuals at that career stage and lower for managers who are seen as older than the 'norm' for that career stage. In general, men who are 'behind schedule' (older than the norm) with respect to schooling, marriage, and job entry are more likely to have lower overall career earnings than men who are on schedule (or similar to the normative age group).

The key factor to keep in mind when defining older workers is that they are often people who are substantially younger than the subjects in more typical gerontological research. Typically, older workers include individuals who are 45, 50, 60, 65, or perhaps 70 years old. In gerontological research, 'older' populations might be 80–100 years old, and are likely to have been out of the workforce for several decades. Therefore, in the discussion of age and work outcomes, employees that might be considered older can range from 40 to over 75 years old.

Entry into Employment

Job Search and Unemployment

During 2002 in the United States, there were approximately 17 700 layoffs, which resulted in almost 2 million claims for unemployment compensation insurance. Although more individuals between 25 and 45 years were unemployed, the average length of time of unemployment was longer for older individuals than for younger individuals (mean = 18 weeks for those over 54 and 12.7 weeks for 25- to 34-year-olds). Little research has been done on job search behaviors of older workers. It is generally assumed that older workers are less likely than younger workers to search for alternative employment if they are presently employed. This is consistent with research showing lower turnover intentions for older workers. Age is viewed as one factor affecting marketability, which influences a candidate's likelihood of seeking jobs. Interestingly, recent research on employed managers showed that age had little impact on job search behavior, whereas job satisfaction, compensation, and perceptions of organizational success were negatively related to job search behavior. This suggests that it is working conditions, not age, that influences job search behavior. Furthermore, research suggests that age does not influence the type of recruitment sources used. Both young and old people are most likely to use newspaper ads.

Hiring and Selection Practices

Research investigating the impact of age on hiring decisions has chiefly focused on issues pertaining to discrimination. Of particular interest is when and if older workers are discriminated against in hiring. Research findings have been quite varied, perhaps due in part to the nature of the samples employed. Meta-analyses of laboratory studies on age and selection show no significant age effects when raters evaluated either a younger or an older applicant. However, when raters evaluated both a younger and an older applicant, younger applicants were rated as more qualified.

Simulation studies using actual workers have also produced varied results. One study showed that young applicants were recommended for hire more often than old applicants. Other studies suggest that factors such as competence and job status moderated age effects; qualified older applicants fare well in high-status jobs.

Studies of actual hire decisions have also shown inconsistent results. One study showed that older applicants received lower hiring recommendations and were rated lower in intelligence than younger applicants. A second study showed that age correlates positively with interview scores, suggesting that older applicants were preferred over younger applicants. However, the latter sample was fairly young (most applicants ranged from 21 to 30 years old), raising questions of generalizability. A final study examined similarity in age between the interviewer and applicant and found that age similarity had no impact on the interview outcome.

All three types of subject samples reviewed showed mixed results in terms of age bias in hiring decisions. A number of possibilities emerge to explain the mixed

findings. First, student subjects and working subjects react somewhat differently to older and younger applicants, particularly in relation to jobs of varying status. This may be due to the differences in the ages of subjects, or difference in work experience. Second, several studies showing age bias had subjects compare old and young applicants with identical qualifications. The design of these studies may actually contribute to age bias effects because subjects may assume that a young person with equal qualifications to an older person is more competent, having reached the same skill level at a younger age. A third possibility is that characteristics of the job in terms of age stereotyping may be at work. A number of studies suggest that jobs are typed in terms of whether they are appropriate for young, middle-aged, or older workers. This age typing in turn affects the treatment of older workers. However, this issue has not been systematically investigated in prior studies of hiring. Finally, the age composition of the applicant pool appears to have an impact on the hiring process, such that older workers are more likely to be hired when other older workers are already in the applicant pool.

Experiences in Organizations

Age and Job Performance

Considerable research in both lab and field settings indicates that job performance does not decline with age. However, there are a number of issues to consider in this research. The first is the definition of the domain of performance. Performance measures used in this research include supervisory ratings, productivity indices and other objective measures (e.g., sales volume), turnover, and absenteeism. There is some indication that the age–performance relationship varies with the type of performance measure used. Further, in recent meta-analyses, a number of problems have been identified with research linking age and job performance, including the following: (1) few studies include workers older than 60 years of age; (2) research designs are cross-sectional; (3) longitudinal research suggests a non-linear relationship with age; (4) age–performance relationships are influenced by occupation; and (5) there are relatively few studies and these often have small sample sizes.

Physical capacity, which refers to outcomes of coordinated activity among major components of the motor system involved in carrying out work, begins to show a decline in middle age. Declines are most noticeable in tasks involving perceptual or psychomotor speed. However, each individual will experience performance declines at different ages, and most often these declines are gradual. Declines in physical capacity should be examined on an individual basis, because they may not translate into any perceptible interference with the essential activities of the job (*see* Motor Control; Perception).

Any modest relationship found between age and performance may be better understood as a relationship between job knowledge and job performance. Some industrial and organizational psychologists have suggested that job incumbents acquire most of the job knowledge needed for successful performance during the first several years on the job. Individual differences in job experience may be associated with significant differences in job performance, especially during the first few years. After a while, however, job experience makes diminishing contributions to job knowledge and thus job performance. Small differences in job experience among younger workers may translate into large differences in job knowledge and job performance. Therefore, among younger workers, age differences will be related to differences in job performance; but as additional job experience contributes little incremental job knowledge, the amount of new job knowledge gained each year becomes less and less such that, overall, age has a weak relationship with job knowledge and little or no relationship with job performance.

Laboratory studies of task performance and age have shown age-related sensory deficits across a wide range of psychological functions, including peripheral and motor mechanisms, memory, and information processing. With complex or demanding tasks, such as in multisource monitoring, older people tend to be particularly disadvantaged. Although it might be expected that older individuals would perform less well on more complicated real-world tasks, the assessment of age effects in occupational settings involves considerable methodological problems. These methodological deficiencies include a lack of reliability and comparability of performance measures across age groups, selective attrition of subjects with healthier ones surviving, and selection biases (*see* Attention; Memory).

Accidents Although research results are mixed, the most common finding is that accident rates are lower among older workers compared to workers aged 24 and 25 to 44 years. However, research has also found a positive age–accident relationship, as well as an inverted-U, U-shaped, or non-significant age–accident relationship. Moderators of this relationship include sex and type of occupation. Accident rates are generally lower for women and higher for blue-collar work (blue-collar jobs account for 70% of all injuries and are eight times riskier than white-collar occupations). Older employees who occupy

jobs normally held by younger workers incurred more accidents than their younger counterparts.

Although older workers may experience lower rates of injury, they generally lose more time per injury than younger workers. The severity of injury may increase with age and may require a longer time to recover. An injury is also more likely to result in a permanent disability for older employees. Deaths due to accidents also increase with age.

Absenteeism

Absenteeism is one form of withdrawal behavior (turnover is the other) that can be costly both to the organization and to individuals. Meta-analyses of the relationship between age and absenteeism showed significant results that depended upon the type of absence measure used. Absence frequency is a measure of avoidable absence, whereas absence duration is a measure of unavoidable absence. Absence frequency is negatively related to employee age; research findings for unavoidable absences are mixed. Recent research suggests that employee age interacts with employee sex for both avoidable and unavoidable absenteeism behavior. Females show a stronger negative relationship between age and time lost than males, whereas males show a negative relationship between age and frequency of absences and females show a positive relationship. Older female employees are more likely to have frequent absences, but are less likely to have a number of consecutive days absent from the workplace compared to male employees. Although multifactor models have been proposed and tested for understanding absenteeism, age itself is thought to be a weak predictor of attendance. Furthermore, with increasing numbers of women in the workforce, career, dual-career, and family issues need to be considered and incorporated into these models.

Age and Training

As the average age of workers increases, the issue of training older workers becomes more important. Research suggests that the relationship between age and success in training depends on both the context of training and the specific criteria used to define success. Age has the greatest influence when the content is novel (e.g., computer use) and the criterion for success is speed in completing training.

Several decades of research on the effectiveness of training interventions with workers of various ages have been carried out. Older workers learn less quickly than their younger counterparts. However, if work procedures remain unchanged for long periods of time, the age difference in mastery time becomes trivial. In rapidly changing occupations that require frequent training in new work methods, older workers may be more costly to the employer and less productive than younger workers (*see* Learning).

Laboratory samples showed consistently larger age differences in training performance than field samples. There are two methodological issues that may exaggerate the actual age differences in training. First, designs typically employed in age training research are extreme group designs. The performance of a younger group of employees (i.e., 23 years old) is compared with a significantly older group (i.e., 55 or 60 years old). Although designs of this kind may accurately assess the difference between the groups, it may exaggerate the degree of the relationship between age (as a continuous variable) and training performance. Second, there may be a bias in the selection of tasks in the lab so as to maximize the possibility of finding large age differences. In the field with real-world tasks, there is more variation in tasks as well as the possibility that practice and experience can counter age-related decrements.

Age and Work Attitudes

An extensive review of the work attitude literature indicates that consistent age-related differences exist in a number of attitudes. Overall job satisfaction has consistently been shown to be positively (but weakly) related to age. This relationship may be moderated by occupation. Human services and white-collar jobs had the strongest relationships between age and job satisfaction, whereas in factory, clerical, and teaching jobs, there appears to be no relationship between age and job satisfaction. In addition, other research suggests that tenure (which is typically strongly associated with age) is a more consistent predictor of job satisfaction than age. Research on facet satisfaction shows that there is, in general, a positive relationship between age and satisfaction with the work itself, whereas studies of satisfaction with pay have produced mixed results. Furthermore, satisfaction with promotion, the supervisor, and co-workers appears to be unrelated to age. This pattern of relationships is consistent with research suggesting that job characteristics may explain the age–job satisfaction relationship in that older employees appear to obtain more intrinsic rewards (but not necessarily extrinsic rewards) out of work than younger employees.

Studies of work values suggest that there may be a positive relationship with age. Although age typically is positively related to job involvement, a number of studies suggest that age may be less important than job and organizational characteristics, as well as

individual differences in determining level of job involvement. A recent meta-analysis showed moderately positive relationships between age and both Protestant work ethic and prestige (the effect a job has on a person's social standing). However, age was not found to be related to Maslow's concept of growth need strength or autonomy.

A number of theoretical models have included age as an antecedent of organizational commitment. Two forms of commitment have been extensively investigated in the literature, including affective commitment and continuance commitment. For affective commitment, it is assumed that as employees age, they become increasingly attached to the organization and their identification with the employer increases. In contrast, for continuance commitment, age is viewed as a factor that constrains future employment options due to non-portable investments in the organization. This makes leaving more costly, leading to higher levels of continuance commitment. A recent meta-analysis suggested that age is more strongly associated with affective commitment than with continuance commitment, but that age is not strongly related to either form of commitment.

In conclusion, although age does appear to be fairly consistently associated with overall job satisfaction and some types of work values, there is less evidence to support links between age and other attitudinal variables. In addition, there is fairly compelling evidence that even when age is associated with work attitudes, other variables, such as job and work conditions, may in fact account for these associations.

Age and Alternative Work Options and Schedules

Both older employees and management can mutually benefit from work arrangements other than the standard 40-hour schedule. Six different job arrangements have been identified in industrial gerontology that can be used effectively to accommodate the work needs of older workers and their employers. These work arrangements can be categorized into two groups: part-time work schedules and job modifications. Increasingly, organizations are experimenting with various forms of part-time employment for older personnel, including job sharing and phased retirement programs. Part-time reemployment of retirees is also an option. Job sharing usually involves two part-time employees sharing one full-time position. In this arrangement, work time is reduced, yet an older individual's expertise and experience, as well as the opportunity to mentor, continue to be available to the organization.

Phased retirement is an option for full-time employees who are 2–3 years away from retirement. In this option, employees are allowed to reduce their weekly work hours from 40 to 30 and then later to 20 hours until retirement. An individual can literally phase into retirement. This slow reduction of hours allows the organization the time to train and replace workers. Reemployment of retired workers on a part-time basis, in which the retiree is retained as a consultant or is rehired on a temporary basis, has become common in fast food industries, banks, and insurance companies. In a random sample of more than 400 organizations, approximately 25% had job sharing programs and another 25% had phased retirement programs. Nearly 50% were reemploying their retirees. These part-time work options appear to be reasonably popular methods for utilizing older personnel.

In contrast, a smaller number of organizations, for example, those within the manufacturing industry, make changes in the actual work performed by older workers. Three kinds of modifications are typically used with older employees: job design, job transfer, and job retraining. Job redesign involves either restructuring the work to be performed or reshaping the physical environment of the worker, for example, special chairs, magnifying glasses, and so forth. A number of these accommodations may fall under the 1991 American with Disabilities Act. Job transfer involves moving an older employee to a less physically or mentally demanding job. Finally, job retraining involves updating the skills of older experienced workers to keep pace with changing technology in their field. This occurs often in engineering-related fields.

Promotions, Challenging Assignments, and Career Plateauing

Most career theories include stages in which before retirement, individuals become 'obsolete' or 'deadwood' in preparation for leaving their employer. This commonly accepted view is inconsistent with the evidence that adults make many career transitions throughout their life span. Furthermore, many individuals in their 60s, 70s, and 80s continue to work and seek ways to expand their careers. Nonetheless, many organizations have strongly held belief systems about the age-related nature of careers, so that promotion and development systems are often designed for younger workers.

One factor that may contribute to lack of career development opportunities for older workers is the negative ways in which these individuals are often viewed. These negative features, however, are often viewed as essential to good performance, and organizations are likely to seek leaders with these types of attributes. Older workers are rated high in attendance,

solid performance record, and punctuality. These attributes are likely to be associated with reliable and dependable employees but also with those who may be viewed as unlikely to advance. These studies also suggest that younger workers may be seen as more appropriate for the types of challenging jobs that many employees are currently faced with in times of downsizing, mergers, and acquisitions. Longitudinal research further indicates that challenging assignments early in one's career are highly predictive of upward career mobility.

Age stereotypes may contribute to less development of older workers than younger workers. Older workers are viewed as resistant to change and are given less feedback and fewer opportunities to improve their performance. Furthermore, research suggests that the age composition of the work group may affect the degree to which older workers receive developmental opportunities. Older workers who work with other older employees are least likely to receive career counseling. In contrast, older workers are most likely to receive on-the-job training when they work with younger people. Nonetheless, older workers are much less likely than either younger or middle-aged workers to receive career counseling and on-the-job training. This shows that although age context affects the degree to which older workers receive developmental opportunities, older workers are still the least likely to receive those opportunities.

Again, age stereotypes may underlie differential performance attributions made about younger and older workers, limiting the upward mobility of older employees. Poor performance by older workers is attributed to more stable factors, such as ability, than similar performance by younger workers. In addition, job simplification is viewed as more appropriate and training (for more demanding tasks) as less appropriate for poorly performing older workers. Older employees are also viewed as causing their own career problems due to loss of motivation or complacency. Thus, differential performance attributions may also explain why older workers receive fewer developmental opportunities than younger workers.

Research on promotability suggests that age context plays an important role. Although middle-aged and older workers are viewed as most promotable when they work with people who are younger than they are, younger workers are seen as most promotable when they work with people who are older than they are. Similar findings have been shown in the performance appraisal area. Managers who are younger than most other managers at their organizational level receive higher performance ratings than those who are older than most others at their organizational level. Because performance ratings are often used in making promotion decisions, this suggests that being younger than the norm may have some distinct career advantages in terms of promotion opportunities.

The pattern of results for studies of developmental opportunities, promotability, and performance suggests that age stereotypes may adversely limit older workers' career opportunities. Age stereotypes regarding older workers' capabilities, willingness to change, and technical obsolescence surely lead to career plateauing and stagnation. Promotion denials for older employees may be more common than outright dismissals and are a frequently cited basis for lawsuits under the ADEA. However, denial of promotion based on age is more difficult to prove than an illegal dismissal. Future research is needed that addresses methods for overcoming stereotypes that limit opportunities for older workers.

Age Discrimination

Although many charges are dropped by the Equal Employment Opportunity Commission (EEOC) due to lack of evidence, some cases do make it to court. The overwhelming percentage of plaintiffs in age discrimination suits are men, especially senior white male professionals and managers. The greatest number of cases concern wrongful termination. Employees tended to lose their cases in court, possibly because in strong cases (for the plaintiff), organizations settled out of court, and employers carried through only on cases they felt sure of winning. Women were more likely than men to win their cases (64 vs. 29%), although these comparisons should be made cautiously due to the small number of women filing age discrimination claims. Regardless, there are some organizational practices that may be indicative of age discrimination, including older workers being passed over in favor of younger workers with similar credentials, being told that no openings exist when they do, being discouraged from jobs by using 'too much experience' as a proxy for age, being replaced by younger workers with the same or fewer skills, being denied opportunities to participate in training programs, being considered not promotable, being laid off before younger workers, being paid less for the same work, being demoted without just cause, and having challenging assignments transferred to other younger workers.

Exiting the Organization

Economics of Age

Many employers seem to believe that older workers are more costly (relative to their productive value)

than younger workers. There is evidence that there are age-specific costs for benefit pension plans and health insurance for active workers. Retiree health insurance plans provide a strong disincentive to hiring older workers not yet eligible for Medicare. Health costs and other compensation costs are greater for older workers despite the finding that most older workers are healthy enough to keep working longer than they do. Wages and salaries tend to increase up until age 50 or so and then level off (e.g., older workers typically earn more than younger workers). During layoffs, downsizing, and mergers, the financial savings realized by reducing the number of more highly paid older workers may be attractive for organizations in the short run. Using salary as a basis for layoff decisions has been ruled acceptable by some US courts even though it disparately impacts older workers.

Proponents of reducing the number of older workers may overlook costs associated with recruiting and training new employees. Further costs are incurred in relocating new workers, assisting spouses in finding work, and the learning curve associated with new workers adjusting to the new work environment.

Age and Turnover

Several reviews suggest that age is negatively related to turnover. However, a recent meta-analysis showed that age provides little useful information about whether an employee will voluntarily leave an organization. However, given the measurement problems associated with turnover (i.e., the wide variety of measures used), the relationship between age and turnover may be underestimated. Intentions to quit and propensity to leave have been found to be the best predictors of voluntary turnover. Older workers consistently show lower turnover intentions. Since older workers tend to have lower voluntary turnover rates than younger workers, this may actually counterbalance the greater costs of benefits. That is, greater stability of an older workforce may offset disadvantages associated with high fringe benefit costs.

Age, Job Terminations, and Retirement

Downsizing is an increasingly popular organizational strategy for reducing costs. Downsizing methods include voluntary severance programs, voluntary early retirement programs, attrition, relocation, pay and hiring freezes, and outright firing. Information is not available on the extent to which older workers are affected by downsizing relative to other age groups. However, voluntary early retirement programs, which have been a very popular downsizing method, are clearly targeted toward older groups. Many of those who take early retirement do so voluntarily, partially due to dissatisfaction with the job, supervisor, and company. Some also recognize the lack of promotion opportunities available to them and thus opt for retirement. However, others are forced to take early retirement or face the prospect of termination. Of particular concern are organizations that change performance appraisal systems or ratings to justify the desire to rid themselves of older workers. Abrupt changes in the performance appraisal system are likely to create mistrust, not only among those who are retiring, but also possibly for those who remain with the organization.

A great deal of research has focused on factors that predict retirement. These factors can be divided into three major categories: personal variables, work-related factors, and environmental factors. In terms of personal factors, the date people choose to retire is influenced by eligibility for a pension plan and their anticipated financial situation at retirement. Health is another personal variable that is related to when people retire. It has also been found that people who anticipate adjusting well to retirement are more likely to plan an early retirement. For work-related factors, a number of studies suggest that work satisfaction may influence when people retire. Unlike for younger workers, organizational commitment is not a good predictor of turnover for older workers. Overall, the evidence for work attitudes as predictors of retirement is not overly compelling. Environmental factors can include family and marital situations (being widowed or still have children in college), as well as leisure activities. Individuals with strong interests outside of work may opt to retire early in order to pursue those interests.

It is not entirely clear what the impact of retirement is on employers. Large numbers of retirements may provide more career opportunities for young people and allow organizations to hire people with up-to-date skills. On the other hand, organizations may lose critical knowledge or skill areas that older, more tenured workers provide. One study found that an early retirement program did not have a substantial effect on the firm's management talent, nor was there any indication that the most capable managers were the most likely to retire early. Moreover, it appeared that the more highly motivated managers with more positive attitudes toward their work and toward the company were less likely to retire. However, additional research is clearly needed in this area to determine whether these results generalize to other organizations (*see* Retirement).

Approaches to Understanding Age at Work

Stereotypes of Older Workers

The negative stereotypes of older workers have been documented in the industrial gerontology and industrial and organizational psychology literatures. Older workers are perceived as less efficient, less creative, less promotable, more resistant to change, slower, disinterested in training or retraining, incapable of adapting to change, undependable, costly, unable to meet the physical and mental demands of work, more rigid, and prone to illnesses and accidents. Furthermore, older workers are viewed as more passive, reserved, obsolete, and inflexible than younger workers. Some human resource managers believe that older workers have different work styles, which clash with the work style of younger workers. However, as people age, some positive characteristics are ascribed to them. For example, older people have also been described as more reliable, loyal, careful, and conscientious than their younger counterparts. Older workers are perceived to take longer and take fewer risks in decision making than younger managers. However, when risks must be taken and decisions made quickly to avoid missing an opportunity, these characteristics may be viewed as a potential negative. Although attitudes toward older workers are generally more negative than attitudes toward younger workers, the magnitude of the difference decreases as the age of the perceiver (the rater) increases. Furthermore, negative perceptions of older workers may play a greater role in some occupations than in others. Older employees in jobs typically occupied by younger persons or requiring skills associated with younger incumbents may be perceived most negatively, whereas older employees in positions occupied by or associated with older individuals may be perceived positively and in nonstereotypic terms (*see* Ageism and Discrimination).

Relational Demography Using relational demography, older workers in older workgroups and younger workers in younger workgroups should experience more positive work outcomes than individuals in workgroups that are dissimilar in age to the target employee. Relational demography draws from both the similarity-attraction paradigm and social identity theory and suggests that similarity to referent others results in favorable outcomes while dissimilarity results in unfavorable outcomes. Further, individuals categorize themselves into meaningful social categories to allow them to maintain positive self-identities. Research has shown support for relational demography when employee age relative to the workgroup has been examined.

Career Timetables The notion of career timetables suggests that age differences may have either positive or negative effects depending upon clear norms regarding where one should be on the organizational chart at a given age. For example, employees who are promoted at a rate similar to their peer group are viewed as 'on schedule' while those who are promoted more quickly are considered 'ahead of schedule' and those who are promoted less often than their peer group are considered 'behind schedule.' The latter two groups both reflect target mismatches, yet the career timetable makes very different predictions about these two groups. Managers who viewed themselves as behind schedule reported lower work satisfaction and work orientation. On the other hand, managers who were ahead of schedule received the highest performance ratings, while behind schedule managers received the lowest performance ratings.

Although the career timetable approach focused on the work group as the referent, other research supports this approach using the manager or the supervisor as the referent. That is, when employees are older than their managers, older workers received the fewest development opportunities and the lowest potential and promotability ratings.

Prototype Matching In the prototype matching approach, the individual's age is compared to the age of the typical incumbent for a given job. A number of studies support the existence of both job and occupational prototypes. This approach suggests that through a cognitive matching process, greater matches between target age and job age prototype result in more favorable selection outcomes and greater mismatches produce less favorable outcomes. Much of the empirical research on prototype matching has studied its impact on selection. More recently, research shows partial support for prototype matching for other decisions, including promotions. In general, research shows mixed support, suggesting that other contextual variables may influence the matching process.

Future Research Issues Concerning Older Workers

The aging of the population in the United States and other industrialized countries needs to be considered in future research and public policy initiatives. This trend reflects both a decline in fertility rates as well as an increased life expectancy. The large baby boom generation moves into normal retirement age between 2011 and 2030. The US Census Bureau predicts that

the present percentage of the population over 65 will rise from the current 13% to 20% in 2050 and 23% by 2100. Furthermore, recent research shows that the employment rate of 55- to 64-year-olds in many industrialized countries is somewhat low, for example, 29.9% in Italy, 38.8% in Germany, 57.7% in the United States, and 63.8% in Japan. Most initiatives to date that encourage older employee participation in the workforce appear largely motivated by economic concerns. Such initiatives are too narrow in focus, and do not consider the key stakeholders that would encourage such continued participation, including governments, employers, professional organizations, and the older workers themselves. This suggests the importance of research on age diversity in work settings, in particular, research examining predictors of age discrimination as well as the potential underutilization of older workers' skill and knowledge due to stereotypes and traditional assumptions about career progression. Furthermore, research examining retirement decision making, with particular emphasis on organizational factors that encourage or discourage retention of older workers, is needed. It is important that such research occur in the near future prior to a potentially large exodus of workers, as the research suggests little proactive efforts to date that address the retention and maximization of the productivity of older populations of employees.

Older Women

Workforce participation rates for women have increased dramatically during the last four decades. For women from 55 to 64 years, participation rates rose from the early 1940s and peaked during the late 1960s. Since the 1980s participation rates have leveled off at approximately 41.7 women in the labor force for every 100 men. In 1987, 56% of women were working, and on average, the woman was married, a mother, and had a high school education. Participation rates of women aged 65 and over reached their record highs between the mid-1950s and 1960s when they ranged from 10.2 to 10.9 for every 100 women in the population. By the mid-1980s, the participation rates drifted downward to 7.5. Furthermore, the proportion of older women who work continues to be substantially lower than the proportion of older men; the proportion who retire early is somewhat higher than for men. Thus, the typical female employee does not resemble the typical male employee. Furthermore, middle-aged and older women are a heterogeneous group in terms of skills, work life expectations, centrality and necessity of work, child-care responsibilities, and elder-care responsibilities. Some researchers have speculated that different standards of aging exist for men and women. Because women are more likely to be judged on their physical appearance than men, women are viewed more negatively as they age. In contrast, as men age, their prestige may be enhanced by increased money and power, and they are judged less on their physical appearance. Some authors have argued that these different standards for judging men and women affect women in the workplace, such that women may be devalued at work at an earlier age than men. Perhaps some of the 'glass ceiling' effects that women experience are partially due to the devaluation of women that occurs as they age. Women may have fewer career opportunities not just because of their lower status in the workplace, but also because of the way in which society views older women. Clearly, future research needs to examine the interactive effects of age and gender to determine whether men and women are treated differently as they age.

Age and Minority Status

In 1980, about 17% of ethnic minorities in the United States were over 65 years. This proportion of the population is growing more rapidly than the White population. Very little research to date has been conducted in this area. Generally, however, older minority males and females tend to be worse off economically and in terms of employment than their non-minority counterparts. With significantly increasing diversity, there is a great need for the existing and future research in this area to be highlighted and mainstreamed in major gerontological and work employment research and practitioner journals. If minorities are concentrated in occupations that require physical labor, speed, and routinization of tasks, minority employees may be at greater risk for potential negative experiences resulting from age bias. Furthermore, because lower-level employees are in the most financial need of work, once retired they are often forced (due to their age) to accept lower-paying jobs if they can find them. Women, Blacks, and Hispanics experience severe hardships because they often lack financial reserves and pension plans and find it harder to gain reemployment at an adequate wage.

Current Organizational Issues

Working in Teams In some types of work groups, there may be a generational problem for older workers. Younger groups may be better able to draw on the performance of the best individuals (e.g., the most knowledgeable) and to identify and use their members' resources. In older groups, members may be more concerned with establishing and preserving

status and leadership and avoiding looking bad to peers. Research suggests that younger people, as compared to older workers, may have more experience in group-process work and group decision making, have less concern with status and control, have less competition in a group, and are more focused on securing optimal results on the task. Furthermore, studies of older managers suggested that they were less often in teams (except in competitive situations), believed informal teams were viewed as cliques and were to be avoided, did not know much about working cooperatively, had been raised in autocratic modes of management and saw asking for or accepting help as a sign of weakness, relied on 'experts', and even when committed to teamwork, lacked the skills needed to make it work. Given the trends toward approaching work using teams of people, this research suggests that older workers who are expected to operate in and contribute to group activities may need to be trained or counseled in how to be effective group members.

Unfortunately, research on the role of mixed age groups on team work is quite limited. However, it could be argued that the knowledge and experience of older workers, along with the team orientation of younger workers, if effectively managed through various organizational interventions (e.g., training and coaching), along with team-based compensation, could yield very effective team processes. Future research is needed that examines factors that encourage effective team function in diverse (mixed age) teams.

Older Workers and Technology High technology, including computer-integrated manufacturing and robotics, frees many workers from hard physical labor and increases the need for workers with a wide range of technical and problem-solving approaches. Jobs created by robotic technology often require at least 2 years of college education as well as additional training and retraining. Technology has influenced work site location. Certain regions of the country have attracted a significant proportion of information-processing and smaller high-tech companies. The computer has played a large role in the development of telework and telecommuting, specifically working from one's home or neighborhood satellite offices. These and other technological changes will affect the increasingly diverse workforce. Older workers will not fare well if speed is a necessary characteristic of working with technology. On the other hand, work that is not contingent on physical labor and that requires alternative methods of problem solving may be a positive source of employment for the older employee. More research is needed to determine how people's perceptions of older workers influence their judgments about their employability in such occupations.

Older Workers and Customer Service Orientation Most of the new job opportunities since 2000 have been in the service sector. Older workers may be appropriate for these jobs, which are assumed not to be physically demanding. However, thorough job analyses of these jobs is necessary because many service positions are stressful and demanding (e.g., nursing, food counter work). For some service positions, task-related experience may be an important requirement. The majority of the occupations with the largest projected job growth are female dominated, including retail sales positions, nurses, secretaries, receptionists, food preparation positions, and teachers (secondary school and kindergarten). Hopefully, a proportionate number of these jobs will go to older women, especially because this is a rapidly expanding group in the workforce.

Generation Issues Research has shown that people of all ages hold stereotypes of other age groups, attributing various physical, intellectual, social, and psychological characteristics based on age. For example, baby boomers (born between 1943 and 1960) view generation Xers (those born between 1961 and 1981) as bleak. Generation Xers were much more likely than baby boomers to be latchkey kids, learning to take care of themselves at an early age. They are more likely than prior generations to change jobs frequently, perhaps in reaction to the treatment their parents received of being rewarded for loyalty and long work hours with layoffs and loss of pensions. Generation Xers put an emphasis on skill variety to enhance marketability, flexibility in work hours, performance-related feedback, and short-term rewards. In contrast, fewer managerial positions means fewer upward movement opportunities, and those available are often held by baby boomers.

Generation Xers are interested in leisure activities and do not want to devote themselves entirely to the welfare of the company. Thus, research shows that baby boomers view generation Xers as disrespectful of authority, low in loyalty, and unwilling to pay their dues. Such generational stereotyping and differences in work and lifestyle preferences are likely to affect relations at work. Research is clearly needed to examine generational as well as age effects and to determine the separate impact of each on a variety of organizational processes and outcomes.

Conclusions

Research on age and employment shows that age affects many work processes. Yet many studies of the

same work process (e.g., hiring, performance evaluation) show inconsistent results. This may be largely due to the influence of the work context and age stereotypes. Contextual variables such as age composition of departments or applicant pools, occupations, and jobs all appear to influence decisions about older workers. Furthermore, age stereotypes of workers and of tasks may serve to limit older workers' career opportunities and may encourage early retirement programs and other forms of downsizing that can adversely affect older workers. More systematic research is needed to better understand how the work context and age stereotypes affect older workers. More theory development pertaining to older working adults is needed. Given the aging of the workforce, research and theory focused on the role of aging at work is particularly timely.

Glossary

European Equal Treatment Directive – A year 2000 directive requiring all 15 EU- as of 2004, all 25 countries- to introduce legislation proscribing discrimination in terms of labor, market activities and training on the grounds of age.

Background

This article considers the issues of extending working lives and promoting age equality, with a particular focus on recent policy developments among European Member States. This is justified on the grounds that while all developed nations experienced a trend toward early retirement in the second half of the twentieth century, it was parts of Europe where this was most pronounced as policy makers sought to manage youth unemployment and industrial restructuring in the 1980s and 1990s, and it is in the area of prolonging working lives that European policy makers have taken particular interest in recent years. By contrast, early retirement on this scale never existed in Japan or the United States. However, in both Japan and much of Europe, declining fertility levels are predicted to have a profound effect on labor supply and consequently, economies. By 2030 the European Union (EU) can expect 14% fewer workers and 7% fewer consumers than there are today, while Japan, over the same period, will experience declines of 18% and 8%, respectively.

However, Europe alone is also dealing with the legacy of early retirement. An Organisation for Economic Co-operation and Development (OECD) study found that, among nine European Union countries, the share of older workers among recent job hires was almost 13 percentage points lower than so-called prime-age workers. Age-related labor market barriers are the result of the complex interplay of a number of factors, including stereotypes concerning the capabilities and motivations of older workers and the existence of early retirement pathways. One view is that companies' policies are indirectly determined by community norms, representations, and stereotypes of younger and older workers. However, others

argue that age is rarely explicitly considered by management or unions and that corporate policies and programs have differential effects on older and younger workers, but these are mostly unintended. Instead, early exit is primarily the result of staffing calculation methods, a desire to maintain harmonious industrial relations, the opportunity to use early retirement mechanisms, and the age structure of workforces.

European policy makers are beginning to turn their backs on early retirement. Instead, the new mantra is one of prolonging working lives as population aging exerts pressure on social welfare systems. This article speculates on the implications for older workers. It begins with a brief overview of the situation of older people in the European labor market, before moving on to discuss European-level actions that are expected to influence public policy at the national level. Next, actions on the part of selected countries are discussed, before conclusions are drawn concerning the prospects for older workers and the state of knowledge.

Statistical Overview: The Aging Labor Force and Trends in the Participation of Older Workers

This section covers trends in economic activity, unemployment, and employment rates, and the average age of retirement from employment. **Table 1** demonstrates the low levels of employment of older workers in EU countries against the OECD average, while **Table 2** also demonstrates variation among European member states. Overall, the most recent members of the EU have had average activity rates some 10 percentage points lower than the previous EU-15. While useful, it should be acknowledged that such comparisons need to be interpreted with caution. For instance, the apparent advantage in terms of employment rates among older workers in the UK compared to Germany is reduced when part-time employment is considered.

Table 1 Employment rates among workers aged 55–64

		Employment rate (%)				
		1990	*2000*	*2001*	*2002*	*2003*
EU 15						
	All	38.5	38.3	39.3	40.6	42.3
	Men	53.2	48.5	49.4	50.6	53.2
	Women	24.9	28.5	29.6	31.0	31.8
OECD						
	All	48.4	47.9	48.5	49.4	50.8
	Men	63.7	59.5	59.8	60.5	62.0
	Women	34.3	37.1	37.7	38.9	40.3

Source: OECD Employment Outlook 2004.

Employment population ratios for men and even more for women decline significantly in the UK when adjusted for part-time employment, whereas in Germany they increase for men and decrease less for women than in the UK. In consequence, the difference in employment rates for older workers, while still in evidence, is less pronounced.

Table 3 compares average life expectancy at 60 with the overall average age of exit from the labor force for the EU. **Table 4** adds to this by providing an additional gender breakdown. These tables are indicative of different pressures facing member states due to demographic aging. For example, in the year 2000, French men could expect to live for over 20 years on average at age 60, while women could expect to live for over 25 years. This compares with an average age of exit from the labor force of just over 58 in 2001. Compare this with the United Kingdom, where in 2000 men could expect to live over 19 years at age 60, and women 23 years. However, the average age of retirement was 62 in 2001.

Table 5 takes a wider perspective still, comparing Europe with Japan and the United States in terms of employment rates over time. This shows a huge gap between Europe and these countries, with employment rates among older workers some 20% higher in Japan and the United States than the EU-15, and even more so when compared to the EU-25, though between 1997 and 2002 the EU closed the gap slightly with the United States, while employment among older workers in Japan fell.

European Public Policy on Age and Employment

The employment of older workers has only recently become an issue for European policy makers. Three agreements should be influencing public policy at national levels. These are the European Equal Treatment Directive, and the Barcelona and Stockholm targets. In the year 2000 EU Council Directive 2000/78/EC established a framework for equal treatment in employment and occupation. The Directive requires all 15 EU – as of 2004, all 25 – countries to introduce legislation proscribing discrimination in terms of labor market activities and training on grounds of age. The directive allows member states until the end of 2006 to implement the provisions on age. A recent review concluded that transposition of the directive has been uneven, with little progress being made in Germany, while France and Italy have complied technically, though more could be done.

The European Council of Stockholm in 2001 agreed on an ambitious target for the employment

Table 2 Employment and economic activity rates of older workers in 2002 (preliminary results)

	Employment rates (% population aged 55–64)			*Activity rates (% population aged 55–64)*		
	Total	*Male*	*Female*	*Total*	*Male*	*Female*
EU15	40.1	50.1	30.5	42.8	53.4	32.5
Belgium	26.7	36.1	17.6	27.8	37.6	18.4
Denmark	57.8	64.5	50.4	60.4	67.0	52.9
Germany	38.4	47.1	29.9	43.0	52.3	33.9
Greece	39.7	56.0	24.4	41.4	58.1	25.5
Spain	39.7	58.6	22.0	42.7	62.2	24.4
France	34.8	39.3	30.6	36.7	41.8	31.9
Ireland	48.1	65.1	30.8	49.3	66.7	31.6
Italy	28.9	41.3	17.3	30.2	43.0	18.1
Luxembourg	28.3	37.9	18.6	28.3	37.9	18.6
Netherlands	42.3	54.6	29.9	43.3	55.8	30.6
Austria	30.0	39.8	20.9	31.8	42.9	21.5
Portugal	50.9	61.2	41.9	52.9	63.5	43.5
Finland	47.8	48.5	47.2	52.1	53.0	51.2
Sweden	68.0	70.4	65.6	71.2	74.3	68.2
United Kingdom	53.5	62.6	44.7	55.4	65.4	45.7
AC10	30.5	41.2	21.4	33.1	45.0	23.0
AC12	31.6	41.1	23.5	34.0	44.6	25.0
EU25	38.7	48.9	29.1	41.4	52.3	31.1
EU27	38.5	48.5	29.0	41.1	51.8	31.0
Cyprus	49.2	67.0	32.1	50.8	68.8	33.7
Czech Republic	40.8	57.3	26.0	42.5	59.4	27.3
Estonia	51.6	58.4	46.5	55.7	63.7	49.8
Hungary	26.6	36.7	18.5	27.5	38.2	18.9
Lithuania	41.6	51.5	34.1	46.9	59.8	37.2
Latvia	41.7	50.5	35.2	46.3	57.1	38.2
Poland	26.1	34.5	18.9	29.1	38.7	20.9
Slovenia	24.5	35.4	14.2	25.2	36.7	14.5
Slovak Republic	22.8	39.1	9.5	26.9	46.3	11.1
Bulgaria	27.0	37.0	18.2	31.8	43.7	21.5
Romania	37.3	42.7	32.6	37.9	43.9	32.8

rate of older workers of 50% by the year 2010 (from 38.8% in 2001). **Table 6** shows that only a handful of countries have achieved this target so far.

The Barcelona European Council agreed on an increase of 5 years in the average age at which people stop working in the EU by 2010. The average exit age in the EU was 59.9 years in 2001. As **Table 4** shows, progress so far has been modest.

In considering progress toward achieving these European objectives, it is worth reflecting on the legacy of early retirement and the way it has been used as a tool for reducing labor supply in order to open up job opportunities for younger people. As **Table 7** shows, among European countries, youth unemployment is a persistent problem, and this may be undermining efforts to promote the employment of older workers.

Thus, European member states face immense challenges in the coming decades in tackling the issues associated with the aging of their labor forces. The following sections focus on national actions, with those of certain member states provided as exemplars.

Strategic Approaches

European institutions, the OECD, and most independent observers would argue for a comprehensive and integrated approach to tackling age barriers in the labor market. However, policy making at the national level in Europe, with one or two exceptions, could be characterized as largely ad hoc and piecemeal. The best known example of a comprehensive approach is the Finnish Program on Ageing Workers (1998–2002). The UK has also sought to coordinate activities across government departments, with some success.

Elsewhere, the Czech Republic has responded to the aging of its population by devising the National Program of Preparation for Ageing (2003–07). Areas for action include the following:

- Equal rights and opportunities
- Lifelong learning and special training measures for older workers
- Attitudes to aging and older persons

Table 3 Life expectancy at the age of 60 and average exit age from the labor force in the EU and acceding countries (AC10)

	Life expectancy at 60 in 2000		*Average exit age from the labor force in 2001 (men and women)*
	Men	*Women*	
Belgium	19.3	23.8	57.0
Denmark	18.9	22.3	61.8
Germany	19.2	23.4	60.7
Greece	20.1	23.1	59.6
Spain	19.8	24.5	60.6
France	20.2	25.3	58.1
Ireland	18.3	21.9	62.9
Italy	19.7	24.1	59.4
Luxembourg	19.3	24.1	56.8

- Social and economic integration of older persons
- Making better use of the capabilities of older workers, e.g. in mentoring roles
- Labor mobility and flexible employment opportunities
- Individual preparation for aging and old age.

The Czech Action Plan for Employment of 2002 proposes an increase in the participation of older unemployed persons in active labor market measures. Interestingly, in the Czech Republic two pilot initiatives offered on a voluntary basis that helped individuals aged under and over 25 to develop individual employment action plans appear to have reduced the likelihood of long-term unemployment. However, new proposals oblige official labor offices to now offer these to the former, while there appears to be greater flexibility regarding the latter.

In 2001 in the Czech Republic, a new regulation was passed that made early retirement more disadvantageous and employment after retirement age more advantageous. If a non-working person takes a job they may no longer lose full benefits. There was a marked decrease in the share of early retirement pensions as a proportion of newly awarded pensions in 2002. However, schemes that encourage early retirement still exist in industries such as steel, mining, and railways.

Reform of Retirement Income Systems

It is in the area of retirement income systems that most recent reforms have taken place in the EU. Yet early exit remains both popular and possible. For instance, despite recent reforms ostensibly aimed at maintaining older workers in employment, a deep early exit culture exists in France, and against this backdrop, few firms, it seems, have developed policies around the employment of older workers and there is not a widespread belief that population aging will necessitate such a reorientation. Moreover, policy making is deeply contradictory, with efforts to extend working life undermined by pressure to tackle unemployment, often at the expense of older workers. Employers, unions, and workers have colluded in the perpetuation of a system in which 55 has become the normal age of retirement, while those in their 40s are now viewed as 'nearly old' and face reduced employment prospects.

In its pension reforms the French government is trying to reduce numbers of those opting for early retirement. The contribution period before an individual is eligible for full pension benefits has been increased, while the age at which a person automatically retires has been increased from 60 to 65. The new pension system provides incentives for those who work beyond 60. Gradual retirement is also being extended. On the other hand, in 2003 a redundant worker aged 56 could receive unemployment insurance benefits worth up to 75% of his or her previous salary for up to 3.5 years, with no job search requirement. Added to this, this period could be counted in the calculation of a pension. Moreover, early pensions are still popular, for example, in the motor industry, while there has been considerable public resistance to pension reform.

Similarly, in Hungary pension reform has taken center stage, alongside a major overhaul of the welfare state more generally. The retirement age increased for men from 60 to 62 in 2002 and will increase for women from 55 to 62 by 2009. An increase of the legal retirement age to 65 years for both sexes is expected between 2015 and 2020. In addition, the minimum contribution period is increasing gradually and will be 20 years by 2009.

Workers will also now receive an enhanced pension if they defer retirement. However, importantly, while pathways to early retirement have been partially closed, if individuals are willing to accept a financial penalty, they may retire at age 55 for women and 60 for men. Another feature of reforms has been the implementation of restrictions on access to disability benefits, with the addition of training programs in an effort to mobilize those with disabilities.

The primary focus of public debate in Italy has been pension reform, and attention has only recently begun to turn to the issue of re-activating older workers. Reforms include increasing the pension age to 65 for men and women, enhancements for pension deferral, increasing the minimum age for claiming a pension, part-time flexible retirement, and the opportunity to mix employment and pension income. A law of 2001 aimed to encourage the deferral of retirement by encouraging workers to move on to a temporary contract. However, take up has been low. Such reforms may be weakened by disinterest in part-time working. Nevertheless, the average age of retirement has risen since the mid-1990s, due in part to pension reforms. Though the increase to date has been modest (0.5 years for men and 3 years for women) it is predicted that new reforms will strengthen the trend.

In Poland pension reforms initiated in 1999 aimed to increase the average age of retirement. The Program of Limiting and Restructuring Social Security Expenditures of 2003 included proposals to equalize male and female retirement ages and to limit opportunities for early retirement. As part of pension reforms, those who have reached statutory pension age are allowed to work without limit. Few take this opportunity, though the numbers of those who do are increasing. Proposals include the possibility of partial retirement at age 62, though it is still possible to retire early without an obligation to seek work.

In Spain, new policies aim to reduce the incidence of early exit and prolong working life. For example, a measure to encourage long-term contracts among older workers has been implemented, though its effect has been slight. Additionally, to encourage older unemployed workers to re-enter the labor market, it

is now possible to receive (reduced) unemployment benefits while working. Equally, there is an option to retire gradually by receiving a pension while working part-time. Also, people who defer claiming their pension receive an enhancement, though it has been argued that this will have little influence on behavior and has more to do with the government's desire to reduce social security expenditure. In addition, there have been efforts to promote greater demand for older workers via reductions in the employer's contribution to the social security system of those aged 45 or older. However, it has been pointed out that a workplace early retirement culture is persistent, which policy makers have been slow to address. Importantly, there has also been resistance from trade unions keen to protect rights to early retirement.

Labor force aging is high on the agenda of British policy makers, and there has been a gradual shift toward an extension of working life in the last 15 years. The government's manifest position is neatly summarized in its recent Pensions Green Paper, in which it sets out proposals for reform in the following areas:

- Help for those aged 50 and over and recipients of disability benefits to help them return to work
- Increases for those deferring claiming their state pension
- Allowing people to continue working for their employer while drawing their occupational pension
- Raising the age from which a pension may be taken from 50 to 55
- Changing public service pension scheme rules, for new members initially, to make an unreduced pension payable from 65 instead of 60.

Active Labor Market Policies

In France, the National Action Plan for Employment of 2003 mentions the desire of the government to embark on a national mobilization plan for workers aged over 55, access to training for those aged 45 or

over, and the accreditation of prior learning. Additionally, long-term unemployed people aged 50 or over will be encouraged to find work through a relaxation of rules concerning combining income from employment with state benefits, wage subsidies are being enhanced to encourage employers to recruit more workers aged over 50, and older workers are to be encouraged to establish a small business. Furthermore, the government wishes to encourage small firms to extend the working lives of employees by establishing a service to assist them in long-term staff planning.

Nevertheless, the aging of the labor force does not appear to have a prominent place in policy debates. Added to this is public support for early retirement. For example, recently, one trade union that pressed an employer to retain older workers found this vetoed by its membership, who preferred early retirement. The reasons are partly cultural. For example, discrimination is a new concept, and previously, generous pre-retirement schemes have encouraged older workers to retire early.

In Germany, the potential of active labor market policies has recently come to the fore. The Hartz Modern Services in the Labor Market Commission, which was established in 2002 as the federal government's plan to modernize public employment services, makes specific mention of initiatives for older workers. On the supply side, the pay guarantee for older employees measure targets unemployed people aged 50 or over. It pays a grant of 50% of the net difference in pay between the job they had before becoming unemployed and their new job if the latter is of lower pay. On the demand side, employers who recruit workers aged 55 or over will be exempted from paying their share of the costs of employee development. In addition, an age limit imposed for part-time and temporary work beyond which such arrangements must be revised is being reduced from 58 to 52, with the intention of improving employment opportunities for older workers.

The Hungarian National Action Plan on Social Inclusion 2004–06 states that employers are being offered incentives to employ unemployed workers

aged 50 years or over in the form of the removal of the obligation to pay health-care contributions.

In Italy, while active labor market programs have tended to favor younger workers, the recent Biagi Law provides for financial hiring incentives for disadvantaged groups, including people aged 50 or over. However, it has been observed that initiatives aimed at increasing access to employment have tended to have a youth focus. On the other hand, some Italian regions are promoting the employment of older people in community-based social solidarity services, with financial incentives sometimes available for employers.

In Spain in 1999, a pilot program was established that mainly targeted those aged over 40 and mixed vocational training with a period of public employment of between 6 and 12 months. Financial incentives are also available to older workers who participate in vocational training and accept assistance in finding a job. Nonetheless, it has been argued that the desire for an extension to working life and a reduction in the use of retirement pathways has not been sufficiently matched by measures to re-integrate older workers.

New Deal 50 plus is the flagship employment program for older workers in the UK. Implemented in April 2000, in its original form it offered employment advice to non-employed older people who had been claiming benefits for at least 6 months. The program was voluntary and open to people inactive on benefits as well as those registered as unemployed. It paid a cash employment credit on top of the wage directly to a person taking a job. The program has subsequently been revised and offers financial support when in work in the form of a working tax credit.

Since its launch, over 110 000 clients have moved into employment via the program, though this represents a minority of those eligible. The majority of employment credit claimants fell into the 50–54 age group (59%) and were previously claiming unemployment benefits (72%), while 7% were claiming disability or sickness-related benefits previously. Clients generally moved into full-time employment, although a large minority – almost one-third – moved into part-time employment. The proportion moving into self-employment increased over time.

Several evaluations have been undertaken. Key findings are as follows:

- The most useful element of the program was felt by clients to be the employment credit, providing an incentive to take low-paying work both in terms of level and reliability of income and reducing reservation wages.

- That this was not known about by the employer was also viewed as a positive by clients as it was felt this would not affect wages. This is particularly important, given that the new working tax credit is administered via the employer.
- However, there was evidence of deadweight, with in one study over half of those clients surveyed stating that they would have taken a job anyway without the employment credit, although it had encouraged almost two-thirds (63%) to take a job earlier than they otherwise would, and over two-fifths (43%) to stay in the job for longer than they might otherwise have done.
- However, it also tended to be most effective in geographical areas where there were low wages and low living costs.
- There was an issue regarding the sustainability of part-time employment, with those unable to increase their hours once the employment credit ended penalized, although the majority of clients tended to remain in employment once they had found it.
- A factor accounting for low take-up among disability-related benefit claimants may have been that financial gains from moving into paid employment could be small, and some would even be worse off.
- Clients tended to move into unskilled and low-paying service or manual jobs, despite the fact that many were previously in higher-paying or more skilled work.
- Self-employed clients tended to be positive about their experiences of claiming the employment credit, which was viewed as helpful in supporting them through the first year of their business.

Other research has considerd what happens to New Deal 50 plus clients once the employment credit ends. For the client group for whom there was 12 months of benefits data after their credit expiry, 84% were not claiming at the 52-week stage and 77% had not returned to claim at any stage during the 12 months following the end of their entitlement. Also, there was a difference in job retention between clients in general and those in receipt of the employment credit 6 months after their job starts. Employment credit claimants had a higher retention rate of 84%, compared to 70% for clients overall.

Tackling Age Discrimination: Regulation, Legislation and Collective Bargaining

As noted previously, the response of national policy makers to the Equal Treatment Directive has been piecemeal. In the Czech Republic an amendment to the labor code in 2001 outlawed any form of discrimination in employment, though recruitment agencies were excluded. Also, employers find ways round the law, and many are simply unaware of its existence. It is also important that, unusually, protection from unfair dismissal is accorded a worker even if they are entitled to receive a pension, though redundancy on grounds of age has still been common.

In France, the Labor Code was amended in 2001 to cover every aspect of working life in relation to discrimination, including age, and to adjust the burden of proof in discrimination cases, making it easier to pursue a case. This has not taken place with strong support from either employers or trade unions, and age discrimination does not feature in collective agreements. Also, the Labor Code had stipulated that an employer terminating the contract of a worker aged 50 and over must pay a special premium known as the Delalande contribution. This appeared to have a small effect on redundancy among older workers, and may in fact have discouraged their recruitment on the grounds that any subsequent layoff could prove costly to the company. The French National Action Plan for Employment of 2003 announced that the contribution would be relaxed for firms laying off employees recruited at age 46 or over.

The German federal government announced in 2006 that it would introduce a law proscribing age discrimination in employment. This belated development is partly due to the fact that the term age discrimination has not found much recognition among politicians or scientists. Furthermore, it may also be the result of strong opposition from employers' associations. By contrast, trade unions favor legislation, although views are split because early retirement is still seen by many as a socially acceptable way to leave the labor market. How the legislation will be overseen is unclear, with the government keen to minimize effects on business.

There are in fact already several legal provisions against age discrimination in the labor market in Germany. Federal employment agencies may only accept age limits for job advertisements from employers if these age limits can be justified. The Law on Labor Relations at the Workplace (*Betriebsverfassungsgesetz*, BVG) stipulates that both employers and works councils may not discriminate against workers on grounds of age and that works councils have the right to promote the employment of older workers. However, these provisions do not prevent these actors from negotiating early retirement.

Elsewhere, Italy addresses discrimination in employment on the grounds of age in its constitution,

which states a general principle of equality and non-discrimination. There are currently no plans to strengthen existing provision, though the recent Biagi Law has added age discrimination to prohibited acts for job recruitment agencies. In addition, the independent Department of Equal Opportunities helps individuals, informs policy and disseminates information to raise public awareness, though the issue of age discrimination has not been high on the agenda in discussions between employers and trade unions.

Similarly, issues of discrimination generally are only just coming on to the policy agenda in Hungary, with primary attention being given to disability, gender, and ethnicity, though measures to encourage firms to recruit older workers are also being implemented. With regard to the implementation of antidiscrimination legislation, transposition of the Equal Treatment Directive took place in May 2004. As far as specific provisions on age are concerned, progress had been made in relation to employment, where legislation and measures exist, and vocational training, where legislation exists. However, the Constitutional Court has decided that age restrictions in employment were not discriminative unless they were arbitrary. In terms of forced redundancy, compulsory retirement appears to be commonplace.

In Spain, primary legislation introduced in 2003 addresses discrimination in employment on various grounds, including age, and in terms of both direct and indirect discrimination. However, the trade unions would also like to see the principle of equality built into collective agreements, while the Spanish Confederation of Employers' Organizations (CEOE) considers that equal treatment with regard to age has already been progressed, with steps to eliminate incentives for early retirement and the ending of seniority pay supplements. CEOE also argues that legislation is not the best way to tackle discrimination, believing that it is burdensome for business, and preferring instead to see greater support for their members in terms of increasing access to employment for disadvantaged groups and workplace adaptation.

While the impact of the Equal Treatment Directive on European governments appears to have been varied, there are instances in which some have taken comprehensive approaches. Such examples include Ireland, the Netherlands, and the United Kingdom. Since the publishing of the directive there has been substantial debate in the UK around the form and content of legislation proscribing age discrimination. This will cover both direct and indirect discrimination in employment and vocational training. In exceptional circumstances, differential treatment according to age will be allowed, though employers must be able to justify this. The issue of a default retirement age being retained caused considerable controversy, with fierce public debate. Such an age (65) has been agreed on by government ministers, though this will be reviewed. A new Commission for Equality and Human Rights (CEHR) will oversee the legislation. In Ireland, where legislation concerning age has existed for some time now, cases brought have been few, and even when claimants have been successful, financial restitution has been modest. It is unlikely therefore that this legislation is sending strong signals regarding Irish society's opposition to age discrimination.

Awareness Raising

In several member states awareness-raising activities are being undertaken. In Germany there have been several actions. One project known as Demographic Change–Public Relations and Marketing Strategy aimed to increase public awareness of the impact of demographic change on employment and to distribute knowledge on effective age management among employers. The number of workshops, presentations, publications, media releases, and Internet/homepage launches indicate a strong outreach.

Since 2002, the Federal Ministry of Education and Research has funded a measure called Demography Initiative. This is led by three trade associations and funds 127 companies to implement policies on age management.

In April 2002, the federal government presented its overall strategy for sustainable development. It includes a subtheme called potential of older people in the economy and society and refers to so-called lighthouse projects run by companies that will promote the employability of older workers and encourage lifelong learning.

In 2003, the Federal Ministry for Economy and Labor implemented a public awareness and network campaign called Team Work for Germany. A public relations agency is providing information on role model companies that employ and recruit older workers.

In 2002, the federal government started the national initiative New Quality of Work. As part of this initiative, it is intended to create a network of occupational health professionals to foster health promotion for older workers and to raise awareness of good practice.

The British government launched its Code of Practice on Age Diversity in 1999, which has subsequently been subsumed under the banner Age Positive. This sets out principles of non-age-biased

employment practices. Included is guidance on the application of the principles and examples of best practice. Government-commissioned research found that a very small number of companies surveyed – 9% – had seen a copy of the code and a small number – 2% – had changed policies afterward.

Concluding Remarks

The issue of tackling age barriers in the labor market was not prioritized by European member states until recently. While there are emerging policy debates, policy making is in its infancy in most countries and barely exists at all in some. Countries such as Finland, the UK, the Netherlands, and recently Germany can be contrasted with this generally gloomy picture. It can also be observed that national policy making is sometimes contradictory, with initiatives on the integration of older workers co-existing with others that facilitate their removal. This points to the value of developing a policy framework on what constitutes active aging from an employment perspective.

It is also arguable whether age discrimination is recognized as an issue in many countries. Elsewhere, much work appears to have taken place. Why it has not been so prominent an issue in some countries is unclear. One explanation may be that the early exit of older workers has simply not been viewed as a problem in some countries where generously funded early retirement programs have cushioned the impact of job loss, or where high levels of youth unemployment may have focused public attention elsewhere.

On the other hand, age and work more generally is an issue of public debate in many countries. Early retirement as a policy tool is now widely discredited, with numerous reports pointing to deleterious effects on economies, employers, and individuals. Pension reform has been undertaken in member states, though the concerns are almost entirely fiscal, being about the sustainability of retirement income systems rather than equality of opportunity. Arguably, the present situation resembles that of the 1980s and 1990s in reverse. Then, older workers were viewed as a burden on European society, preventing the ascendancy of younger workers, with early retirement considered the solution. Now, along with an incessant rhetoric around dependency ratios, later retirement is viewed as the solution. Older workers are again being presented as a burden, though this time the conclusion is that they must take their place once more in the labor market. Whether this will benefit the vast majority of older workers is a matter of conjecture. Also, a background of persistently high levels of youth unemployment raises the question of whether policy making toward older workers will gain much traction.

Such a perspective does not sit well with the European Commission's stated desire for the promotion of active aging, except in the starkest and weakest of terms. Older workers are barely valued in their own right, their primary value coming from relieving the burden on younger people. They may be obliged to seek work against a background of labor market age discrimination. While some may benefit financially and socially from access to employment, others may find themselves at risk of long-term unemployment or in precarious employment.

Thus, the challenge for European policy makers will be to nurture the development of labor markets that provide meaningful opportunities for older workers, willing and able to make a contribution, while at the same time, those with skills deficits or other barriers that severely limit their employability have the opportunity to retire sooner or flexibly. However, this preliminary assessment suggests that they are some way short of achieving such a goal.

What can a non-European observer learn from these developments? First, Europe has put extending working lives at the center of its vision for economic growth. At the Lisbon European Council it set itself a strategic goal for the next decade of becoming the most competitive and dynamic knowledge-based economy in the world, capable of sustainable economic growth with more and better jobs and greater social cohesion. As noted previously, targets on the employment of older workers are proving difficult to attain, pointing perhaps to difficulties in Europe of promoting policies aimed at increasing labor supply via an extension of the end of working lives at a time when some economies are struggling to grow and going against a deep-rooted early retirement culture. On the other hand, a vast range of initiatives across the member states may offer insights to policy makers elsewhere. Finally, scholarly debate on the aging of the European labor market flourishes, with major advances in our understanding of the nature of age discrimination and the role of public policy in both encouraging and overcoming age-related labor market barriers over the last 20 years.
