
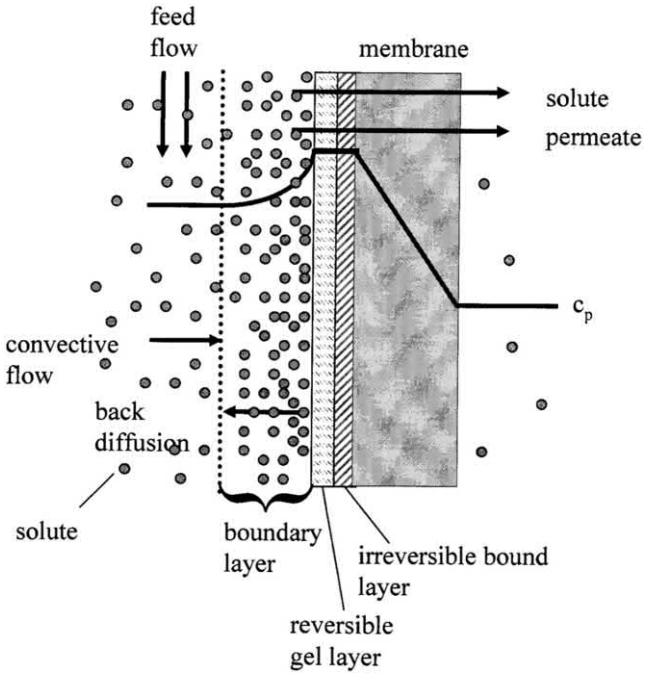

FIGURE 25.4 A schematic representation of concentration polarization and fouling at the membrane surface.

Concentration polarization is a fluid dynamics phenomenon, whereas fouling is a chemical phenomenon between solutes and the membrane. In a laminar flow regime, decreasing channel height, increasing inlet velocity, and decreasing channel length can decrease concentration polarization. Disrupting the boundary layer by mechanically inducing turbulence in the fluid stream can improve permeate flux. The flux can be improved with dynamic turbulence promotion involving acrylic resin plastic spheres moving randomly in the retentate channels of an RO system. The permeate flux can also be improved with reciprocating flow. Depending upon the pulse rate and flow velocity conditions, the permeate flux improved from 1.7 to 5.1 L/m^{2}h for 24% solids orange juice. Backwashing is another technique where the flow is intermittently reversed from feed-side-to-permeate-side flow to wash solutes off the membrane surface and out of the system. Other options such as ultrasonic vibration, rotational motion, and spongy balls have also been investigated [6, 24].

25.7 CLEANING MEMBRANES

Effective cleaning after processing is important to reduce the fouling on the membrane surface. This way flux could be restored and membrane life and performance can be maximized. A wide variety of acid/alkaline–detergent/sanitizer combinations can be applied to remove foulant accumulated in the membrane systems. Membrane manufacturers have spent considerable amounts of effort to identify the appropriate detergent and its strength suitable for particular application. For juice processing, the cleaning involves rinsing the membrane system with water initially, then using alkaline detergent and hypochlorite solutions at recommended temperatures (40–60°C). Typically, a membrane unit used for filtration of apple juice can be cleaned-in-place at 50°C using a 0.1–0.5% alkaline detergent solution (pH 10 to 11) with 100 to 1000 ppm free chlorine, the rates being specific to the type of membrane [98, 99]. Following a rinse with water, the cleaning cycle can be repeated. Mixtures of nitric and phosphoric acid are recommended for dairy processing for dissolving minerals and salt foulant. For most commercial membrane systems, cleaning instructions are provided by the membrane manufacturers. The cleaning protocol includes type of chemicals, time of exposure, and temperature. RO membranes tend to be more susceptible to damage than MF and UF. In general, PVDF membranes can withstand higher rates of chlorine than cellulose acetate or polyethersulfone. It is important to monitor the sanitizer strength and ensure contact with all areas of the membrane system.

26 Stickiness and Caking in Food Preservation

Bhesh Bhandari and Thao M. Ho

CONTENTS

26.1 INTRODUCTION

Dry solid food materials can exist in various forms and dimensions. This may range from pieces to very fine nanosize powders. The dimensions of individual particulates may vary from a few microns (or even nanosize) to several millimeters or centimeters. Food powders generally have the dimension of few millimeters down to a few micrometers. Granular products (diameters of a few millimeters) are also categorized as powders. In this chapter, dried foods are referred to as powders, since the powder form is the most common dry state of food materials.

Various methods are employed to produce foods in dried form. These processes include various methods of drying, crystallization, grinding, milling, or mixing (liquid to solid) with other ingredients. Depending on the type of process employed and the nature of the components present, the dried product may exist in amorphous, crystalline, or mixed (semicrystalline) form. Some examples of food powders in these states are listed in Table 26.1. The physical form of the powders and their individual properties influence many functional properties such as flowability, bulk density, ease of handling, dust forming, mixing/segregation, compressibility, and surface activity. The stickiness and caking behavior of powders are also related to the physical forms and dimensions of particulates. Fundamental understanding of the sticking and caking behavior of powder is important since these phenomena alter the expected functional and nutritional properties and stability of the food powders.

TABLE 26.1
Physical States of Various Food Powders

Forms	Examples of Powders
Amorphous	Milk, some whey powders, encapsulated powders, instant coffee and tea, spices, cheese, protein, coffee whitener, cocoa, spice mixes (gravy, soup, etc.)
Crystalline	Refined sugar, organic acids, polyols, salts
Mixed	Some whey powders, starch powders, ground icing sugar

26.2 STRUCTURE OF FOOD SOLIDS

26.2.1 Crystalline Structure

Many dried solid foods are in crystalline form. Thermodynamically, the crystalline form is at the lowest energy level or stable equilibrium state. The crystalline state has a defined molecular arrangement in the long-range order (Figure 26.1). The molecules in crystalline form are tightly packed; therefore only radical or functional molecular groups on the external surface of the crystals can interact with external materials such as water (absorption). Powders in the crystalline state are the most stable. No caking occurs unless the surface of the crystals dissolves due to a high humidity environment.

26.2.2 Amorphous Structure

The majority of processed dried foods exist in an amorphous form. Thermodynamically the amorphous state is at a higher entropy level than the corresponding crystals. Molecules in this state are nonaligned, tangled, more open, and porous. An amorphous solid may also possess short-range order and regions of high and low densities (Figure 26.1) and have higher entropy than the corresponding crystals. Since an amorphous state is at a high energy level, it can undergo crystallization to achieve equilibrium. Amorphous powders are the most prone to stickiness and caking.

26.2.3 Mixed Structure

Mixed structure dried foods (coexistence of amorphous and crystalline structure) have both amorphous and crystalline regions. The mixed structure occurs during processing, such as partial crystallization or by grinding the crystalline structure. These powders are also prone to stickiness and caking due to the presence of an amorphous structure.

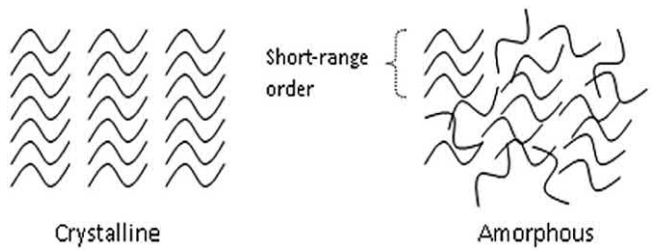

FIGURE 26.1 Schematic representation of crystalline and amorphous molecular structure. (From Bhandari and Hartel [1].)

26.2.4 Characterization of the Structure of Food Solids

The differences in molecular arrangement between amorphous and crystalline solids lead to differences in their physical properties (as shown in Table 26.2) and consequently their stability and functionality in food production. Food solids are very stable in crystalline form, while those existing in an amorphous form are likely to experience various undesirable changes (structural relaxation, stickiness, caking, lumping, agglomerating or crystallization) during handling, storage, and processing. Thus, the presence of an amorphous phase, even a very small amount in food solids, greatly affects the properties and stability of the whole product. Moreover, the production of partial or completely amorphous solids is an intrinsic property of many processes of food production (freeze-, spray-, and drum-drying of a solution, or milling of solid materials). Therefore, characterization of the structure of food solids is essential to determine the further utilization of the product.

Many analytical techniques have been developed to differentiate the structure of food solids, such as X-ray diffraction, microscopic analysis (scanning electron microscope or polarized light microscopy), differential scanning calorimetry, gravimetric vapor sorption, and spectroscopy approaches (Fourier transform infrared spectroscopy, Raman spectroscopy, or ^{13}C nuclear magnetic resonance spectroscopy) [3, 4]. Under these analytical techniques, solid materials with different structures will respond differently. Table 26.3 shows the differences between pure amorphous and crystalline solids analyzed by various techniques. The mixed structure solids can display a combination of properties of completely amorphous and crystalline ones. A typical example of differences among 100% amorphous, 100% crystalline, and mixed structure solid materials under X-ray diffraction (XRD) and differential scanning calorimetry (DSC) is shown in Figure 26.2. In this figure (a) denotes pure crystalline beta-cyclodextrin (β-CD) powder, (b) denotes pure amorphous β-CD powder, and (c) denotes mixed structure complex powder of tea tree oil and β-CD powder [5]. For XRD, there were many sharp peaks for crystalline β-CD powder and three broad peaks were observed for amorphous β-CD, while a combination of the peak shape of pure crystalline and amorphous β-CD powders was witnessed for mixed structure complex powder. Similar results were also found for DSC analyses. The DSC thermogram of crystalline β-CD was depicted by an endothermic peak at 90–140°C, while the amorphous one exhibited an endothermic hump at 40–170°C, and the mixed structure complex powder displayed a combination of the DSC thermograms of completely crystalline and amorphous β-CDs.

TABLE 26.2
Differences in Physical Properties of Amorphous and Crystalline Solids

Characteristics	Amorphous Solids	Crystalline Solids
Structure	• Loosely packed • Unsymmetrical	• Highly packed • Symmetrical
Strength of molecular bonds	Different and small	Equal and large
Heat of fusion	None	Defined
Melting point	Wide range	Extremely sharp
Physical properties	Isotropic	Anisotropic
Scattering produced by incident X-ray	Weak and spread throughout reciprocal space	Strong and concentrated into a few sharp diffraction peaks
Adsorption of external molecules	• Hygroscopic • Adsorption into the bulk of solids	• Nonhygroscopic • Adsorption primarily on the surface of solid particles
Water dissolution ability	High and fast	Low and slow
Compressibility	High	Low
Nature	Pseudo-solids or supercooled liquids	True solids
Clearage property	Irregularly	Defined
True density	Low	High

Source: Ho et al. [2].

TABLE 26.3
Differences between Completely Amorphous and Crystalline Solids under Various Analytical Techniques

Analytical Techniques	Amorphous Solids	Crystalline Solids
X-ray diffraction	One or several broad peaks	Many sharp peaks
Scanning electron microscopy	Spherical shape particles	Irregular shape particles
Polarized light microscopy	Homogenously dark background	Colored bright crystal granules with different shapes
Differential scanning calorimetry	- A big hump or broad peaks representing water (volatiles) evaporation - A signal of structure relaxation, glass transition, and crystallization	- Many sharp peaks representing water (volatiles) evaporation - A signal of melting
Fourier transform infrared spectroscopy Raman spectroscopy	Less defined and high intensity peaks	Sharp or low intensity peaks
Gravimetric vapor sorption	High water adsorption ability and changes of water adsorption behavior due to phase transitions at high relative humidity	Low water adsorption ability and quite stable at high relative humidity
^{13}C Nuclear magnetic resonance spectroscopy	Broad peaks for each carbon atom	Sharp, splitting, or even overlapped peaks for each carbon atom

26.3 STICKINESS OF FOOD SOLIDS

Stickiness of foods is generally an undesirable property. This can cause difficulty in processing, handling, mixing, and storing of food materials. In certain food processing situations, the same property can be useful, such as in agglomeration and coating processes. Stickiness relates to both cohesiveness within the same food material and adhesiveness to different materials. Since stickiness is a surface property, the surface energy of both similar and dissimilar materials plays a role.

26.3.1 Cohesive Forces and Stickiness

Various interparticulate cohesive forces (Figure 26.3) involved in stickiness are (i) liquid bridges, (ii) solid bridges, (iii) van der Waals forces, (iv) electrostatic forces, and (v) mechanical interlocking.

26.3.1.1 Liquid Bridges

Liquid bridges are produced due to melting, wetting, and dissolution of the external surface of the particles or the release of mobile liquid components from the interior of the particles

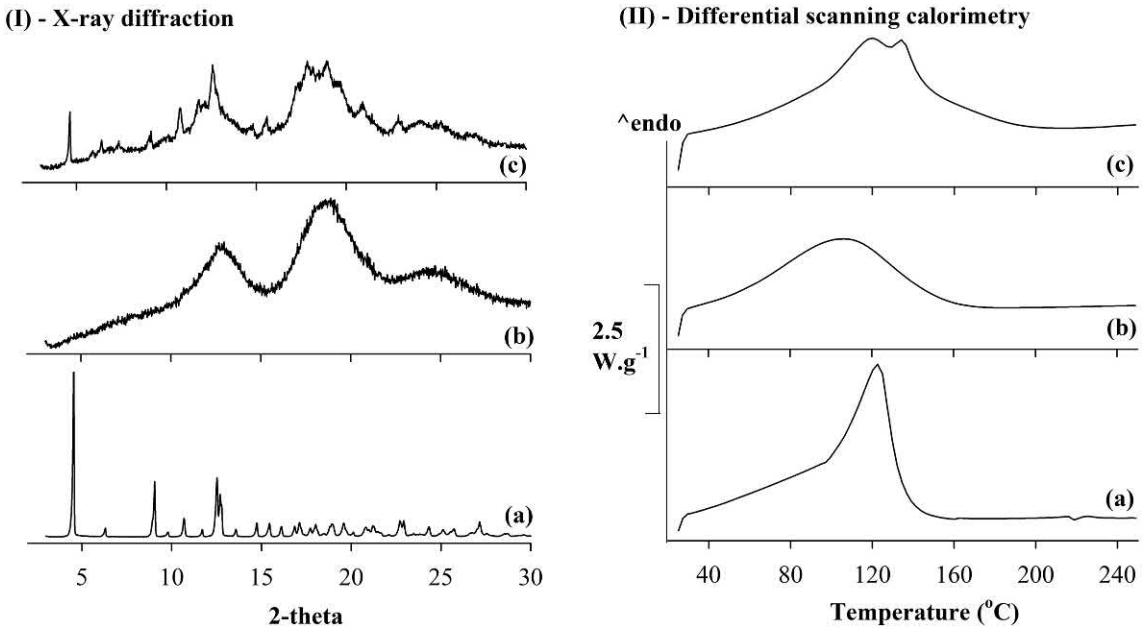

FIGURE 26.2 An example about differences in X-ray diffraction (I) and differential scanning calorimetry (II) analyses among pure amorphous, pure crystalline, and mixed structure. (a) Pure crystalline beta-cyclodextrin (β-CD) powder, (b) pure amorphous β-CD powder, and (c) mixed structure complex powder of tea tree oil and β-CD powder.

(Figure 26.3a). This type of cohesion is mainly dominated by the surface tension and capillary properties. For example, during rewetting of the particles in an agglomeration process there is a flow of liquid between two adjacent particles. Upon removal of solvent (such as water), the mobile liquid bridges turn into solid bridges. However, this type of solid bond can be fragile due to the narrowness of the bridge. The presence of low melting point components (such as oil) also results in liquid bridges. This type of nonaqueous bond is weak due to the noncompatibility with other solids present in the powder. The powder flow is adversely affected by the presence of liquid bridges. Many high-fat powders do not flow well for this reason. Solidification of these liquid bridges due to temperature fluctuation makes the bond stronger.

26.3.1.2 Solid Bridges

Solid bridges between particles are formed by melting and solidifying (sintering) and crystallization of dissolved solids (Figure 26.3b). The interparticulate contact area is large and the strength of the agglomerate is high. Lowering of the temperature of the powder converts the liquid bridges to solid bridges. In some powders, such as milk powders or high sugar powders, this type of bond is so strong that it could need a hammer to break the lump.

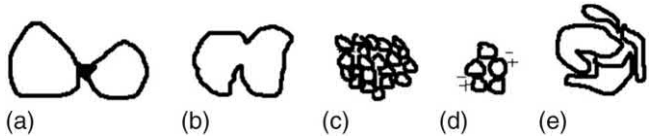

FIGURE 26.3 Schematic diagram of interparticulate cohesive forces. (a) Liquid bridges, (b) solid bridges, (c) van der Waals forces and (d) electrostatic forces, and (e) mechanical interlocking.

26.3.1.3 Van der Waals Forces

All molecules possess weak attraction forces at very close distances. This is due to the electrostatic attraction of the nuclei of one molecule to the electrons of the other. This may result in polarization of the molecules at the surface. Fine powder particles (<1 μm size), which have a very small interparticulate space, tend to stick to each other due to this force (Figure 26.3c). The oscillation of the molecules and vibration of the bonds may also cause such attractions due to facilitation of the alignment of the positive and negative forces. When the force of gravity (e.g., larger particles) is larger than the van der Waals forces, the particles do not show such cohesive behavior. Generally higher molecular weight materials having more electrons tend to be more cohesive. The fundamental mechanism of van der Waals forces is electrostatic in nature [6]. This type of stickiness will be common in submicron or nanoparticles. Deposition of fine powders into the dryer wall, equipment surfaces, and room walls is the result of van der Waals forces. This force is relatively weaker, and therefore can be easily broken. However, due to close proximity and minimum interparticulate space, this force accelerates other types of caking.

26.3.1.4 Electrostatic Forces

There is normally confusion over electrostatic forces and van der Waals forces. The van der Waals is a short-range force, whereas the electrostatic is a long-range force. The fine particles can have some excess electrons due to friction. If these excess electrons are not dissipated (due to low conductivity), the electron-rich particles can realign themselves with electron-poor (oppositely charged) particles to balance the charge (Figure 26.3d). This results in cohesion or adhesion of particles. In fact, van der Waals forces and electrostatic forces

act in combination in the case of cohesion/adhesion of fine powders [6].

26.3.1.5 Mechanical Interlocking

Mechanical interlocking occurs due to the irregular or uneven shape and size of the particles (Figure 26.3e). The fibrous, bulky, and flaky particles interlock with each other or "bird nest" [7]. Under compaction or vibration, particles are repositioned and become more entangled. Upon heating, wetting and drying these physical bonds can become very strong.

The energy of interactions between particles depends on the type of material, moisture content, size, and shape of the particles and external electrical field. In general, the solid bridges are stronger than liquid bridges. The van der Waals forces are the weakest one and their dominance is high when particles are very small and the gravitational effect becomes nominal. The interlocking energy depends on the surface roughness of the particles and the amount of distortion and packing. Barbosa-Cánovas and Juliano [8, 9] compiled some information on the energy of binding of various forces (Table 26.4).

26.3.2 Adhesive Forces and Surface Energetics

As stated earlier, stickiness is related to both cohesion to similar and adhesion to dissimilar surfaces. In the case of adhesion of food particulates onto different surfaces, it is influenced by the adhesive balance between contacting surfaces. In fact, the stickiness property is directly related to the interfacial surface energy of contacting materials. Adhesion of fine particles to dissimilar surfaces is also influenced by their electrostatic charges and the electric conductivity of the contact surface.

In some food processing situations, food adhesion can be of significant concern, particularly in the case of foods that are more adhesive than others. One of the important processes where stickiness has been an issue is the drying of high-sugar and high-fat products [10, 11]. This causes difficulties in drying equipment design and processing and results in frequent downtime and high losses of product due to the adhesion of powder onto the equipment surfaces. Several research and review papers have been published in this regard. However, inadequate focus has been given to both the interfacial and interphase surface energies that contribute to stickiness.

TABLE 26.4
Dissociation Energy of Particle–Particle Cohesion

Interparticulate Forces	Dissociation Energy
Liquid bridges	Dependent on the composition of powder
Solid bridges	200–800 kJ/mol
Van der Waals forces	4–40 kJ/mol
Electrostatic forces	Dependent on the particle surface, shape, external electric field, and prehistory
Mechanical interlocking	Variable depending on shape, bulkiness, and flakiness

The wetting of the solid surface is related to the surface energy of the adhesive and adherend (also called substrate). If the liquid wets the surface, it can spread out on the solid surface. If the adhesive has low energy levels or low surface tension, it is absorbed by high energy level solids; the contact angle decreases and the wetting is effective. If the surface of the solids has lower energy, the contact angle is high and the wetting is poor. In other words, to achieve wetting, the surface energy of the solid material should be higher than that of the liquid. The surface energy of various solid materials is listed in Table 26.5. Similarly, the surface energy of some liquids is presented in Table 26.6. Normally inorganic materials have higher surface energy than organic materials; this means that organic materials have poor wettability (fewer tendencies to cause sticking of materials). Metals have high surface energy; therefore materials tend to stick more on a metal surface. Polymers have low surface energy, therefore these are difficult to wet. One polymer, Teflon, has very low surface energy. Since water is a very high energy material (Table 26.6) and Teflon has a very low surface energy (Table 26.5), these events are energetically incompatible; therefore the wetting angle is very large. Currently, the drive in nanoparticle technology has been to attempt to manufacture an ultrahydrophobic surface

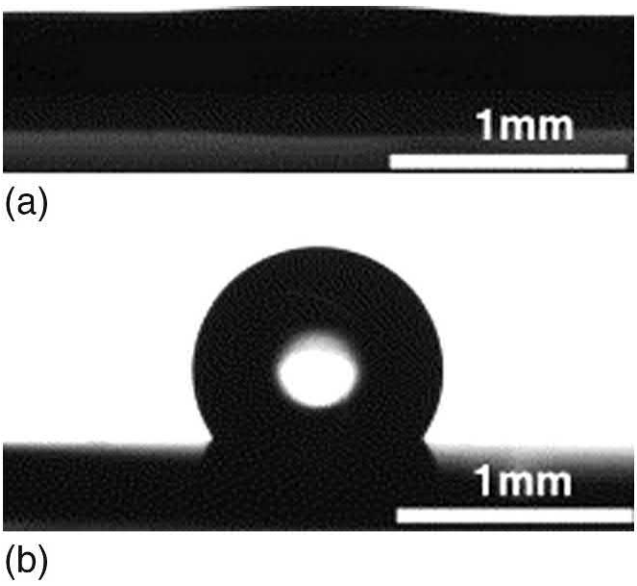

FIGURE 26.4 Nanoparticle coating results in low surface energy self-cleaning surface and water droplets on the surface (a) with nonfluorinated nanostructured TiO_2 coating, and (b) with nanostructured fluorinated TiO_2 coating, which gives a contact angle of the water drop around 150°. (From Burmeister et al. [13].)

with a very low energy level that can be nonadhesive and self-cleaned [12, 13]. An example is presented in Figure 26.4, which shows the effect of surface coating with nanostructured fluorinated and nonfluorinated titanium oxide (TiO_2). The coating with the former nanomaterial is rendered a contact angle of 150° [13]. A surface with a more than 150° water droplet contact angle has ultrahydrophobic, self-cleaning, and nonsticky properties. In the future, this material has potential applications in the food and powder processing (such as drying) industries handling sticky products.

26.3.3 Occurrence of Cohesion and Adhesion during Drying

Stickiness is encountered during drying and handling of some key dried food materials such as whey, lactose, protein hydrolysate, high-fat milk, fruit juices, honey, and high dextrose equivalent glucose syrups. Spray drying is the liquid food drying method where stickiness is the most common major issue. The powder may deposit on the wall or blockage may occur in the duct or cyclone. In spray drying the stickiness is not purely by adhesion onto the dryer wall. At the accumulation stage, the cohesive force between the particles can play a role, since the wall can be completely covered with the material. It is important to avoid the early stage of adhesion, which can act as a seed for further accumulation of underdried or sticky particles.

The concentration of solutes during drying can increase the surface tension, but the most influential factor is the rapid increase in viscosity. The increased viscosity results in increased time required to wet the wall because of the high resistance to flow. Thus the stickiness mechanism involves both the viscous flow of the droplets and surface energy of the droplets and dryer wall [14]. Once the product (as droplets) is in contact with the system, the liquid flow can be dictated by the surface tension or energy of the system. The liquid bridge between the dryer wall/product (adhesion) and product/product (cohesion) occurs as a function of time. If the contact area is very small and the drying continues, the dried particles may be carried away from the wall. To reduce the contact area, it is important that the wall material has a low surface energy. In many drying situations, stainless steel is used as the wall material because of its durability, ease of cleaning, and hygienic reasons, but this metal has a high surface energy (Table 26.6). Teflon (PTFE) has been found to be very useful in the handling and processing of food materials due to its extremely low surface energy (18 mN/m), relative inertness, high tensile strength, and thermal stability. There are many other polymeric materials that are hydrophobic and also have a low surface energy level. Due to their poor physical and thermal stability, and possible interaction with the food components, they are not used in many food processing situations, particularly in high temperature drying processes.

Many studies have sought to relate stickiness to the glass transition property of a drying food material. The glass transition normally signifies the conversion of an amorphous solid (or glass) to a rubbery state. In surface energy terms, a solid glass has low surface energy and is unable to stick on any other low energy solid surfaces. Due to the transition from glass to a rubbery (or liquid) state, the surface energy of the material increases and the molecules start interacting with the solid surface. In a food drying operation, the product is in a liquid or rubbery state and, due to the removal of plasticizer (water), the liquid/rubbery food is converted to the glassy state. If the food material does not go through the transition due to a higher drying temperature than the glass transition temperature, the product remains in a high energy sticky state. If this food comes in contact with a high energy solid surface, it can stick or cling to it [1].

The issue of adhesive/cohesive force is also important in the case of fluidized bed dryers handling pasty or solid particulates. The development of cohesive forces resulting from interparticulate liquid bridges can make the operation complex in fluidized and spouted beds [15]. The surface energy of dried or semidried particles can also be influenced by the electrostatic energy generated during their movement. Ciborowski and Wlodarski [16] reported the occurrence of electrical forces in fluidized beds. They found that electric charges that accumulate on solid particles may cause the adhesion of a layer of solid particles to the walls of the fluidizing equipment, the agglomeration of particles into larger aggregates, and the change of a fluidized bed into a channeling bed. Machowski and Balachandran [17] also stated that cohesive powders are generally much more difficult to transport due to short-range molecular forces (van der Waals) as well as electrostatic forces, which cause agglomeration and adhesion of particles, impeding the flow. The surface energies of particulates and binding agents are also very important factors in the agglomeration process applied to instant dry food powders.

26.3.4 Stickiness Testing Methods for Powders

26.3.4.1 Testing for Cohesion

26.3.4.1.1 Propeller-Driven Method

Originally developed by Lazar et al. [18], the propeller-driven method has been used by several researchers with or without modifications to evaluate the effects of temperature on powder stickiness (Figure 26.5). The tester basically comprises a test tube containing powder with known moisture content. The test tube is immersed in a water bath. A machine-driven impeller stirs the powder. When the temperature of the powder is slowly raised by increasing the water bath temperature, at the sticky point a maximum force of stirring is recorded. In a search for a simpler and more efficient technique, Özkan et al. [19] developed a viscometry technique based on the measurement of the torque required to turn a propeller inserted into powders.

26.3.4.1.2 Optical Probe Method

A method based on the changes in the optical properties of a free-flowing powder was reported by Lockemann [20]. The motion of the powder in a constantly rotating tube is observed with a fiber-optic sensor (Figure 26.6). The tube and sensor are all immersed in an oil bath to maintain the temperature. A sharp rise in reflectance of a freely flowing powder is observed at its sticky point.

26.3.4.1.3 Blow Test

Paterson et al. [21] attempted to develop a blow test for measuring the stickiness of powders (Figure 26.7). This method measures the velocity of air needed to blow a channel into a packed bed of powder, and the stickiness of powder is classified based on the air velocity range. The apparatus consists of a multisegmented circular distributor (sample holder) where the preconditioned sample is packed in the distributor.

26.3.4.1.4 Fluidization Method

Bloore [22] described a small fluidized bed set up to study the stickiness property of powder at different humidity and temperature conditions (Figure 26.8). The positive point of this method as compared to other tests is that the particulates are in a dynamic condition, which is closer to the spray drying and fluidized bed drying situations.

26.3.4.1.5 Cyclone Method

A cyclone technique (previously conceptualized and developed by Bhandari and Howes at the University of Queensland, Brisbane, Australia) is described by Boonyai et al. [23] and used to investigate stickiness behavior of food powders as a function of temperature and moisture conditions. It simulates the dynamic condition in a spray drying system (Figure 26.9). The powder particles are individually in contact with a preconditioned air stream and hence a rapid simultaneous heat and moisture transfer occurs at the surface. The cyclone consists of a detachable sample holder at the bottom. A few grams of sample are put in the sample holder for the test. Stickiness is observed within 1–2 minutes when particles become cohesive and stick to each other, and some adhere to the chamber wall due to adhesive force. If a longer time is allowed, all particles become completely immobilized. The testing time may also depend on the hygroscopicity of the material and particle size.

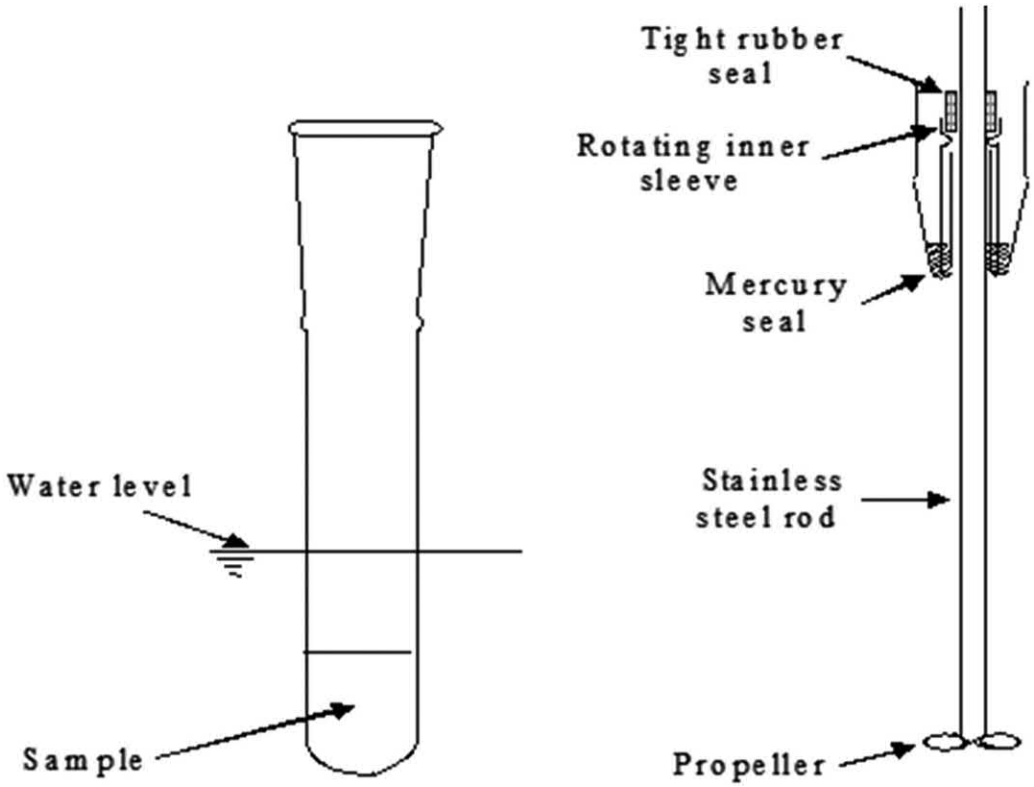

FIGURE 26.5 An early stickiness measuring device reported by Lazar et al. [18].

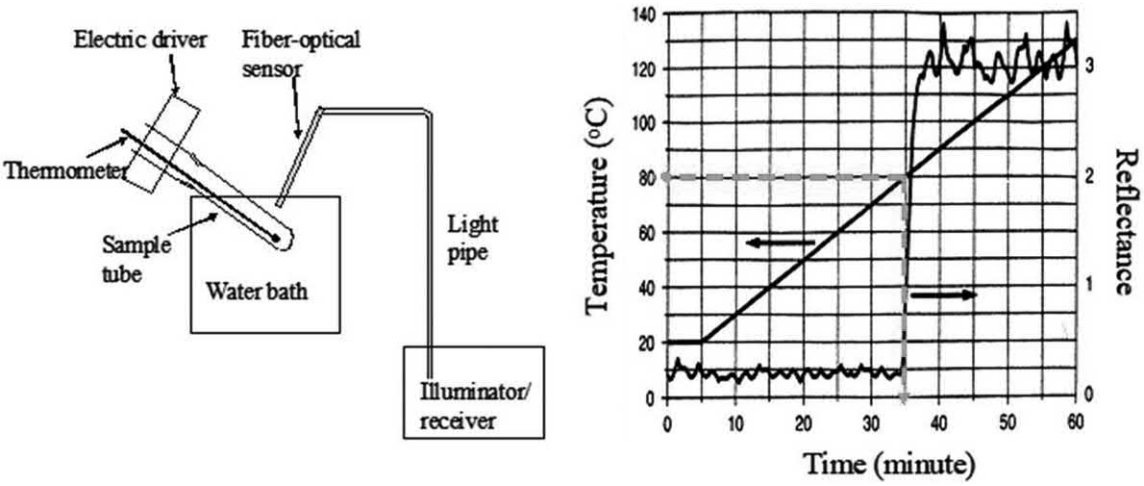

FIGURE 26.6 A stickiness device using an optical probe. (From Lockemann [20].)

26.3.4.1.6 Thermal Mechanical Compression Test (TMCT) Method

The thermal mechanical compression test assumes that the critical point of the stickiness of powders is at their rubbery state. During drying, the product is progressively transformed from liquid to rubbery and to glassy states. The product at the glassy state is totally solid in behavior and is not sticky. If the powder is not converted to the glassy solid state from the rubbery state during drying, it exhibits stickiness behavior (both adhesive and cohesive in nature). The reversible conversion from rubbery to glassy or vice versa is called glass transition temperature. The stickiness occurs when the powder glass transition temperature is below the outlet air temperature in the dryer. A common technique to measure the glass transition is differential scanning calorimetry (DSC). Since this technique is expensive and also requires expensive consumables (such as an aluminum pan), a simple technique called the thermal mechanical compression test (TMCT) was conceptualized and developed by Bhandari and Howes at the University of Queensland. The TMCT technique measures the phase change of a material based on mechanical changes during the transition (Figure 26.10a). The powder sample is axially compressed at constant pressure (1–3 kg/cm^2) until equilibrium, and the temperature is scanned in creep mode in a texture analyzer (such as TA.XT2). When the powder reaches its glass transition temperature, the probe displacement takes place and this point is considered as the stickiness point of that particular sample, as depicted in Figure 26.10b [24]. In dynamic and very short contact time situations, the stickiness usually occurs at 10–20°C above the measured glass transition temperature.

26.3.4.2 Testing for Adhesion

Surface properties of a droplet, such as film formation and dried wall material properties, can greatly influence stickiness. The film formation property once again is a function of drying conditions. Adhikari et al. [25] developed a rig for testing the *in situ* stickiness behavior of a drying droplet (Figure 26.11). There are two setups in this rig: one for measuring stickiness and the other for studying drying kinetics. Both of the setups are housed inside a glass chamber supplied with hot air with controlled flow, temperature, and humidity. The linear actuator with an appropriate step size is used to achieve the forward and backward

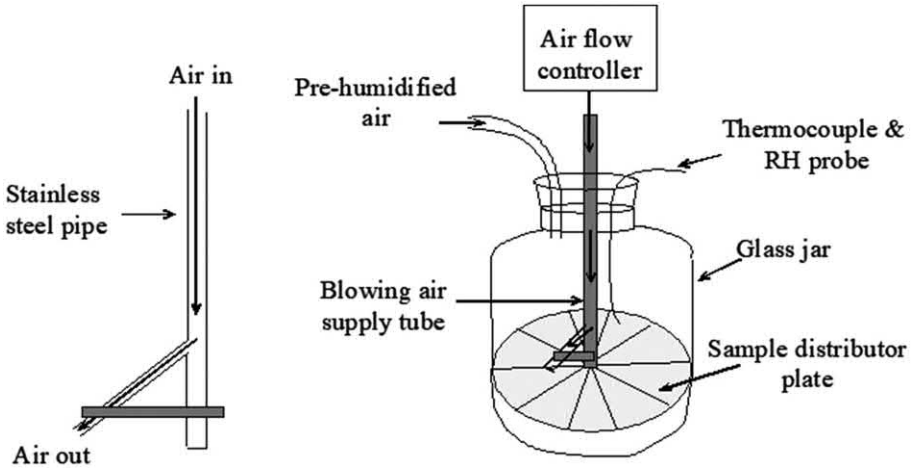

FIGURE 26.7 Blow test to measure the stickiness property of powders. (From Paterson et al. [21].)

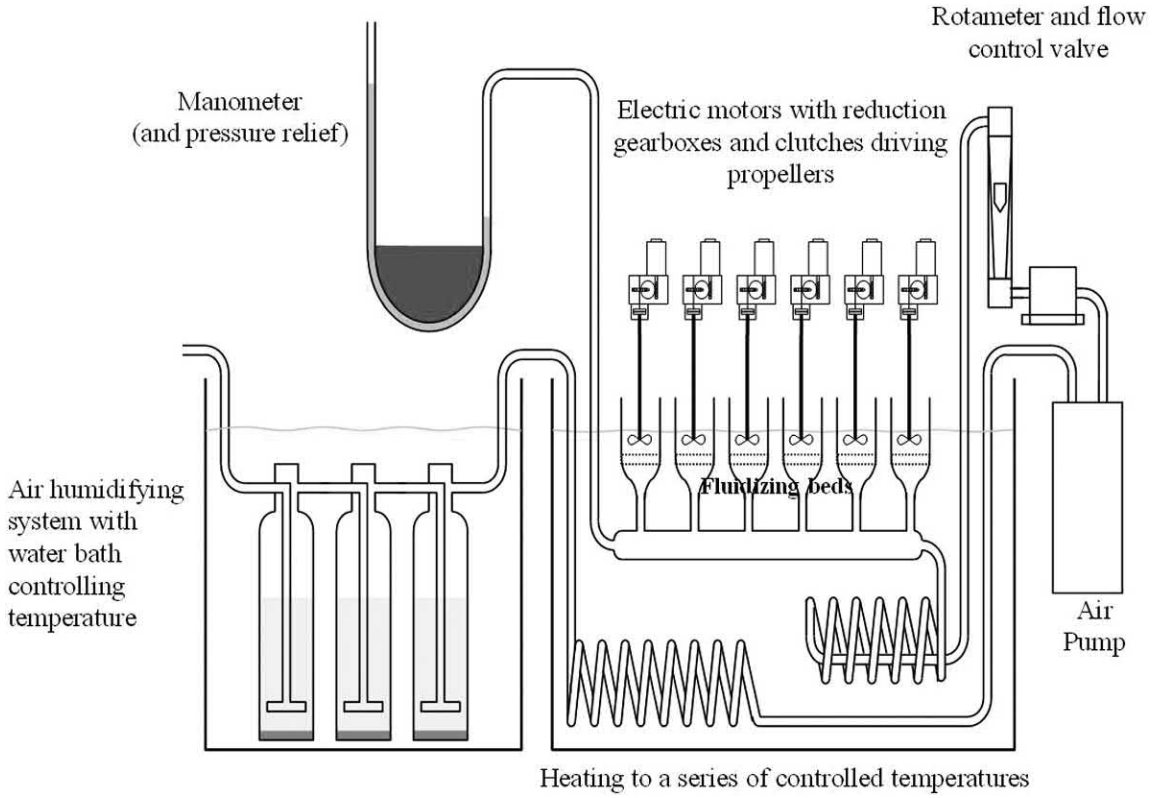

FIGURE 26.8 Fluidized bed stickiness testing device. (From Bloore [22].)

movements of the probe. The probe surface is made up of various materials (e.g., glass, stainless steel, Teflon, polyurethane). The tensile and compression force during stickiness testing and air temperature is continuously logged. The temperature history of the sample is recorded using micro-thermocouples. Images of bonding, debonding, and failure modes during the testing are captured using a color camera and recorded on a personal computer through a frame grabbing card. The same image capturing system is also used to monitor the drying droplet.

26.4 CAKING OF POWDERS

Stickiness is the preliminary stage of caking. In general, stickiness is an instantaneous phenomenon, whereas caking occurs over time. As previously mentioned, all amorphous products are metastable and therefore can potentially crystallize (for crystallizing species) during storage. The amorphous state is the most vulnerable to caking. The crystalline state is less prone to caking, however, the presence of an amorphous glassy layer around the crystal, dissolution of the outer surface of the crystal due to moisture absorption, and compaction can provoke caking of crystalline powder, too. Longer contact times increase the tendency toward sticking and caking, all other things being equal. Thus, a dried product with a relatively free-flowing property immediately after drying could also cake in a collection or packaging container over a period of time if the surface viscosity is still relatively low due to higher temperature or moisture levels. For this reason, the dried product needs to be cooled immediately to an appropriate temperature before packaging. Temperature changes and moisture migration in the bags during travel through different climate zones and consolidation pressure can cause undesirable caking in the powders [19]. The moisture fluctuations during day and night (or during shipment) also result in internal moisture migration in bulk solids due to the vapor pressure differentials in cold and hot conditions. This temperature fluctuation at the outer surface of packaging can be as high as 25°C in some climates. Due to the lack of conductivity of heat of the solids and cyclic heating and cooling, there is a formation of crust at the surface of the bulk powder. As stated earlier, the amorphous powders are most prone to caking due to their high hygroscopicity. Crystalline powder can also form cake due to surface dissolution and recrystallization. Mixed powders (coexisting amorphous and crystalline structure) have a mixed tendency to form cake. Various factors that influence the caking behavior of powder are depicted in Table 26.7.

26.4.1 Factors Responsible for Caking

There are four major causes of caking: (i) presence of liquid component, (ii) moisture absorption, (iii) crystallization, (iv) consolidation, and (v) deliquescence.

26.4.1.1 Presence of Liquid Component

Some of the food components can be in liquid state, such as fat in milk powders, oil in microencapsulated flavor powders, or viscous juice in dried fruits (such as raisins). In powder, such a liquid state should be in discontinuous phase, and so be encapsulated by the solid continuous

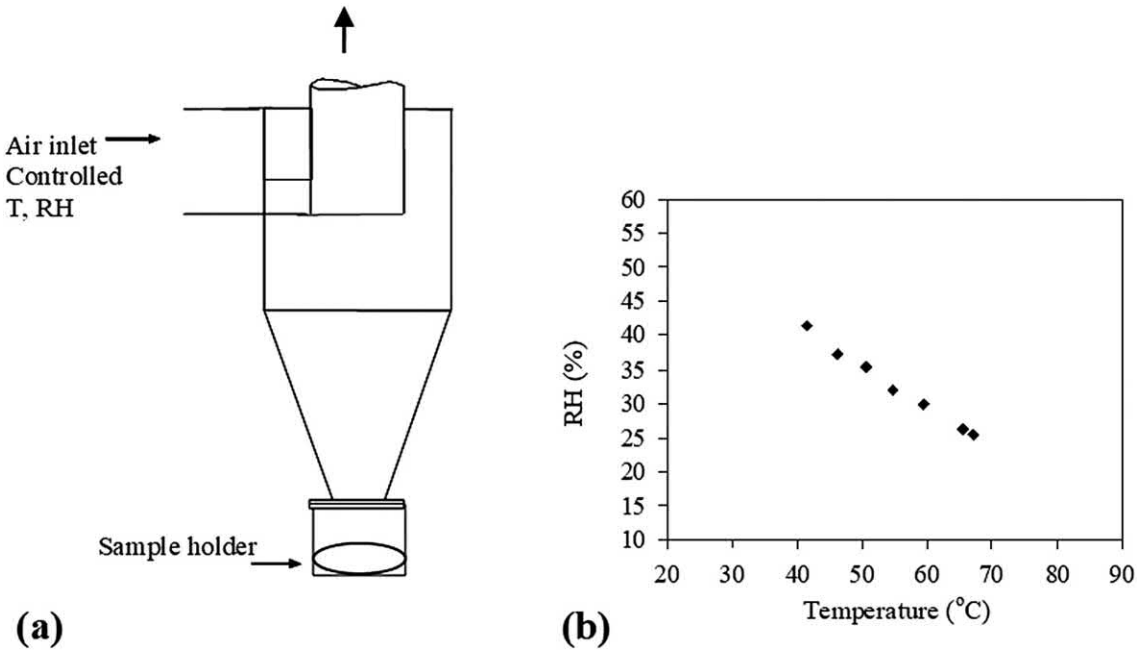

FIGURE 26.9 (a) Design of the cyclone chamber and sample holder. (b) Stickiness curve of skim milk powder as a function of temperature and relative humidity measured using a cyclone setup. (From Bhandari and Hartel [1].)

phase. However, leaching or breaking the structure can cause release and coalescence of such liquid at the surface of particles. This results in particles sticking together. This is manifested by decreased flowability and sluggish powder behavior. Free fat or oil in the powders cause caking, but the cakes are not as strongly held together as in the case of caking as a result of other factors, such as lactose crystallization in milk powder during storage. The increased temperature can also result in melting of the solid phase (fat to oil) or state change (glassy to rubbery), consequently resulting in caking of powder.

26.4.1.2 Moisture Absorption

Water absorption by the powder can cause the dissolution of the outer surface of the crystals or particles or the condensation of the capillary moisture in amorphous material (Figure 26.11). This eventually creates a liquid bridge. Upon dehydration, these liquid bridges are converted to strong solid bridges. The distance between the particles and hygroscopic property of the particle components influences the rate of caking. The higher the compactness of the particles and the finer the particles, the faster the cake formation.

26.4.1.3 Crystallization

Crystallization is also encouraged by water absorption by an amorphous powder (Figure 26.12). The extent of water absorption by powder depends on its sorption property. If a local portion of the product in a package picks up moisture, the glass transition temperature is locally depressed for that particular portion and the crystallization rate at that spot is accelerated. Formation of the lattice during crystallization generally excludes water molecules and the excess moisture is lost to the environment. Absorption of this ejected moisture at the surface of neighboring particles creates interparticulate liquid bridges resulting in caking [26]. Surrounding particles that absorb moisture are also crystallized and crystallization

TABLE 26.7
Process and Product Characteristics Influencing Caking Behavior of the Dried Foods (Powder)

Factors	Specific Details
Processing condition	Melting or dissolution of components in the powder due to high temperature processing or moisture addition
Microstructure	Extent of amorphous structure, very low average particle size (increased van der Waals attraction due to large surface area)
Product composition	Presence of liquid components at room temperature (such as oil, organic acids), presence of highly hygroscopic component, usually low molecular weight sugars, polyols, or organic acids
Storage condition	High humidity and/or temperature conditions causing melting and solidifying, glass–rubber transition, or crystallization of part or all of the components, powder consolidation due to overload, capillary condensation in crystalline particles

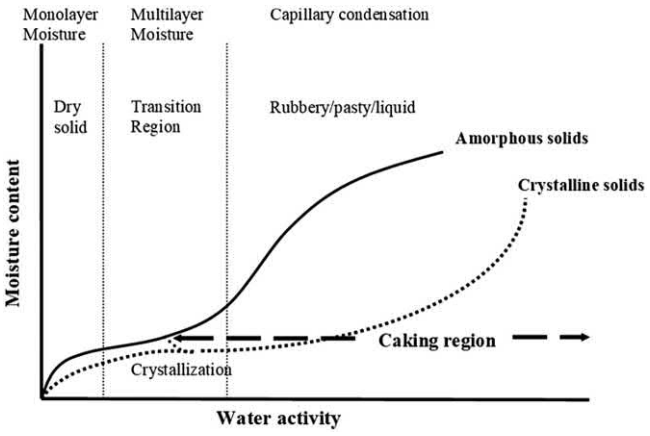

FIGURE 26.12 Indicative graph of water sorption isotherm of amorphous, crystalline, or crystallizing solids and their relationship to caking.

proceeds as a chain phenomenon. Crystallization of sugars is delayed by other ingredients present in the concentrated powder system by the same mechanism as in the supersaturated solution [27, 28]. The crystallization process rejects impurities including volatiles. Senoussi et al. [29] found a loss of diacetyl as a function of the rate of crystallization of lactose during storage. They found that when the lactose was stored at 20°C above glass transition, the amorphous product went through immediate crystallization and practically all diacetyl was lost after 6 days. Levi and Karel [30] also found an increased rate of loss of a volatile, 1-*n*-propanol, in an amorphous sucrose system as a result of crystallization.

26.4.1.4 Consolidation

Consolidation or compression of powders decreases the distance between the particles, and consequently van der Waals and other forces become predominant. This results in caking. This is more important if the powders are fine or brittle or break due to the compression force. The filling of the voids during compression, absorption of the moisture, leakage of liquid fraction, particle shape and size, and increased bulk density will contribute to caking during compression [31]. In some cases, this is desirable, such as during tableting where the binders are sometimes added in some powders to increase the tensile strength of the tablets. In the case of food, caking of the powder at the bottom of the stack is a commonly observed problem due to high consolidation force.

26.4.1.5 Deliquescence

Deliquescence is the liquefaction property of the crystalline materials (e.g., inorganic and organic salts, sugars, organic acids and bases, preservatives, flavor enhancers, or even vitamins) that occurs at a particular relative humidity, known as deliquescent relative humidity, which is specific for each type of deliquescence and temperature [32]. The deliquescent humidity is equal to the water activity (×100) of the saturated solution of that compound. Table 26.8 illustrates deliquescent relative humidity of several crystalline biological and inorganic materials at 25°C. At high relative humidity, water adsorption of solid materials results in the deliquescence of the solid surface and the formation of a concentrated thin film of solution on the surface of powder particles. The fusion of liquid films leads to the formation of liquid bridges between particles, which is the most common cause of the caking process of powders. Upon dehydration of powder particles (e.g., as exposing them to lower relative humidity), these liquid bridges are converted to solid bridges, as a result of recrystallization of solid materials, and consequently caking of powder is formed [33]. It is important to note that deliquescent relative humidity of a mixture of solid materials is always lower than that of any individual component. This causes the mixture of deliquescent solids to be more vulnerable to caking than individual components. It was reported that exposure of the mixture of citric acid anhydrous crystals and fructose crystals to 56% RH (25°C) for 16 h led to complete deliquescence of the fructose crystals and rounding of the edges of citric acid crystals, while at the same conditions citric acid and fructose crystals were both intact as they were separated [34]. Similar results were also reported for a mixture of amorphous maltodextrins and sodium chloride [35], a mixture of sodium chloride and sucrose [36], fructose–citric acid anhydrous and sucrose–sodium chloride systems [37], and a sucrose–citric acid mixture [38]. This is due to the capillary condensation effect at the contact point of the particles. The Ross equation was able to predict the deliquescent humidity of the binary mixture of solutes [34].

TABLE 26.8
Deliquescent Relative Humidity of Several Solid Materials (25°C)

Solid Materials	Deliquescent Relative Humidity (%)
Sucrose	85
α-Lactose monohydrate	95
β-Lactose	95
α-Glucose monohydrate	91
α-Glucose anhydrous	89-91
β-Glucose	74
Ascorbic acid	95
Malic acid	59
Sorbic acid	95
Sodium chloride	75
Potassium chloride	85
Monosodium glutamate	87
Magnesium chloride	33
Calcium chloride	28

26.4.2 Measurements of Degree of Caking

There are various methods employed to characterize the degree of caking by analyzing the change in the basic properties of the powders, such as flowability, angle of repose, interparticulate cohesion, size distribution, and particle morphology (Table 26.9). Among these techniques,

TABLE 26.9
Methods Employed to Measure the Degree of Caking

Method	Principle
Flowability	Discharge mass flow rate from a bin or funnel
Angle of repose	Heap angle along the horizontal plane (<40° for free-flowing powder)
Cohesion	Negligible shear stress for a free-flowing powder (Jenike shear cell method)
Caking index	Weight fraction retained by a mesh with an opening size of maximum particle size of the powder
Microscopic attributes	Ratio of interparticulate bridge diameter to particle diameter (microscopic techniques)

Source: Aguilera et al. [39].

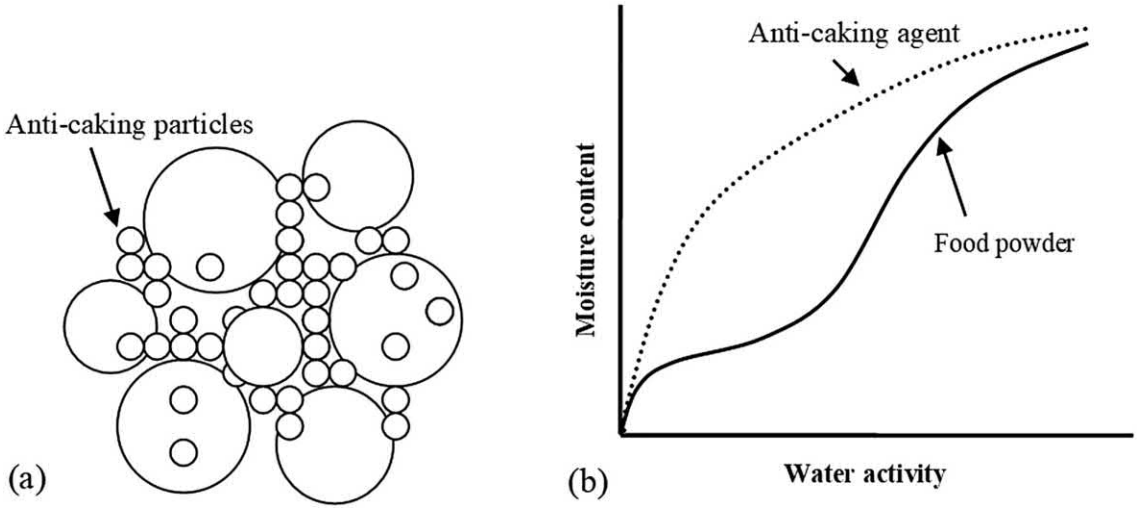

FIGURE 26.13 (a) Schematic representation of finer anticaking particles incorporated into larger particles. (b) Sorption isotherm property of anticaking agents.

microscopic observation or measurement of the increased size of the particles (indicated by the caking index) is the most appropriate method.

26.4.3 Anticaking Agents

Anticaking agents prevent the powder particles from sticking together. These agents are natural, inert, and bland in taste. Normally the anticaking agents are very fine powders (1–5 μm). Due to their smaller size, they tend to stick and coat bigger particles and separate two surfaces likely to adhere together (Figure 26.13a). A similar process is applied in dry coating of particles [40]. The van der Waals and electrostatic forces are responsible for sticking of fine particles to the bigger one. Anticaking powders have more surface area per unit weight; therefore, they absorb moisture faster than the actual powder. They have the capacity to absorb a large amount of water without exhibiting stickiness (Figure 26.13b). These can be inorganic and organic products. The inorganic powders include calcium and magnesium phosphates; aluminum, calcium, sodium, magnesium, potassium and ammonium salts of fatty acids; magnesium oxide; silicon dioxide (amorphous); calcium, aluminum, potassium and magnesium silicates or talc; bentonite (clay); and polydimethylsiloxane or dimethylpolysiloxane. These inorganic anticaking agents are mostly used in dairy powders and salts. The organic anticaking agents include microcrystalline cellulose, isomalt, fruit and vegetable fibers, corn starch, cereal (corn, rice) starches, and vegetable oil. These agents are widely used in fine icing sugars, shredded cheese products, dried fruit pieces, and fruit leathers. The level of addition of anticaking agents is normally less than 1% and should comply with good manufacturing practices (GMP). Criteria for GMP are (i) quantity shall be at the lowest level possible, (ii) it is not intended to accomplish any physical or technical effect in the food itself, and (iii) these need to be prepared and handled the same way as the food ingredient.

27 Drying Methods Used in Food Preservation

Mohammad Shafiur Rahman and Conrad O. Perera

CONTENTS

27.1 INTRODUCTION

The preservation of foods by drying is the time-honored and most common method used by communities and the food-processing industry. The dehydration of food is one of the most important achievements in human history, making us less dependent upon a daily food supply even under adverse environmental conditions [1]. Drying in earlier times was done in the sun; now many types of sophisticated equipment and methods are used to dehydrate foods. During the past few decades, considerable efforts have been made to understand some of the chemical and biochemical changes that occur during dehydration and to develop methods for preventing undesirable quality losses. Foods can be divided into three broad groups based on the value added through processing by drying. In the case of cereals, legumes, and root crops, very little value is added per kilogram processed. More value per unit mass is added to foods such as vegetables, fruits, meat, and fish, and considerably more to high-value crops such as spices, herbs, medicinal plants, nuts, bioactive materials, and enzymes.

27.1.1 State of Water in Foods

The terms drying and dehydration are not synonymous. The US Department of Agriculture lists dehydrated foods as those with no more than 2.5% water (dry basis), while the term dried foods applies to any food product with more than 2.5% water (dry basis) [2]. The concept of bound and free water has been developed from drying principles, and it is important for dried products for their stability during processing and storage. A product containing no water is termed as bone-dry. Water in foods exists in different forms or states. Water in foods having properties different from those of pure water can be defined as bound water. In the literature different forms of bound water are defined [3], for example, unfreezable, immobile, monolayer, and non-solvent water. However, the fraction of bound water depends on its definition and the measurement techniques used to measure it [3]. The binding energy of different states of bound water affects the drying process since it requires more energy to remove bound water than free water.

27.1.2 Endpoint of Drying

Equilibrium in the drying system is the ultimate endpoint for the process. Water activity is commonly used to estimate the equilibrium point in the cases of thermal and osmotic drying processes. In mechanical dewatering, the magnitude of the applied force and rheological properties of the foods affect the equilibrium point. Generally, meat, fish, and dairy products are dehydrated to a moisture content of 3% or less, vegetable products usually to 5%, and cereal products frequently to as much as 12% [4]. A maximum moisture level is usually established for each dried product separately based on desired acceptable quality after drying and during storage. Different attributes of quality can be targeted; thus the endpoint should be determined based on all aspects, such as safety first and then consumer acceptance.

27.1.3 Heating Methods in Drying

Heating of air by electric heater or flue gas is the conventional heating method used for drying processes used in foods. In this case, heat transfer from the gas to the product occurs mainly through convection. The heating method is another important aspect of drying in terms of quality as well as energy cost. Microwave, infrared, radiofrequency, refractance window, and dielectric heating use the electromagnetic wavelength spectrum as a form of energy, which interacts with the materials, thus generating heat and increasing the drying rate dramatically. Dielectric drying uses frequencies in the range of 1–100 MHz, whereas microwave drying uses frequencies in the range of 300–300,000 MHz. Microwave heating is rapid, more uniform in the case of liquids, and more energy-efficient than the hot-air method [5]. Applying microwave energy under vacuum affords the advantages of vacuum drying and microwave drying, providing improved energy efficiency and product quality. The energy can be applied by pulsed or continuous modes. Pulsed microwave drying is more efficient than continuous drying. The use of electro-technology in drying is getting priority in the food industry to improve the drying efficiency as well as quality.

27.2 DRYING METHODS

Drying processes can be broadly classified, based on the water-removing method applied, as (i) thermal drying, (ii) osmotic dehydration, and (iii) mechanical dewatering. Thermal drying is one of the most widely used methods of drying foods. In this process, heat is mainly used to remove water from the foods. In thermal drying a gaseous or void medium is used to remove water from the material; thus thermal drying can be divided into three types: (i) air drying, (ii) low-air-environment drying, and (iii) modified-atmosphere drying. In osmotic dehydration, a solvent or solution is applied to remove water, whereas in mechanical dewatering physical force is used to remove water. Consideration of many factors should be given before selecting a drying process. These factors are (i) types of product to be dried, (ii) properties of the finished product desired, (iii) allowable temperature tolerance, (iv) the product's susceptibility to heat, (v) pretreatments required, (vi) capital and processing cost, and (vii) environmental factors. There is no one best technique of drying for all products [2, 6].

The mechanisms of moisture transfer depend mainly on the type or physicochemical state of food materials and the drying process. The food materials can be classified as (i) homogeneous gels, (ii) porous materials with interconnecting pores or capillaries, and (iii) materials having an outer skin that is the main barrier to moisture flow [7]. The type or structure of foods always played an important role in the drying process.

27.3 DRYING FUNDAMENTALS

In terms of transport phenomena, both heat and mass transfer processes are considered within the foods and outside atmosphere of drying. Hence, there are two resistances: heat transfer and mass transfer. During the *constant rate period*, it is assumed that there exists a thin film of water on the slice and there is no internal or external mass transfer resistance. Hence, the drying is controlled by external heat transfer. In the *falling rate period*, the drying is controlled by internal mass transfer resistance. The absence of a constant rate period indicates that the drying is controlled from the beginning by internal mass transfer resistance. The moisture content at which the drying period changes from a constant to a falling rate can be considered the critical moisture content. The critical moisture content depends on the characteristics of the foods and the drying conditions. The critical moisture contents varied from 0.78 to 0.83 (kg/kg, wet basis) for vegetables and 0.85 to 0.89 (kg/kg, wet basis) for fruits [8]. At high moisture contents, liquid flows due to dominated capillary forces. At decreasing moisture content, the amount of liquid in the pores also decreases and a gas phase is built up, causing a decrease in liquid permeability. Gradually the mass transfer is taken over by vapor diffusion in a porous structure. At the saturation point, there is no longer liquid available in the pores and mass transfer is taken over completely by vapor diffusion [9].

The moisture is transferred from the solid materials by diffusion or capillary mechanisms. In a diffusion mechanism, the driving force is the concentration gradient. Water diffusion can be in the form of liquid or vapor. In the case of liquid diffusion, osmotic pressure could be the driving force for water movement. In the capillary mechanism, the moisture moves due to surface tension force and does not conform to the laws of diffusion. A porous material contains a complicated network of interconnecting pores and channels, and at the surface mouths of pores of various sizes exist. As water is removed, a meniscus is formed across each pore, which sets up capillary forces by the interfacial tension between the water and the solid. Capillary forces act in a direction perpendicular to the surface of the solid. It has been suggested that a combined mechanism of capillary forces and vapor diffusion is responsible for moisture movement in the drying of potato [10, 11]. The drying experiments of Saravacos and Charm [8] with surface-active agents failed to show any importance of capillary forces during the dehydration of potatoes and other vegetables. Surfactants are known to reduce the surface tension of water, thus increasing the capillary forces in porous materials. Thus, capillary flow is not significant in the vegetables studied by Saravacos and Charm [8]. Waananen and Okos [12] showed that during drying of pasta at temperatures close to the boiling point, liquid flow dominates moisture transport at high moistures and vapor flow is significant only at low moistures. Achanta and Okos [13] reviewed the shrinkage of different biopolymers and concluded that shrinkage on drying is equal to the volume of moisture leaving; thus it is conceptually difficult to justify that capillary flow is important during the drying of high-moisture biopolymers.

The strength of capillary forces at a given point in a pore depends on the curvature of the meniscus, which is a function of the pore cross section. Small pores develop greater capillary forces than large ones; thus large pores tend to empty their water content first. In large pores, the capillary forces are small. The force of gravity is then large in comparison with the capillary forces, and there is a directional effect due to gravity [14].

27.3.1 Drying Curve

A drying curve usually plots drying rate (or moisture content) versus moisture content or drying time. There are three major stages of drying which could be observed in the drying curve (Figures 27.1 and 27.2):

1. Transient early stage, during which the product is heating up (transient period)
2. Constant or first period, in which moisture is comparatively easy to remove (constant rate period)
3. Falling or second period, in which moisture is bound or held within the solid matrix (falling rate period)

Typical drying rate curves are shown in Figures 27.1 and 27.2. The moisture content at which the change from the first to the second period occurs is known as the critical moisture content.

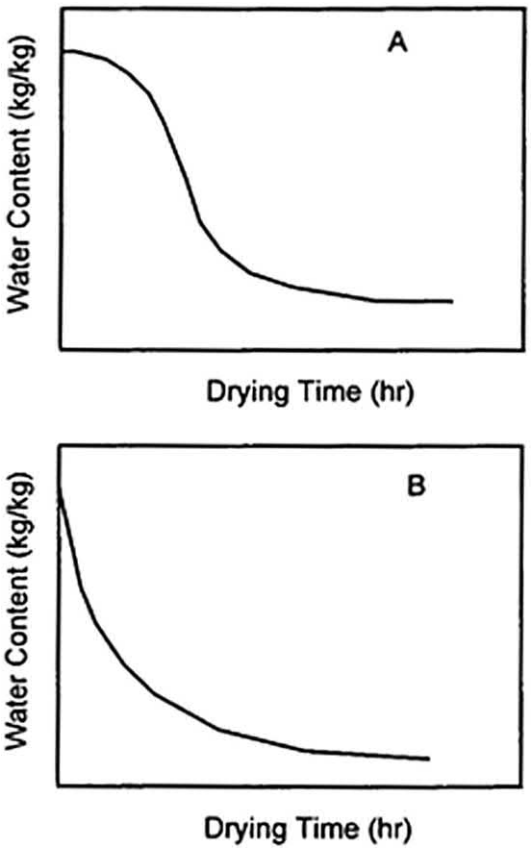

FIGURE 27.1 Typical drying curves (water content versus drying time): (A) with a lag period, (B) without a lag period.

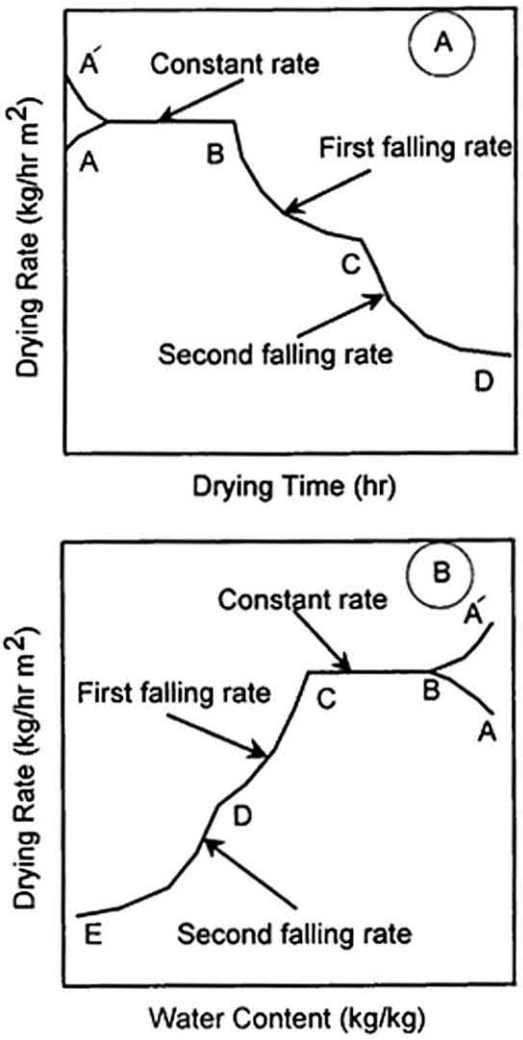

FIGURE 27.2 Typical drying rate curves: (A) drying rate versus drying time, (B) drying rate versus water content.

Typically, two falling rate periods are observed for both hygroscopic and non-hygroscopic solids [15]. The first falling rate period is postulated to depend on both internal and external mass transfer rates, while the second period, during which drying is much slower, is postulated to depend entirely on internal mass transfer resistance only. The slower rate may be due to the solid–water interaction or glass–rubber transition [13].

The drying behaviors of food materials depend on the porosity, homogeneity, and hygroscopic properties. The immediate entrance into the falling rate is characteristic of hygroscopic food materials. Lee et al. [16] studied the effect of sodium sulfate on the surface evaporation of a porous medium during the constant rate period. The drop in the drying rate was significant due to the decrease of surface vapor pressure and the change of liquid surface curvature due to meniscus effects by surface tension.

27.3.2 Energy Aspects of Air Drying

Drying is one of the most energy-intensive processes in the food industry. Apart from the rise of energy costs, legislation on pollution and sustainable and environmentally friendly technologies created greater demand for energy-efficient drying processes in the food industry. Thus, novel thinking in the technology of drying methods and dryer design is evident. The food industry could save a lot of money by avoiding costly energy waste. Improving energy efficiency by only 1% could result in as much as a 10% increase in profits [17]. Conducting an energy survey is the traditional way to approach the problem. The energy survey analyzes the energy defect level at each stage of processing and strategies for their remedy [17]. It is an inspection, survey, and analysis of energy flows in the system, which can enable the reduction of energy input without negatively affecting the output. It is a reliable, rational, and systematic approach to quantifying energy usage and energy efficiency [18]. The use of energy management, energy-saving technologies, and energy-saving policies are the keys to achieve savings [19, 20].

Microwave drying is an efficient method, and it provides high drying rates, high energy efficiency, and improved product quality [21–26]. It makes the core temperature of foods higher than the surface temperature, and this causes water transport to the surface and forms a porous structure [27, 28]. Air drying can be coupled with microwave drying. Microwave drying requires a high-temperature gradient between the core and surface, while air drying requires a high surface temperature to evaporate surface water. Optimization of the two different energy sources needs to be done in order to achieve the desired performance [29]. Material temperature, temperature difference, and size of the sample were optimized for desired quality of the dried products [30].

The use of infrared (IR) energy in combination with hot-air drying has attracted interest for the drying of foods due to the synergistic effect of infrared radiation on air drying [31]. It improves the final product quality, reduces the overall energy consumption and drying time, and reduces the total operating cost as compared to convective hot-air drying [32, 33]. However, appropriate combined strategies need to be followed to reduce energy consumption and to improve product quality [32].

27.3.3 Energy Losses in Air Drying

Heat losses during drying can be grouped as heat loss with the exhaust air, heat loss with the product, radiation heat loss from the dryer, heat loss due to leakage of air from the dryer, and heat loss due to over-drying of products. Table 27.1 shows the possible energy savings for walnut dehydration. Re-circulating exhaust air in grain dryers is popular because of its energy conservation and effect on grain quality. The higher-humidity air damages grains to a lesser extent than low-humidity air.

Grains are severely damaged by high drying temperatures. Thus, by changing the dryer design energy losses can be avoided while achieving higher product quality. Energy can be saved by (i) reducing drying time or increasing throughput (better control), (ii) avoiding heat losses with exhaust air and dried products, (iii) avoiding over-drying of products (i.e.

TABLE 27.1
Energy Savings for Walnut Dehydration

Method	Possible Savings (%)
Preventing over-drying	25–33
Recirculation of drying air	25
Reducing airflow rate	≤25
Improved burner design and operation	≤10
Insulation of drying	3–4

Source: Strumillo and Lopez-Cacicedo [35]

optimum drying with proper control), (iv) avoiding leakage of air through doors and seals, (v) increasing heat transfer efficiency by checking fouling, (vi) avoiding improper and damaged insulation around dryer, air ducts, heat exchanger, and burner, and (vii) heat recovery from exhaust gas and dried product [34]. The potential for energy conservation by design and changes in drying operation is significant. The energy could be recovered from exhaust air, heat exchangers (pipe and plate types), thermal wheel, heat pipe installation, and runaround coil. These methods recover mainly sensible heat from the exhaust, while most of the heat is lost with the latent heat of water vapor in the exhaust air [35]. This latent heat can be recovered by condensing out water using a refrigeration system. However, a refrigeration system will consume extra power before further use. Among these methods, the heat pump dryer (using a dehumidifier) has a high potential for use in the food industry (discussed later). In addition, improved options for dryer design can increase energy efficiency. These include the appropriate selection of dryer types and operating temperature, energy switching, hot-air recirculation, thermal insulation, and appropriate flow control inside the dryer [36, 37]. The broad classes of thermal drying are air-drying, low-air-environment drying, and modified-atmosphere drying.

27.4 AIR DRYING METHODS

In the case of air drying, atmospheric air is used as a drying medium, and heat in different modes could be applied in the process.

27.4.1 Sun Drying

In the past, only sun drying was used for drying. In this process, foods are exposed to the sun by placing directly on mats or stone or hanging in the air. The main disadvantages are (i) contamination from the environment, (ii) product losses and contamination by insects and birds during drying, (iii) the need for more floor space, (iii) difficulty in controlling the process, and (iv) production of bad smells for the neighbors. Where the climate is not particularly suitable for air-drying or when better quality is desired, mechanical air-drying is mainly used. However, sun drying is the cheapest method of drying foods. Nowadays, solar and mechanical air-drying is widely used commercially.

27.4.2 Solar Drying

Solar drying is a further extension of sundrying by using radiation energy from the sun. Solar drying is a non-polluting process and uses renewable energy. Moreover, it is an abundant energy source that cannot be monopolized [38]. Solar drying has several drawbacks, which limit its use in large-scale production. These are the need for large areas of space and for high labor inputs, the difficulty in controlling the rate of drying, and insect infestation and microbial contamination [6, 38]. More options in designing are now available in the literature in order to avoid or reduce the above difficulties [39]. Solar dryers can be classified into three major groups (Table 27.2): (i) direct, (ii) indirect, and (iii) mixed type.

27.4.2.1 Direct Solar Dryer

There are different types of direct solar dryer designs available. In a wooden box type solar dryer, the sides and bottom of the cabinet are painted black internally to absorb solar radiation, which is transmitted through an inclined glass cover. Ventilation holes are included in the bottom and upper sides of the walls. Food samples are spread on a mesh tray. The warm moist air passes through upper ventilation holes by natural convection, creating a partial vacuum and drawing fresh air through the base holes [39]. Other designs are presented by Jairaj et al. [39]. Chauhan et al. [40] reviewed the applications of software in designing solar drying systems.

27.4.2.2 Indirect Solar Dryer

In the case of indirect natural solar dryers, a solar air heater is coupled with the drying chamber and the air is circulated to the drying chamber by natural convention. In order to enhance the air circulation, different designs such as a chimney and top hood are used [39]. In the forced convection, air is heated first by a solar collector and then force-circulated to the drying chamber by a blower or fan [41]. The specific energy consumptions of ghost chili and ginger were observed

as 18.7 and 8.8 kWh/kg, respectively [42]. Different design options are compiled in the literature [39].

Solar-assisted solid desiccant was used for the drying of crushed oil palm fronds [43]. In this system, solar energy was used to heat water with a solar collector and heat was transferred to the air through two heat exchangers: one used for regeneration of the desiccant wheel and another one to heat air after dehumidification. The drying time was reduced to 40 min instead of 30 h sun drying (moisture from 69 to 29%). A solar crop dryer was developed with phase change thermal energy storage [44, 45] and a packed-bed thermal energy storage system [46–48].

27.4.2.3 Mixed Type Solar Dryer

In the mixed type, an additional heater and fans are used. Solar photovoltaic cells are also used to generate electricity for the air circulation fan [39]. Sablani et al. [49] studied the performance of open rack, convection created by a fan operated by solar battery, and multi-rack dome dryer. In addition to the dryer performance, quality attributes of dried sardines were assessed by determining yeast, mold, and bacterial counts, peroxide value, and color. A significant variation in drying rates and quality attributes was observed. The dome drying could use a multi-rack tray in a big dome to increase the floor space for high loading, efficient use of energy, and better control of the process.

27.4.3 In-Store Drying

In-store drying can also be called low-temperature in-bin drying. It may be used where grain remains in store until milled or sold. Weather conditions in tropical climates are less favorable for in-store drying due to high ambient temperatures and relative humidity values. Two-stage drying can produce good quality by preventing discoloration of high-moisture grain and reducing cracking of dry kernels.

27.4.4 Convection Air Drying

Cabinet- and bed-type dryers (i.e. kiln, tray, truck tray, rotary flow conveyor, and tunnel) fall into the first generation [2]. This is the simplest drying technique, taking place in an enclosed and heated chamber. The drying medium, hot air, is allowed to pass over the product, which has been placed on open trays. Convection drying is often a continuous process and is most often used for products that are relatively low in value. Air-drying is usually accomplished by passing air at a regulated temperature and humidity over or through the food in a dryer. Factors that affect the rates of drying are temperature, humidity, air velocity and distribution pattern, air exchange, product geometry and characteristics, and thickness. The sample is usually placed on mesh trays in one layer or in bulk bed or hung from a string for better air circulation over the product. The air circulation can be horizontal or vertical to the layer or bed.

The structure and composition, such as the fat content, of a product affect the drying rate. In general, the hotter the air temperature, the faster is the drying rate, and similarly, the higher the velocity the higher the drying rate. The lower the air humidity, the higher the drying rate. The relative humidity (i.e. a measure of dryness) is lower when the air temperature is raised. The dryer must expel air to get rid of moisture, thereby allowing new, lower-humidity air to enter the system. However, this process causes heat loss from the dryer. In many cases, two or more stages with different conditions could be used, for example, initial drying at 90°C and then a second or final stage at 60°C. In the case of grains, re-circulating exhaust air in dryers is popular because of its energy conservation and beneficial effect on grain quality.

27.4.5 Explosive Puff Drying

Explosive puff drying uses a combination of high temperatures and high pressure and a sudden release of the pressure (explosion) to flush superheated water out of a product. This method gives the product good rehydrability. However, the high heat can degrade the food quality, and the explosion puffing may compromise product integrity [6]. An optimization of explosion puff drying with superheated steam on granny smith apple chips was reported by An et al. [50].

27.4.6 Spray Drying

Spray drying is used to remove water from free-flowing solution droplets, thus transforming them into a powder product. The fluid to be dried is first atomized by pumping it through either a nozzle or a rotary atomizer, thus forming small droplets with large surface areas. The droplets immediately come into contact with a hot drying gas, usually air. The liquid is very rapidly evaporated, thus minimizing contact time and heat damage. Disadvantages include that the size of the equipment required to achieve drying is very large, and very oily materials might require special preparation to remove excessive levels of fat before atomization [6]. Ultra-sonication in the chamber can be used instead of complex atomization to produce small-diameter droplets in spray drying.

27.4.7 Fluidized-Bed Drying

This technique involves the movement of particulate matter in an upward-flowing gas stream, usually hot air. Fluidization mobilizes the solid particulates, thus creating turbulences on the solid surfaces, which increases the drying rate. The hot gas is introduced into the bottom of a preloaded cylindrical bed and exits at the top. In some cases, a vibratory mechanism is used to increase the contact of the product with the hot gas. Fluidized-bed drying is usually carried out as a batch process, and it requires relatively small, uniform, and discrete particles that can be readily fluidized [6]. The main advantages of fluidized-bed drying are uniform temperature and high drying rates, and thus less thermal damage. A rotating chamber is also used with fluidized-bed drying, thus increasing the centrifugal force to increase the drying rate and mixing. The use

of a solid carrier, such as sea sand, and wheat bran could be used to prevent the biomaterial from deterioration due to thermal shock [51].

27.4.8 Spouted-Bed Drying

In a spouted-bed dryer, the heated gas enters the chamber at the center of a conical base as a jet. The particles are rapidly dispersed in the gas, and the drying occurs in an operation similar to flash drying. This works very well with larger pieces that cannot be dried in a fluidized-bed dryer [6].

27.4.9 Ball Drying

In this method, the material to be dried is added to the top of the drying chamber through a screw conveyor. The material within the drying chamber comes into direct contact with heated balls made from ceramic or another heat-conductive material. Drying occurs primarily by conduction. Hot drying air is passed through the bottom of the chamber. When the product arrives at the bottom of the chamber, it is separated from the balls and collected [6].

27.4.10 Rotary-Drum Drying

Rotary-drum dryers are cylindrical shells 1–5 m in diameter, 10–40 m in length, and rotating at 1–8 rpm with a circumferential speed of approximately 0.2–0.4 m/s. These conditions depend on the product types used for drying. They are designed to operate at a nearly horizontal position, inclined only by 2–6° to maintain the axial advance of solids, which are fed from the upper end of the dryer body [52].

27.4.11 Drum Drying

This technique removes water from a slurry, paste, or fluid that has been placed on the surface of a heated drum. The dryer may be comprised of either a single or a double drum. Drum drying is typically a continuous operation, and care must be taken to ensure that the product that is to be dried adheres well to the drying surface; in some cases, it may be necessary to modify the liquid product by additives to change its surface tension or viscosity [6].

27.4.12 Membrane Drying

Membranes are used to separate water vapor evaporated from the products, and the process is usually called membrane drying [53]. In the case of membrane drying, hydrophilic membranes (such as chitosan) are generally used because water is readily incorporated and diffused through these materials. The hydrophilicity is caused by functional groups present in the polymer chain [54]. This drying method could be carried out at room temperature and thus is beneficial to the product quality. In this method, foods are kept in one side of the membrane, and the permeation side of the cell is kept under vacuum; permeate vapor is collected in liquid nitrogen traps [53].

27.4.13 Electro-Hydrodynamic Drying

In the case of electro-hydrodynamic drying, air flowing is ionized between two electrodes applying a high voltage electric field, and it is known as corona wind or ionic wind [55]. This method passes charged air through a pointing electrode on the surface, and it enhances heat and mass transfer [56, 57]. This enhancement is due to the boundary layer disturbed by the ionic wind when it hits the surface of the wet food, causing reduced latent heat of vaporization [58]. In the case of quince slice, the selected quality attributes of electro-hydrodynamic drying were improved as compared to hot-air drying [59]. The average energy used in hot-air drying was 49 times as much as the average energy consumption of the electro-hydrodynamic method [60]. The drying rate of a wheat sample was significantly increased by increasing applied voltage and air velocity, and wheat protein conformation was significantly affected by hydrogen bonding pattern [61]. A combined electro-hydrodynamic and convection drying of mushroom slices showed that higher voltage or airflow velocity resulted in a higher drying rate, porosity and rehydration ratio, and a lower residual moisture content, while it caused a wrinkled and broken structure with higher shrinkage and shear strength [62]. Similarly, apple slices showed a higher drying rate with higher voltage and air velocity [63].

27.4.14 Intermittent Batch Drying

Progress is being made in intermittent drying, which can be applied to any direct dryer and batch dryer, such as tray dryers, convective dryers, conveyor dryers, fluidized-bed dryers, and spouted-bed dryers. Two strategies could be implemented: (i) time-varying or cyclic operating conditions, and (ii) step-wise change of operating conditions [64].

The main reasons for using the first strategy are (i) enhanced drying kinetics, (ii) reduced energy consumption, and (iii) improved quality [65–68]. In this strategy, internal moisture migrates to the material surface during the non-active phase of drying (i.e. tempering or non-active period). In the active period, heat input is applied to the drying medium. These two periods are carried out in an alternating mode. The drying rate is enhanced during the active period since surface water is increased during the tempering period. However, drying time is increased due to the passive period. This could be offset by lower energy consumption and better quality of the dried products [64].

In the second intermittent drying strategy, the stepwise change of operating conditions is applied to minimize energy requirements. The purpose is to gradually reduce the heat input since the drying process at the end is controlled by internal diffusion and external factors have limited effects [64]. However, the final temperature should not be as low as the equilibrium moisture content in the sample since it is temperature dependent [69]. In this stage, multiple modes of heat input, such as infrared, microwave, and radiofrequency, can be used to remove both surface and internal moisture simultaneously.

27.5 LOW AIR ENVIRONMENT DRYING

27.5.1 Vacuum Drying

The vacuum drying of food involves subjecting it to a low pressure and a heating source. The vacuum allows the water to vaporize at a lower temperature than at atmospheric conditions; thus foods can be dried without exposure to high temperatures. In addition, the low level of oxygen in the atmosphere diminishes oxidation reactions during drying. In general the color, texture, and flavor of vacuum-dried products are improved compared to air-dried. In some cases, the product quality is comparable to that of freeze-dried products. The potential of microwave-assisted vacuum and freeze-drying processes have also been explored for foods [70].

27.5.2 Freeze Drying

In freeze drying, the material that has been frozen is subject to a pressure below the triple point (at 0°C, pressure 610 Pa) and heated to cause sublimation of ice to water vapor. A schematic diagram of different states of water with triple point is shown in Figure 27.3. This method is usually used for high-quality dried products, which contain heat-sensitive components such as vitamins, antibiotics, and microbial culture. The virtual absence of air and low temperature prevent deterioration due to oxidation or chemical modification of the product. This method also gives very porous products, which results in a high rehydration rate. However, freeze drying is a slow and expensive process. The long processing time requires additional energy to run the compressor and refrigeration units, which makes the process very expensive for commercial use. Thus, it is mainly used for the high-value products [6]. Moisture in freeze-drying is usually removed by two mechanisms: (i) sublimation during the early stage until freezable water remained as ice in the sample, and (ii) vacuum drying when the sample contains unfreezable solvent or bound water (i.e. final stage of drying).

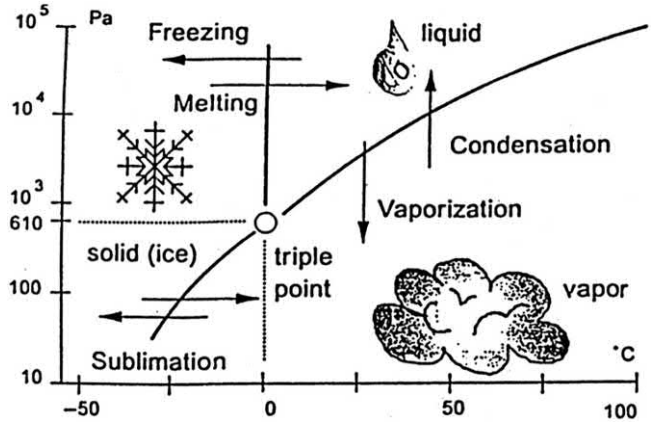

FIGURE 27.3 Schematic diagram of the different states of water showing triple point. (From Nijhuis et al. [133].)

27.5.3 Heat Pump Drying (HPD)

The heat pump dryer is a further extension of a conventional convection air-dryer with an in-built refrigeration system. The dry, heated air is supplied continuously to the product to pick up moisture. The humid air passes through the evaporator of the heat pump where it condenses, thus giving up its latent heat of vaporization to the refrigerant in the evaporator [71]. This heat is used to reheat the cool dry air passing over the hot condenser of the heat pump; thus the latent heat recovered in the process is released at the condenser of the refrigeration circuit and used to reheat the air within the dryer (Figure 27.4). The use of the heat pump dryer offers several advantages over conventional hot-air dryers for the drying of food products, including higher energy efficiency, better product quality, the ability to operate independently of outside ambient weather conditions, and zero environmental impact [71]. In addition, the condensate can be recovered and disposed of in an appropriate manner, and there is also the potential to recover valuable volatile components from condensate [72]. One of the main reasons for quality improvements in heat pump-dried products is due to the ability of heat pumps to operate at low temperatures. If a heat pump dryer is used at low temperatures (10–60°C) for highly perishable food products, adequate precautions need to be taken to prevent potential spoilage. There is also the potential to use a heat pump dryer as a modified atmosphere dryer to obtain better-quality products [72]. New developments in heat pump drying systems include the microwave-assisted HPD, modified atmosphere HPD, microwave-assisted modified atmosphere HPD, and desiccant-assisted HPD, all of which are discussed by Perera [71].

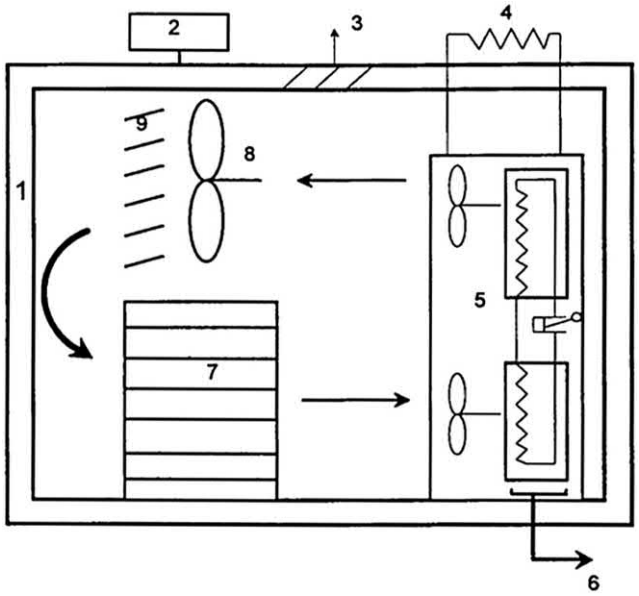

FIGURE 27.4 A schematic diagram of the operation of a typical heat pump dryer. 1, vapor-sealed and insulated structure; 2, humidifier; 3, overheat vent; 4, external condenser; 5, heat pump dehumidifier; 6, condensate; 7, product tray; 8, primary air circulation fan; 9, air distributor. (From Perera and Rahman [72].)

27.5.3.1 Energy Efficiency

The removal of water in its liquid state rather than the vapor state allows the latent heat of vaporization to be captured, and only a small amount of sensible heat is lost with condensate. The energy spent in drying is usually expressed as the "specific moisture-extraction rate" (SMER). The SMER for a well-designed heat pump dryer lies between 1 and 4 kg/kWh, whereas the SMER of a single-pass hot dryer is only 0.95 kg/kWh [72]. A general comparison of heat pumps with vacuum and hot-air drying is presented in Table 27.3.

27.5.3.2 Process Efficiency

Heat pump drying has the ability to operate at set conditions independently of outside ambient weather conditions. In addition, it is environmentally friendly, i.e. no gases or fumes are given off to the atmosphere. Since drying takes place in a closed system, a low air-leakage rate gives negligible heat loss.

Increasing the humidity in the drying air slows down the drying process but improves the energy efficiency [73]. In general, heat pump drying efficiency and capacity are dependent on temperature and humidity. In general, the SMER increases with an increase in humidity in the dryer [72]. In a conventional air dryer at low temperatures (10–30°C), it is not possible to run the drying operation due to high ambient relative humidity (0.70–0.90), but heat pump drying can be performed at these low temperatures since the relative humidity can be lowered to 0.10.

The thermal insulation and gas-tightness of the seals of the chamber structure are important in achieving high energy efficiency for the heat pump. In addition to the electrical energy required to drive the compressor, energy is also required to preheat the product and chamber structure, to drive the fan for primary airflow over the product that is to be dried, and to replace any heat loss through conduction and air leakages. The motors driving the fan and the compressor can be located within the chamber so that the residual heat produced by them is absorbed within the drying chamber instead of being lost to the atmosphere [72].

27.5.3.3 Progress and Applications

There are a number of technological problems to be overcome before the process can be applied in the food industry.

Capital cost: the capital cost of a heat pump dryer is higher than for a conventional hot-air dryer due to the additional refrigeration system requirement. However, its cost should be much less than that of vacuum or freeze drying.

Limited drying temperature: while low-temperature drying is a potential advantage, too low a temperature will limit the drying rate, which has implications for throughput. Also, slower drying rates at low temperatures may give rise to potential microbial growth problems [72].

Process control and design: like vacuum and freeze dryers, heat pump dryers are more amenable to batch drying because the drying takes place in a hermetically sealed container. The construction of continuous drying may involve high engineering modeling and design costs. Therefore, benefits need to be evaluated on the basis of cost rather than energy efficiency alone [72].

Innovative heat pump drying systems, such as multistage compression, cascade, tunnel, vapor adsorption, vacuum condition, and multiple evaporators in series and parallel, are presented [74–76]. In addition, heat pumps with two or more drying chambers in cylindrical mode can be used to dry different products in different chambers [77]. Heat pump drying can be incorporated with other drying methods, such as spray drying [78], and atmospheric frozen drying [78, 79], and solar drying [80]. It is possible to operate at various strategies, such as cyclic temperature, step-down temperature, cyclic pressure, and variable gas flow [81].

27.5.4 Superheated Steam Drying

Superheated steam is used as a drying medium. The main advantages of this type of drying are that it can provide an oxygen-free medium for drying, and process steam available in the industry can be used without any capital cost. An oxygen-free medium has the potential to result in high-quality food products, however, it is important to generate more information regarding quality improvement and processing efficiency. An et al. [50] optimized the conditions for instant pressure drop puffing with superheated vapor (IPDPSV) to the physical properties of granny smith apple chips and found that at 23% moisture content of pre-dried samples, puff drying at 122°C for 41 s gave the best color, porous structure, and suitable hardness compared to those processed by hot-air drying or freeze drying. Superheated steam provides other advantages, such as pasteurization, sterilization, and deodorization of dried products, which could give a high standard of hygiene, decontamination of hazards, provide higher drying

TABLE 27.3
General Comparison of Heat Pump Dryer with Vacuum and Hot Air Drying

Parameter	Hot Air Drying	Vacuum Drying	Heat Pump Drying
SMER (kg water/kWh)	0.12–1.28	0.72–1.2	1.0–4.0
Drying efficiency (%)	35–40	≤70	95
Operating temperature range (°C)	40–90	30–60	10–65
Operating % RH range	Variable	Low	10–65
Capital cost	Low	High	Moderate
Running cost	High	Very high	Low

rates in constant and falling rate periods, and the possibility of capturing desirable organic compounds from the condensate of effluent steam [64]. If products are not stable at 100°C, lower operation pressure could reduce the operating temperature. However, this could reduce the drying rate significantly [64].

27.5.5 Impingement Drying

Impingement drying is an old technology that has only recently been applied to food products. An impingement dryer consists of a single gas jet (air or superheated steam) or an array of such jets, impinging normally on a surface. There is a great variety of nozzles that can be used, and the selection of the nozzle geometry and multi-nozzle configuration has important relevance in the initial and operating costs and product quality [82]. Some characteristics of impingement drying include rapid drying, popularity in convection drying, and the large variety of nozzles available (multi-zones). Typically, the temperature and jet velocity in impingement drying may range from 100 to 350°C and 10 to 100 m/s, respectively [83].

27.5.6 Modified Atmosphere Drying

This is a new concept for drying foods for better quality and preserving their constituents using a modified atmosphere by flashing different gases, such as nitrogen and carbon dioxide [84]. Modified atmosphere heat pump dehumidifier (MA-HP) drying is a relatively new development described by Perera [85, 86] and Hawlader et al. [87–89]. The fact that heat pump dehumidifier (HP) drying is conducted in an enclosed, insulated chamber is made use of in the development of the MA-HP drying system. The air in the dehumidifier chamber is replaced with an inert atmosphere such as nitrogen, carbon dioxide, or their mixture. Replacement of the air inside the chamber is easily carried out, by exhausting the chamber using a vacuum pump and then breaking the vacuum using an inert gas. Therefore, vacuum exhaustion is a more cost-effective way to replace the air than by direct purging with the specific inert gas. Replacement of air with carbon dioxide or nitrogen by purging requires over 50 volumes to achieve an oxygen level of less than 0.5%. A schematic diagram of the MA-HP drying system is shown in Figure 27.5. This consists of a sealed drying vessel connected to the heat exchanger unit. The drying vessel has provisions for the introduction of nitrogen or for evacuation through a valve connection.

The MA-HP system has shown provision for introducing microwave energy for heating the product, through a slotted wave-guide running down the wall of the chamber parallel to the axis of the chamber. A PLC control panel connected to a remote PC and monitor controls the whole system. The product is carried on microwave-transparent plastic-trays stacked vertically on a rotating platform, which is mounted on a load cell, so that weight loss can be monitored and recorded on the PC. The current prototype is essentially a batch process, but it can be semi-automated depending on the products and pre-treatments required for specific products. Some of the pre-treatments may include vacuum infusion or osmotic dehydration before MA-HP drying. After the product is loaded on to the trays and stacked on to the platform, the

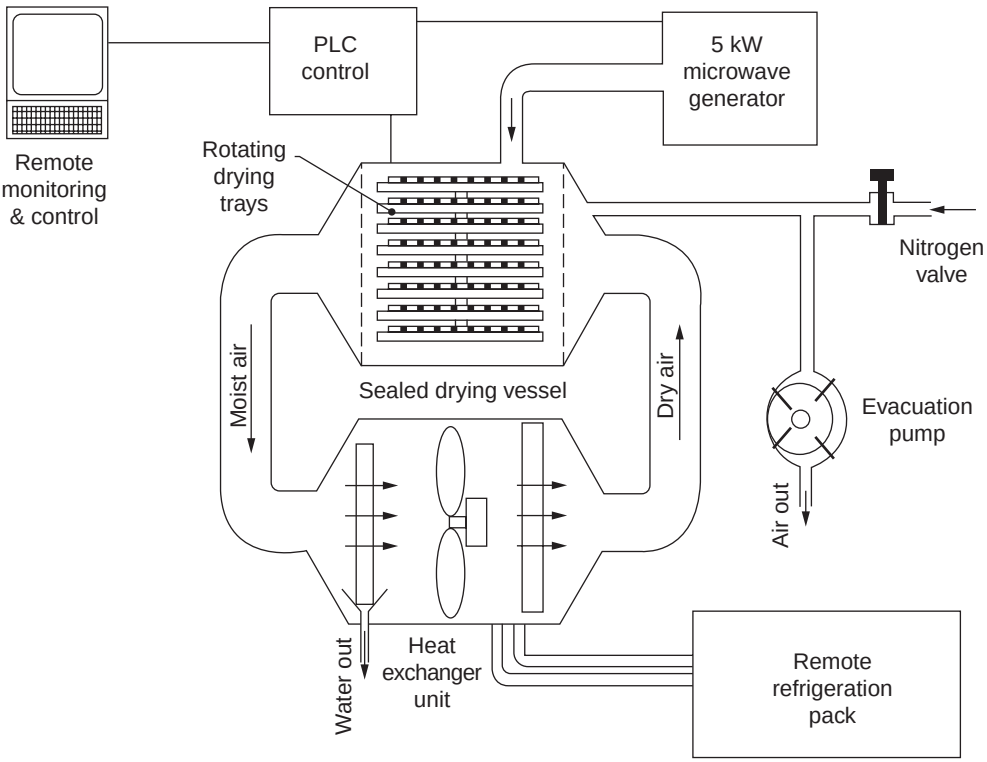

FIGURE 27.5 Schematic diagram of the MAHPD drying system. (From Perera [85, 86].)

drying chamber is evacuated to 600–700 Pa for 30 minutes, after which the vacuum is broken with the selected modified atmosphere and normal HP drying is carried out in this modified atmosphere. The use of microwave energy improves the drying rate. The surface temperature of the product is monitored using an infrared detector. Controls can be set for the microwave energy to cut off at a pre-set surface temperature of the product, so that overheating can be minimized.

Busic et al. [90] tested carbon-dioxide drying of basil for retention of bioactive components and improvement of taste and appearance. The moisture was reduced to 8.1 from 90.5 g/100 g sample within 3 days of drying when 100 bar pressure of carbon dioxide was used, while air-drying reduced moisture content to 23.0 g/100 g sample when dried for 26 days. However, drying at 80 and 100 bar did not show any significant effect on MA drying. The atmosphere in the MA drying can be modified by adding volatile compounds, such as ethanol, to reduce volatilization of volatile compounds in the foods inside the dryer [91].

It was observed that added ethanol 0.5% (v/v) in the air stream in the MA dryer could allow the retention of important volatile compounds of fresh pineapple aroma [91], and L-ascorbic acid in dried pineapple [92]. In addition to quality improvement, ethanol in the drying atmosphere promoted intense water evaporation, and thus reduced the drying time. The energy consumption of fluidized-bed drying of wheat kernels with carbon dioxide was reduced 20% and had a shorter drying time as compared to air fluidized-bed drying. This reduced energy consumption to 3% of input heat [93]. An additional energy savings of 4% of the heat load can be achieved for drying in carbon dioxide atmosphere at temperatures below 100°C due to the lower wet bulb temperature of carbon dioxide [64].

27.6 DRYING PRETREATMENTS

27.6.1 Blanching

Pretreatments are common in most of the drying process in order to improve product quality, storage stability, and/or process efficiency. In recent years an improvement in quality retention of dried products by alteration of the processing strategy and/or pretreatment has gained much attention. Blanching is a process of preheating the product by immersing in water or steam. The main purpose of blanching is to inactivate the naturally occurring enzymes present in foods since enzymes are responsible for off-flavor development, discoloration or browning, deterioration of nutritional quality, and textural changes in food materials. Blanching provides other advantages: (i) removing microorganisms from vegetable surfaces and intercellular spaces, thus reduces the initial microorganism load, (ii) cleaning raw food materials and facilitating preliminary operations, such as peeling and dicing, and (iii) improving color, texture, and flavor under optimum conditions [94–96]. Blanching may have disadvantages: it may cause changes to the texture, color, and flavor because of the heating process [97, 98], it increases the loss of soluble solids, such as vitamins [99, 100], especially in the case of water blanching, it may change the chemical and physical state of nutrients and vitamins [94, 101, 102], and it has adverse environmental impacts, such as large water and energy use and problems of effluent disposal.

Time and temperature of blanching are the important factors for achieving optimum quality of the dried product [103]. The normal blanching temperature varied from 80 to 100°C. Recently low-temperature and long-time blanching has been proposed for better texture and the retention of some nutrition components [104, 105]. The low temperature used is between 50 and 70°C. Blanching time correlated with flavor and sensory attributes of dried fruits and vegetables [98]. Limiting blanching time, rapid cooling, and alternative blanching methods and/or combinations may result in dried products with better flavor. Processing methods that include steam and/or microwave blanching and non-thermal enzyme inactivation such as high-pressure and ohmic heating may have potential for future blanching processes with fewer detrimental effects on flavor and maintenance of optimum texture.

27.6.2 Sulfur Dioxide Treatment

Sulfur dioxide preserves the texture, flavor, vitamin content, and color that make food attractive to the consumer. Sulfur dioxide treatment is used widely in the food industry to reduce the fruit darkening rate during drying and storage, and it preserves ascorbic acid and carotene. The sulfur dioxide taken up by the foods displaces air from the tissue in plant materials, softens cell walls so that drying occurs more easily, destroys enzymes that cause darkening of cut surfaces, shows fungicidal and insecticidal properties, and enhances the bright attractive color of dried fruits [106]. Permitted levels of sulfur dioxide and other additives (solutes) in dried foods vary from country to country. According to an IFT (1990) [107] expert panel, fruits can contain the highest levels of sulfur dioxide of all food products. The allowed limit is 2000 mg SO_2/kg of dried fruit.

Sulfiting treatment can be done by burning sulfur or soaking in a sulfite solution. The smoke of sulfur dioxide can be produced by burning sulfur with oxygen in the air and then circulating to the smoking chamber. Potential advantages in using a bisulfite solution are (i) decreased air pollution, (ii) better control of the sulfuring process, (iii) greatly shortened sulfuring time, and (iv) decreased desorption losses during drying [106].

The chemical reactions of sulfur dioxide when it is added to fruits and other food products are complex [108]. Sulfite can be bound or free in the food matrix. This bound sulfite is considered to have no retarding effect on product deterioration; thus it is important to know the factors that influence binding [108]. The amount of bound sulfite depends on pH, carbonyl groups of aldehydes, acetaldehyde, pyruvic acid, availability of oxygen, sugars, and starch [108–110]. Sulfiting and blanching are also used together as pretreatment [111]. Sulfiting ruptured and collapsed cells resulting in a smaller cell volume and hardness of dried samples [112, 113]. A number of factors

affect sulfur dioxide uptake by fruits and vegetables, including concentration and temperature of dipping solution, time of dipping, geometry and conditions of sample (i.e. peeled or unpeeled, whole or sliced), and agitation of solution [106, 114].

27.6.3 Salting or Curing

Salting or curing is a type of osmotic dehydration. Curing was originally developed to preserve certain foods by the addition of sodium chloride. In the food industry,y the application of curing is related only to certain meat, fish, and cheese products. Today sodium chloride, sodium, and potassium nitrite (or nitrate) are considered curing salts. Salting is one of the most common pretreatments used for fish products. Salting converts fresh fish into shelf-stable products by reducing the moisture content and acting as a preservative. In combination with drying, these processes contribute to the development of characteristic sensory qualities in the products, which influence their utilization as food [115]. Although curing was originally a mechanism for preservation by salting, over several millennia additional processes concomitant with curing have evolved, notably fermentation, smoking, drying, and heating. Curing may have different connotations: in meat, salt and nitrite are always added; in fish salt is always added, but nitrite only rarely; and in cheese, which always contains salt, but infrequently contains nitrate, and the term curing is applied to the production of desirable proteolytic and lipolytic changes. In the past half-century, cured products have been developed that are not stable unless refrigerated. Indeed, most cured meat products must be refrigerated to remain safe and wholesome, and during the past two decades even the packaging of many classes of cured products has become important in extending the period during which the product remains wholesome [116]. Cured meats can be divided broadly into three groups: unheated, mildly heated (pasteurized to center temperature of 65–75°C), and severely heated (shelf-stable after heating to 100–120°C) [116].

In addition to the curing salts and related processes mentioned above, additives collectively known as adjuncts are used in many cured meat products. These include ascorbates, phosphates, glucono-D-lactone, and sugars. Adjuncts are used primarily to obtain or maintain desirable changes, the ascorbates in connection with color and the others in connection with pH, texture, and in some cases flavor. Adjuncts may also affect safety. The concentration of each curing agent depends on the nature of the food products and on the technology used in individual countries [116].

27.6.4 Other Dipping Pretreatments

Dipping treatment with chemicals is also used in addition to blanching or sulfite treatment (Table 27.4). The dipping treatment is a process of immersion of foods in a solution containing additives. The concentration level is usually below 5%, and dipping time is usually below 5 minutes, whereas osmotic dehydration is usually carried out at higher concentrations and for long processing times. The main purpose of the dipping treatment is to improve drying characteristics and quality. Certain chemicals are used to enhance the rate of dehydration [97]. Among these compounds, methyl and ethyl oleate, or olive oil are the most common [117–120]. Methyl oleate has realized the greatest usage because of economics and its higher taste threshold. A carbonate–oleate combination was superior to their use alone in accelerating the drying rate [121–123]. A synergistic effect results from the combined use of alkali carbonates and methyl oleate for drying. When excess carbonate was used, drying was further accelerated. Sodium carbonate was less effective than potassium carbonate; however, the cost of sodium salt is about a fifth that of potassium.

Type	Compounds
Chemicals	
Esters	Methyl oleate, ethyl oleate, butyl oleate
Salts	Potassium carbonate, sodium carbonate, sodium chloride, potassium sorbate, sodium polymetaphosphate
Organic acids	Oleic acid, steric acid, caprillic acid, tartaric acid, oleanolic acid
Oils	Olive oil
Alkali	Sodium hydroxide
Wetting agents	Pectin, tween, nacconol
Others	Sugar, liquid pectin
Surfactants	
Nonionic	Monoglycerides, diglycerides, alkylated aryl polyester alcohol, polyoxyethylene sorbitan monostearate, sorbitan mono stearate, D-sorbitol, polyoxyethylene
Anionic	Sodium oleate, steric acid, sorbitan heptadecanyl sulfate, Dimethyl-benzyl-octyl ammonium chloride

Esters affect the waxy surface of fruits by altering the physical arrangement of the surface wax platelets, thus allowing moisture to more readily evaporate from the fruit. This was confirmed using electron microscopy for grapes and sweet cherries [124]. The hydrophilic groups on the wax surface increased by a reversible attachment of long-chain fatty acids and their esters. The increase in hydrophilic groups on the normally lipophilic wax surface would form a sequence of attachment sites to facilitate the transfer of water through the crystalline wax layer [125, 126]. The addition of potassium carbonate is necessary, possibly acting by saponification of fatty acids such as oleic, steric, and oleanolic acids, which are known constituents of grape wax. Table 27.3 shows the chemicals used for dipping treatment.

27.6.5 Freezing Pretreatment

Freezing treatment affects the drying process. The re-hydration rate of air- and vacuum-dried fruits and vegetables with freezing treatment increased to a level comparable to that for freeze-dried products [127]. It was also noticed that the longer the duration of freezing, the better the rehydration kinetics

of dried products. This was due to the formation of large ice crystals by slow freezing. In the case of blueberries, the temperature significantly affected the drying rate, whereas insignificant effects of cultivar and grade were observed [128].

27.6.6 Cooking

Cooking at different pressure levels before drying can destroy microorganisms and affect the physicochemical properties of dried products. The bacterial load on the final product can thus be much reduced, and cooked product can be minced and spread evenly on drying trays with much less trouble than raw material. Pre-cooking is usually used for rice, beef [129], fish, and beans [130]. The formation of superficial pellicle (case-hardening) may be avoided by pre-cooking, which considerably retards drying. It is clear that the more severe the initial conditions of cooking, the more stable is the subsequently dehydrated product. When an animal or plant is killed, its cells become more permeable to moisture as pointed out by Potter [131]. When the tissue is blanched or cooked, the cells may become still more permeable to moisture. Generally, cooked vegetable, meat, or fish is dried more easily than its fresh counterparts, provided cooking does not cause excessive shrinkage or toughening [131]. Cooking also results in a decrease in water-holding capacity of meat products [132].

27.7 CONCLUSION

Drying is a time-honored and energy-intensive method of food preservation. Thermal drying is divided into three types considering the atmosphere used in the drying system. These are air-drying, low-air-environment drying, and modified-atmosphere drying. Wide varieties of designs are available for each category. Significant efforts have been made to develop more energy-efficient drying systems considering improved dryer design as well as varied operating strategies. Different modes of energy, such as microwave, infrared, and radiofrequency, are being used to improve the process efficiency and quality of the dried products. It is also important to apply appropriate pre-treatments in order to improve product quality.

28 Quality Changes during Drying of Foods

Mohammad Shafiur Rahman and Conrad O. Perera

CONTENTS

28.1 INTRODUCTION

Drying reduces the water activity, thus preserving foods by avoiding microbial growth and deteriorative chemical reactions. The heating effects on microorganisms and enzyme activity are also important in the drying of foods. In the case of foods to be preserved by drying, it is important to maximize microorganism and/or enzyme inactivation for preventing spoilage and enhanced safety, and to reduce the components causing dried foods' deterioration. On the other hand, in the case of drying bacterial cultures, enzymes, or vitamins, minimum inactivation of the microorganism and/or enzyme is required. Thus, the detrimental effects of drying may be desirable or undesirable depending on the purpose of the drying process. Initial freshness plays an important role in determining the quality of dried foods. The fresher the raw material, the better the stability and quality of the dried products. Suitable varieties or species of produce with desired maturity should be used to achieve the desired product with the best possible quality [1]. The quality characteristics of dried foods can be grouped as microbial, chemical, physical, and nutritional (Table 28.1).

28.2 MICROFLORA IN DRIED FOODS

Multiplication of microorganisms should not occur in properly processed dehydrated foods, but they are not immune to other types of food spoilage. If dried foods are safe in terms of pathogenic microbial count and toxic or chemical compounds, then acceptance depends on the flavor or aroma, color, appetizing appearance, texture, taste, and nutritional value of the product. Microbial standards are usually based on the total number of indicator organisms or the number of pathogens [2]. The microbial load and its changes during drying and storage are important information for establishing a standard that will ensure food safety. Perishable foods, such as meat and fish, are prone to rapid microbial spoilage, thus adequate care must be taken in drying. Poor processing, handling, and storage practices often result in a limited storage life of dried fish [3]. The microbial load for dried mackerel ranged from 3×10^3 colonies per gram sample to too numerous to count. No evidence of spoilage was detected in samples having water activity from 0.72 to 0.74. The isolates found were *Alcaligenes*, *Bacillus*, *Leuconostoc*, *Micrococcus*, *Halobacterium*, *Flavobacterium*, *Halococcus*, *Aspergillus*, and *Penicillium*. All the samples were positive for coliform,

TABLE 28.1
Quality Characteristics of Dried Foods

Microbial	Chemical	Physical	Nutritional
Pathogens	Browning	Rehydration	Vitamin loss
Spoiling	Oxidation	Solubility	Protein loss
Toxin	Color loss	Texture	Functionality loss
	Aroma development	Aroma loss	Fatty acid loss
	Removal of undesired components	Porosity	
		Shrinkage	
		Pores' characteristics	
		Crust formation	
		Structure	

Streptococcus, and Staphylococcus. *Vibrio* and *Clostridium* were not detected, while Salmonella was detected only in some samples [2]. Brining and drying decreased the microbial load but did not eliminate the pathogens. Wheeler et al. [3] studied the common fungi involved in spoiling of dried salted fish. They studied the mycoflora of dried salted fish with emphasis on visible spoiled fish and spoilage fungi. A total of 364 isolates from 74 fish were cultured and identified.

Wheeler and Hocking [4] studied the effect of water activity and storage temperature on the growth of fungi associated with dried salted fish. Microorganisms did grow during drying of highly perishable products such as fish (Trevally) in heat pump dehumidifier drying at low temperatures of 20°C to 40°C. Lower temperatures gave lower counts regardless of the relative humidity of drying. Sulfur-producing organisms were a significant portion of the total flora of fish drying. Rahman et al. [5] studied the endogenic microflora changes in tuna mince during convection air-drying between 40°C to 100°C. The drying temperature of 50°C or below showed no lethal effect on the microflora and showed significant growth. The drying temperature of fish must be above 60°C to avoid microbial risk in the product. The actual optimum temperature above 60°C should be determined based on other quality characteristics of the dried fish [5].

Reducing the water activity of a product inhibits growth, but does not result in a sterile product. The highest possible drying temperatures should be used to maximize thermal death even though low drying temperatures are best for maintaining organoleptic characteristics [6]. Another alternative is to use a high drying temperature initially at high moisture content and then drying at a low temperature. The microbial deactivation kinetics depends on several factors: variety, water content (i.e., water activity), temperature, and compositions of the medium (acidity, types of solids, pH, etc.) as well as the heating method [7–9]. Models to predict the decimal reduction times (D-values) were also developed as a function of temperature, pH, and water activity for isothermal conditions [10, 11]. These models could not be used in case of drying conditions since the level of water content does not remain same for each temperature studied. Bayrock and Ingledew [12] measured the D-values for the changing moisture content (i.e., drying) and for moist conditions (i.e., no change of moisture during heating). The heat resistance of microorganisms increased significantly during drying compared to the moist heat conditions. During drying of tuna, Rahman et al. [5] found that the D-value for endogenous microflora varied from 12.66 to 2.64 h when drying temperature varied from 60°C to 100°C, respectively. As expected the values were decreased with the increase of temperature, which indicates that an increase in drying temperature increased the lethal effect. The D-values at 100°C was much lower than the drying temperature at 90°C or below. This may be due to the high drying rate at 100°C [5, 13]. Rahman et al. [14] investigated the changes of endogenous bacterial counts in minced tuna during dry-heating (convection air-drying) and moist-heating (heating in a closed chamber) as a function of temperature. The D-values for total viable counts decreased from 2.52 to 0.26 h for moist heating and 2.57 to 0.34 h for dry-heating, respectively, when temperature was maintained constant within 60°C and 140°C. In both cases, increasing temperature caused significant decrease in D-values, whereas the effect of heating methods was not significant. The Z-values were 144°C and 46°C for temperatures within 60–100°C and 100–140°C, respectively. Rahman et al. [14] also identified the types and characteristics of endogenous microbes present in fresh and dried tuna. Initially tuna contained a mixture of different microbes, of which some are more heat- and/or osmo-tolerant than others. In dried tuna, the predominant microbes were moderately osmo-tolerant, and the dominant microbes were heat-sensitive.

Most of the vegetative cells of microorganisms will be destroyed by normal hot air-drying at 60–80°C with only a few exceptions (e.g., heat-resistant bacteria, yeast, and molds) [15]. Although there are some concerns about the potential for growth of microorganisms at the temperatures used in heat pump dryers, in practice there have been no reports of increased numbers of microorganisms in heat-pump-dried foods as compared to those dried by conventional means [16]. Serious microbiological problems may arise if the dryer is designed poorly.

Mold infections such as by *Aspergillus flavus* of fruits and vegetables could be a major source of contamination in dried products and can begin before harvest, especially under rainy and humid conditions, or during storage prior to drying or when these are damaged by insects [17]. Mold-infected products are usually removed during the sorting operation to prevent aflatoxin production and contamination that could make the product unsalable, since the maximum levels of aflatoxin allowed in nuts, grains, dried fruits, and milk are in the range of 0.5 to 15 parts per billion [18]. The best way to prevent fungal growth on harvested products is to maintain the optimum range of temperature and relative humidity throughout the handling system. Mold infection could also occur during the storage of products that have not reached a safe water activity level of 0.65 or less [17].

28.3 CHEMICAL CHANGES

28.3.1 Browning Reactions

Browning reactions change color, decrease nutritional value and solubility, create off-flavors, and induce textural changes. Browning reactions can be classified as enzymatic or nonenzymatic with the latter being more serious as far as drying processes are concerned. Two major types of nonenzymatic browning are and Maillard browning. In addition to the moisture level, temperature, pH, and the composition are all parameters that affect the rate of nonenzymatic browning. The rate of browning is the most rapid in the intermediate moisture range and decreases at very low and very high moistures. Browning tends to occur primarily in the middle of the drying period. This may be due to the migration of soluble constituents toward the central region. Browning is also more severe near the end of the drying period when the moisture level of the sample is low and less evaporative cooling is taking place, which occurs when the product temperature rises. Several suggestions are found to reduce browning during drying. In all cases, it was emphasized that the product should not experience unnecessary heat when it is in its critical moisture content range [6].

In meat products without nitrites, browning takes place during drying due to the denaturation of the globin protein in myoglobin [19]. Maillard-type nonenzymatic browning reactions in processed meat products also contribute to their external surface color. The main browning reaction involves the reaction of carbonyl compounds with amino groups, although lesser amounts of carbonyl browning also occur. Muscle usually contains small amounts of carbohydrates in the form of glycogen, reducing sugars and nucleotides, while the amino groups are readily available from the muscle proteins. Browning occurs at temperatures of 80–90°C and increases with time and temperature [20]. A loss of both amino acids and sugars from the tissue occurs because of the browning reaction. Lysine, hystidine, threonine, methionine, and cysteine are some of the amino acids that may become involved in browning [21]. Maillard browning proceeds most rapidly during drying when moisture content is decreased to a range of 15–20% [82]. As the moisture content drops further, the reaction rate slows so that in products dried below 2% moisture further color change is not perceptible even during subsequent storage. Drying systems or heating schedules generally are designed to dehydrate rapidly through the 15–20% moisture range to minimize the time for Maillard browning. In carbohydrate foods, browning can be controlled by removing or avoiding amines and conversely in protein foods by eliminating the reducing sugars. Ascorbic acid browning is another important browning reaction, which occurs when drying products rich in ascorbic acid. Green fruit and vegetables also turn brown during drying due to conversion of chlorophyll to pheophytin [17].

28.3.2 Lipid Oxidation

Dehydrated foods containing fats are prone to develop rancidity after a period, particularly if the water content is reduced too much. Fish oils or fats are more unsaturated than beef or butter, and they are usually classified as drying oils because they contain considerable proportions of highly unsaturated acids. The behavior of drying oils toward atmospheric oxygen is well known, and oxidation is a serious problem for commercial drying of fatty fish and seafood. The flesh of some fatty fish, such as herrings, contains a fat prooxidant that is not wholly inactivated by heat [22].

Lipid oxidation is responsible for rancidity, development of off-flavors, and the loss of fat-soluble vitamins and pigments in many foods, especially in dehydrated foods. Factors affected the oxidation rate include moisture content, type of substrate (fatty acid), extent of reaction, oxygen content, temperature, presence of metals, presence of natural antioxidants, enzyme activity, ultraviolet (UV) light, protein content, free amino acid content, and other chemical reactions. Moisture content plays a big part in the rate of oxidation. At water activities around the monolayer ($a_w \approx 0.3$), resistance to oxidation is greatest.

The elimination of oxygen from foods can reduce oxidation, but the oxygen concentration must be very low to have an effect. The effect of oxygen on lipid oxidation is also closely related to the product porosity. Freeze-dried foods are more susceptible to oxygen because of their high porosity. Air-dried foods tend to have less surface area and pores due to shrinkage, and are thus not affected by oxygen. Minimizing oxygen level during processing and storage, and the addition of antioxidants as well as sequestrants was recommended to prevent lipid oxidation [6]. Fish oils or fats are drying oils, which rapidly absorb oxygen from the air and harden just as paints harden on exposure to air. Fatty fish must be dehydrated quickly in a vacuum and must be stored in vacuum or in an atmosphere of an inert gas [23].

Antioxidants added to the herrings before drying are ineffective, but addition during drying with wood smoke, which contains simple antioxygenic phenols, stabilizes the fat of the dehydrated products considerably [22]. Oxidation of the fat normally occurs during dehydration. Herrings and haddock dried at 80°C to 90°C compared to lower temperatures were found more stable during storage [22]. One factor that may be important is the production of browning products from protein or nonfatty parts that gave antioxidant activity. The effectiveness of nonenzymatic browning products in preventing lipid oxidation was one of the mechanisms hypothesized by Karel [24] to prevent lipid oxidation.

The effect of water on the destruction of the protective food structure in some specific dehydrated foods is probably involved in the prevention of lipid oxidation in heated meat systems [24]. In systems in which there are both surface lipids and lipids encapsulated within a carbohydrate, polysaccharide, or protein matrix, the surface lipids oxidize readily when exposed to air. The encapsulated lipids, however, do not oxidize until the structure of the encapsulated matrix is modified and/or destroyed by adsorption of water [25]. Another reason is the increase of oxygen diffusion by increasing molecular mobility above glass–rubber transition [26].

The peroxide values of different dried meat samples were studied by Rahman et al. [27]. The values were significantly different according to the method of drying. Freeze-drying

gave the highest value, while air-drying gave the lowest value. Similar results were also observed in the case of air-dried, vacuum-dried, and freeze-dried tuna meat [28]. This was due to the increased oxygen diffusion and exposed surface area with the increase of porosity for freeze-dried samples [28].

Lowering the water activity by the removal of water brings about the extension of the shelf life of dried products, which almost always brings about some effect on the components of the dried products [17]. For example, drying retards the growth of bacteria, yeast, and molds. It can also result in lowering the enzymatic and chemical reaction rates. Dried products generally have greater stability, but water activity below the monomolecular layer could promote oxidation reactions.

28.3.3 Changes in Proteins

The protein matrix in muscle has a marked effect on its functionality and properties [29]. The nonfatty part of fish is very susceptible to changes caused by high temperatures during initial cooking, drying, and storage. Every process involved in the conversion of muscle to meat alters the characteristics of the structural elements [30]. Heating is believed to cause the denaturation of the muscle proteins even below 60°C, but not enough to affect much shear resistance [31]. The decrease in shear observed at 60°C was attributed to collagen shrinkage. Hardening at 70–75°C was believed to be due to increased cross-linking and water loss by the myofibrillar proteins, while decreasing shear at higher temperatures may indicate solubilization of collagen [20]. After 1 h at 50°C, the collagen fibrils of the endomysium appear beaded, which is brought about by their close association with the heat-denatured noncollagenous proteins in the extracellular spaces. Heat denaturation of the lipoprotein plasmalemma results at a temperature of 60°C for 1 h. The breakdown products of the plasmalemma are large granules and are often associated with the basement lamina, which appears to survive intact even after heating at 100°C for 1 h [32, 33]. Protein changes in relation to solubility, Maillard reaction, and protein cross-linking in whole milk powder during storage at different relative humidities were evaluated by Le et al. [34]. They found that the cross-linking of casein strongly influences the decrease in solubility of whole milk powder.

28.3.4 Volatile Development or Retention

In addition to the physical changes, drying generates flavor or releases flavor from the foods. Drying changes the composition of volatiles by evaporating most volatiles and by forming new volatile odor compounds by chemical reactions [35, 36]. Such changes in volatiles might affect the aroma of fresh foods after drying, for example, off-flavors were produced in peanuts when drying air temperatures were above 35°C. The amount of off-flavor detected in peanuts appeared to be a function of drying air temperature and moisture content, and the off-flavor was more likely to occur in immature peanuts than in mature peanuts [37]. Off-flavors resulting from high-temperature drying can be passed on to peanut butter and roasted peanuts. Acetaldehyde and ethyl acetate may be better indicators of off-flavor. Higher temperature drying of pasta was also related to off-color and off-flavor [38].

A substantial volatile loss occurred during the first three stages of spray drying, and there should be zero or very little loss of volatiles during the fourth stage due to selective diffusion [39]. Loses can occur during atomization, from undisturbed drops, and morphological development. Several factors affect volatile retention, including control of atomizer pressure or rotation speed, choice of spay angle, configuration of air input, alteration of air temperature profile, feed concentration, presence of an oil phase and/or suspended solids, foaming of the feed, feed composition, surfactant, and steam blanketing of the atomizer [39–41]. The retention increases with increasing initial concentration of solids, increasing air temperature and velocity, and decreasing humidity. This is due to the selective diffusion mechanism, when surface water content is reduced sufficiently so that the diffusion coefficients of volatile substances become substantially lower than that of water [40, 41].

There are potential improvements in the quality of heat-pump-dried products with optimum drying conditions in terms of a closed system with controlled temperature and humidity. Usually, dried products have low aroma volatile content, suffer a loss of heat-labile vitamins, and have a high incidence of color degradation. Ginger dried in a heat pump dryer was found to retain over 26% of gingerol, the principal volatile flavor component responsible for its pungency, compared to only about 20% in rotary-dried commercial samples [42]. The higher volatile retention in heat-pump-dried samples may be due to reduced degradation of gingerol at the lower drying temperature used compared with the commercial dryer temperatures. The loss of volatiles varies with concentration, with the greatest loss occurring during the early stages of drying when the initial concentration of the volatile components is low. Since heat pump drying is conducted in a sealed chamber, any compound that volatilizes remains within it, and the partial pressure for that compound gradually builds up within the chamber, retarding further volatilization from the product [43].

28.3.5 Color Retention or Development

High temperature and long drying time degrade a product's original color. Color in foods can be preserved by minimal heat exposure or applying high temperature and short time with pH adjustment. Water activity is one of the important factors degrading chlorophyll. Another cause of color degradation may be due to enzymatic browning causing rapid darkening, mainly of the leafy portions. The formation of dark pigments via enzymatic browning is initiated by the enzyme polyphenol oxidase (PPO). Another reason for discoloration is photooxidation of pigments, caused by light in combination with oxygen.

Development of a brown center sometimes occurs in macadamia nuts if high-moisture nuts are dried at elevated temperatures [44]. Heat pump drying of macadamia nuts did not result in brown centers, even when they were dried at 50°C [45]. Mason [46] studied the heat pump drying of macadamia kernels and herbs with temperature and relative humidity ranges of 30–50°C and 0.10–0.50, respectively. Freshly harvested macadamia nuts can be dried rapidly up to a moisture content of 0.015 with no loss in quality, and there was no significant difference of quality when dried under the aforementioned conditions. This may be due to the faster drying rates in the heat pump drying process [43]. The losses in color, flavor, and nutritive value associated with dried products are attributed to nonenzymatic browning. It is recognized that the rate of reaction for nonenzymatic browning in dried products is highest at moisture levels that are commonly attained toward the end of the drying cycle, when the drying rate is low and the product temperature approaches that of the drying medium. However, the lower drying temperatures used throughout the drying cycle in heat pump dryers reduce the extent of nonenzymatic browning reactions.

The color and aroma of herbs (e.g., parsley, rosemary, and sweet fennel) can be improved when compared with commercial products. The sensory values were nearly doubled in the case of heat-pump-dried herbs as compared to commercially dried products. There was no significant difference in the quality of herbs dried below moisture content 0.04 for the experimental drying temperatures (40°C and 50°C) and relative humidity (0.30 and 0.40). A wide range of quality characteristics can be obtained by running the dryer within wide ranges of temperature and relative humidity. The use of modified atmospheres for drying of sensitive materials such as food products is another important potential aspect of heat pump drying technology. During drying, oxygen-sensitive materials, such as flavor compounds and fatty acids, can undergo oxidation, giving rise to poor flavor, color, and rehydration properties. Using modified atmospheres to replace air could permit development of new dry products without oxidative reactions [43].

Technologies to create modified-atmosphere (MA) drying are now evolving. Apple tissues dried by modified-atmosphere heat pump (MA–HP) drying had lighter color, lower bulk density values, porous (noncollapsed) structure, and better rehydration properties, as compared to those dried by most other common drying methods [47]. O'Neill et al. [48] showed that browning of apple cubes during drying could be arrested when the oxygen level in the atmosphere is less than 0.5%. Apple cubes dried in nitrogen atmosphere gave more open pores and uniform shrinkage than those dried in air and vacuum. Rahman et al. [27] studied the microbial (aerobic plate count, *Pseudomonas*, *Staphylococcus*, molds) and physicochemical (pH, expressed juice, fatty acid profile, rehydration ratio, color) characteristics of sun, air, vacuum, freeze, and modified atmosphere (nitrogen gas) dried goat meat. The modified atmosphere drying showed significant improvement in selected quality attributes, such as shrinkage, color, types of molds, and peroxide values.

28.4 PHYSICAL CHANGES

28.4.1 Structural Changes

Structural changes in food during drying are usually studied by microscopy. It provides a good tool to study this type of phenomena as well as other types of physical and chemical changes during the drying of food materials. Shrinkage occurs first at the surface and then gradually moves deeper into the food with increase in drying time [49]. The cell walls became elongated. As drying proceeds at higher temperatures, cracks are formed in the inner structure. From microscopy, it was found that the shrinkage of apple samples dried by convection is significantly anisotropic, while less damage to the cell structure during freeze-drying leads to a more isotropic deformation [50]. The cellular structure of microwave-vacuum dried apple with and without osmotic treatment indicated collapse of the cellular structure in the untreated apple [51]. Osmotic treatment prior to vacuum drying preserved the cellular structure by retaining the three-dimensional nature. Electron microscopic investigations of the cell structure in dried carrots and green bean showed that drying leads to shrinkage and twisting of the cells and clumping of the cytoplasm [52]. Histological changes in air-dried, freeze-dried, and osmotically treated freeze-dried samples showed that air-dried samples showed the elongated and thinned cell wall and enlarged intercellular air spaces [53].

Heating produces major changes in muscle structure. Voyle [54] reviewed modifications in cooked tissue observable with a scanning electron microscope. Alternation in muscle structure due to heating include coagulation of the perimysial and endomysial connective tissue, sarcomere shortening, myofibrillar fragmentation, and coagulation of sarcoplasmic proteins [54, 55]. Heating and/or drying intensifies the detachment of the myofibrils from the muscle fiber bundles, which is caused mainly by electrical stunning or stimulation, and improper conditioning following slaughter [56].

Rehydration is maximized when cellular and structural disruption such as shrinkage is minimized [6]. Chang et al. [57] illustrated the morphological changes that occur in the appearance of the muscle fiber bundles during cooking and drying in a convection-heated rotary dryer. They found that after cooking the fibers are bound together in a compact bundle. The bundle size is gradually reduced due to the effects of heating and tumbling during the early stage of predrying in the modified clothes dryer. Apparent bundle size is expanded with the endomysial capillary moisture being removed during drying.

28.4.2 Case Hardening or Crust Formation

During drying, the concentration of moisture in the outer layers is less than in the interior, since outer layers necessarily lose moisture before the interior. This surface shrinkage causes checking, cracking, and warping. This type of shrinkage causes moisture gradient and resistance near the surface. In extreme cases, shrinkage and drop in diffusivity

may combine to produce a skin practically impervious to moisture, which encloses the volume of the material so that interior moisture cannot be removed. This is called case hardening. In food processing, case hardening is also commonly known as crust formation. Extension of crust formation can be reduced by maintaining flattening moisture gradients in the solid, which is a function of drying rate. The faster the drying rate, the thinner the crust [58]. Crust (or shell) formation may be either desirable or undesirable in dried food products. In microencapsulation of flavors, rapid crust formation is required to prevent flavor losses. Achanta and Okos [58] pointed that crust formation may be inhibited by allowing the drying rate to be slow enough that moisture loss from the product surface is replenished by moisture from inside. Crust formation is also important in explosion puffing. In this case the high-moisture product is exposed to rapid drying conditions such as high temperature and vacuum, which create crust. The impermeable crust coupled with the extreme drying conditions results in rapid moisture vaporization and causes large internal pressures to build up, resulting in product expansion/puffing. During the expansion stage, stress buildup in the glassy surface may cause the surface to crack, allowing vapor to escape.

28.4.3 Shrinkage or Collapse and Pore Formation

Two types of shrinkage are usually observed in food materials: isotropic and anisotropic. Isotropic shrinkage can be described as the uniform shrinkage in all geometric dimensions of the materials. Anisotropic shrinkage is described as the nonuniform shrinkage in the different geometric dimensions. In many cases, it is important to estimate the changes in all characteristic geometric dimensions to characterize a material. In fish and seafood shrinkage in the direction parallel to muscle fibers was significantly different from that perpendicular to the fibers during air-drying [59, 60]. This is different from the very isotropic shrinkage of most fruits and vegetables.

Shrinkage is an important phenomenon, which impacts the quality of dried food product by reducing product wettability, changing product texture, and decreasing product absorbency. Depending on the end-use, crust and pore formation may be desirable or undesirable. If a long bowl life is required for a cereal product, a crust product that prevents moisture reabsorption may be preferred. If a product (such as dried vegetables in instant noodles) with good rehydration capacity is required, it should be highly porous with no crust. Rahman [61] provides the present knowledge on the mechanism of pore formation in foods during drying and related processes. The glass transition theory is one of the proposed concepts to explain the process of shrinkage and collapse during drying and other related processes. According to this concept, there is negligible collapse (more pores) in material if processed below glass transition, and the higher the difference between the process temperature and the glass transition temperature, the higher the collapse. The methods of freeze-drying and hot air drying can be compared based on this theory. In freeze-drying, since the temperature of drying is below T_g' (the maximally freeze concentrated glass transition temperature), the material is in the glassy state. Hence, shrinkage is negligible. As a result the final product is very porous. In hot air drying, on the other hand, since the temperature of drying is above T_g' or T_g, the material is in the rubbery state and substantial shrinkage occurs. Hence, the food produced from hot air drying is dense and shriveled [58]. However, the glass transition theory does not hold true for all products. Other concepts such as surface tension, structure, environment pressure, and mechanisms of moisture transport also play important roles in explaining the formation of pores. Rahman [61] hypothesized that as capillary force is the main force responsible for collapse, counterbalancing of this force causes formation of pores and lower shrinkage. The counterbalancing forces are due to generation of internal pressure, variation in moisture transport mechanism, and environmental pressure. Another factor could be strength of the solid matrix (i.e., ice formation, case hardening, and matrix reinforcement).

28.4.4 Stress Development and Cracking or Breakage

During air-drying, stresses are formed due to nonuniform shrinkage resulting from nonuniform moisture and/or temperature distributions. This may lead to stress crack formation, when stresses exceed a critical level. Crack formation is a complex process influenced interactively by heat and moisture transfer, physical properties, and operational conditions [62]. Air relative humidity and temperature are the most influential parameters needed to be controlled to eliminate the formation of cracking.

The cracking and breakage of dried foods have two undesirable consequences: loss of valuable product and loss of consumer satisfaction [58]. Cracking is detrimental to grain quality since affected kernels are more susceptible to mold attack during storage and pathogenic invasion after seeding. Cracked grains are also of lower organoleptic quality, which limits their use in direct food preparation. Internal cracking in the starchy endosperm of a grain is induced by mechanical stress due to the high humidity gradient inside the kernel and/or to thermal stress. The fissure is a large internal fracture usually found to be perpendicular to the long axis of grain [63]. The drying rate, which is a function of drying temperature and humidity, is the main cause of fissures [64–66]. The process of fissures also continues after drying. Most fissuring occurs within 48 hours after drying, but additional fissures develop at a low rate for another 72 hours thereafter [67]. In microwave drying, stress cracking can be even more pronounced due to superposition of the pressure gradient that may build up within the material under certain drying conditions [83]. In case of wheat it also depends on the variety [68]. High-humidity air damages grains to a lesser extent than low-humidity air. Grains are severely damaged by high drying temperatures [69]. The effect of drying air temperature on the mechanical properties of corn kernels was investigated by Abasi and Minaei [70], who found that an increase in drying

temperature from 40°C to 70°C increased kernel deformation at the rupture point by an average of 12%.

In the case of plant materials, cracks also formed. At higher drying rates the outer layers of the material become rigid and their final volume is fixed early in the drying. As drying proceeds, the tissues split and rupture internally forming an open structure, and cracks are formed in the inner structure. When the interior finally dries and shrinks, the internal stresses pull the tissue apart [49]. The initial structure before drying can also create different types of cracks inside as well as on the surface.

28.4.5 Rehydration

Rehydration is a process of moistening dry material. It is usually done with an abundant amount of water. In most cases, dried foods are soaked in water before cooking or consumption, thus rehydration is one of the important quality criteria. In practice, most changes during drying are irreversible and rehydration cannot be considered simply as a process reversible to dehydration [71]. In general, absorption water is fast at the beginning and thereafter slows down. Rapid moisture uptake is due to surface and capillary suction. Rahman and Perera [72] and Lewicki [71] reviewed the factors affecting the rehydration process. These factors are porosity, capillaries and cavities near the surface, temperature, trapped air bubbles, amorphous-crystalline state, soluble solids, dryness, anions, and pH of soaking water. Porosity and capillaries and cavities near the surface enhance the rehydration process, whereas the presence of trapped air bubbles is a major obstacle to the invasion of fluid. Until the cavities are filled with air, water penetrates the material through its solid phase. In general, temperature strongly increases the early stages of water rehydration. The resistance of crystalline structures to solvation causes development of swelling stresses in the material, whereas amorphous regions hydrate fast. The presence of anions in water affects volume increase during water absorption.

28.4.6 Solubility

Many factors affect solubility, including processing conditions, storage conditions, composition, pH, density, and particle size. It was found that increased drying temperatures are accompanied by increasing protein denaturation, which decreases solubility. Thus, more protein is denatured and solubility decreased [6]. Removal of water by evaporation results in formation of an amorphous state. Le at al. [34] found that the cross-linking of casein strongly influences the decrease in solubility of whole milk powder.

28.4.7 Caking and Stickiness

Caking and stickiness of powders, desirable or undesirable, occur in dried products. Caking is desirable for tablet formation and undesirable when a dry, free-flowing material is required. To reduce caking during drying, a logical option is to dry rapidly so that moisture content drops to a level where caking is inhibited. The rapid drying will form a crust, which may be undesirable, thus product optimization or solutes in product formulation may be considered. Tendencies to form surface folds on particles during spray drying are governed by the viscosity of the concentrated solution. Stickiness and agglomeration tendencies also depend upon the viscosity of the concentrated solution, surface tension, particle size, and exposure time [41]. For viscosities below the critical value, stickiness usually occurs. The predicted critical viscosity was within the range of 10^8–10^{10} Pa s. The mechanism of sticking and agglomeration was postulated through viscous flow driven by surface tension and forming bridges between particles [73]. Adhikari et al. [74] presented a complete review of stickiness in foods including mechanisms and factors controlling the process. The main factors affecting stickiness are temperature, viscosity, and water followed by low molecular sugars, organic acids, and compaction or pressure. The use of a model based on glass transition temperature provides a rational basis for understanding and characterizing the stickiness of many foods. Much scientific progress has been made recently in understanding the physical phenomena surrounding stickiness. They involve combining the science of soft matter, along with molecular dynamics simulation and/or particle interaction simulation based on physical principles, and various approaches to the measurement of stickiness and related aspects of glass transition [75].

28.4.8 Texture

Factors that affect texture include moisture content, composition, variety or species, pH, product history (maturation or age), and sample dimensions. Texture is also dependent on the method of dehydration and pretreatments. Purslow [76] stated that meat texture is affected by the structure of the solid matrix. He concluded that it is important to have a fundamental understanding of the fracture behavior of meat and how it relates to the structure of the material. Stanley [30] stated that many researchers now believe the major structural factors affecting meat texture are associated with connective tissues and myofibrillar proteins. Moreover, two other components—muscle membranes and water—also deserve consideration not because of their inherent physical properties but rather as a result of the indirect influence they have on the physical properties. It should be noted that sarcoplasmic proteins could be important for the same reason, although little information on their role is available. He suggested that these structures merit particular attention.

Kuprianoff [77] referred to the possible adverse effects of removing bound water from foods: (i) denaturation of protein by concentration of the solutes, (ii) irreversible structural changes leading to textural modification upon rehydration, and (iii) storage stability problems. Stanley [30] stated that the water-holding capacity of muscle is related to its sorption properties. The bound water in the muscle is primarily a result of its association with the myofibrillar proteins as indicated by Wismer-Pedersen [78]. Protein–water interactions

significantly affect the physical properties of meat [79]. Changes in water-holding capacity are closely related to pH and to the nature of muscle proteins.

28.5 NUTRITIONAL CHANGES

28.5.1 Vitamin Retention

In general, losses of B vitamins are usually less than 10% in dried foods. Dried foods do not greatly contribute to dietary requirements for thiamin, folic acid, and vitamin B-6. Although vitamin C is largely destroyed during drying due to heating, meat per se is not a good source [20]. From non-fatty vegetables, such as cabbage, as much water as possible should be removed, because this helps to conserve ascorbic acid. The loss of vitamin A and ascorbic acid in dried products could be avoided in the absence of oxygen. Even though most amino acids are fairly resistant to heating–drying, lysine is quite heat-labile and likely to be borderline or low in the diet of humans and especially so in developing countries where high-quality animal proteins are scarce and expensive [80]. The fruits dried by MA–HP drying retained the highest level of nutrients, such as vitamin C and flavor compounds [43]. These observations suggest that MA–HP is highly suited for the drying of sensitive food and pharmaceutical products.

28.5.2 Polyphenol Retention

In the case of blueberries, freeze-drying resulted in higher retention of total polyphenols and anthocyanins, and these are comparable to hot air microwave vacuum drying. Similarly, freeze-drying retained higher antioxidant activity followed by hot air microwave vacuum drying and hot air drying. Aglycone polyphenols are more stable as compared to glycosides under dehydration conditions [81].

28.6 CONCLUSION

Drying is a process of water removal that results in reduced water activity and that can cause microbial destruction, prevent microbial growth, reduce deteriorative chemical reactions, and control physical changes. These changes in dried foods depend on the drying methods and their operating conditions as well as pretreatments used. The most important factors are temperature, pressure, atmosphere of drying, and electro-energy used. In addition, the types of foods, and their compositions and structure play a role in achieving desired quality of the dried foods.

29 Smoking and Food Preservation

Mohammad Shafiur Rahman and Kutaila Al-Farsi

CONTENTS

29.1 INTRODUCTION

Smoking of foods is one of the most ancient and traditional food preserving processes, and in some communities one of the most important. The use of wood smoke to preserve foods is as old as open-air drying. Smoking is a slow process and it is not easy to control as a drying process. Although it is not primarily used to reduce the moisture content of food, the heat associated with the generation of smoke also causes drying. Smoking has been mainly used with meat and fish [1]. It also can be applied to chicken [2], mushrooms [3], and cheese [4, 5]. The degree of freshness and proper handling and storage conditions play a role in achieving a good quality smoked product. Presmoking treatments, such as splitting, salting, and hanging, are also used, depending on the type of product [1].

29.2 PURPOSE OF SMOKING

The main purposes of smoking are it imparts desirable sensory flavors and colors to the foods, it inactivates enzymatic compounds and microorganisms, and some of the compounds formed during smoking have preservative effects (i.e., bactericidal and antioxidant) due to presence of a number of antioxidant and antimicrobial compounds [1, 6, 7]. In many cases, smoking is considered as a pretreatment rather than a drying process. It was found that smoke is effective in preventing lipid oxidation in meat and fish products [8]. Smoke deposition is effective only in controlling surface spoilage [9]. Smoking technology is used in the food industry to enrich meat products for a desired organoleptic profile [10, 11]. It can effectively preserve white fish for a longer time as compared to fatty fish [12].

29.3 SMOKING PROCESSES

Smoking is a slow process and it is not easy to control. Smoke contains phenolic compounds, acids, and carbonyls, and smoke flavor is primarily due to the volatile phenolic compound [13, 14]. Wood smoke is extremely complex and more than 400 volatiles have been identified [15, 16]. The smoke generated depends on the type of generator, wood type, humidity, and temperature of the smokehouse [17]. Polycyclic aromatic hydrocarbons are ubiquitous in the environment as pyrolysis products of organic matter, and its concentrations in smoked food could reach levels hazardous for human health, especially when the smoking procedure is carried out under uncontrolled conditions [18]. Wood smoke contains nitrogen oxides, polycyclic aromatic hydrocarbons, phenolic compounds, furans, carbonylic compounds, aliphatic carboxylic acids, tar compounds, carbohydrates, pyrocatechol, pyrogallols, organic acids, bases, and carcinogenic compounds like 3:4 benzpyrene. Nitrogen oxides are responsible for the characteristic color of smoked food, whereas polycyclic aromatic hydrocarbon components and phenolic compounds contribute to its unique taste. These three chemicals are also the most controversial from a health perspective [16]. The level of fats in fish affects texture, oiliness, and color of smoked salmon during storage [13, 19].

It is important to use processing conditions, which must be standardized, controlled, monitored, and documented so that the potential of toxic-component generation in food products is eliminated or reduced. This is especially true for seafood products, which may contain food poisoning organisms of marine origin that are more difficult to control than land sources [9]. Color development in smoked fish is a complex process. Maillard type with glycolic aldehyde and methylglyoxal in the dispense phase of smoke play a dominant role. Several types of synthetic colors, paprika, caramel, and seasoning can also be used [20].

29.3.1 Cold Smoking

Cold smoking is defined as the smoking of food at low temperatures (i.e., below 33°C). Cold-smoked food is neither cooked nor protein coagulated in the process and it needs additional preservation hurdles, which include thermal processing, vacuum packaging, salting, and chilled storage. The main steps

of cold smoking are salting, drying, and smoking at temperature lower or equal to 30°C [18]. Several studies investigated the effect of these methods on the final product's properties and compositions. Indrasena et al. [21] studied the effect of cold smoking and drying on the textural properties of farmed Atlantic salmon. Atlantic salmon fillets were brine-salted at concentrations ranging between 2.2% and 3.6%, chilled, and cold smoked for different times. They found that the moisture content varied inversely with salt and it decreased with the increase of salt content. The breaking strength increased with the decrease in moisture.

Birkeland et al. [22] investigated the effect of process parameters (i.e., brine injection pressure, number of repeated injections, needle speed, injection of brine in one or two directions, and resting the chilled fillet before smoking) on the final product yield. They found that repeated injections increased the yield up to 5.3% (w/w) and the increase of injection pressure increased the fillet gaping by 18%. Birkeland et al. [23] also studied the quality parameters of cold-smoked fillets of Atlantic salmon using two different cold smoke methods: gentle cold smoking (i.e., manual filleting and dry salting) and tough cold smoking (i.e., machine filleting, injection salting, extended drying). They found that the product yield, water content, and gaping score were high and softer in texture in tough cold smoking than gentle cold smoking. However, the quality traits of the smoked products were difficult to predict from raw material characteristics. It is difficult to consistently retain the quality traits due to differences in color, texture, gaping scores, and total liquid loss of raw material. The stability of a smoked fish depends on the choice of processing method and processing hurdles used to preserve the product.

Birkeland and Skara [24] studied two different methods to produce cold smoke: liquid smoke protocol (SCP) and wood chips protocol (WCP). Salmon fillets were dry salted (18 h, 4°C) before being smoked by SCP or WCP. SCP included drenching for 1 min in smoke condensate (1:3 smoke:water) and drying for 150 min at 28.4°C ± 2.2°C. WCP included drying and smoking in a smoking chamber at 23°C for 480 min using wood chips for smoke production. The quality of cold-smoked salmon was assessed at 0, 7, 14, and 31 days of storage at 3.4°C. The SCP procedure resulted in a significantly higher processing yield (89.6%) compared to the WCP (88.6%). At the beginning, the SCP fillets showed light and yellow color and had a lower chroma (color C*) and hue (color h*) as compared to the fillets processed with WCP, but after one week the color differences were very small. Texture profile analysis (TPA) showed significant differences between the processing protocols, but the SCP fillets were significantly softer than the WCP fillets. The SPC or drenching method could be used to produce cold-smoked salmon with quality characteristics similar to traditional products.

The temperature used in cold smoking is important and could be a critical factor that can affect the final characteristics of the smoked product. Hultmann et al. [25] investigated the effect of smoking temperature (21.5°C, 24.3°C, 28.2°C, and 29.9°C, for 6.5 h) on different properties of proteins and enzymes in cold-smoked salmon. The smoking temperature was important for the protein solubility properties and myofibrillar protein composition in smoked salmon. The increase in smoking temperature caused a reduction in the extractability of myofibrillar proteins, and free amino acid content was increased with the increase of smoking time and storage duration. However, smoking temperature did not affect the composition of free amino acids as well as the proteolytic activity, and the effect of processing parameters was mostly observed at the early stages of the product's shelf life.

Fish are highly perishable and can easily spoil after a short time. Cold smoking could be used as a method to add value to fish products. Gomez-Guillen et al. [26] studied the suitability of sardine (i.e., lean and fatty), dolphin fish, and blue whiting for cold smoking. The samples were assessed by sensory, chemical, and microbial analysis over the storage time. They found that cold smoking could be used to add value to sardine and dolphin fish catches, if these are in excess. The water-holding capacity was stable for some species, and rancid flavors were only detected in sardine at the end of the storage period. In terms of microflora, lactic acid bacteria were dominant and Enterobacteriaceae did not show any growth. However, the blue whiting was found unsuitable for smoking due to softening of muscle tissue and the development of bitter taste and off-flavors. However, smoking of fish could add value to fish and decrease fish waste due to spoilage.

It was reported that the cold-smoked fishes had the highest prevalence of bacteria among other minimally processed foods [27]. The application of cold smoking does not apply severe stress to kill pathogens such as *Listeria monocytogenes*, and this is due to the application of low temperature (<30°C), salt (3–5%), and low storage temperature [28]. Therefore, there is a need to add other hurdles to inhibit the growth of microorganisms. *Listeria monocytogenes* is the most common microorganism found in cold-smoked foods. All smoked fish must be stored in chilled conditions or vacuum packed to prolong shelf life. Hansen et al. [29] identified the microflora on spoiled, sliced, and vacuum-packed cold-smoked salmon from three different sources. Lactic acid bacteria dominated, with large numbers of *Enterobacteriaceae*. The microflora on cold-smoked salmon appeared to be related to the sources of contamination, i.e., the raw material and/or the smokehouse.

Neunlist et al. [30] studied the effect of different steps of the cold smoking process and vacuum storage on the culture ability and viability of *Listeria monocytogenes* inoculated in sterile salmon samples. Salmon portions were inoculated with *Listeria monocytogenes* at a level of 6 log cfu/g, then salted (5.9%), smoked, partially frozen, vacuum packed, and stored for 10 days at 4°C followed by 18 days at 8°C. Neunlist et al. found that salting was the only step that had a significant effect on *Listeria monocytogenes* with 0.6 log reduction; other processing steps did not show any immediate effect. However, the combination of steps significantly lowered *Listeria monocytogenes* by 1.6 log cfu/g, and the count remained less than 7 log cfu/g until the end of the storage period, whereas unprocessed (control) samples reached up to 9 log cfu/g. This indicates that there is a need to add other hurdles to preserve the cold-smoked product.

Nykanen et al. [27] studied the inhibition effect of nisin and sodium lactate or their combination on *Listeria monocytogenes*, and mesophilic aerobic bacteria in cold-smoked rainbow trout. Nisin of 4000–6000 IU/ml, sodium lactate of 60%, and a combination of both substances (1:1) were injected into rainbow trout fish before the smoking process, or injected in the finished smoked product. A *Listeria monocytogenes* level of 10^3–10^4 cfu/g was inoculated in the fish samples. All samples were packed under vacuum and stored at 8°C for 17 days or at 3°C for 29 days. Both nisin and lactate inhibited the growth of *Listeria monocytogenes* in smoked fish, but the combination of nisin and sodium lactate decreased the count from 3.3 to 1.8 log cfu/g at 8°C for 16 days of storage (i.e., autosterilization occurs to some extent). These preservatives showed no effect on sensory properties of the product until a period of 23 days stored at 3°C.

29.3.2 Hot Smoking

The traditional method of smoking fish uses hot smoke, from a range of woods, passed over the fish to partially dry it and impart the flavor and aroma of the smoke. The disadvantages of this method include a lack of control over the process and health concerns if the surface of the fish is not properly dried. The smoking process involves extensive handling of raw and finished products. Smoked food is prepared with two basic procedures. One cooks the product (hot smoking) and the other does not (cold smoking). Cold-smoking devices have one basic function: to apply smoke to the product. Hot-smoking devices provide the added function of applying heat. The hot-smoke process for smoking fish differs from the cold-smoke process in a fundamental way. The cold-smoke process requires that the fish reaches an internal cooking temperature below 35°C, while the hot-smoke process cooks the fish center to at least 62.8°C for at least 30 minutes, and fish must contain at least 3.5% water phase salt for both processes [9]. A traditional wood-burning kiln has a temperature of between 300°C and 700°C while an oven's temperature is usually above 80°C [31]. A temperature between 4°C to 61°C (i.e. risk zone) can create an environment favorable to bacteria growth. As an additional safety margin, hot-smoked fish should always be cooled to less than 3.3°C immediately after smoking and held at that temperature until consumed. Both hot- and cold-smoked fish are preserved primarily by controlling salt (i.e., water phase salt), moisture content, and chilled condition.

The hot smoking of fish requires five steps, each one with different goals and operating conditions. These steps are surface drying, smoking, drying, heating/cooking, and cooling. Surface drying is the removal of surface moisture leaving a protein coating (pellicle) on each piece of fish and adsorbing an even deposition of smoke. A dense smoke atmosphere, where smoke is deposited evenly on the surface of each piece, is important and it ensures good flavor, color, and surface preservation. Often color does not develop until the surface of the fish reaches 54.4°C to 60°C during the cooking step. Evenly drying the fish is needed to reduce moisture, and raises salt in the water phase and establishes final texture. This is a critical step in producing safe products. It is required to heat each piece of fish to at least 62.8°C and to hold that temperature for at least 30 min. This is also a critical step in producing safe smoked fish. Cooling the fish below cooking temperature (48.9–60°C) in the smokehouse as quickly as possible is needed. A suitable sanitary refrigerated room is usually more practical and cost-effective than a refrigerated smokehouse. Cold-smoke procedures do not use step 4 of heating/cooking. Usually these five cycles take 8–12 hours. Cycles of 4 hours or less are possible with thin and lightly smoked products [9]. The differences in the process employed depend primarily upon the type of fish and regional preferences for a particular product.

Hot smoking is preferred because it extends the shelf life of food products. Hot smoking uses a thermal process, which combines heating and drying with smoking, leading to the creation of unfavorable conditions for the growth of harmful microorganisms. However, processing at high temperatures is considered responsible for the qualitative degradation of processed products. Thus, several techniques are required to minimally heat the hot-smoked products [1, 32]. Moreover, the rate of deposition of volatile compounds depends on temperature, moisture, flow rate, and density of the smoke; the water solubility and volatility of the particular compounds; and the properties of the fish surface [33].

Fafioye et al. [34] studied the fungal infestation of five traditionally smoked dried freshwater fish. They isolated and identified 11 different fungal species, and *Aspergillus flavus* was the most frequently encountered fungi on the fish species. Adebayo-Tayo et al. [35] reported the presence of aflatoxin and other metabolites due to *Aspergillus flavus* in smoked fish sold in Nigeria and confirmed that consumers could have been at risk of aflatoxin poisoning.

Smoking methods (traditional drum and convective kilns) affected the proximate composition, quality, and safety (heavy metals and microbial) of traditional smoked fish (i.e., five types) [36]. In the case of traditional drum kiln, the fish was skewed, salted, and smoked to 60–90°C for 36 hours. The fish for convective kiln were cut into uniform pieces (fillet) so that no parts would get overheated, and cooked to an internal temperature of 80°C (checked by thermocouple) for 12 hours. The moisture content of fresh fish samples ranged from 73.5% to 75.9%, and drum-smoked fish samples ranged from 11.9–13.4% and 8.6–9.4% for convective-smoked fish samples. The proximate composition, rancidity indices (i.e., peroxide value [PV], thiobarbituric acid [TBA], total volatile base-nitrogen [TVB-N], trimethyl amine value [TMA]), fatty acids, and pH varied with the types of fish. Four heavy metals (i.e., lead, cadmium, mercury, and chromium) investigated in the fish samples were generally below the maximum permissible levels set by the World Health Organization (WHO). Fresh fish showed the presence of *Listeria monocytogenes* (1.2×10^2–1.7×10^2 cfu/g), *Staphylococcus aureus* ($1.2–1.7\times10^2$ cfu/g), *Salmonella paratyphi* ($1.0–1.5\times10^2$ cfu/g), and *Escherichia coli* ($1.3–1.6\times10^2$ cfu/g), and the total viable count varied from $8.4–9.2\times10^8$ cfu/g. The convective and drum smoked showed total viable count varied from $8.4–9.2\times10^2$ cfu/g and

2.3–6.4×10^4 cfu/g. The convective-smoked fish showed the absence of *Listeria monocytogenes*, *Salmonella paratyphi*, and *Escherichia coli*, while *Staphylococcus aureus* varied from absent to 2.2 × 10^2 cfu/g. The drum-smoked fish showed absence of *Salmonella paratyphi* and *Escherichia coli*, but the presence of *Listeria monocytogenes* (4.4–12.2×10^1 cfu/g) and *Staphylococcus aureus* (2.1–5.7×10^2 cfu/g). Traditional drum-smoked fish may pose higher microbiological risks due to the presence of *Listeria monocytogenes*.

A hybrid fish-smoking kiln that uses propane gas as a source of heat in combination with biomass (i.e., sawdust, rice husk, and wood) was successfully designed and fabricated [37]. The smoking temperature of 120°C (i.e., maximum recommended) was reached in 2 h when 1 kg of each biomass was used in combination with propane gas, and the temperature dropped to 60°C in 1 h when the propane gas was switched off. Similar weight loss, proximate composition, smoke density, phenol content, and sensory qualities of the smoked fish were obtained for the three biomasses used. Catfish smoked in the hybrid kiln were generally acceptable. The hybrid kiln yielded quality smoked fish in terms of phenol content, biomass utilization, reduced smoking time, reduced cost of production (low wood consumption, smoke dusting, and drying rate), and uniform product.

After hot smoking, the smoked product is stored at chilled or refrigerated conditions for about a month [38]. In order to increase the shelf life of hot-smoked products, they should be stored at very low temperatures. In fact, hot-smoked foods can be preserved at –30°C for more than 6 months. Preservatives are used in order to increase the shelf life of hot-smoked food products. Coban et al. [39] investigated the effects of some oils on the chemical, microbiological, and sensory quality of smoked rainbow trout fillets packed in vacuum. They found that the essential oils (natural antioxidants) can be used in vacuum packs to enhance hot-smoked fish quality and increase the shelf life of the products up to 112 days. Other preservatives including chitosan, sodium lactate, sodium diacetate [40], thyme and garlic oil [12], and essential oils [41, 42] to extend the shelf life of vacuum-packed hot-smoked products. Da Silva et al. [43] examined the microbial safety and quality of smoked blue catfish steaks treated with antimicrobials and antioxidants during 6 weeks of ambient storage.

In addition, different processing schemes are specified for different fish species [13]. The smokehouse is equipped with a smoke generator where smoke is passed over water to remove tar and solid particles. Good Manufacturing Practices (GMP) from the U.S. Food and Drug Administration (FDA) sets minimum standards for time/temperature smoking cycles, salt and moisture content, manufacturing procedures, holding and shipping temperatures, process monitoring and record keeping, and packaging.

29.3.3 Liquid Smoking

Modern methods of smoked fish use formulated liquid smoke and these provide flavor with reduced water activity on the surface. In this method, the fish are dipped in smoke solutions prior to drying. Most drying methods use heat to change the relative humidity of the air passing over the fish. This is an inefficient use of energy and the heat drives off many of the aromatic chemicals that go to make up the aroma, flavor, and color of the product. This could be overcome using an energy-efficient heat pump drier, where drying is performed in a closed chamber.

Smoke solutions are available, either being condensed products from the dry distillation of wood or synthetically prepared mixtures of phenols. The use of smoke condensates offers some advantages. These are easily applied and their concentration can be controlled. These can be analyzed, purified if necessary, and the antimicrobial activity can be evaluated. Sunen [44] identified the minimum inhibitory concentration of smoke wood extracts against spoilage and pathogenic microorganisms associated with food. It was found that the effectiveness of inhibition varied with the type of commercial liquid smoke. Synthetic smokes are nearer to actual smoke curing, and harmful components can be eliminated from synthetic smokes.

The odor, composition of flavor compounds, and antimicrobial activity of the smoke are recognized to be highly dependent on the nature of the wood. Some studies have recognized beech and oak woods to produce wood smoke with the best sensory properties [45]. Further, herbs, spices (bay leaves, black peppers, cloves, coriander seed), or pinecones may also be added to produce unique aromatic smoke flavors [14]. Bacteriocin treatment was found effective inhibiting *Listeria monocytogenes* on salmon packaged under vacuum or modified atmosphere [46]. Lingbeck et al. [47] reviewed the functionality of liquid smoke as a natural antimicrobial in food preservation. The review showed that several common foodborne pathogens such as *Listeria monocytogenes*, *Salmonella*, pathogenic *Escherichia coli*, and *Staphylococcus* are sensitive to liquid smoke in food systems.

29.4 CONCLUSION

The main purpose of smoking is to provide desired sensory flavors and colors to the foods as well as to inactivate enzymes and to deliver an antimicrobial effect. Smoked products are commonly stored under chilled or refrigerated conditions, but they are high-risk products as compared to dried and frozen food products. In many instances, other preservation hurdles, such as herbs, spices, and nisin are used to enhance preservation and stability. The smoking processes are cold smoking, hot smoking, and liquid smoking, and each one has specific advantages and disadvantages. Quality management tools, such as GMP, HACCP (Hazard Analysis and Critical Control Point), and hygienic conditions are important to deliver high-quality and safe smoked foods.

30 Osmotic Dehydration of Foods

Mohammad Shafiur Rahman

CONTENTS

30.1 THE OSMOTIC PROCESS AND ITS DYNAMICS

30.1.1 Osmotic Dehydration

Osmotic dehydration of foods has potential advantages in fruit and vegetable processing industries. This dehydration process generally does not produce a product of low moisture content to be considered shelf-stable. Consequently, the osmotically treated product should be further processed (generally by air-, freeze-, or vacuum-drying methods) to obtain a shelf-stable product or the process could be used as a pretreatment for canning, freezing, and minimal processing.

Osmotic dehydration is the process of water removal by immersion of cellular solid in a concentrated aqueous solution. The driving force for water removal is the concentration gradient between the solution and the intracellular fluid. If the membrane is perfectly semipermeable, solute is unable to diffuse through the membrane into the cells. However, it is difficult to obtain a perfect semipermeable membrane in food systems due to their complex internal structure, and there is always some solute diffusion into the food and leaching out of the food's own solute. Thus, mass transport in osmotic dehydration is actually a combination of simultaneous water and solute transfer processes (Figure 30.1).

The removal of water during the osmotic process is mainly by diffusion and capillary flow, whereas solute uptake or leaching is only by diffusion. The fundamental knowledge for prediction of mass transport is still a gray area, although considerable efforts have been made over the past decade to improve the understanding of mass transfer in osmotic dehydration [1]. Empirical models have been developed for mass transfer that are easy to use when kinetics parameters are correlated with dimensionless processing conditions [2]. Rastogi et al. [3] conducted a review on enhanced mass transfer.

The osmotic dehydration process can be characterized by equilibrium and dynamic periods [4]. In the dynamic period, the mass transfer rates are increased or decreased until equilibrium is reached. Equilibrium is the endpoint of the osmotic process, i.e., the net rate of mass transport is zero. Rahman

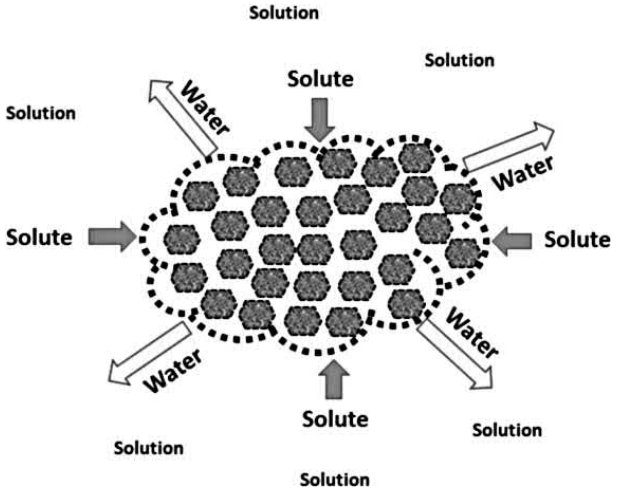

FIGURE 30.1 Water and solutes transfer in osmotic process.

[4] proposed equilibrium distribution coefficients for the *i*th component as

$$\lambda_i^e = \frac{X_i^e}{Y_i^o} \tag{30.1}$$

where λ_i^e is the distribution coefficient, and Y_i^o and X_i^e are the mass fractions (wet basis) of the *i*th component in the initial osmotic syrup and food product at equilibrium, respectively. The distribution coefficients for water can be defined as:

$$\lambda_w^e = \frac{X_w^e}{Y_w^o} \tag{30.2}$$

Similarly, the distribution coefficient for total solids can be defined as

$$\lambda_s^e = \frac{X_s^e}{Y_s^o} \tag{30.3}$$

The equilibrium coefficients varied with concentration, temperature, types of solutes, geometry, and food–syrup mass ratio. The $_w^e$ varied from 0.74 to 1.43 and $_s^e$ varied from 0.82 to 1.12 in case of osmotic dehydration of pineapple when temperature and syrup concentration varied from 30°C to 60°C and 50% to 75% (w/w), respectively [5]. Similarly, distribution coefficients were measured for pineapple [6], potato [7], apple [8], and mango [9]. In the case of apple, at constant syrup concentration, the distribution coefficient of water decreased and the distribution coefficient of solids increased with the increasing temperature. The influence of syrup concentration on distribution coefficients showed opposite trends, i.e., increasing syrup concentration increased the distribution coefficient of water but decreased the distribution coefficient of solids [8]. Sablani et al. [8] also developed correlations as a dimensionless function of temperature and syrup concentration. Sablani and Rahman [9] developed correlations for mango as

$$\lambda_w^e = 2.05\left(\frac{T}{T_r}\right)^{-1.60}\left(Y_s^o\right)^{0.397}\left(\frac{A_s}{l^2}\right)^{-0.007} \tag{30.4}$$

$$\lambda_s^e = 0.468\left(\frac{T}{T_r}\right)^{2.04}\left(Y_s^o\right)^{0.317}\left(\frac{A_s}{l^2}\right)^{0.023} \tag{30.5}$$

where T is the process temperature (K), T_r is the reference temperature (273 K), A_s is surface area of the sample (m^2), and l is the smallest geometric dimension of the sample (m).

30.1.2 Curing by Salts

Curing was originally developed to preserve certain foods by addition of sodium chloride. In the food industry, the curing is related only to certain meat, fish, and cheese products. Today sodium chloride, sodium, and potassium nitrite or nitrate are considered curing salts. Salting is one of the most common pretreatments used for fish products. Salting converts fresh fish into shelf-stable products by reducing the moisture content and acting as a preservation method. In combination with drying, these processes contribute to the development of characteristic sensory qualities in the products, which influence their utilization as food [10, 11]. Although curing was originally a mechanism for preservation by salting, over several millennia additional processes concomitant with curing have evolved, notably fermentation, smoking, drying, and heating. Curing may have different connotations: in meat, salt and nitrite or nitrate are always added; in fish, salt is always added, but nitrite only rarely; and in cheese, which always contains salt but infrequently contains nitrate. The term curing is applied to the production of desirable proteolytic and lipolytic changes. In the past half-century, cured products have been developed that are not stable unless refrigerated. Indeed, most cured meat products must be refrigerated to remain safe and wholesome, and even the packaging of many classes of cured products has become important in extending the shelf life [12]. Cured meats can be divided broadly into three groups: unheated, mildly heated (pasteurized to center temperature of 65–75°C), and severely heated (shelf-stable after heating to 100–120°C) [12].

In addition to the curing salts and related processes mentioned, additives collectively known as adjuncts are used in many cured meat products. These include ascorbates, phosphates, glucono-D-lactone, and sugars. Adjuncts are used primarily to obtain or maintain desirable changes; the ascorbates in connection with color; and the others in connection with pH, texture, and in some cases flavor. Adjuncts may also affect safety. The concentration of each curing agent depends on the nature of the food products and on the technology used in individual countries [12].

Salting can be done by placing fish in salt solution or covering with dry salt. During salting, water is being removed from the flesh, salt enters the tissues of the fish, and the body juices become a concentrated salt solution. When enough salt enters, it interacts with all the proteins causing coagulation. When the tissue cells shrink because of the loss of a large share of the moisture content, the fish flesh loses most of its translucent appearance and does not feel sticky to the touch. At this stage, it is said to be *struck through* [13]. A review of

the osmotic treatment of fish and meat products is provided by Collignan et al. [14].

30.2 EFFECTS OF OSMOSIS ON BIOLOGICAL MATERIALS

The cell viability of osmotic-treated apple revealed that the first layer of cells at a depth 1–2 mm from the surface died as a result of severe osmotic shock. The depth of the layer of severely injured or dead cells coincided with the penetration depth of the osmotic solute [15]. Cell viability of onion protoplast did not suffer any significant change regarding the nature of the sugar and the sucrose concentration. Sucrose solution dramatically decreased the cell viability in strawberry tissue [16]. During osmotic treatment, a redistribution of the components in cell membrane took place causing a reduction of the surface membrane available for swelling. It might explain that protoplasts swell until plasma membrane broke during the rehydration with isotonic solution with respect to fresh tissue. Maltose and trehalose had a protective effect on plasma membrane of onion epidermis cell, maintaining its properties as a barrier. Trehalose played a major role during the rehydration of onion epidermis, leading to the highest swelling rate. Contrarily, parenchymatic cells of strawberry tissue were not susceptible to any protective effect regarding the kind of disaccharides employed [16].

Electronic microscopy of strawberry [16, 17], apple [18], onion [16], orange peel [19], kiwifruit [20], and eggplant [19] was studied to explain the modification of cellular structure and disruption of cell membrane by the osmotic process. The rehydration kinetics of osmotic-pretreated and air-dried carrot slices decreased with the increased syrup concentration used in osmotic dehydration. In addition, solute loss increased during rehydration possibly due to structural changes induced by the osmotic process [21].

Water sorption characteristics of osmotically treated apple slices shifted to the right [22]. Osmotic treatment changed the moisture isotherm of air-dried sweet potato [23]. Salting or solute addition affects the air-drying process by reducing water diffusivity [24–27]. The concentration of the osmotic solution used in the pretreatment influenced the drying process, and a variable diffusivity and shrinkage were more suitable to describe the experimental data [28]. In the case of sweet potato, osmotic treatment with corn syrup did not affect the water diffusivity during air-drying [23]. Water diffusivity in strawberry during air-drying increased in the case of blanching or blanching followed by osmotic treatment [17]. The effective diffusivity of pomegranate arils during air-drying of ultrasound-assisted osmotic pretreatment was increased by 43% during the first falling rate period and by 66% during the second rate falling rate period. It was due to the structural changes for arils and the frequency of 40 kHz being more effective than 25 kHz [29]. Ultrasound during osmotic drying showed satisfactory results in terms of color, but increased hardness and decreased anthocyanin in air-dried arils. The ultrasound-assisted osmotic dehydration prior to hot air drying (60°C and air velocity 1.5 m/s) decreased the total drying time of persimmon fruit [30]. First, osmotic dehydration (30°C, 45°Brix) was performed at 35 kHz (10–30 min) followed by dehydration in 70°Brix sucrose solutions with shaking at 100 rpm. The air-drying rate increased 21% in the effective water diffusivity by 30 min. The pretreatment affected the rehydration rate and total phenolic content, while there was no significant difference between the color parameters.

Quality attributes and structure of hot air (1080 min drying and energy consumption 135.2 kJ/g), vacuum microwave (34 min drying, energy consumption 26.5 kJ/g), osmotic microwave (3 min drying, energy consumption 11.5 kJ/g), and osmotic vacuum microwave (11 min drying, energy consumption 24.0 kJ/g) drying of tilapia fillets were assessed [31]. Osmotic treatment was performed by submerging fish in a salt solution (20%, w/w) at 30°C for 2 h. The final moisture contents of all dried products were around 11.0 g/100 g sample. Vacuum drying promoted the formation of a porous structure. The shrinkage rate, rehydration rate, hardness, and elasticity of osmotic-vacuum-microwave fillets and vacuum-microwave fillets showed similar results. The osmotic vacuum microwave drying improved the quality of the fillets better in terms of microstructure, energy consumption, and color change. Therefore, combined methods could be better options for the quality of the dried products. The salt concentration has also great influence on the rate of surface evaporation [32]. In addition, depending on the salt concentration and relative humidity, the salted fish may reabsorb moisture from the environment during storage [33].

30.3 POTENTIAL ADVANTAGES FOR INDUSTRY

The use of the osmotic dehydration process in the food industry has several advantages: (i) quality improvement in terms of color, flavor, and texture; (ii) energy efficiency; (iii) packaging and distribution cost reduction; (iv) chemical treatment not required; and (v) product stability and retention of nutrients during storage.

30.3.1 Quality Improvement

It is well established that osmotic dehydration improves product quality in terms of color, flavor, pigment, vitamins, and texture. The merits of osmotic dehydration for product quality improvement and process efficiency were reviewed [1, 4, 34, 35]. Air-dried cashew apple pretreated with an osmotic solution of sodium chloride and sucrose showed improved color, firmer texture, astringency, and overall acceptability [36]. Fluidized bed air-dried blueberries pretreated with an osmotic solution showed low shrinkage, better rehydration, and soft raisin-like texture [37]. Agreeable flavor, color, and texture of osmo-air-dried peppers with whey and sorbitol were developed without preservatives [38]. Osmo-air-dried peas were developed with attractive color and acceptable organoleptic properties with preosmotic dehydration in sucrose and citrate solution [39]. Microwave-dried apple and strawberry pretreated with osmotic dehydration showed high quality in terms of color, taste, vitamin C, and structure retention.

Scanning electron microscopy (SEM) analysis revealed that the cellular structure was preserved better with osmotic treatment [40]. Structural and compositional profiles in osmotically dehydrated apple were studied by Cryo-SEM analysis [41]. The firmness of osmo-dehydro-frozen apple measured by oscillation rheometry showed in the following order: no treatment > sorbitol = sucrose > corn syrup > blanched [18]. Vacuum pulse did not favor either preservation of kiwi and mango mechanical response or their cryo-preservation. The mechanical response of strawberry was better preserved by air-drying osmotic treatment, but the freezing–thawing process provided similar results. Thus, it is necessary to optimize the process treatment based on each fruit [42]. Atmospheric-osmotic-treated kiwifruit with glucose, glycerol, or sucrose showed lower failure forces than fresh fruit. Calcium lactate infiltration or vacuum infusion increased failure forces due to enhanced cell cohesion and increased cell wall integrity. Relaxation tests showed that infusion (atmospheric or vacuum) sharply decreased the elastic component of rheological behavior of kiwifruit [20]. In the case of potato, longitudinal stiffness was affected much more by osmotic treatment than was shear stiffness [43].

In the literature, there is not much fundamental understanding of the mechanisms of flavor entrapment in the food matrix, color retention, and the physics of textural improvement. The phenomena that retain aroma are (i) adsorption of volatiles onto the infused solute matrix, (ii) physicochemical interactions between volatiles and other substances, and (iii) microregional encapsulation in which volatile compounds are immobilized in *cages* formed with the association of dissolved solids [44–50]. For papaya, the loss of hydrosoluble solutes, such as vitamin C could be reduced, most likely because of a sugar barrier layer that is formed at the periphery [51]. In case of kiwifruit, high temperatures and high sugar concentrations could reduce the loss of vitamin C and chlorophyll due to the preferential increase of water loss compared to solutes [52].

Processing at 50°C or more leads to disadvantageous modifications of color, ascorbic acid, and chlorophyll contents. Processing at 40°C or lower gave satisfactory ascorbic acid and pigment contents in the finished product. Furthermore, additions of ascorbic acid in syrup, as well as calcium and/or copper chlorides, can enrich the quality, in particular the color [52]. Talens et al. [53] found that osmotic treatment caused changes in the volatile profile of the kiwifruit depending on the treatment conditions. The concentration of the ester fraction increased, whereas aldehydes and alcohols decreased. Vacuum pulse application and process time promoted ester formation. The decrease in the aldehydes and alcohols was greater in treatments carried out at atmospheric pressure. After one month in frozen storage, a severe reduction of all compounds (esters, aldehydes, and alcohols) resulted in the same volatile profile in a treated and directly frozen sample. The use of high sucrose concentration (40–65%) in osmotic dehydration of kiwifruits can be recommended in order to minimize microbial adhesion and to slow microbial growth during storage, even if it has to be taken into account that high sugar concentration could determine problems of solubility and sugar recrystallization [54].

Minerals or functional substances could be fortified in vegetables and fruits by applying the osmotic process. The effect of Ca and Fe ions incorporation in the structural matrix of apple during the vacuum osmotic dehydration process at 30°C was studied by Barrera et al. [55]. Only calcium had the ability to strengthen the cell structure, which diminished effective diffusivities. Osmotic-dried apple showed much lower and uniform shrinkage compared to air-dried apple at the same level of moisture content [56]. Calcium infiltration in osmotic-treated apple showed better retention of cellular microstructure during subsequent high temperature and a short blanching process [57].

Osmotic pretreatment kept residues of the solute inside the product, influencing the taste and flavor of the product, as well as the dielectric properties. The increased salt concentration has a strong effect on the loss factor. Osmotic-treated mushrooms dried by microwave hot air produced more homogeneous heating due to the reduced center heating, slightly shorter drying time, improved rehydration properties, reduced shrinkage, and a higher open-pore porosity [58]. Fito et al. [19] explored the possibility of formulating functional, stable, and fresh-like products by incorporating minerals, vitamins, and health-beneficial functional components in the osmotic solution, in addition to water activity or pH depressors, and antimicrobial components.

Osmotic pretreatments (sugar, sodium chloride, and maltodextrin) affect the quality attributes of french fries [59]. Osmotic pretreatment decreases oil and moisture content of french fries, while the porosity increased and provided improved structure. Color darkening took place during osmotic dehydration, and browning reactions during frying are promoted resulting in a darker and red-colored fried product. Salt-treated samples have the most acceptable color.

Shrinkage and deformation of apple cubes of 1.5 cm showed significant deformation including cell and pore collapse during hot air drying at 80°C [60]. Only osmotic pretreatment or instant control pressure drop (DIC) could not improve the appearance and texture properties of air-dried apple cubes. However, osmotic pretreatment and DIC combined with maltodextrin or microcrystalline cellulose could increase crispness (i.e., 57–64; air-dried only: 10) and reduce hardness (i.e., 138–145 N; air-dried only: 15 N) of apple cubes. In addition, and the deformation of volume was increased by 1.6 times as compared with hot air drying alone. Therefore, combined technology could be used to obtain air-dried products with good appearance and texture properties.

30.3.2 Energy Efficiency

Osmotic dehydration is a less energy-intensive process than air- or vacuum-drying because it can be conducted at low temperatures. Energy consumption in osmotic dehydration at 40°C (with syrup reconcentration by evaporation) was at least two times lower than convection air-drying at 70°C [61]. In the frozen food industry, high energy levels are used

for freezing, because a large quantity of water is present in fresh foods. A significant proportion of this energy could be saved if plant materials were concentrated prior to freezing [62, 63]. A reduction in the moisture content of food can reduce refrigeration load during freezing. This is typified by salting, which is one of the oldest methods for preserving fish and vegetables. The high level of solute in osmotically treated products decreases water activity and preserves them, and thus energy-intensive drying processes can be avoided. Following osmotic treatment, the resultant syrup can be used in the juice or beverage industries as a by-product, thereby improving process economy.

Osmosis pretreatment with 7% (w/w) sodium chloride for 30–90 min showed no significant effect on energy and exergy loss of microwave air-drying (90–900 W) of 4 cm thick orange slices [64]. Increasing the microwave power increased the energy and exergy efficiency of drying, leading to a reduced drying time. Osmosis pretreatment increased the absorption of heat in orange, leading to an increase in the energy and exergy efficiency during air-drying. Osmosis time showed more effect on the energy efficiency than the exergy efficiency. Considering the effective moisture diffusivity and mass transfer coefficient, the optimum energy and exergy efficiency was considered at power 900 W and osmotic time 90 min. The maximum exergy loss was observed at 360 W and osmosis time of 60 min.

30.3.3 Packaging and Distribution Cost Reduction

Partially concentrating fruits and vegetables prior to freezing saves packaging and distribution costs [65]. The product quality is comparable with that of conventional products. The process is referred to as *dehydro-freezing.*

30.3.4 Reduction of Chemical Treatment

Canning of apples is not practiced commercially due to some inherent problems associated with the high gas volume in apple tissue and difficulty of its removal during exhausting, less drained weight, and mushy texture [66]. There have been a few attempts of canning apple slices by the use of calcium chloride, a firming agent, in order to improve texture [67]. However, using osmotic-treated apple pieces in the canning process resulted in a firmer texture and improved quality of the product [66]. This process is known as *osmo-canning.* Similarly, firmer apple slices were possible when calcium ion was used in the osmotic syrup [55].

Chemical treatment to reduce enzymatic browning can be avoided by the osmotic process [68]. There are two effects of sugar in producing a high-quality product: (i) effective inhibition of polyphenol oxidase, the enzyme that catalyzes oxidative browning of many cut fruits; and (ii) prevention of the loss of volatile flavor during further air- or vacuum-drying [69]. However, if the final product after air-drying contains 10–20% moisture, enzymatic and nonenzymatic browning cause slow deterioration of color and flavor [70]. Therefore, Ponting [70] suggested adding a blanching step after the osmotic process and using sulfur dioxide during or after the osmotic step if the final moisture content of the fruits and vegetables is more than 20%.

30.3.5 Product Stability during Storage

The product obtained by osmotic processing is more stable than untreated fruits and vegetables during storage due to low water activity by solute gain and water loss. At low water activity, deteriorative chemical reactions and growth and toxin production by microorganisms in the food are low. In the case of canning, using high-moisture fresh fruits and vegetables, water can flow from the product to the syrup brine causing dilution. This can be avoided using the osmo-canning to improve product stability [66]. Similarly, the use of osmo-dehydro-frozen apricot and peach cubes in yogurt can improve consistency and reduce whey separation of the yogurt [71]. Solute exerts a germicidal effect. Salt reduces the solubility of oxygen in the substrate, thereby, restricting the growth of aerobes.

30.4 FACTORS AFFECTING OSMOTIC DEHYDRATION PROCESS

The mass transport during osmotic dehydration depends on the factors described in the following sections.

30.4.1 Type of Osmotic Agent

The most commonly used osmotic agents are sucrose for fruit and sodium chloride for vegetables, fish, and meat. Other osmotic agents include glucose, fructose, lactose, dextrose, maltose, polysaccharide, maltodextrin, corn starch syrup, whey, sorbitol, ascorbic acid, citric acid, calcium chloride, and combinations of these osmotic agents. A number of researchers investigated the use of binary mixtures of solutes with sucrose as a means of reducing solute cost and improving the effectiveness of osmosis [72, 73]. The ultimate choice of blend will depend on many factors, such as solute cost, organoleptic compatibility with the end product, and additional preservative action by the solute. Calcium from a calcium chloride brine approximately iso-osmotic with cucumber cell sap penetrated cucumber fruit much more slowly than did calcium ions from a mixture of sodium chloride and calcium chloride. After 96 h, calcium that penetrated from the isoosmotic brine was localized mostly in the exocarp and relatively little in the interior tissues, while calcium that penetrated from the supa-osmotic brine reached higher concentrations and was more evenly distributed among the exocarp, mesocarp, and endocarp sections [74]. It was A synergistic action of two solutes (sucrose and sodium chloride) was observed on soluble solids gain in apple. With respect to the sensory analysis of apple samples dehydrated in ternary solutions, it is possible to assert that salt gain was not sufficient to balance the excessive sweetness of the product processed at high sucrose concentrations. Small additions of sodium chloride (up to 1%) did not determine the complete decay of product acceptability if coupled with limited sucrose concentration (<54.5%) [75].

30.4.2 Concentration of Osmotic Solution

Both the water loss to equilibrium level and osmotic drying rate increase with the increase in osmotic syrup concentration, since water activity (i.e., mass transfer driving force) of syrup decreases with the increase in solute concentration in the syrup [65, 76–82]. A dense solute-barrier layer at the surface of the product is formed with increase in syrup concentration, thus enhancing the dewatering effect and reducing the loss of nutrients during the process [83, 84]. A similar solute barrier is also formed in the case of syrups with higher molecular weight solutes at even low concentration.

30.4.3 Temperature of Osmotic Solution

The rate of osmosis is markedly affected by temperature [85]. This is the most important parameter affecting the kinetics of water loss and solute gain. Water loss increases with increase of temperature, whereas solid gain is less affected by temperature. In the case of high temperature, solute cannot diffuse as easily as water through the cell membrane and thus the approach to osmotic equilibrium is achieved primarily by the flow of water from the cell [82]. This type of equilibrium results in a lower solute gain by the product. Askar [86] recommended a high temperature and short time for osmo-solar-dried peach since it can produce good texture with high aroma and color retention. Main influence in osmotic dehydration was observed at a high temperature of 50°C, and at 26°C no appreciable change in solids concentration was observed at distances deeper than 0.5 cm from the cube surfaces even at 168 h. At 50°C, all the layers were affected even at shorter times (8 h) [87].

Fish are salted over the temperature range of 0°C to 38°C. The higher the temperature, the faster the salt infusion and the quicker the process reaches equilibrium. In general, fish absorbs salt faster as the brining temperature increases. It is best to standardize brining at a cool temperature (1.1–1.7°C) to achieve consistent and predictable results and to discourage bacteria growth. Using ice in the brine can accomplish this, but caution must be used to make sure no ice remains in the finished brine. Brining in a cold room is also a good way to keep brines cool and is advisable for long brining times [88].

In general, salt absorption is affected by brine concentration and temperature, brining time, thickness and geometry of fish, texture and fat content of fish, species, and fish quality [88]. Fish flesh absorbs salt faster from higher salt brine concentration. Brine greater than 15.8% tends to remove moisture from the fish, which can be advantageous in some products. However, strong brines and short times may not allow even distribution of salt into the center of the fish geometry prior to smoking. Dry salting has the advantage of removing moisture, but has the disadvantage of uneven salt absorption. Dry salting is a technique that covers fish with a thin layer of salt (0.64–1.27 cm) between layers of fish [88]. Tilapia was processed by dry salting (fish:salt ratio, 3:1) varying salting time (0–24 h), air-drying time (6–20 h), and drying temperature (40–60°C). The critical salting times for attaining minimum moisture were 20.5, 12 and 8.5 h, respectively, for products air-dried at 40°C, 50°C, and 60°C. The hardness, color, and overall acceptability of salted dried tilapia were found to be dependent on the process variables, salting time, drying time, and temperature [33].

30.4.4 Properties of Solute Used in Osmosis

The osmotic process is affected by the physicochemical properties of the solutes employed. These differences arise mainly from differences in molecular weight, ionic state, and solubility of the solute in water. According to the principle of osmosis, the rate of water loss from the fruit to the syrup having large molecular weight solute is lower than that of syrup having small molecular weight solutes when both syrups are at the same mass concentration. This is due to low vapor pressure of the syrup having low molecular weight solute. However, contrary to this physical chemistry principle, for osmotic syrups with equal concentrations at the early stage, those with high molecular weight solutes will have a greater rate of water removal and lower solute transfer (due to low solute penetration) than those of low molecular weight. This was demonstrated by a model agar gel [89] and apple [90].

The pH of the syrup can also affect the osmotic process. Acidification increases the rate of water removal by changes in tissue properties and consequential changes in the texture of fruits and vegetables [91]. Water removal was maximal at pH 3 for apple rings using corn syrup [92]. In a more acidic solution (i.e., at pH 2), the apple ring became very soft. However, firmness was maintained at pH values within 3 to 6. The softening may be due to hydrolysis and depolymerization of the pectin.

30.4.5 Agitation of Osmotic Solution

Osmotic dehydration can be enhanced by agitation or circulation of the syrup around the sample [72, 78, 92]. However, the improvement is so small that in some cases it might be more economical to use no agitation when consideration is taken of equipment needs and breaking of fruits [68]. The effect of agitation on the osmotic dehydration of kiwifruit slices was found to depend on the ratio of syrup to fruit mass and syrup concentration [93].

30.4.6 Material Geometry

Osmotic concentration behavior depends on the geometry of sample pieces, due to the variation of surface area per unit volume (or mass) and diffusion length of water and solutes involved in mass transport. Contreras and Smyrl [92] found that mass loss was about 1.3 times higher when apple slice thickness decreased from 10 mm to 5 mm. Lerici et al. [79] found that solute gain increased as the ratio of surface area to minimum diffusion length increased, while water loss increased to a maximum (depending on the shape) and then decreased. This decrease in water loss was probably due to a reduction of diffusion caused by high solid gain at the surface

and consequent formation of a solute layer. At the same operating conditions, fresh fruit having different sizes and shapes can give final products with very different characteristics [79]. In the case of osmotic dehydration of apple, water loss and solids gain generally increased with contact time, temperature, and concentration, and decreased with an increase in size of cylindrical sample [94].

30.4.7 Osmotic Solution and Food–Mass Ratio

Both solid gain and water loss increase with the increase of the ratio of syrup to food mass [68, 95]. Uddin and Islam [96] studied the effect of the ratio of syrup and fruit slice mass on the osmotic treatment of pineapple at 21°C. They observed that weight loss increased until the syrup-to-fruit ratio was 4:1, but by increasing the ratio up to 6:1 no further gain was observed. Thus, they defined the optimum ratio as 4:1 for pineapple. The rate of solid gain and water loss increased significantly: the ratio of syrup to fruit mass was increased from 1:1 to 6:1 in case of osmotic drying of potato in 61% sucrose syrup [61]. At equilibrium, the solute content in potato was the same at syrup–fruit ratios of 1:1 and 10:1. Thus, the ratio of syrup to fruit mass has a negligible effect on potato composition at equilibrium.

30.4.8 Physicochemical Properties of Food Materials

The chemical composition (protein, carbohydrate, fat, salt, etc.), physical structure (porosity, arrangement of the cells, fiber orientation, and skin) and pretreatments may affect the kinetics of osmosis in food. A steam-blanching step for 4 min before osmosis gave lower water loss and higher solid gain when applied to fresh potato slices [73]. The loss of membrane integrity due to heating was the cause of the poor osmotic concentration behavior [73]. Freezing raw fruit disrupts cells and results in poor osmosis of thawed fruit [70]. Saurel et al. [84] studied osmosis of frozen apple without thawing in ethylene glycol and polyethylene glycol at 30°C to 70°C. They observed similar results as fresh apple.

Soft-textured fish tend to absorb salt faster than tough or firm-textured fish. Frozen flesh absorbs negligible salt, and thus need thawing. Mishandled fish with gaping (separated flesh fibers) may have decreased brining times. High-fat-content fish absorb salt slower than low-fat fish. However, they may need less salt to obtain adequate final water phase salt content. Fat content in flesh varies at different locations on the body of the fish. Salmon, for example, tend to have less fat at the tail. Different species of fish have different flesh characteristics and may absorb salt at different rates. Salting times should be specific for each species. Moreover, geometrical shapes of fish having different thickness and width along the length also make it difficult to control the salting process and causes nonuniform salt distribution. Frozen-thawed fish or low-quality fish have flesh characteristics that may affect (usually increase) the rate of salt absorption. The rate of freezing affects flesh cell structure and therefore the subsequent rate of salt absorption [88]. In some cases, for example in the case of salmon, the fish is soaked overnight in fresh water or for a period of 12–16 h before curing. The water is changed two or three times. Ten or 12 h of freshening should be sufficient, but a more thorough soaking may be required to satisfy some markets.

Diffusivity of manganese ion in cured pork was varied $0.42–1.0 \times 10^{-10}$ m^2/s [97]. Salt diffusion in pork meat was found $3.6–1.2\ 10^{-10}$ m^2/s (temperature –2°C to 36°C) and for fat it was $0.07\ 10^{-10}$ m^2/s [98]. Salt has a profound effect on the ultrastructure and hence moisture binding of fish muscle. It has a greater effect compared to freezing, drying, or heat treatment [99].

30.4.9 Operating Pressure and Other Forces

Vacuum osmotic dehydration results in a change of behavior of mass transfer in fruit–sugar or salt–solution systems [93, 100–105]. Vacuum treatments intensify the capillary flow and increase water transfer, but have no influence on solute uptake [101]. The total water transfer results from a combination of traditional diffusion and capillary flow, and it is affected by the porosity or void fraction of the fruit [103, 105]. The reduction in pressure causes the expansion and escape of gas occluded in the pores, and pores can be occupied by osmotic solution, thus increasing the mass transfer rate. Pulsed vacuum osmotic drying proved effective for figs with higher water loss and solids gain [28].

In addition to vacuum drying, applications of high hydrostatic pressure [106], centrifugal force [107], high electric pulse [108, 109], and ultrasound [110] are used to improve the mass transfer [3]. The increased mass transfer in high electric field and high pressure was due to the irreversible increase in cell wall permeability [106], and the initiation and growth of the pores were time-dependent [108]. Petrotos and Lazarides [111] reviewed osmotic concentration of liquid foods by applying osmotic membrane techniques, namely, direct osmosis, membrane distillation, and osmotic distillation.

The acoustic increases the mass transfer by reducing the thickness of the boundary layer by generating localized pressure fluctuations [112]. Ultrasound (i.e., 25 and 40 kHz at different intervals) was applied to enhance the efficiency of moisture removal during the osmotic dehydration of pomegranate arils [29]. It was observed that more detachment of cell wall increased water loss (i.e., 2-fold and 2.7-fold increment for water loss at the frequencies of 25 and 40 kHz, respectively) and solute gain. Microscopic analysis of ultrasound-assisted (20 kHz, 130 W) osmotic dehydration (i.e. solutes: sodium chloride and 12 DE maltodextrin) showed the formation of microchannels due to the loss of cellular adhesion, which produced large cell interspaces and other tissue structures of potato [113]. This resulted in higher moisture and solid mass transfer. At solute concentration of 30%, ultrasound-assisted osmotic dehydration enhanced the effective diffusivity of water by about 5.5–260%, whereas the ultrasound pretreatment in water increased up to 130% when solute concentration of 70% was used in osmosis. A more intense dense cell breakdown was observed when ultrasounds were

applied in the osmotic process as compared to application before the osmotic dehydration process. The solids gain of potato cubes submitted to ultrasound pretreatment was lower than that of ultrasound-assisted osmosis, thus reduced calorie low sugar or salt products could be achieved.

Water loss of garlic slices treated with vacuum osmotic dehydration (21.12%) was higher than slices treated with normal osmotic dehydration (10.67%), while vacuum pretreatment osmotic and multifrequency mode ultrasound-assisted osmotic dehydration showed water loss as 14.1% and 11.2–13.6%, respectively [114]. Low-field nuclear magnetic resonance showed the moisture migration in the vacuole, cytoplasm and intercellular space, and the cell wall of garlic cells. The allicin content, surface color change and firmness of vacuum-osmotic treated garlic slices were better than the other treated samples.

30.5 CHALLENGES TO APPLICATION IN THE FOOD INDUSTRY

There are a number of technological problems to be overcome before the osmotic process can be applied to the food industry. These are discussed in the following sections.

30.5.1 Product Sensory Quality

The main disadvantage of the osmotic process is that it may increase the saltiness or sweetness, or decrease the acidity of the product, which may not be desired in some cases. This can be avoided by controlling the solute diffusion and optimizing the process to improve the sensory assessment of the product. Adequate protective edible coating enriched with specific antimicrobial additives can be used to reduce surface microbial growth and other barriers during storage [115]. Edible semipermeable membrane coatings can also be used to reduce solute uptake and increase water loss [116]. Salting of cod fillets was achieved in osmotic solutions (sucrose and salt, or corn starch syrup and salt) with high molecular solutes allowed better control of salt entrance, thus produced light-salted fish [117]. However, microbiological and organoleptic validations need to be carried out for complete process validation.

30.5.2 Syrup Management

Syrup management with the batch process is difficult due to the dilution of solution and microbial contamination (Figure 30.2). The microbial validation of the process for long-time operation and reuse of the syrup by recycling are important factors for industrial applications [1]. The management of syrup is the major challenge to make the process industrially viable. These include syrup composition and concentration, syrup recycling, solute addition, reuse of the syrup, and waste disposal. The cost of the syrup is a key factor for the success of the process. The compositional changes related to leaching from the fruit or vegetable may influence the product quality (such as color, acids, sugar, minerals, and vitamins).

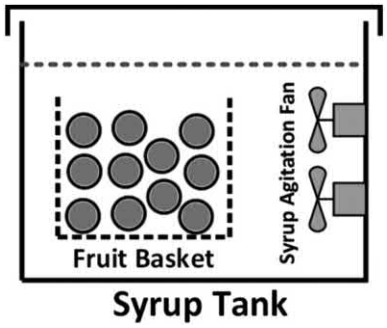

FIGURE 30.2 Schematic diagram of a batch osmotic process.

A continuous osmotic process is shown in Figure 30.3, where diluted solution is concentrated and recycled back to the osmotic process. Microbial contamination can increase with the number of times that the syrup is recycled. Depending on the environmental process conditions, the microbial load after several osmotic cycles can range from 2 10^2 cfu/ml to high levels of yeast and fungi only after 15th cycle, and 10^5 cfu/ml after 8 h of continuous treatment [118]. A pilot recycling system was validated for salt in the case of meat and fish. Over a 6-day processing period, the microbial load of the brine was kept at a low level (8.37 10^4 cfu/g of fungi; 1.19 10^3 cfu/g of yeasts and molds), and the mass transfer potential of the solution (water loss and salt gain) remained steady [14]. The options to reduce microbial contamination are more care for low-acid foods, avoid too much dilution of the solution, the processing environment should use an air-filtering system, and hygienic management of osmotic solution [118]. The control of solute composition in recycling for single-solute syrups is easier than mixed-solute syrups.

Barranco et al. [119] considered the following options for osmotic solution management: (i) direct reuse after some degree of regeneration; (ii) reuse with the final product, after preconditioning or a partial regeneration process; and (iii) use of the spent solution to produce substances of interest. These could be obtained either directly or through a microbiological process, and (iv) treated with a specific process. During the recycling process, the diluted syrup can be reconcentrated by evaporation, reverse osmosis, membrane filtration, freeze concentration, and/or treated with active carbon [14, 118, 119]. The unused syrup needs to be adequately treated before disposal in wastewater [118, 119]. The ratio of syrup to fruit mass

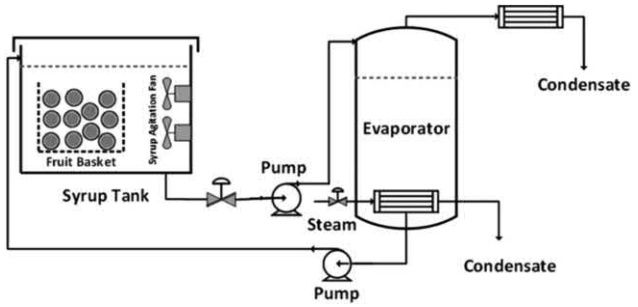

FIGURE 30.3 A process flow diagram of a continuous osmotic process.

should be kept as low as possible to reduce the production costs. Torreggiani [120] emphasized that the problems of the microbial growth in syrup and the effects of repeated reconcentration and recycling of syrup on its properties, need to be overcome in order to develop large-scale industrial process. Acidifying sucrose could result from the acidic fruits (or added) and this could increase the rate of osmosis; however, this caused darkening and quality losses during the subsequent drying process. Kubiak et al. [121] studied the effect of pH (4–10), temperature (50–60°C) and sucrose concentration (50–70°Brix) on sucrose hydrolysis rate. The sucrose hydrolysis at pH rage of 6–10 was insignificant and did not depend on temperature and sucrose concentration. Sucrose hydrolysis significantly increased and depended on hydrogen ion and sucrose concentration, temperature, and time with pH values below 5.0.

30.5.3 Process Control and Design

Inadequate information about the experiments presented in the literature and limited data available have precluded effective design and control of this process by the food industry. Further studies are necessary to get a clear understanding of the variation of equilibrium and rate constants with process variables and characteristics of the food materials. Most of the osmosis studies have been concerned with the qualitative prediction of the processing factors, but more quantitative prediction is necessary for industrial use in process design and control. On-line measurements of syrup properties can provide continuous control of the process. Fruits and vegetables tend to float on the concentrated syrup due to the higher density of the syrup. Moreover, the viscosity of the syrup exerts considerable mass transfer resistance causing difficulty in agitation, and the syrup tends to adhere to the surface of the food material. Breakage of fruit or vegetable pieces may occur by flow of syrup in the case of the continuous process or by mechanical agitation in the case of the batch process.

Marouze et al. [122] provided different possible equipment (batch and continuous processes) designs for osmotic dehydration. They found the following need to be considered:

(i) Creating relative movement between the solution and the food, characterized by relative speed and homogeneity for all food
(ii) Control of treatment time and for equipment used for continuous processing, and control of the spread of residence times in the contactor to ensure homogeneous treatment of the food
(iii) Ability to accept different shapes of food (whole or in cubes, slices, or fillets)
(iv) Reduction of the ratio of solution mass to food mass (a low mass ratio is of particular interest if the cost of the solution is high; it also restricts equipment size)
(v) Avoidance of oxidation in food in contact with air
(vi) Allowing a system for the solution to be introduced and removed
(vii) Allowing the food to be introduced and removed (for continuous processing: continuous introduction, and removal of food when it has reached required state of treatment)
(viii) Allowing control of the process control parameters (food and solution temperature, solution concentration, static pressure of food and solution, agitation)
(ix) Complying with the appropriate mechanical, electrical, and food-related standards
(x) Reasonable cost of equipment manufacture

Equilibrium is the endpoint of osmosis, but for practical purposes a number of other factors should be considered to ensure the quality of the final product. These include damage to the cells and development of off-flavor due to longer processing time as well as reuse of the syrup [4]. Finally, adequate packaging systems should be used to make sure that consumers are getting good sensory quality and safe products.

30.6 CONCLUSION

The osmotic process is widely used as a pretreatment for developing many shelf-stable dried, frozen, canned, and intermediate-moisture food products. The main advantage of this process is to improve the product quality attributes. The process dynamics depend on many factors, such as types and properties of osmotic agents; solution concentration, temperature, and agitation; the food's size, shape, and physicochemical properties; osmotic and food mass ratio; and other external applied forces. Other external forces, such vacuum and high pressure, centrifugal force, high electric pulse, and ultrasound are also used to enhance the mass transfer as well as to improve the quality. The main issue of the osmotic process is the inclusion of the solutes in the product, and syrup management, process design, and control are the challenges to be addressed.

31 Fundamentals of Water Activity Concept

Mohammad Shafiur Rahman and Theodore P. Labuza

CONTENTS

31.1 IMPORTANCE OF WATER ACTIVITY

Water is an important constituent of all foods. Why water activity and not water content? In the middle of the 19th century, scientists began to discover the existence of a relationship between water in a food and its relative tendency to spoil. They also began to realize that the *active water* could be much more important to the stability (i.e., reactivity) of food than the total amount of water present. Scott [1] clearly identified that the water activity of a medium correlated well with the deterioration of food stability due to the growth of microorganisms. Thus, it is possible to develop generalized rules or limits for the stability of foods by using water activity. This was the main reason why food scientists started to emphasize water activity rather than total water content. Since then, the scientific community has explored the great significance of water activity in determining the physical, chemical, and sensory characteristics; effects of processing; and shelf-life prediction of foods.

Other applications of water activity extend to the process design and control, ingredients, and packaging selection. Water activity data are important to food processing, such as osmotic dehydration and air-drying. In drying operations, desorption isotherms at the process temperature are needed for design and control purposes. The endpoint of drying or the osmotic dehydration process could be determined from the equilibrium moisture content. In the drying process, the foods are equilibrated

to the air equilibrium relative humidity (i.e., water activity); in osmotic or salting processes, foods equilibrate with the osmotic solution water activity. Hence, water activity plays an important role in designing, operation, and control of drying processes and reverse osmosis. Water activity depressing power of solutes need to be considered when selecting ingredients or additives for food product formulation. When food materials are packed in a semipermeable membrane, foods could adsorb moisture if their water activity is lower than the external relative humidity of the air or could lose moisture if their water activity is higher than the relative humidity. The sorption isotherm is necessary to predict the moisture transfer rate through the packaging film and edible food coating, and so that shelf life can be predicted based on the water gained through packaging. The mathematical equations used to determine the isotherms for moisture transfer through packaging material are available in the literature [2, 3]. The water activity of fresh foods, as shown by Chirife and Fontan [4], is 0.970–0.996. It is important to understand the terminologies related to the water activity concept and factors affecting it in order to properly utilize it in food preservation and processing.

31.2 THERMODYNAMICS OF WATER ACTIVITY

Water activity, a thermodynamic property, is defined as the ratio of the vapor pressure of water in a system and the vapor pressure of pure water at the same temperature, or the equilibrium relative humidity of the air surrounding the system at the same temperature (Figure 31.1). Water activity is

$$a_w = \frac{\text{Vapor Pressure of Water in Food}}{\text{Vapor Pressure of Pure Water}} = \text{ERH} \quad (31.1)$$

where ERH is the equilibrium relative humidity of the air around the foods. A number of methods have been reported in the literature to measure or estimate the water activity of foods. Water activity measurement methods include the following: equilibrium sorption rate method (isopiestic method), vapor pressure measurement method, and hygrometric instrument method. In addition, water activity can be predicted from other thermodynamic properties, such as freezing point. The accuracy of most methods lies in the range of 0.01–0.02 water activity units [5]. Details of the various measurement techniques are described by Labuza et al. [6], Rizvi [5], Rahman [7], Rahman and Sablani [8], Rahman et al. [9], Fontana [10], Sablani et al. [11], and Rahman and Al-Belushi [12].

Water activity can be lowered or controlled by several methods, such as separating water (e.g., drying, baking), and/or adding solutes. Processes that can be used to remove water are drying, concentration, and dewatering by centrifuge. Solutes can be added to foods to reduce water activity as well as to improve the functional and sensory properties of foods, for example, adding salt to meat and fish and adding sugars to fruits. Specific antimicrobial effects and the cost of solutes or humectants should be considered for food product formulation when solutes are used to reduce the water activity. The factors affecting the selection of humectants are summarized in Table 31.1.

31.3 SORPTION ISOTHERM

The moisture sorption isotherm is the relationship of moisture content with the water activity of a food at a specified temperature. It is usually presented in graphical form or as an equation. Brunauer et al. [13] classified adsorption isotherms of materials into five general types (Figure 31.2). If water-soluble crystalline components are present in foods, e.g., sugars or salts, the isotherm appears as concave shape type III. Most other foods result in sigmoid isotherm type II. The inflection point of the isotherm indicates the change of water-binding capacity or of the relative amounts of free and bound water. Type I is indicative of a nonswelling porous solid, such as silicate (i.e., anticaking agent). For most practical purposes, the isotherm is presented in an empirical or theoretical model equation. However, none of the isotherm models in the literature are valid over the entire water activity scale of 0–1. The GAB model is one of the most widely accepted models for foods over a wide range of water activities from 0.10 to 0.9. The details of the isotherm models with their parameters are compiled by Rizvi [5], Okos et al. [14], Lomauro et al. [15], Lomauro et al. [16], and Rahman [7].

31.3.1 Hysteresis

The difference in the equilibrium moisture content between the adsorption and desorption curves is called hysteresis and

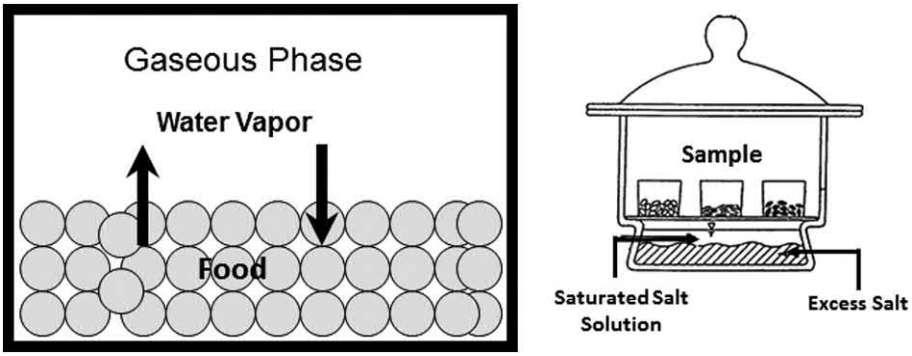

FIGURE 31.1 Thermodynamics of water transfer within food and the environment in a closed chamber.

TABLE 31.1
Some Criteria for Humectants to Be Used in Foods

Safe
Approved by regulatory agencies
Effective at reasonable concentrations
Compatible with the nature of food
Flavorless at used concentrations
Colorless and/or imparts no color changes in food

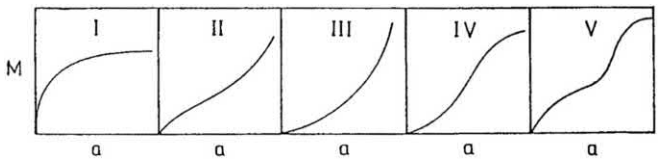

FIGURE 31.2 The five types of van der Waals adsorption isotherms proposed by Brunauer et al. [13].

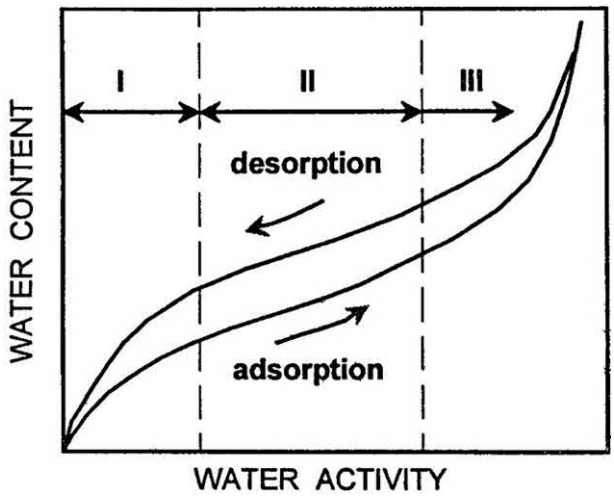

FIGURE 31.3 Sorption isotherm for typical food product showing the hysteresis.

shown in Figure 31.3. In region II of this figure, the water is less tightly held and is usually present in small capillaries; whereas in region III, water is held loosely in large capillaries or is free [17]. Hysteresis in sorption has important theoretical and practical implications in foods. The theoretical implications are evidence of the irreversible sorption process and the validity of the equations derived based on equilibrium thermodynamic functions. The practical implications deal with the effects of hysteresis on chemical and microbiological deterioration, and its importance on low- and intermediate-moisture foods [18]. The changes in hysteresis could be used as an index of quality deterioration, since hysteresis loops of foods change with storage time [19, 20], however this is not a widely accepted method of evaluation. Rahman and Al-Belushi [12] present a review on the sorption hysteresis in foods.

31.3.1.1 Factors Affecting Hysteresis

The desorption hysteresis loop usually ends at the monolayer, but in some cases, it extends down to an activity of zero [21]. In foods, a variety of hysteresis loop shapes can be observed, depending on the types of foods and the temperature [22]. The principal factors affecting hysteresis are composition of the product, isotherm temperature, storage time before isotherm measurement, pretreatments, drying temperature, and the number of successive adsorption and desorption cycles.

Variations in hysteresis can be grouped into three types of foods [18]:

(i) Hysteresis in high-sugar foods—In high-sugar or high-pectin foods, such as air-dried apple, hysteresis occurs mainly in the monomolecular layer water region, below the first inflection point of isotherm region I in Figure 31.3 [14]. Although the total hysteresis is large, there is no hysteresis above 0.65.
(ii) Hysteresis in high-protein foods—In pork, a moderate hysteresis begins at about 0.85 (i.e., in the capillary condensation region) [23].
(iii) Hysteresis in high-starch foods—In starchy foods, a large hysteresis loop occurs, with a maximum water activity of about 0.70, which is within the capillary condensation region [14].

Total hysteresis decreases as sorption temperature increases [22]. Desorption isotherms usually give a higher water content than adsorption isotherms. Chinachoti and Steinberg [24] found hysteresis in sugar containing starch up to 0.60 and Bolin [25] in resin (with very high sugar content) up to 0.30. Tsami et al. [26] observed significant hysteresis below 0.5 or 0.6 and at temperatures above 30°C in fruits (raisin, currant, fig, prune, and apricot). They mentioned that the absence of hysteresis at higher temperatures was due to the dissolution of sugars at high temperatures. The water activity below which a significant hysteresis effect was manifested was inversely proportional to the sugar content of the fruits [26]. In high sugar or high pectin foods such as air-dried apple, hysteresis occurs mainly in the monomolecular layer of water region [14]. Although the total hysteresis is large, there is no hysteresis above 0.65.

In the case of pork, a moderate hysteresis begins at about 0.85 (i.e., in the capillary condensation region) [23]. In starchy foods, a large hysteresis loop occurs with a maximum at about water activity 0.70, which is within the capillary condensation region [14], whereas in kudzu starch, hysteresis continues up to 0.90 [27]. Increasing temperature decreases the total hysteresis [20]. Iglesias and Chirife [28] estimated and compared the isosteric heat of water adsorption and desorption for a number of foods, and reported that the effect of temperature on the magnitude of hysteresis varied. There was no direct relationship between the observed differences in adsorption and desorption heats and the distribution of hysteresis along the isotherm. For some foods (thyme, winter savoy, sweet marjoram, cooked trout, raw and cooked chicken, and tapioca), increasing temperature decreased or eliminated hysteresis,

while for others the total hysteresis remained constant (ginger and nutmeg) or even increased (anise, cinnamon, chamomile, and coriander) [18].

The type of changes encountered upon adsorption and desorption depends on the (i) initial state of the sorbent (amorphous versus crystalline), (ii) transitions taking place during adsorption, the (iii) final water activity adsorption point, and (iv) sorption rate. If the saturation point has been reached and the material has gone into sorption, rapid desorption may preserve the amorphous state of supersaturated solution [18]. Some water remained after desorption (even after prolonged storage) due to hydrogen-bonded trapped water in amorphous sugar microregions as well as crystalline water [20, 29].

In some cases, hysteresis seems to be reproducible a second time [19, 30], and for some cases the second sorption–desorption cycle resulted in the elimination of hysteresis [31]. Elimination of hysteresis upon the second or subsequent cycles may take place for a variety of reasons, such as the change in crystalline structure when a new crystalline form persists in subsequent cycles [32], swelling and loss of elasticity (i.e. ability to return its original structure) of capillary walls resulting in a loss of ability to retain trapped water [33–35]. This loss of elasticity is due to the denaturation effects of surface-active agents [36], and mechanical treatments, and these may affect the capillary structure [18].

31.3.1.2 Theories of Sorption Hysteresis

Several theories have been formulated to explain the phenomenon of hysteresis, and at present a complete theory to encompass several responsible mechanisms is missing [26], and quantitative prediction of hysteresis is a challenge. Several theories have been proposed to explain hysteresis. The mechanisms proposed in the literature to cause hysteresis are discussed in the following sections.

31.3.1.2.1 Capillary Condensation

Capillary condensation can mostly account for hysteresis in nonswelling porous solids and can be explained using the Kelvin equation. Due to the presence of impurities, such as dissolved gas, the contact angle of the receding film upon desorption is smaller than that of the advancing film upon adsorption. Therefore, capillary condensation forms along the adsorbed moisture, and the sorption isotherm results in a higher relative vapor pressure [23].

31.3.1.2.2 Ink Bottle Theory

Rao [33] assumed capillaries to be composed of narrow necks with a large pore, somewhat like an ink bottle. On adsorption, the capillary does not completely fill until the water activity corresponding to the large radius of the pore is reached. During desorption, the smaller radius of the pore neck controls the emptying of the capillary, resulting in considerably lower water activity [21]. This theory was confirmed by Labuza and Rutman [37] for a cellulose model system. Cohan [38] elaborated upon the open-pore theory by extending the bottleneck theory, including considerations of multilayer adsorption. This was based on the difference as affected by the shape of the meniscus.

31.3.1.2.3 Mechanisms of Physicochemical Changes

The physicochemical changes in food components also cause hysteresis, such as deformability and elastic stresses of the sorbent, a deformation of the polypeptide chains within the protein molecule [18], and the energy surplus of unfolding (swollen) protein phase transition [39]. Kapsalis [18] discussed that adsorption from the dry state by biopolymers is due to (i) side-chain amino groups, (ii) end carboxylic and other groups, (iii) peptide bonds, and (iv) secondary structure.

In general, below 0.5 water activity, the main sites of sorption are the polar side-chain groups. The contribution of the polypeptide chain becomes progressively more important at higher activities, for example, at 0.80 activity the peptide bonds account for almost half the adsorbed water in wool keratin. Deamination of methylation of side-chain groups in wool and benzoylation in casein did not show any appreciable changes of hysteresis [40]. This suggested that it was the main chains of the biopolymers that are primarily responsible [18]. Sheehof et al. [41] supported the polar group interpretation of hysteresis, where binding mainly involves the free basic groups of the protein.

Kapsalis [18] showed a correlation of the maximum amount of hysteresis with the sum of arginine, histidine, lysine, and cystine groupings. Besides the free basic groups of the protein molecule, sulfur linkages are also of prime importance in hysteresis [42]. In contrast to this work, hysteresis in casein was observed to be independent of the free amino groups [40]. Thus, a two-fold nature of hysteresis was proposed: constant hysteresis, independent of the relative humidity desorption point; and hysteresis proportional to the amount adsorbed above the upper adsorption break of the isotherm 18]. In a swelling polymer, hysteresis depends on the mechanical constants contributed by the elastic properties and cannot be interpreted by capillary condensation [43]. Van Olphen [44] described retardation of adsorption due to the development of elastic stress in crystallites during the initial peripheral penetration of water between the unit layers. The shift toward higher relative vapor pressure during adsorption is caused by the required activation energy to open the unit layer stacks. The glass–rubber transition during adsorption and desorption also causes hysteresis due to the nonequilibrium state of the phase transition.

31.3.1.2.4 Structural Collapse

With sorption, the capillary pores of the adsorbent become elastic and swell. Upon desorption, the removal of water causes shrinkage, and a general collapse of the capillary porous structure occurs. Alteration of structure causes the elimination of hysteresis due to the absence of capillary condensation [18]. The collapse of capillaries during desorption also affects sorption hysteresis.

31.3.2 Water Activity Shift in the Isotherm

Typical water activity shifts by temperature at constant moisture content are shown in Figure 31.4. The water activity shift by temperature is mainly due to the change in water binding,

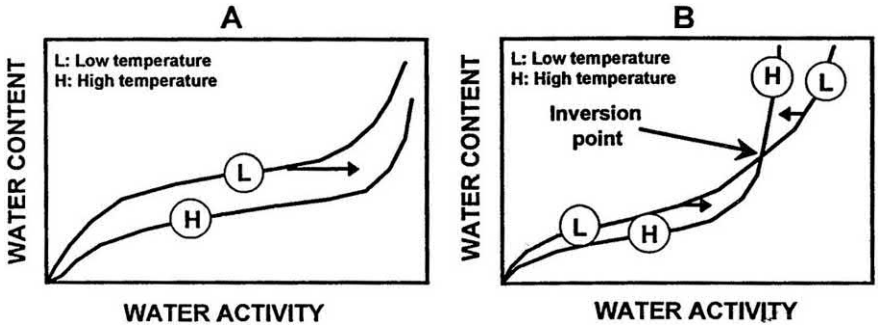

FIGURE 31.4 Water activity shift of food by temperature. (A) Shift without intersection. (B) Shift showing the point of intersection or inversion point.

dissociation of water, physical state of water, or an increase in the solubility of solute in water. The isotherm shift due to temperature can usually be estimated by the well-known Clausius–Clapeyron equation [45]:

$$\ln \frac{(a_w)_2}{(a_w)_1} = \frac{q + \lambda_w}{R}\left[\frac{1}{T_2} - \frac{1}{T_1}\right] \tag{31.2}$$

The slope of a plot of ln a_w versus $1/T$ should give the value of $(q + \lambda_w)/R$, where q is the excess heat of sorption (kJ/kg) and λ_w is the latent heat of vaporization for water (kJ/kg). It is widely accepted that an increase in temperature results in decreased equilibrium moisture content (Figure 31.4A). Tsami et al. [26] found similar results for the dried fruits up to a water activity of about 0.55–0.70. In that region the curves for several temperatures intersect. At water activity values higher than 0.7 there was an inversion of the effect of temperature (i.e., equilibrium moisture content increased with temperature) due to an increase in solubility of sugars in water. The intersection (or inversion) point depends on the composition of the food and the solubility of sugars [22]. For sultana raisin and currant, the inversion point was about 0.55, likewise, 0.65 for fig, 0.70 for prune, 0.75 for apricot (possessing the lowest sugar content of fruit) [26], 0.55 for quince jam (Ferbar brand), and 0.65 for quince jam (Tapada Nova brand) [46]. A similar intersection was also found for sultana raisin [47] and sugar alcohol [48]. Apple (a low-sugar fruit) does not show intersection [49]. For products with protein or starch content, there is also no intersection point with the increase of temperature [31].

31.3.3 Water Activity Break

In a pure component isotherm, the change of solute from the amorphous state to a crystal affects the isotherm. A break is observed in the isotherm, as shown in Figure 31.5. In some foods, one part of the solute (salts and sugar) is bound to a polymer (protein and starch), and the other part is crystalline or amorphous. Bound and free forms of solutes are in equilibrium, which is strongly dependent on the actual water activity. If the change in water activity takes place slowly, this equilibrium may be maintained, whereas during rapid changes nonequilibrium conditions are likely to be attained. Bound, crystalline, and amorphous solutes produce characteristic changes (i.e., break and shift) in the water sorption isotherm [50]. A typical curve showing a break is shown in Figure 31.4B, where a break is also observed due to the transformation of the solute from an amorphous to a crystalline state. This break was observed for sodium chloride–starch mixtures [51]; sucrose–starch mixtures [52]; sucrose albumin, and gluten mixtures [53]; and sucrose–casein mixtures [54].

31.3.4 Concept of the Local Isotherm and Different Types of Bound Water

Rockland [55] proposed the concept of the local (i.e., segment) isotherm to characterize the physical state or special type of water binding in foods. The local isotherm can be identified by graphical analysis of experimental sorption data according to Henderson's equation. The three localized isotherms may be distinguished by plotting experimental sorption data as ln[–ln(1 – a_w)] versus ln M_w. Three straight lines rather than a single straight line are observed, each being identified as a local isotherm. The three regions are identified as three types of water. Iglesias and Chirife [28] analyzed 235 isotherms based on this concept and concluded that although in a broad sense the local isotherms proposed by Rockland [55] may be related to the different modes of water binding, they cannot be used to give a precise and unequivocal definition of the physical state of water in foods. Moreover, the original Henderson equation should give only one curve and

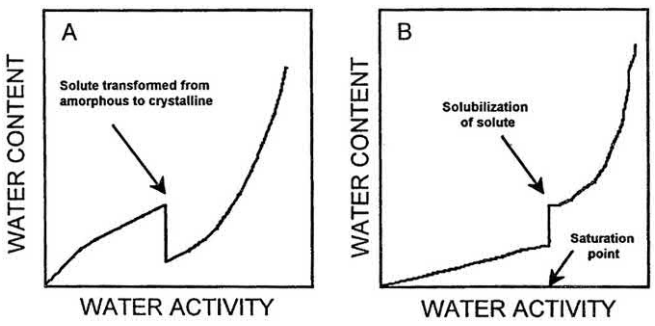

FIGURE 31.5 Water activity shift of food by physicochemical parameters. (A) Shift with solute transformation from amorphous to crystalline. (B) Shift with solubilization of solute.

segmented curves could present a poor fit. Caurie [56] used isotherm data fitted to the Caurie [57] model and determined three types of bound water along a decreasing energy gradient. They defined type I as nonfreezing strongly bound nonsolvent, type II as nonfreezing weakly bound solvent, and type III limited freezing loosely bound solvent. They argued their estimation was more justified over Rockland [55] since the proposed three types of bound water were estimated from only one linear fit of the data rather than segmentation of the isotherm.

31.3.5 Thermodynamic Properties Prediction

Thermodynamic properties such as the freezing point, boiling point, and heat of sorption can also be predicted from water activity. For example, the freezing point (Equation 31.3) and boiling point (Equation 31.4) can be estimated as follows [58]:

$$\ln a_w = 9.6934\times10^{-3}\Delta + 4.761\times10^{-6}\Delta^2 \qquad (31.3)$$

$$\ln a_w = 1.1195\times10^{-4}\Delta - 3.5127\times10^{-2}\Delta^2 \qquad (31.4)$$

where Δ is the freezing point depression or boiling point depression. The preceding equations could be very useful when measurement of the freezing point is very fast and easy. However, the freezing point is not easy to measure for low water content, especially unfreezable water.

31.3.6 Porous Structure Investigation

Water sorption can be influenced by the surface area and porosity of the food material. The characteristics of a material (e.g., porous or nonporous) can be determined from sorption isotherms. It is proposed in the literature that water activity could be used to calculate the food surface area as well as the pore size. However, Nagai and Yano [59] found the surface area and pore size calculated from the water sorption to be misleading. They suggested that water adsorption occurs not only on the surface, but mainly on the water-binding sites inside the structure, and these do not increase with an increase in surface area.

31.4 FACTORS AFFECTING WATER ACTIVITY

31.4.1 Food Components

Protein and starches adsorb much more water at low water activity than do fatty materials or crystalline substances like sugar. Pretreatment, such as heating, has little effect on proteins. On the other hand, such pretreatment increases the amount of water-impenetrable crystalline starch at the expense of amorphous starch. The smaller active site for adsorption means that less water could be adsorped [21]. Sugars and salts present a difficult problem because the change from an amorphous to a crystalline state occurs fairly rapidly at a normal temperature [60]. This change releases water, which may be picked up by other components if the sugar is present in a mixture such as dried milk. The material could become sticky and lumpy, making it undesirable. Salwin [61] observed that the equilibrium condition obtained is not an equal moisture content in all components of a multicomponent mixture but an equal activity.

31.4.2 Physicochemical State of Food Components

Many food components are in several states: crystalline solids, amorphous solids whether rubbery or glassy solids, aqueous solution, or bound to other components. Sorption in such systems is complex. Crystalline sugars adsorb very little water, but amorphous sugars adsorb substantially more water at the same conditions. The adsorption of water results in the breaking of some hydrogen bonds and an increase in the mobility of sugars molecules, resulting eventually in the sugars transforming to the crystalline state. In this process, sugar loses water [62]. However, the sugar–polymer interaction and physical state play an important role in separating out water from the system. Gelatinization followed by freeze-drying results in only minor differences in water-binding behavior up to water activity 0.94; above 0.95 the gelatinized samples adsorb considerably more water [63]. Saltmarch and Labuza [64] studied the effects of water activity and temperature on the transition of lactose from the amorphous to the crystalline state. Results from scanning electron microscopy indicated that lactose crystallized at 0.40, 0.33, and 0.33 water activity after one week at 25°C, 35°C, and 45°C, respectively. Water activity also influences protein conformation. The annealing effect of water, time, and temperature can alter the structural and functional properties of cereal starch (Figures 31.6 and 31.7). When crystalline starch is transformed into an amorphous form, polar sites are developed in the starch molecule, which could form hydrogen bonds with water molecules [65].

31.4.3 Porous Structure of Foods

Structure or pore size and distribution of materials may also affect the water activity, especially sharply increasing in the region in the isotherm at higher water activity. In this region, pores are expanded and water could adsorb in the capillary region.

31.4.4 Temperature

Above freezing temperature, the isotherm shift due to temperature can be estimated by the Clausius–Clapeyron equation as discussed earlier.

Information in the literature on water activity of the frozen state below freezing is limited [18]. The vapor pressures of animal tissues over the temperature span of –26°C to –1°C ranged from 13% to 20% lower than those of pure ice at the same temperature [66, 67]. Other researchers demonstrated that the vapor pressures of frozen biological materials were equal to the vapor pressure of ice at the same temperatures [68–71]. Water activity values at subfreezing temperatures can be calculated (rather than measured) as [18]

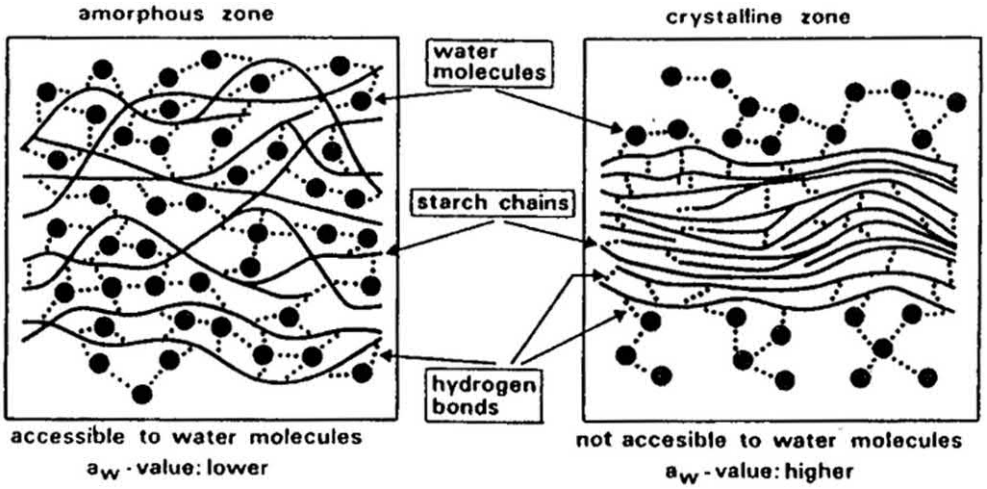

FIGURE 31.6 Schematic model of starch structure during amorphous and crystalline state. (From Munzing [65].)

$$a_w = \frac{\text{Vapor pressure of solid water (ice)}}{\text{Vapor pressure of liquid supercooled water (not ice)}} \tag{31.5}$$

The equation indicates that water activity does not depend on the composition, but only on the temperature. In a two-phase system (ice and solution) at equilibrium, the vapor pressure of solid water as ice crystals and the interstitial concentrated solution are identical, thus water activity depends only on the temperature, and not on the nature and initial concentration of solutes, present in the third or fourth phase (i.e., irrespective of the kind of food). This creates a basis to estimate the water activity of foods below freezing using Equation 31.5. Thus, Fennema [69] concluded that changes in properties can occur below freezing without any change in water activity. These include changes in diffusion properties, the addition of additives or preservatives, and disruption of cellular systems. The water activity data of ice from 0°C to –50°C is correlated with an exponential function as

$$a_w = 8.727\left[\exp\left(-\frac{595.1}{T}\right)\right] \tag{31.6}$$

where T is the temperature (K). The maximum error in prediction is 0.012 unit water activity and the average is 0.0066. The data of Fennema [72] are used to develop the preceding correlation.

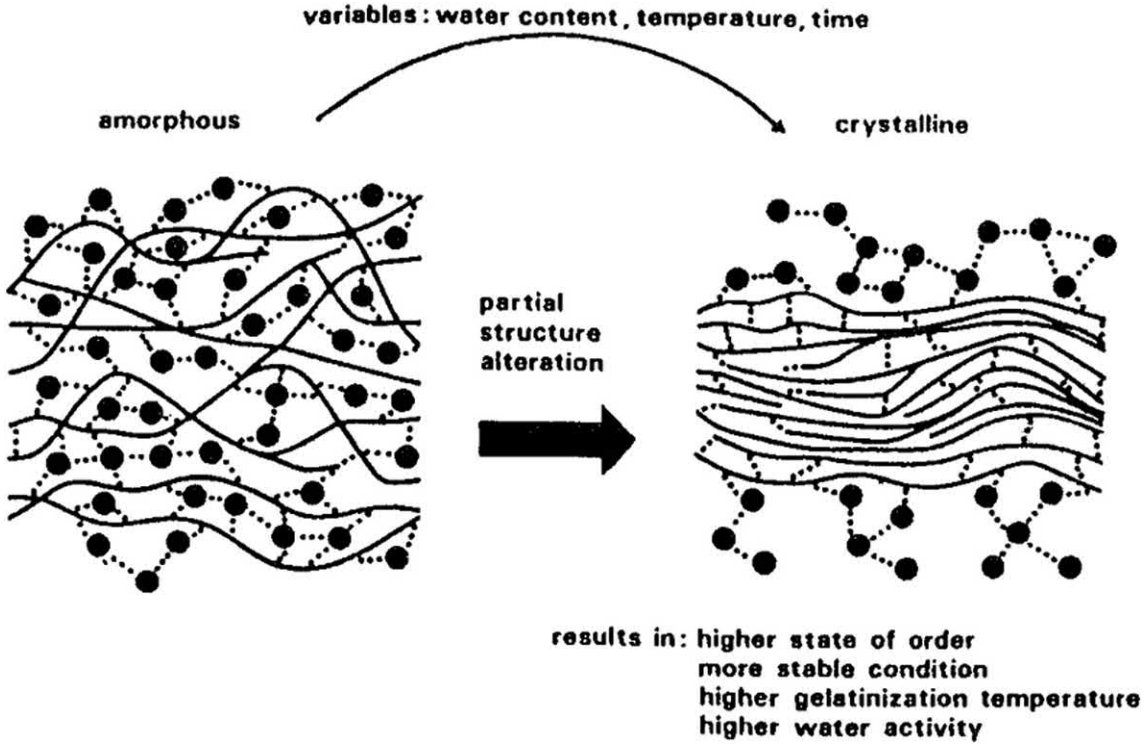

FIGURE 31.7 Annealing effects of starch induced by water, temperature, and time. (From Munzing [65].)

31.4.5 Pressure

The effect of pressure on the sorption isotherm is relatively small and negligible at reasonable pressure levels [14]. At constant moisture content, the variation of water activity with pressure can be derived thermodynamically as [14]

$$\ln\frac{a_2}{a_1} = \frac{\lambda_w}{\rho_w RT}[P_2 - P_1] \tag{31.7}$$

where a_1 and a_2 are the water activity at P_1 and P_2, R is the gas constant (82.05×10^{-3} m^3 atm/kg mole K or 8.314×10^3 m^3 Pa/kg mole K), T is the temperature (K), and P_1 and P_2 are total pressure (atm or Pa).

31.4.6 Surface Tension

The effect of capillary action on water activity can be estimated from the Kelvin equation as

$$a_w = \exp\left(-\frac{\Delta P V_m}{RT}\right) \tag{31.8}$$

For the spherical interface:

$$\Delta P = \gamma_s\left[\frac{1}{r_1} + \frac{1}{r_2}\right]\cos\theta \tag{31.9}$$

where ΔP is the pointing pressure (Pa), V_m is the liquid molar volume (18 m^3/kg mole), R is the gas constant (8.314 N m/kg mole K), T is the temperature (K), γ_s is the surface tension (N/m), cosθ is the contact angle, and r is the radius of curvature (m). If the droplet is spherical, then $r_1 = r_2$ and the preceding equation can be written as

$$a_w = \exp\left[-\frac{2\gamma\cos\theta V_m}{rRT}\right] \tag{31.10}$$

If the surface tension is reduced by a factor of 0.5, the ratio of water activities at the two conditions can be calculated using the preceding equation. The ratio is 0.995 at 20°C, thus the effect of surface tension cannot be measured. Chen and Karmas [73] reported that in the case of intermediate food solutions, water activity increased very little as the surface tension decreased. They suggested that ingredients that result in a reduction of surface tension should be avoided in order to attain low water activity. Alzamora et al. [74] found that surface tension did not appear to have any significant effect on water activity, at least within the range of apparatus error from 0.004 to 0.005 water activity unit.

31.5 WATER ACTIVITY PREDICTION MODELS

31.5.1 Raoult's Law

Ideally, water activity of pure water is 1 and solute depresses the water activity lower than 1. The water activity of an ideal solution could be predicted by Raoult's law, which indicates that water activity is equal to the mole fraction of water in a solution. It can be written as

$$a_w = m_w = \frac{X_w}{X_w + E X_s} \tag{31.11}$$

where a_w is the water activity, m_w is the mole fraction of water, X_w and X_s are the mass fractions of water and solute (g/g sample), and E is the molecular weight ratio (λ_w/λ_s) of water and solute. Raoult's law is not valid for macromolecular solute due to the very low value of E since it predicts nearly equal to 1 for all solute concentrations due to the high molecular weight of the macromolecules. Smith [75] mentioned that Raoult's law can be applied only to dilute solutions having water activity over 0.95. The nonideal behaviors are due to the molecular size and intermolecular force differences of solute and solvent, solvation effects, varied properties of water as affected by many factors, solute–solute and solute–solvent interactions, solute ionization, capillary action, and order of mixing in the cases of multiple solutes [7].

31.5.2 Activity Coefficient Model

In order to include the nonideality effect, Raoult's law is modified by introducing the water activity coefficient as

$$a_w = f_w m_w \tag{31.12}$$

where f_w is the water activity coefficient. The activity coefficient reflects the nonideal behavior of a molecule in solution and it is equal to 1 for dilute solution, when m_w tends to 0. It could be linked with different components as affected by differences in molecular sizes of water and solutes, and interaction among the functional group [76]. The activity coefficient values of food solutions are not readily available or predicted.

31.5.3 Flory–Huggins Model

The Flory–Huggins model, based on a statistical approach arising from entropy, is expressed for the nonideality due to the size differences between solute and solvent as [77, 78]

$$\ln a_w = \left[\frac{(\phi - 1)X_S}{X_w + \phi X_s}\right] + \ln\left[\frac{X_w}{X_w + \phi X_s}\right] \tag{31.13}$$

where ϕ is the ratio of the molar volumes of the solute and the solvent.

31.5.4 Schwartzberg Model

There are many models developed based on Raoult's law. Considering the effects of the nonsolvent water term in Raoult's law, Schwartzberg [79] developed the following model:

$$a_w = \frac{X_w - NX_s}{X_w - NX_s + EX_s} \tag{31.14}$$

where N is the nonsolvent water (g/g dry solids), and E is the molecular ratio of solutes and solvent. Solute interactions can enhance or decrease the effective amount of water acting as solvent, and it fits better to the nonelectrolyte solutions in some cases. However, considering a constant value of N over the entire concentration range is not reasonable, since interactions could vary with concentration [7]. A similar model is proposed by Chen [80] considering another additional parameter with E.

31.5.5 Norrish Model

Norrish [81] derived a model from thermodynamics for the prediction of water activity of nonelectrolyte solution as

$$a_w = m_w\left[\exp\left(\sum_i^n -\alpha_i m_{s,i}^2\right)\right] \tag{31.15}$$

where $m_{s,i}$ is the mole fraction of solute i, α_i is the Norrish model parameter for solute i, and n is the total number of solutes. For only one solute, the preceding equation can be written as

$$a_w = m_w\left[\exp\left(-\alpha m_s^2\right)\right] \tag{31.16}$$

The Norrish model is the most widely used model due to the availability of α values for a wide range of solutes. The values of α can be estimated from the slope of the plot ln (a_w/m_w) versus m_s^2 and this model considers constant slope within the whole range of concentration and the line should pass through the origin [82]. In many cases, the change in slope with concentration and deviation from the origin are observed, and two slopes and two intercepts are estimated diving one segment into two segments [82]. The values of α for different solutes are compiled in Tables 31.2 and 31.3.

The molecular weight of solute is needed to calculate the mole fractions. Therefore, the preceding equation could be extended into a two-parameter model for a multicomponent mixture or food when the effective molecular weight is not known [83]:

$$a_w = \frac{X_w}{X_w + E X_s}\left[\exp\left(-\alpha\left(1-\frac{X_w}{X_w + E X_s}\right)^2\right)\right] \tag{31.17}$$

where E is the molecular weight ratios of water and solute. Water activity data and mass fractions data could be used to estimate both parameters, α and E. Baeza et al. [84] tested Norrish model for correlating the water activity of highly concentrated solutions of sugars, polyols, and polyethylene glycols up to water activity 0.30. The variations of α for the same solution in Table 31.2 are due to the concentration range used to estimate the parameter. In the cases of polyethylene glycol 400 and 600, the Norrish model deviates significantly when considering high concentration (i.e., up to water activity 0.30). In this case, Baeza et al. [84] proposed the model as

$$a_w = m_w\left[\exp\left(-\alpha m_s^{\delta}\right)\right] \tag{31.18}$$

The exponent 2 in Equation 31.18 is now changed to a new parameter, δ. The values of α for polyethylene glycol 400 and 600 are observed as 1.49 and 1.98, while the values of δ are observed as 0.98 and 0.94, respectively [84].

31.5.6 Ross Model

Ross [85] derived an equation to estimate the water activity of a multicomponent mixture if the water activity of each component is available. It is under the assumption that

solute–solute interactions cancel on average and the equation could be written as

$$a_w = a_1 a_2 a_3 \ldots\ldots\ldots\ldots a_n \tag{31.19}$$

where a_1, a_2, and a_3 are the water activities of the individual components based on the total water in the system. Lilley [86] attempted to point out the apparent weakness of Caurie's equation and proposed his development by pointing out a series of factors: size differences between solute(s) and solvent, solvent binding, solute interactions, solvation, and volume differences. The equation is proposed considering the heterotactic term from the binary solutions [87]:

$$a_w = \frac{a_{12}\, a_{23}\, a_{13}}{a_1\, a_2\, a_3} \tag{31.20}$$

31.5.7 Caurie Model

The interaction terms are included in the Ross model. Caurie [88] derived an equation from the Gibbs-Duhem equation to predict the water activity of solution with mixed solutes:

$$a_w = a_1 a_2 a_3 - \left[\frac{n\left(\omega_1\omega_2 + \omega_1\omega_3 + \omega_2\omega_3\right)}{55.5^2} + \frac{(n+1)\omega_1\omega_2\omega_3}{55.5^2} \right] \tag{31.21}$$

where ω is the molality of solute, and n is the number of components in the mixture. The second and third terms of Equation 31.21 determine the interactions among solution components. It is the advance of the Ross equation considering the nonideal behavior of the solution.

31.5.8 BET Model

In the case of foods, the moisture sorption isotherms are mainly modeled with the Brunauer–Emme–Teller (BET) [89] and Guggenheim–Andersen–de Boer (GAB) [90–92] models. The BET equation is

$$M_w = \frac{M_b\, B\, a_w}{\left(1-a_w\right)\left[1+\left(B-1\right)a_w\right]} \tag{31.22}$$

where M_b is the BET monolayer water content (g/g dry-solids), M_w is the total water content (g/g dry-solids), a_w is the water activity, and B is a constant related to the net heat of sorption. The data of the moisture sorption isotherm within the water activity of 0.05 and 0.55 are used to fit the theoretical BET model to determine the parameters M_b (i.e., monolayer moisture content) and B [21]. The parameters of BET can be estimated graphically from the straight line by plotting $[a_w/(1–a_w)M_w]$ versus a_w and from the slope $[(B – 1)/M_b\, B]$ and intercept $[1/M_b\, B]$ the parameters can be estimated. The BET monolayer values showed a decreasing trend with the increasing equilibrium temperature. The value of B indicates how strongly bound the water in the solid matrix and can be related to temperature as

$$B = \gamma\left[\exp\left(-\frac{Q_s}{RT}\right)\right] \tag{31.23}$$

where Q_s is the excess heat of sorption (kJ/kg) and γ is the pre-exponent factor. The monolayer value is generally at a water activity of 0.2 to 0.4 [93]. In addition, the BET monolayer calculation is an effective method for estimating the amount of bound water to specific polar sites in dehydrated food systems [94]. The BET monolayer values usually vary from 0.01 to 0.14 (dry basis) in the case of foods and food components. Macromolecules, such as starch, protein, and agar usually have higher BET monolayers, whereas high fat content foods, such as avocado, peanuts, and whole milk, showed lower monolayers. Iglesias and Chirife [28] found that monolayer values decreased significantly with increasing temperature after studying 100 foods and food components. This may be due to the thermodynamics where higher temperatures increase the escaping tendencies of gas molecules.

31.5.9 GAB Model

Anderson [90] modified the BET equation from multilayers for strengthening the physical meaning and the fitting ability; however, Anderson's equation was later derived kinetically by DeBoer [91] and statistically by Guggenheim [92]. This equation was later named the GAB equation, and it is now one of the most popular and widely used for foods [12]. The GAB equation is

$$M_w = \frac{M_g\, C\, K\, a_w}{\left(1-K\,a_w\right)\left[1-K\,a_w+C\,K\,a_w\right]} \tag{31.24}$$

where M_g is the GAB monolayer moisture content (g/g dry-solids), C is a constant related to the monolayer heat of sorption, and K is a factor related to the heat of sorption of the multilayer. The parameters C and K can be correlated as the Arrhenius equation as

$$C = C_o \exp\left(\frac{\Delta H_c}{RT}\right) \tag{31.25}$$

$$K = K_o \exp\left(\frac{\Delta H_k}{RT}\right) \tag{31.26}$$

where T is the temperature (K), R is the universal gas constant (8.314 kJ/mole K), and ΔH_c and ΔH_k are the heat of sorption functions (kJ/mole). The GAB isotherm equation is an extension of the BET model considering modified properties of sorbate in the multilayer region and bulk water using the third constant K. It is valid up to water activity 0.9, while BET is valid up to water activity 0.55. The parameters of the GAB model are usually estimated by nonlinearizing regression and linear multiple regression after parabolic transformation of the nonlinear Equation 31.24.

31.5.10 Regression Parameters of BET and GAB

The BET and GAB parameters of foods are compiled in the literature for different types of foods [7]. Rahman and Al-Belushi [12] provided a comprehensive discussion on the physical meaning of the BET and GAB parameters. It is important to understand the regression methods and the physical meaning of the parameters before their uses in different applications. The convergence strongly depends on the initial values used in nonlinear regression. Two important points need to be considered while selecting the isotherm models. First is the accuracy of prediction, and the other is the physical meaning of the model's parameters. The accuracy indicates the mathematical representation of the experimental data, but physical meaning indicates the valid explanation of the physicochemical process (i.e., if parameter could be experimentally determined and compared) [12].

The BET monolayer is commonly used as an effective method for estimating the amount of bound water. However, the physical meaning of heat of sorption (i.e., derived from B) may not be considered a very acceptable physical meaning. This is due to many reasons. One is the limited validity of the relationship of B with the heat of sorption due to the number of assumptions used in the BET equation [28]. In many instances, the heat of binding of water from temperature dependency was completely wrong [28], and it was difficult to explain the negative values B in many instances [12, 95–98]. Another reason is the explanation of the physical meaning of very high estimated values (i.e., in the order of 10^6 to infinity). For example, Young [99] found the infinity value for B in the case of peanuts. In the case of hazelnut, the value of B was found in the order of 10^6 at 3°C, whereas at 10 and 30°C the values were in the order of 100 and 10 [100]. However, the lack of reliability of the energy parameter B does not preclude the use of the BET equation for determination of the monolayer value [28]. It is well documented for its physical meaning and validity for its monolayer value [12].

The GAB model is found accurate up to water activity 0.90 and it is now well accepted that the GAB model is one of the most accurate models for predicting isotherms of foods. The physical meaning of GAB may not be valid in all cases, although it is emphasized in the literature [12]. The main reasons are discussed as follows. In many instances, completely unreliable monolayer values are observed even when it gives the most accurate prediction [101]. Theoretically, the values of K should be less than unity [102]. The GAB model described well sigmoidal isotherms when parameters are kept as $0.24 < K < 1$ and $5.67 \leq C \leq \infty$, and outside these regions the isotherm is no longer sigmoid or the high estimation of monolayer value (i.e., ±16) [103]. In addition, these regions fulfill the requirement of BET. Commonly, different regression methods and optimization techniques could be used to estimate the parameters, and this may result in varied values due to many local optimized regions. In addition, the estimated parameters could be varied based on initial values used in nonlinear regression. In many instances, it is very difficult to obtain convergence for the C value and estimated negative values of C [12]. However, these are the generic problems when the theoretical model is extended to fit the experimental data and attempted to be related to the physicochemical process [104]. It is important to point out that the BET monolayer has more physical meaning and acceptability to be used for food stability compared to the GAB monolayer, although GAB provided better mathematical prediction of isotherm over the wide range of water activity as discussed by Rahman and Al-Belushi [12].

31.5.11 Grover Model

Grover [105] used actual measured data for the water activity of confectionery solids to develop a polynomial expression:

$$a_w = 1.04 - 0.10\mu + 0.0045\mu^2 \tag{31.26}$$

$$\mu = \sum_i^n \frac{\beta_i}{W_i} \tag{31.27}$$

where W_i is the moisture content based on component i mass (kg water/kg solute), and β_i is the constant for the ith component. The values of β_i are given in Table 31.4.

31.5.12 Composition-Based Models

Gabriel [106] developed the water activity of glucose syrup as a function of pH and degrees Brix using a second-order polynomial equation. Moreira et al. [107] proposed an algorithm of prediction of the water sorption isotherm considering soluble components (i.e., glucose, fructose, sucrose, and salt) and insoluble components (i.e., protein, fiber, and starch) of food and temperature (20–40°C). There are many models available in the literature, which may explain the physicochemical processes; however, at the end, the parameters are not available for a wide variety of foods.

31.6 CONCLUSION

Water activity is defined from fundamental thermodynamics and used to determine food stability during processing and storage. It indicates the state of water foods, which indicate the reactivity of water in physical changes, chemical reactions and availability to the microorganisms. The fundamental aspects of the isotherm (i.e., hysteresis, water activity shift and break, local isotherm concept, and relationships with other colligative properties), factors affecting water activity (i.e., food components, states or phases, structure, temperature, pressure, and surface tension), and their prediction models are explained in this chapter.

32 Water Activity and Food Preservation

Mohammad Shafiur Rahman and Theodore P. Labuza

CONTENTS

32.1 INTRODUCTION

The water activity concept has been widely used in food processing and preservation, as Scott [1] emphasized that active water is much more important to the stability (i.e., reactivity) of food than the total amount of water present. It is possible to develop generic rules or limits for food stability based on water activity, and microbial growth, chemical reactions, and physical changes can be correlated with water activity. This chapter discusses the effects of water activity on microbial growth, fat oxidation, nonenzymatic and enzymatic browning, vitamin losses, and texture.

32.2 MONOLAYER CONCEPT

The moisture sorption isotherm could predict that water bonds strongly (i.e., Brunauer–Emmett–Teller (BET)-monolayer) to the polar sites of a food matrix (Figure 32.1). It is considered that physical and chemical changes are minimum at its BET monolayer, thus foods are most stable at this moisture content. Water at this point or below is considered strongly bound and microorganisms are unable to use it; and, in general, reactants are also unable to use it for any reaction to be progressed.

32.3 FOOD STABILITY DIAGRAM

The moisture sorption isotherm is an extremely valuable tool for food scientists because of its usefulness in predicting food stability. Most foods have a critical moisture content below which the rate of quality loss is negligible. Quality is understood to include growth and toxin production by microorganisms as well as chemical deterioration and decrease of sensory intensity, such as crispness, hardness, caking, texture, color, flavor, and aroma [2]. A general food stability map is presented in Figure 32.2 [3, 4]. As discussed by Labuza [2], the rate of quality loss begins to increase above water activity 0.2–0.3 for most chemical reactions (Figure 32.2). At this water activity,

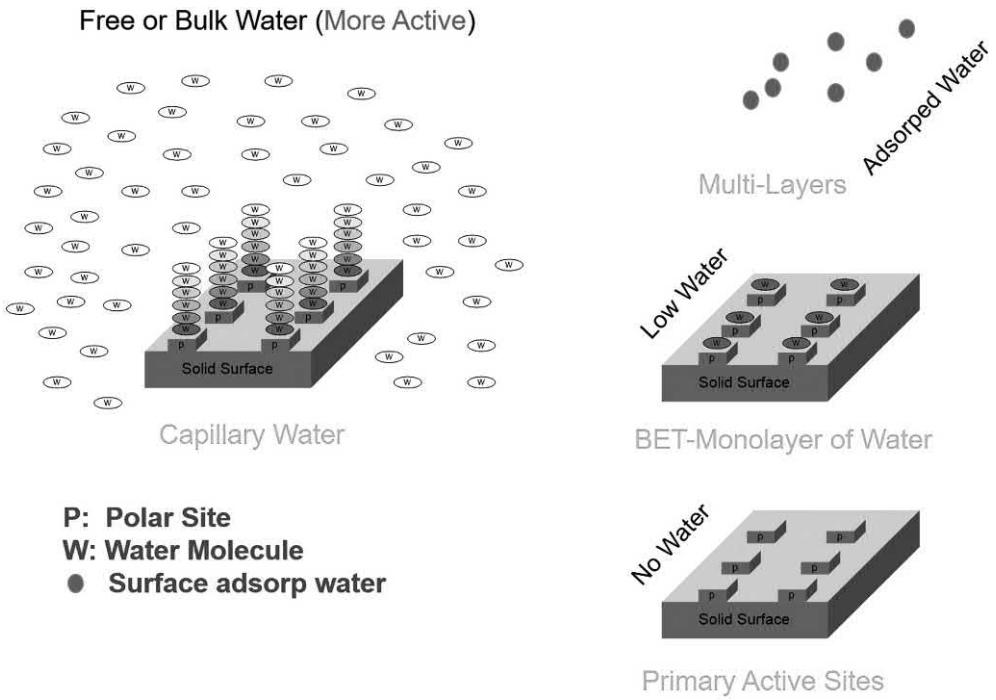

FIGURE 32.1 Different types of water on a surface (i.e., polar sites, monolayer, multiplayer, bulk or free water, and surface adsorbed water). (Adapted from Rahman [148].)

the amount of water adsorbed on surfaces and in capillaries is enough to affect the overall dielectric properties, such that the water can now behave as a solvent. Thus, chemical species can dissolve, become mobile, and are reactive.

The higher the water activity, the faster the reaction rate because of the greater solubility and increased mobility of the reactants. However, at some higher water activity no more species dissolve and therefore an increase in water activity decreases the concentration of the reacting species. Since the rate of a reaction is proportional to concentration on a molecular basis, the rate should reach a maximum and then fall as in Figure 32.2. Between this maximum and the monolayer, a semi-log plot of rate versus water activity generally results in a straight line. For most dry foods, an increase of 0.1 water activity units in this region decreases shelf life two to three times [2].

32.4 MICROBIAL MINIMUM WATER ACTIVITY LIMIT

A microorganism or group of microorganisms can no longer reproduce below a minimum water activity limit. Hypothetical curves showing the effects of water activity on the growth curves are presented in Figure 32.3. The initial portion of this growth curve is composed of a lag phase during which the physiological machinery is being created for later growth. The lag period is increased with an increase in solutes content or a decrease in water activity. The growth or logarithmic phase also affected by water activity is shown in Figure 32.3 [5]. Secondary metabolites produced by some microorganisms are highly toxic and/or carcinogenic to humans. The factors that affect spore formation can influence the formation of these metabolites. Beuchat [6] summarized the effects of water activity on spore formation and germination as well as toxin production by microorganisms commonly associated with foods and food spoilage.

Minimal water activity values for growth and toxin production by microorganisms of public health significance are listed in Tables 32.1–32.8. The concern of food safety increases with increasing water activity. The water activity values of some foods are their susceptibility to spoilage microorganisms are shown in Table 32.8 [6]. There is a critical water activity below which no microorganisms can grow. For most foods, this is in the 0.6–0.7 water activity range. Pathogenic bacteria cannot grow below a water activity of 0.85–0.86, whereas yeast and molds are more

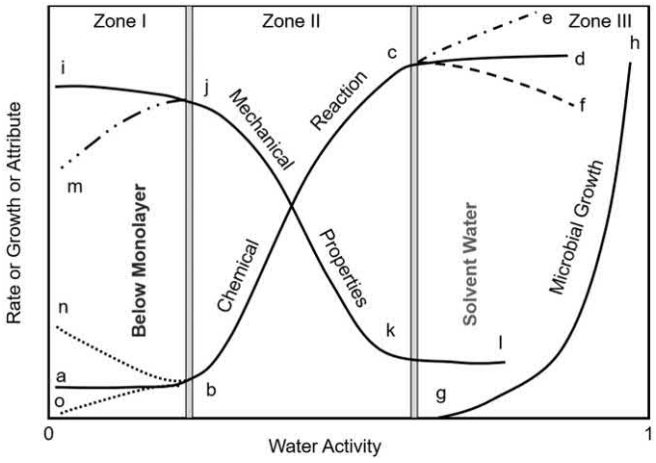

FIGURE 32.2 Food stability as a function of water activity. (From [4, 148].)

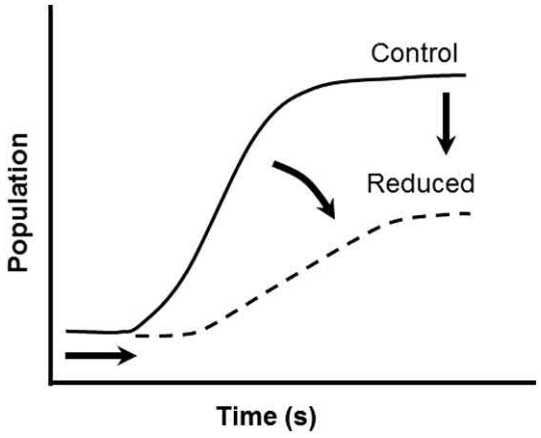

FIGURE 32.3 Hypothetical curves showing the effects of water activity reduction on growth bacteria. (From Troller [5].)

tolerant of a reduced water activity of 0.80, but no growth usually occurs below a water activity of about 0.62 [7]. The critical limits of water activity may also be shifted to higher or lower levels by other factors, such as pH, salt, antimicrobial agents, heat treatment, and temperature of storage. The rate of microbial death during frozen storage can be reduced by a decrease in temperature and no fluctuation in temperature [8]. The microbiological quality of frozen foods could be improved by initial storage of foods at –10°C (a_w = 0.90), to reduce the number of undesirable organisms followed by freezing at very low temperature (i.e., –30°C) [9]. In the case of selected penicillia, spores produced on media at 0.99 water activity appeared more heat resistant compared to those produced at 0.88 water activity [10]. All treated spores were more sensitive to benzoate and sorbate but more resistant to cycloheximide. McClure [11] provided review on the effect of water activity to the growth of microorganisms.

The growth and aflatoxin B_1 production in 20 isolated *Aspergillus flavus* were studied as a function of water activity and storage temperature [12]. The critical water activity (a_c) was determined by probability model considering 39 days of storage and it was observed that a_c varied with storage temperature. For examples, the critical water activity limit was 0.85 at 25–30°C, white it was increased to 0.94 at 15°C and 0.93 at 40°C. Garcia-Cela et al. [13] studied the secondary metabolites in stored natural wheat and inoculated with *Fusarium graminearum* as a function of water activity (0.95–0.90) and temperature (10–25°C). They observed that both temperature and water activity affected the numbers and types of metabolites. Kapetanakou et al. [14] observed the growth rate and ochratoxin A production by *Aspergillus carbonarius* as a function of water activity (0.90–0.99), temperature (15–25°C) and structure formed by gelatin (0–20%, w/v). They observed all three factors affected growth rate nonlinearly and they modeled a quadratic form equation.

32.5 WATER STRESS (DESICCATION) AND ADAPTATION MECHANISMS

Microorganisms are adapted in a wide range of environments, and their genetic and physiological adaptability enables them to withstand harsh environmental factor(s), single or in combination [15]. The ability to adapt and persist depends on the sensing and responding to physicochemical and other environmental changes. It requires profound physiological changes in the sessile (i.e., multicellular aggregates adhering to biotic or abiotic surfaces and/or to each other), planktonic (i.e., free suspension in liquid medium), and biofilm (i.e., microcolonies of bacteria associated with an inert surface attached by a matrix of complex polysaccharide-like material and enclosed nutrients with trapped microorganisms). A biofilm is a unique environment that microorganisms generate for themselves, and cells apply their regulations of gene expression in response to various signals [16]. *Listeria monocytogenes* in a biofilm survived up to 49 days against a desiccated environment (43% RH and 15°C) [17].

Recently, Esbelin et al. [18] reviewed the adaptation mechanisms of bacteria during desiccated bacteria. The degree of adaptation varied with the type of bacteria. For examples, *Deinococcus radiodurans* [19] and *Mycobacterium* [20] are extremely resistant to prolonged desiccation, whereas

TABLE 32.1
Minimal a_w for Growth and Toxin Production by Bacteria of Public Health Concern

	Minimal Water Activity		
Bacteria	**Growth**	**Toxin Production**	**Toxin**
Bacillus cereus	0.93–0.95	—	—
Clostridium botulinum	0.93–0.95	0.94-0.95	Type A
	0.93–0.94	0.94	Type B

[a] In laboratory media, water activity adjusted with salts (NaCl and KCl) or sugars (sucrose and glucose).

Neisseria gonorrhoeae [21] can survive only a short period of desiccation. called Xerophiles are microorganisms that can grow and multiply in an environment of extremely low water activity, even lower than 0.80 [22]. Worldwide, between the years 2007 and 2012, 7315 cases of bacterial infection and 63 deaths due to consumption of contaminated low water activity foods were reported [23].

32.5.1 Heat Resistance in Desiccation

Thermal resistance of microorganisms increases with the decrease of water activity and *D*-value is commonly used to explain the thermal resistance [24–26]. For example, it was observed that *D*-values of *Salmonella enteritidis* PT 30 increased from 0.96 to 6.97 min as water activity values decreased from 0.946 to 0.720 [27]. A more detailed review is given by Zhang et al. [28]. Pathogens exhibit resistance at decreasing water activity and fat protected against inactivation [29]. Considering *Salmonella*, other factors include types of solutes in the matrix, acidity, growth medium, stage of cell growth, stress prior to heating, species, and strain [30].

Zhang et al. [28] identified that nonisothermal heating (i.e., heating rate) also affects the heat resistance in addition to isothermal heating temperature. Considering three strains of *Staphylococcus aureus* ATCC 25923 in walnut shell powder (moisture: 18.0 g/100 g sample), they showed that these became more thermo-tolerant at lower heating rate. The *D*-value decreased with decreasing water activity and heating rates (<1°C/min). A significant increase in heat resistance was observed at heating rates of 0.2 and 0.5°C/min, whereas no effect at 1, 5, and 10°C/min. A rapid reduction was achieved at elevated temperature from 26 to 56 at a heating rate of 0.1°C/min. Thus, appropriate moisture, temperature, and heating rate are required for thermal inactivation.

TABLE 32.5
Minimal a_w for Growth of and Toxin Production by Molds of Public Health Concern

	Minimal Water Activity

Farakos et al. [29] determined that the Weibull model was the most accurate model to predict the survival of *Salmonella* as a function of temperature (21–80°C) and water activity below 0.6. The Weibull model is

$$\log N = \log N_o - \left(\frac{t}{\delta}\right)^{\beta} \tag{32.1}$$

where N and N_o are the population at any time and initial population, respectively; t is time (s); δ-value is the time required for first decimal reduction (minutes), and β-value is a fitting parameter that defines the shape of the curve. D-value is defined as

$$\log N = \log N_o - \frac{t}{D} \tag{32.2}$$

where D is the decimal reduction time (s) (D-value). Farakos et al. [29] developed predicted models for log δ and log βas

$$\log \delta = -0.10T - 4.34a_w + 9.91$$

$$\log \beta = -0.006T$$

The temperature varied from 10°C to 90°C and water activity from 0.1 to 0.7. Figures 32.4 and 32.5 show a high variability in log δvalues and log βvalues, and the influencing factors are temperature, water activity, types of products, and serotype [31].

32.5.2 Influx and Outflow through Membrane

For many years scientists believed these mechanisms relied mainly on the influx and outflow of small, charged inorganic particles, primarily the ions of sodium, potassium, hydrogen, and chloride. Cell physiologists are coming to appreciate that changes in a cell's volume compromise more than just the shape or even the integrity of a cell. Any imbalance in the number of dissolved particles between the interior and exterior of a cell can cause water either to rush in and burst the cell's membrane, or to seep out, causing the cell to shrink. In the case of hypertonic, the cells shrink, whereas in case of hypotonic, cells expand [32].

A decrease in water activity in the environment increases the osmotic stress to microbial cells because the cell always tries to maintain a slightly lower internal osmolality (i.e., water activity). This causes an influx of water into the cell to maintain surface integrity. It is the disruption of this process by solutes that leads to cell damage and death. In addition to osmotic stress, solutes may have other effects on microorganisms, including enzyme inhibition, cytoplasmic coagulation, and damage to the cell wall. Zhu and Dai [33] observed a cross-protection effect of *Escherichia coli* to antibiotic tetracycline and chloramphenicol at a high salt level. This protection originated from the increased AcrAB-TolC efflux pump expression level when high salt was applied. Water activity can explain only the osmotic stress. Genetic control is closely tied to the amino acid pool, especially betaine and praline, and the potassium level in the cell.

32.5.3 Adaptation (K^+ Transport Systems)

A variety of mechanisms may avoid water loss or gain from microorganisms [34]. Such mechanisms are reviewed by Troller [5]. Potassium ion is essential for cell turgor pressure recovery despite its toxicity [35]. Although potassium may or may not be the trigger that initiates the process of osmoregulation, its transport into the cell is the primary modulatory event [36]. Helmer et al. [37], in a series of experiments, demonstrated that at least two and probably four K^+ transport systems exist in *Escherichia coli*. The first is accomplished, in part, by a series of four high-affinity genes. The first three

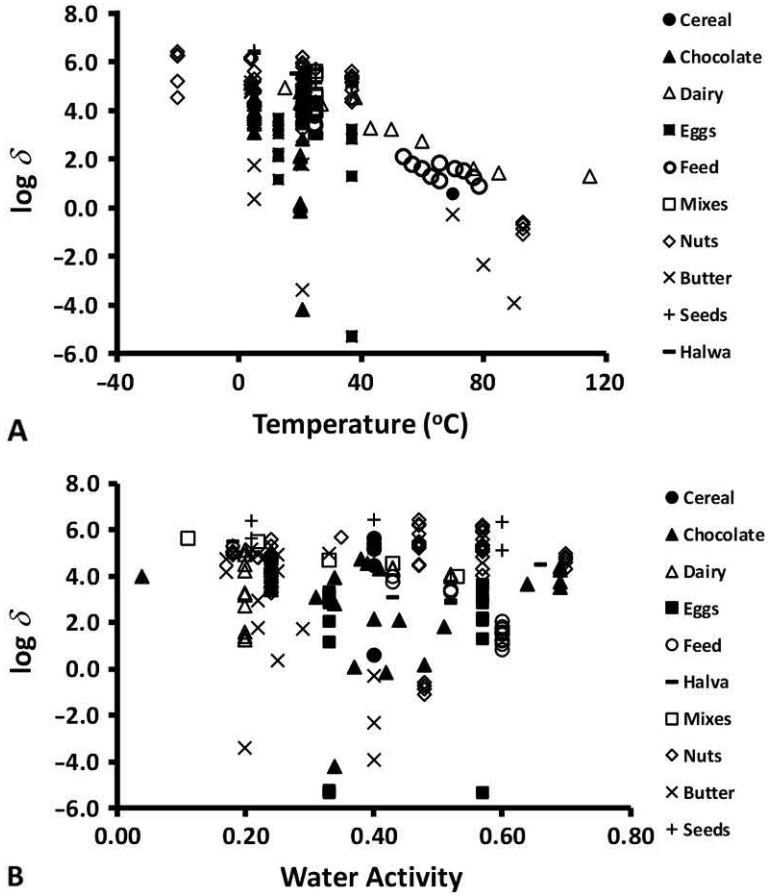

FIGURE 32.4 Log δvalues of *Salmonella* survival in various food products are plotted against (A) temperature and (B) water activity. (From Farakos et al. [31].) (Data for fat-containing products are in bold.)

genes in inner membrane proteins of various molecular weights act as gatekeepers. The fourth gene alters its conformation in a manner that permits and intensifies transcription to maintain cytoplasmic K^+ content [38].

The second system is constitutive and requires ATP and a proton motive force to supply energy for net K+ uptake. Helmer et al. [37] identified a proton motive force as supplying the primary energy to drive this reaction, whereas ATP supplies the energy to turn off K^+ transport. Another system, the K^+ export model, has only been postulated and is of some interest because of the potential existence of export-blocking proteins that might be synthesized by the cell in response

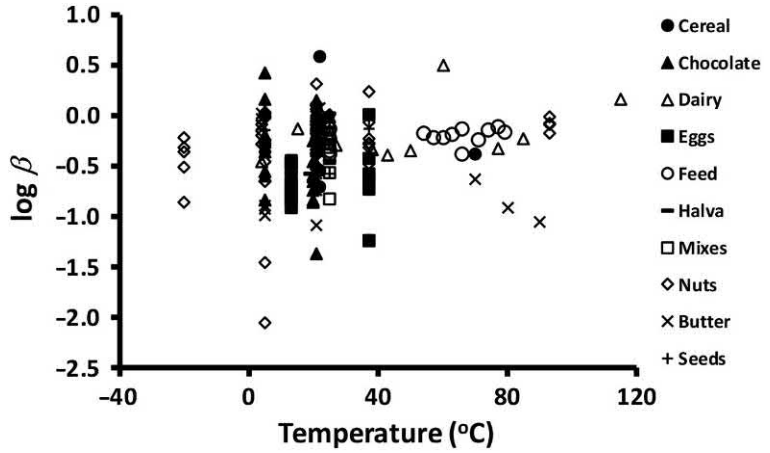

FIGURE 32.5 Log βvalues for survival of *Salmonella* serotypes in various food products plotted against temperature. (From Farakos et al. [31].)

to osmotic challenge. In this case, K^+ would not be pumped out of the cell but would be retained to trigger a metabolic response or to provide primary isoosmotic conditions across the membrane [5]. Bacteria imports K^+ through Kup, Trk, and Kdp transport systems [39].

32.5.4 Adaptation (Compatible Solutes)

The loss of turgor pressure increases the molecular crowding and is called the *water replacement hypothesis* [40]. In this process, the nonreducing disaccharides sucrose and trehalose are considered to preserve protein structures and preserve the membrane function by replacing bacterial membranous water [41]. The development of trehalose and sucrose hydrogen bond with the membrane phospholipids and replaces the water shell around macromolecules. This prevents the membranes to form gels [42, 43] and maintains the fluidity of the membrane [44]. In addition, sugar molecules protect the cells to form vitreous cytoplasmic matrix by chemical balancing the macromolecules when water is lost [45].

Christian [46] and Christian and Waltho [47] observed first that the growth of *Salmonella oranienburg* at low water activity was stimulated by the addition of the amino acid praline. They observed a reversal of plasmolysis when exogeneous proline was supplied to the bacteria growing at low water activity. Although uptake from the media may be one method of accumulating proline in response to water stress, most organisms appear to be able to synthesize proline. In fact, synthesis probably is the most common mechanism for accumulating proline in osmotically inhibited bacteria [48]. This is called *compatible solute*. A number of osmoregulatory solutes protect proteins against denaturation by heat [34]. Measures [49] and Gould and Measures [50] showed K^+ was required to maintain electrical neutrality or to balance the charges within cells exposed to environments with low water activity in which various amino acids, such as αketoglutarate and glutamic acid, accumulate intracellularly. The principal reaction involves the conversion of αketoglutarate to glutamic acid by glutamate dehydrogenase, an enzyme activated by K^+. Glutamic acid reduces the intracellular water activity to reverse plasmolysis by reducing relative amounts of K^+ and glutamate dehydrogenase. This leaves the cell at a balanced, osmotic null point by virtue of the increased glutamic acid pool. For some bacteria, the process stops at this point, but for other organisms, glutamic acid is converted to γaminobutyric acid or proline, neither of which are highly charged. Accumulation of high concentrations of glutamic acid would require concomitant acquisition of K^+ to keep the system at neutrality. This excessive amount of K+ could be detrimental to the organism and, at the very least, costly in terms of energy expenditure. Both γaminobutyric acid and proline are remarkably efficient at reducing intracellular water activity without interfering in the cell's metabolism and for this reason have been termed compatible solutes [51].

Compatible protoplasmic solutes in bacteria include glycylbetaine, proline, glutamic acid, γaminobutyric acid, and glycerol. Polyols of various types are compatible protoplasmic solutes in many fungi (Table 32.8). The uptake or synthesis of sugars, free amino acids, polyols, quaternary amines, sulfate esters, inositol phosphates, or mannosylglyceramides is common [52]. It is also known that the accumulation and production of xeroprotectants (e.g., trehalose) by some microbes and plants enables them to endure in extreme abiotic stresses [18]. Exactly how these solutes are able to avoid interference is not fully understood [5]. Gould [34] suggested that specific binding between solutes and intracellular enzymes is not the mechanism. Jones and Pollard [53] suggested that because these solutes may be excluded from the hydration sphere of proteins, the term benign solutes might more accurately describe the nonparticipatory nature of these materials. These steps (i.e., flashing out water, K+ transport, and compatible solutes) are shown in Figure 32.6.

32.5.5 Adaptation (Changing Cell Metabolism)

An important role of the membrane may be to exclude Na^+, which, if permitted to enter the cell, can quickly inactivate a number of vital enzymatic systems. Kanemasa et al. [54] attributed the barrier properties of *Staphylococcus aureus* membranes to Na^+. They found that Na^+ alters the types and amount of phospholipids within the membrane [5]. How a bacterial spore maintains such low cytoplasmic water content or water activity even when suspended in pure water is not yet understood [34].

32.5.6 Adaptation (Repair of Protein)

Bacterial membrane proteins are responsible for detecting environmental signals, promoting downstream regulatory events, and metabolic functions [18]. Protein could be damaged by aggregation, enzymatic inactivation, and changes in tertiary architecture [55, 56]. This damage can be linked to desiccation resistance and intracellular Mn/Fe concentration ratios [57]. Desiccation stress can enhance rapid synthesis of stress proteins. Heat shock proteins (HSP) have the ability to counterbalance the loss of water by the formation of hydrogen bonds to other molecules [58].

The efficiency of DNA repair and replication systems determines whether a bacterial cell lives or dies [59]. The protection theory against reactive oxygen species indicates that bacteria have robust systems of protecting proteins [57] and cells use DNA to stabilize proteins, thus it could be a molecular shield against desiccation stress [60].

32.5.7 Adaptation (Biofilms Formation)

Microbial biofilms provide better protection against various stresses than planktonic growing cells. These microbes are in strong isolation and embedded in a matrix of polysaccharides, proteins, lipids, and nucleic acid; and they possess the ability to cope in extreme temperature, hypersalinity, periodic desiccation, low temperature, disinfectants, and relative humidity

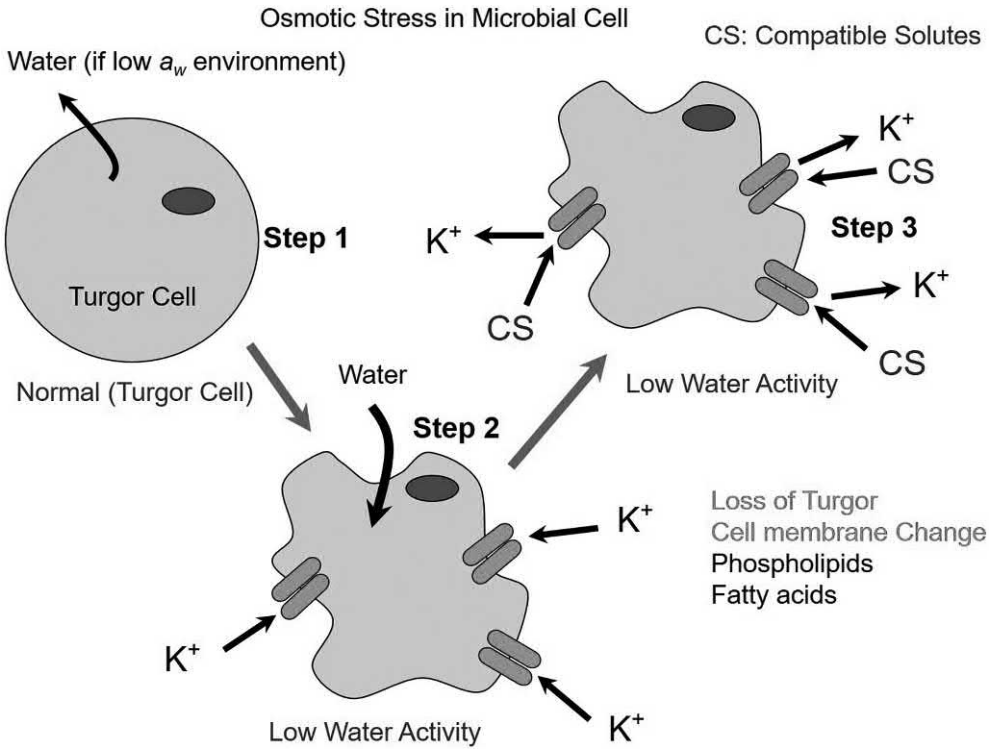

FIGURE 32.6 Microbial response to low water activity. (Adapted from Rahman [148].)

variations. The results affect maturation, physiology, antimicrobial resistance, virulence, and dispersal [61].

The desiccation tolerance is linked to the protective effect of the biofilm matrix due to the following reasons [18]: (i) aggregate formation and modifications in cell envelop composition and fluidity and/or shift in metabolism; (ii) formation of water-rich hydrated gel (about 95% moisture) around bacterial cells [62–64]; (iii) formation of upper (i.e., separation between cells) and lower layers, which are surrounding milieu [17, 65–67]; (iv) nutritional advantages due to concentrated organic molecules and ions close to the cells [68] and energy generation and cell envelop structure [69]; (v) high hydrophilic properties due to the formation of exopolysaccharides and extracellular DND and peptidoglycans [70, 71]; (vi) upregulation of alginate synthesis genes as well as flagella genes [72]; and (vii) formation of outer membrane antigen of lipopolysaccharide and cell surface components, like fimbriae and cellulose [73].

Salmonella can survive for extended periods of time in low-moisture environments. Finn et al. [74] isolated 46 *Salmonella* from low moisture survival phenotypes. Most of the isolates could form biofilms with different characteristics: (i) 57% being positive for curli fimbriae production and (ii) 75% was characterized with positive for cellulose production. These are linked with stronger biofilm formation. Cellulose-producing isolates were better survivors when exposed to a biocide compared with cellulose-negative isolates. Eighteen serotypes showed that glycerol was least inhibitory as compared to salts (i.e., sodium chloride and potassium chloride), and it was related to the biofilm.

32.5.8 Adaptation (Genetic)

The genetic components controlling osmoregulation in microorganisms are being investigated. *Escherichia coli* appears to have evolved a particularly advanced scheme for protection against osmotic stress through a proline-overproduced mutation, which confers osmotolerance. *Klebsiella pneumoniae* experiences an increase in intracellular free proline when it is exposed to high levels of sodium chloride. Thus, an enhanced level of osmoresistance in the organism results in its ability to fix nitrogen while under osmotic stress [5]. Considering *Salmonella*, a total of 266 genes were differentially expressed under desiccation stress as compared with a static broth culture [75]. It was observed that the osmoprotectant transporters *proP*, *proU*, and *osmU* (STM1491 to STM1494) were highly upregulated by drying, and deletion of any one of these transport systems resulted in a reduction in the long-term viability. The *proP* gene was found to be critical for survival; and *proP* deletion mutants could not survive long periods under desiccation (i.e., undetectable after 4 weeks) [76]. A total of 138 genes were differentially expressed, with upregulation observed for genes such as *proP*, *proU*, and the phosphate transport genes (*pstACS*) when rehydrated. Considering *Salmonella*, Chen et al. [77] identified the fatty acid biosynthesis associated genes in low water activity foods. They observed that low water activity increased expression of gene fabA (involved in unsaturated fatty acid biosynthesis), while the increased expression of cfa was associated with cyclopropane fatty acid synthesis. Salmonella ARI-33 always showed its potential in enhancing *Salmonella* survival as compared to other bacteria in low a_w foods.

32.6 FAT OXIDATION

Figure 32.2 shows a quality loss by oxidation can occur below monolayer value (i.e., line bn). If a food is susceptible to oxidation of unsaturated fats, such as occurs in cereal grains, the rate increases as water activity decreases below the monolayer. Oxidation and rancidity are aggravated by drying of foods to very low moisture levels [78]. Attack by oxygen is also responsible for pigment instability and loss of vitamins and sometimes initiates nonenzymatic browning reactions [79]. The attachment of an oxygen molecule to a binding site of a protein would produce an incongruity in the aqueous covering sheath, which could distribute the hydration structure of neighboring sites [80]. Competition with oxygen is not the sole basis for explaining the protective effects of water. The bond energy of the adsorbed water would inhibit interactions between polar groups on adjacent carbohydrate or protein molecules and thereby preserve rehydration ability, reconstitution ability, and texture of foods [78]. Moreover, with respect to fat oxidation, the catalytic effect of metallic compounds is reduced when they form coordination spheres with polar groups [81].

Water is important in lipid oxidation because it acts as a solvent, mobilizes reactants, and interacts chemically or by hydrogen bonding with other species. The basic protective function that water exhibited when the moisture content increased the absolute dry state could be accounted for by two factors: (i) water interacts with metal catalysts, making them less effective through changes in their coordination sphere; and (ii) water hydrogen bonds with hydroperoxides, tying them up so that these were no longer available for decomposition through initiation reactions. When the moisture content is higher than the value at the monolayer, the solvent and mobilization properties of water become more important and the catalysts present are more easily mobilized, and possible swelling of the solid matrix exposes new catalytic sites, making oxidation rates even higher [82, 83]. Thus foods having unsaturated fat should be kept at the critical water activity to maximize shelf life. Ling et al. [84] studied the lipid oxidation (hydrolytic rancidity, i.e., free fatty acid formation; and oxidative rancidity, i.e., peroxide value) in radio-frequency-heated bran as a function of water activity. The hydrolytic rancidity showed a sigmoidal shape similar to line abc in Figure 32.2 (i.e., rate of free fatty acid decreased with the decreasing water activity and reached the lowest value at water activity 0.241). This could be due to the low availability of water at low water activity, thus effectively inhibiting the hydrolysis of lipid [85]. In the case of oxidative rancidity, it showed a similar curve as nbc in Figure 32.2 (i.e., rate decreased with decreasing water activity and reached to the lowest value 0.111 meq/kg day at water activity 0.241 and then rapidly increased to 0.747 meq/kg day with a further decrease in water activity to 0.141). Bell [86] mentioned that the oxidation rate could increase as water activity decreased lower than its water activity corresponding to the monolayer of water. This could be due to direct contact of oxygen molecules and lipids, as a water protective layer does not exist. Similar minimum water activity values are reported as 0.33 for dried foods [87]; 0.23 to 0.43 for oatmeal muesli, peanuts, and pork scratchings [88]; and 0.44 for macadamia nut [89].

The water activity at the BET monolayer can be defined as the *critical water activity*. Autoxidation of lipids occurs rapidly at low water activity levels, decreasing until a water activity range of 0.3–0.5 is reached [90]. At low water content, especially in porous substrates in the complete absence of water, peroxidation of unsaturated lipids proceeds very rapidly. The addition of small quantities of water tends to produce a protective effect if the substrate is still free of oxidation products and reactive intermediates. However, reactions of oxidation products with proteins follow a more complex pattern [91]. In a model system consisting of methyl linoleate and lysozyme, the free radicals and other reactive species formed by the linoleate react with the protein, resulting in increased fluorescence, decreased enzyme activity, and decreased protein solubility. Water activity has an inhibitory effect on the initial oxidation of the lipid, but the secondary reactions of the lipid degradation products with the protein are accelerated by increasing water activity [92]. Schaich [93] studied free radical formation in proteins reacted with peroxide lipids and found that the amount and type of free radicals formed in the proteins were strongly affected by water activity. It appears that water facilitates the recombination of free radicals and as a consequence the steady-state concentration of radicals, whereas various radical-initiated processes such as protein cross-linking increase at high water content. In the case of freeze-dried model systems, certain amino acids including histidine, βamino-butyric acid, lysine, and cysteine showed substantial antioxidant activity [94].

32.7 NONENZYMATIC ACTIVITY

Browning reactions in foods affect the nutritional value as well as color and texture [95]. The induction period, defined as the time to visually detectable browning, is inversely proportional to water activity [96, 97]. Browning reactions are influenced by the types of reactant sugars and amines, pH, temperature, water activity, and the types of solutes or humectants used to adjust the water activity [90].

32.7.1 Types of Browning

There are three major pathways by which nonenzymatic browning can occur: high-temperature caramelization, ascorbic acid oxidation, and the Maillard reaction [95]. The browning reactions of sugars heated above their melting point in the absence of proteins or amino acids are called caramelization. This can be either beneficial or detrimental to the quality of a food product and can be prevented by avoiding high-temperature processing and low storage temperatures. It is enhanced in alkaline or acid conditions and is used to make commercial caramel colorings and flavors.

Ascorbic acid (vitamin C) oxidation, a second type of browning reaction, is catalyzed by low pH and elevated temperatures. The decomposition products resulting from the oxidation of ascorbic acid cause a brown discoloration as well as

decreased nutritional value. The Maillard reaction is a result of reducing compounds, primarily sugars, reacting with proteins or free amine groups. This changes both the chemical and the physiological properties of the protein. In general, the accumulation of brown pigments is the most obvious indication that Maillard browning has occurred in a food containing both carbohydrate and protein. It is used as an indicator of excessive thermal processing in the milk industry [95]. In the early stages of the Maillard reaction, the carbonyl group of the reducing sugar reacts with the free amino group of the amino acid to form a Schiff base and then the N-substituted glycosylamine as well as a molecule of water. Glycosylamines are converted to the 1-amino-1-deoxy-2-ketose by Amadori rearrangement (cyclization and isomerization) [98]. The Maillard reactions forming Amadori compounds do not cause browning but do reduce the nutritive value [99]. The advanced Maillard reaction has five pathways. The first two pathways start from the 1,2-enol or 2,3-enol forms of the Amadori product, yielding various flavor compounds. The third pathway is Strecker degradation, which involves oxidative degradation of amino acids by the dicarbonyls produced in the first two pathways. The fourth pathway involves transamination of the Schiff base. The fifth pathway starts with a second substitution of the amino-doxy-ketose. The final step of the advanced Maillard reaction is the formation of many heterocyclic compounds, such as pyrazines and pyrroles [98]. Brown melanoidin pigments are produced in the final stage of the Maillard reaction. The pigments are formed by polymerization of the reactive compounds produced during the advanced Maillard reaction, such as unsaturated carbonyl compounds and furfural. The polymers have a molecular weight greater than 1000 and are relatively inert [99]. These pathways depend upon environmental conditions such as pH and temperature.

32.7.2 Factors Affecting Browning

The browning reaction rate increases from water activity at the BET monolayer, sharply increases to a maximum, and then decreases (Figure 32.2). Water can retard the rate of the initial glycosylamine reaction of which water is a product. This results in product inhibition by some of the intermediate reactions. A second factor is the dilution of reactive components with increasing water content. The mobility of the reactive species increases due to a decrease in viscosity with increasing water activity. However, the reactive species increase due to a decrease in viscosity with increasing water activity. However, the first two factors eventually overcompensate for the decreased viscosity at higher water activity, and thus the overall rate of browning decreases [95].

Wolf et al. [100] demonstrated that losses of free lysine and methionine were highly dependent on water activity, protein, and sugar. Thermal degradation of both amino acids followed first-order kinetics, and rates decreased at 65°C and 115°C with increasing water activity. A more rapid decrease of lysine, tryptophan, and threonine at higher water activity in model systems is observed when heated at 95°C [101]. The retention of tryptophan was greater than lysine at water activity 0.75, but lysine retention was greater than that of tryptophan at water activity 0.22. At higher water activity, the Maillard reaction predominates and a rapid loss of lysine occurs. At lower water activity, browning proceeds at a slower rate and reactions involving the indole ring of tryptophan become significant [98]. Glucose utilization in a model system consisting of glucose, monosodium glutamate, corn starch, and lipids during nonenzymatic browning was investigated by Kamman and Labuza [102]. The rates of glucose utilization at water activity 0.81 were higher than at 0.41. Lipids accelerated the reaction rates at 0.41 but had virtually no effect at 0.81 water activity. Liquid oil is more effective than shortening in increasing the degradation rate of glucose. These can be explained by the mobility of solutes in both water and oil [98].

Cerrutti et al. [103] studied browning in a model system consisting of lysine, glucose, sodium chloride, and phosphate buffer. They showed that water had little or no effect on the rate of glucose loss at water activity 0.90–0.95, but the rate was highly dependent on temperature and pH. Similar behavior was observed for the accumulation of 5-hydroxymethylfurfural, fluorescent compounds, and brown pigments. Seow and Cheah [104] found that nonenzymatic browning decreased with an increase of water activity and temperature in a water–glycerol–sorbate–glycine model system at pH 4. For dehydrated orange juice (a_w: 0.44) stored at 30°C and 50°C, the total amino acids lost due to nonenzymatic browning were 30% and 65% of initial concentration [105].

32.7.3 Maximum Browning Region

The region where the maximum browning occurs is usually near 0.65–0.80 water activity. In model freeze-dried foods the maximum browning rate is in the range of 0.40–0.67 [106], in whey powders at 0.44 [95], and in dehydrated foods in the range of 0.65–0.75 [107]. Petriella et al. [108] found that water had relatively less effect on the browning rates at water activity of 0.90–0.95. At this range, pH and temperature are the determining factors. At very high water content, i.e., water activity greater than 0.95, moisture strongly inhibits the browning rate by diluting the reactive species [90]. Warmbier et al. [107] studied the influence of solutes on the maximal range of browning. For example, if glycerol is employed to reduce water activity, the range of maximal browning shifts from 0.65–0.75 to 0.40–0.50. They concluded that glycerol can influence the rate of browning at lower water activity values by acting as an aqueous solvent and thereby allowing reactant mobility at much lower moisture values than would be expected for water alone. The overall effect of glycerol or other liquid humectants on the maximum for nonenzymatic browning is to shift it to a lower water activity [95]. Obanu et al. [109], on the other hand, observing browning in glycerol-amino acid mixtures stored at 65°C, concluded that glycerol itself might participate in the browning reaction. Moreover, Troller [90] indicated that product quality relative to browning could be improved by reducing the water activity and, more importantly, the temperature during the final stage of drying. It is somewhat paradoxical that at water activity

levels that minimize browning, autooxidation of lipids is maximized.

32.8 ENZYMATIC ACTIVITY

Enzyme-catalyzed reactions can proceed in foods with relatively low water contents. Karel [91] summarized two features of results mentioned in the literature as follows: (i) the rate of hydrolysis increases with increasing water activity, with the reaction being extremely slow at very low activities; and (ii) at each water activity, a maximum extent of hydrolysis appeared, which also increases with water content. The apparent cessation of the reaction at low moisture cannot be irreversible in activation of the enzyme, because upon humidification to a higher water activity, hydrolysis is resumed at a rate characteristic of the newly obtained water activity [91]. Silver [110] investigated a model system consisting of avicel, sucrose, and invertase, and found that the reaction velocity increased with water activity. Complete conversion of the substrate was observed for water activities greater than or equal to 0.75. Below water activities of 0.75, the reaction continued to 100% hydrolysis. In solid media, water activity can affect reactions in two ways: lack of reactant mobility and alteration of active conformation of substrate and enzymatic protein [111]. Effects of varying the enzyme-to-substrate ratios on reaction velocity and the effect of water activity on the activation energy for the reaction could not be explained by a simple diffusion model, but required more complex postulates [91]: (i) the diffusion resistance is localized in a shell adjacent to the enzymes, and (ii) at low water activities, the reduced hydration produces conformational changes in the enzyme affecting its catalytic activity. Tome et al. [111] tested the simple diffusion-related hypothesis on the basis of experiments in liquid systems in which water activity was reduced by the addition of glycerol, ethylene glycol, propylene glycol, diethylene glycol, sorbitol, methanol, or ethanol. In these solutions the effects of polyphenoloxidase on tyrosine were very similar to those obtained in solids systems.

The optimum pH of activity is shifted slightly toward alkaline values. Three characteristics curves were observed: (i) for low water activity there was an almost total inhibition; (ii) in the intermediate range, the reaction rate was very dependent on water activity; and (iii) for high water activity zones, activity was weakly affected by organic additives. In general, the rate increased rapidly with increasing water activity, and the reaction stopped at a certain level before all reactants were consumed; the higher the water content, the higher was the plateau. The authors were unable to find a correlation of enzyme activity with viscosity, solubility of oxygen and tyrosine, or dielectric constant. It also appeared that the more the mixture deviated from the ideal, the more the enzymatic activity was inhibited, regardless of whether the deviation was positive or negative. Thus, solvent–water interaction is the main parameter in polyphenoloxidase inhibition. The minimum water activities for enzymatic reactions in selected food systems are given in Table 32.8.

32.9 VITAMIN LOSS

The nutrition loss of dehydrated foods depends on the storage temperature, light, oxygen, and water activity. The loss of thiamine due to heating is affected by (i) the state of the thiamin molecule (incorporated into enzyme or protein-bound), (ii) pH (the rate of destruction increases especially in the alkaline region), (iii) metals (free metals act as catalysts to increase the rate of thiamine destruction), and (iv) oxygen (oxygen can accelerate thiamine destruction especially in solutions above 70°C) [112]. The thiamin destruction during heat treatment strongly depended on pH and insignificant influence of water activity within 0.9–1.0 values [113]. Products with a pH value of 3 showed excellent thiamin retention, while those with a pH value approaching 7 showed a strong instability during the thermal process. The destruction of thiamin in the model system was less than 5% at storage temperatures ≤37°C and was independent of water activity at a_w ≤0.65. A significant increase in the thiamin loss occurred in the model system stored at 45°C when the water activity was at or above 0.24. Riboflavin is considered more heat stable than thiamin but highly sensitive to degradation by light. The stability of riboflavin in dry products is considered to be excellent in the absence of light [114]. With only one expectation, the reaction rates of vitamins A, B_1, B_2, and C increased with increasing water activity 0.24–0.65 [98]. B vitamins are more stable than vitamins A and C at various water activity values [98].

Hemery et al. [115] observed that the type of packaging (i.e., paper, PET, and aluminum foil), fortification (i.e., ferrous sulfate), water activity (i.e., 0.65 and 0.85), and storage temperature (25°C and 40°C) affected the vitamin A stability in fortified wheat flour. Considering aluminum foil (i.e., where there was less change in water activity during storage), both storage time and temperature severely affected the stability, whereas it was marginally affected by the addition of ferrous sulfate and water activity. For example, in the case of water activity 0.65 stored at 1.5 months of storage, retentions were 80% and 65% when storage temperature was 25°C and 40°C, respectively. Similarly, in the case of water activity 0.85, the retentions were 85% and 60% when stored at 25°C and 40°C, respectively. After 3 months storage, the retentions were nearly 55% (water activity 0.65) to 50% (water activity 0.85), and 15% (water activity: 0.65 and 0.85) when stored at 25°C and 40°C, respectively. There was little difference between 3 and 6 months of storage. In addition, vitamin A retention was related to the extent of oxidation reactions that occurred in flours during storage.

32.10 TEXTURE

Rockland [116] defined food texture as a function of localized moisture sorption isotherms as follows: (i) region I (low water activity)—dry, hard, crisp, and shrunken; (ii) region II (intermediate water activity)—dry, firm, and flexible); and (iii) region III (high water activity)—moist, juicy, soft, flaccid, swollen, and sticky). Table 32.9 shows textural characteristics of model food products via water activity. The effect

TABLE 32.9
Critical Values for Ingredients in Model Food Products

Moistness	Crispness	Chewiness	Toughness
Cereal		>0.40	<0.50
Fruit	<0.30	>0.50	>0.30
Nuts		>0.65	

Source: Bourne [117].

of water activity on textural measurements for different types of foods was reviewed by Bourne [117]. At this time there are insufficient data to predict what the textural properties of a given type of food will be at a given water activity, and no sound theories exist to predict in advance the textural properties of a food at a given water activity. Cenkowski et al. [118] studied the mechanical behavior of canola kernels by bringing them to equilibrium, adsorption or desorption, at the same final moisture. The ratio of elasticity was 18–38% higher for kernels brought to equilibrium through adsorption than those through desorption for a moisture range of 9.5–7.5% (dry basis). At higher moisture contents, the differences in module of elasticity were not significant. For dry snacks, the loss of crispiness occurred close to the BET monolayer [88]. In the case of potato chips [119] and corn chips [120] the critical water activity when the product was unacceptable was found at 0.40 water activity. The change in sensory crispiness of potato chips, popcorn, puffed corn curls, and saltines generally fell in the 0.35–0.50 water activity range [121]. Instron analysis showed that the force–deformation curve changed distinctly near critical a_w for saltines and puffed corn curls, while the curve changed more gradually with increasing a_w for popcorn.

32.11 ISSUES OF WATER ACTIVITY CONCEPT

The major drawbacks of the water activity concept are the validity of equilibrium conditions, discontinuity or break in the isotherm, effects of different solutes, dilution effects, and it explains only the binding nature of water without giving an explanation of molecular mobility.

32.11.1 Validity of Equilibrium Conditions

Water activity is defined at equilibrium, whereas foods with low and intermediate water content may not be in a state of equilibrium. Instead, they may be in an amorphous multistate, which is very sensitive to changes in moisture content and time. In low-moisture and intermediate-moisture foods, the concept of water activity may be meaningless because the measured vapor pressure of water is no longer the equilibrium vapor pressure as defined in the literature. A stationary state may be reached under a given set of environmental conditions and mistaken for equilibrium. In moisture-sorption studies, the situation is further complicated if the amorphous material undergoes a glass–rubber transition during the course of the measurement.

Chirife and Buera [7] believe that an analysis of various literature data may throw some light on equilibrium aspects. An important comprehensive collaborative study within the framework of the European Corporation in the Field of Scientific and Technical Research (COST) was conducted to determine the precision of data (e.g., repeatability or reproducibility) in the determination of sorption isotherms. In the water activity range of interest to microbial growth (0.6–0.9), the average standard deviation of all data from 24 laboratories was ±2.6% for equilibrium moisture content of microcrystalline cellulose (MCC) and ±3.8% for potato starch. The repeatability was 2% for both MCC and potato starch. Chirife and Buera [7] also reported data on isotherms from different sources of the same material and found good reproducibility within a wide range of water activity. Lomauro et al. [122] concluded from a study of a large number of foods that a pseudoequilibrium was reached when the moisture content (dry basis) did not change by more than ±0.5% during three consecutive sample periods at intervals of no more than 7 days. This criterion for equilibrium moisture content was compared with the values obtained after 6 months of storage in closed mason jars, which were considered to be very close to the equilibrium moisture content.

Lomauro et al. [122] concluded that the foods tested reached (or were very close to) equilibrium within 1 month, based on the above criterion. Various authors reported their equilibrium times for isotherm determinations of different food systems using the gravimetric static method over saturated salt solutions, and their equilibrium times in the gravimetric static method over saturated salt solutions, and it was observed that equilibrium times ranged mostly between 1 and 4 weeks, depending on the temperature and relative humidity. Bizot et al. [123] utilized a practical equilibrium time of about 7 days (±0.02% water per 24 h) for a 1 g sample, but they also stored their starch samples over saturated salt solutions for 2 years. They noted a slow drift in desorption pseudoequilibrium, but there was only a 1% difference in water content (dry basis) over this long time. Thus water activities measured are likely to be close to equilibrium, and the differences should be within the uncertainties associated with the experimental determination of isotherm [7].

32.11.2 Break in the Isotherm

Chirife and Buera [7] reviewed sorption isotherms of fruits containing sugars (which have ability form crystals) that constitute a nonequilibrium system. For example, in raisins the discontinuities in the isotherm are not noticed at water activity 0.30–0.90, suggesting that sugars remained amorphous even at very high temperatures above the glass transition. The sorption isotherms of other fruits reported in the literature did not show discontinuities [7]. Bolin [124] observed little effect on isotherm with raisins sealed in glass jars held at 21°C or 32°C for up to 12 months. This suggested that nonequilibrium effects are very slow, at least in their

experiments. Chirife and Buera [7] also presented data on fruits, but they overlooked the crystallization of sugars in dairy products and formulated products having sugars or salts, as discussed in Chuy and Labuza [125] and Saltmarch and Labuza [126]. A recently developed dynamic sorption apparatus could measure the water activity within a couple of hours of sample size in the range of micrograms. Although the break in the isotherm creates a problem for the measurement, it provides a practical importance as far as detecting any change in structural components when stored on a specific water activity environment.

32.11.3 Effects of Solute Types

The microbial response may differ at a particular water activity when the latter is obtained with different solutes [7, 127]. Thus the proposed basis of water activity limit for growth may not be universal. Corry [128] reported that the survival of vegetative bacteria is influenced by nutrients in the food matrix. These influences show no consistent inhibitory pattern and are greatly affected by the matrix. Mugnier and Jung [129] studied the survival of bacteria and fungi in biopolymer gels with and without nutritive solutes. They observed that survival is increased at the point of mobilization of solute in the case of mannitol. While comparing a gram-positive bacterium and a gram-negative one, they concluded that low molecular weight compounds (C_3–C_5) had a deleterious effect on survival compared to higher molecular weight compounds (C_6–C_{12}), which had a protecting effect.

The glass–rubber state of solutes may also play an important role since higher molecular weight solutes have higher glass transition temperatures than low molecular weight solutes. The degree of protecting effect was in the order of mannitol > dextrin > ribose > glycerol. Above a certain amount of hydration (the mobilization point), there exists a second fraction of solute in the polymer system, which can serve as a true solvent for the microbial nutrient to maintain the organism's metabolic activity [9]. Brown [130] stated that freeze-drying of microorganisms with a nonelectrolyte such as glycerol or sugar reduces mortality during dehydration, storage, and rehydration. This indicates that the nonelectrolyte functions directly as a solvent molecule for nutrients. Gould [34] acknowledged that in some instances solute effects may depend on the ability of the solute to permeate the cell membrane. Glycerol, for example, readily permeates the membrane of many bacteria and so does not initiate the same osmoregulatory response as nonpermeate solutes like sodium chloride and sucrose, therefore there is a different, usually lower, inhibitory water activity. Scott [131] noted that minimal water activity for the growth of microbial organisms was independent of the solutes employed to adjust the water activity of a medium. It was observed later that some solutes were more inhibiting than others, thus water activity of a medium is not the only determining factor regulating microbial response. The nature of the solute used also plays an important role [132, 133]. This is referred to as *specific solute effects* by Chirife [134].

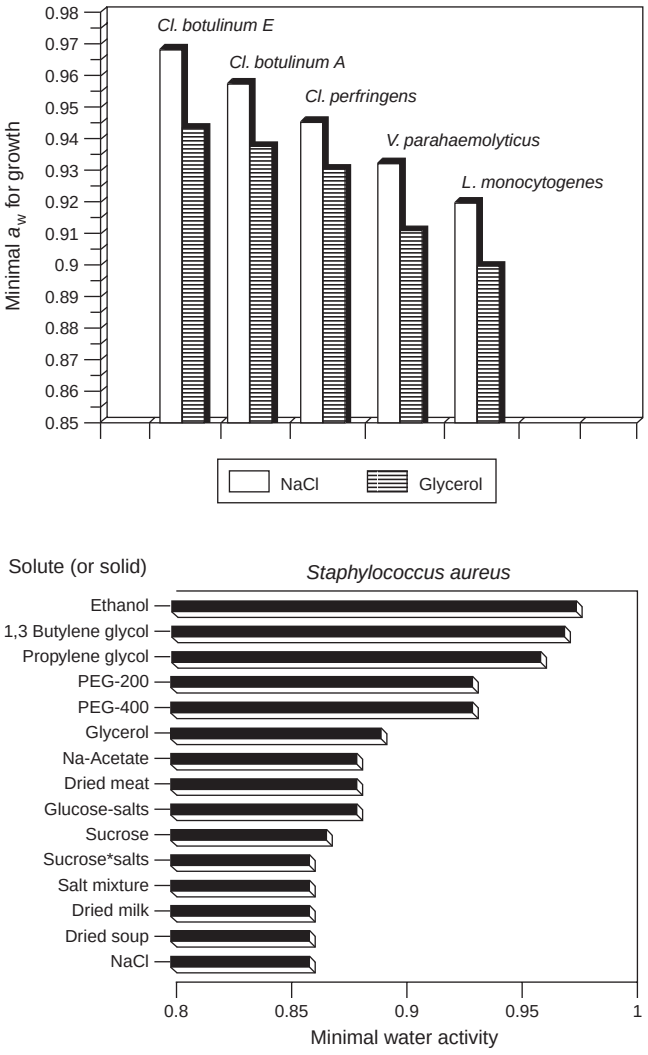

FIGURE 32.7 Effect of minimum water activity levels on growth of bacteria in different solutes. (From Chirife and Buera [7].)

Figures 32.7 and 32.8 compare the minimal water activity supporting the growth of various pathogenic bacteria when sodium chloride or glycerol are used to control the water activity. In all cases, glycerol is less inhibitory than sodium chloride. Glycerol readily permeates the membrane of bacteria and does not initiate the same osmoregulatory response as the nonpermeate solute sodium chloride [134]. It is conclusive that the water activity limit varies with the type of solute used and the microorganisms in the medium. Thus, it is important to identify the range of variation and the possible causes of variation. Table 32.4 shows the effects of solute types on *Staphylococcus aureus*. The range of water activity varies from 0.860 to 0.966. Propylene glycol is more effective in *S. aureus*, which is explained by Chirife [134]. The points in Figure 32.7 are distributed on both sides of the line, indicating a high correlation of water activity with growth and fluctuation due to other factors in the microorganisms. The effect of solute type on different microorganisms should be clearly identified in order to recognize generalized trends or at least the limitation of validity. Electron micrographs of *S.*

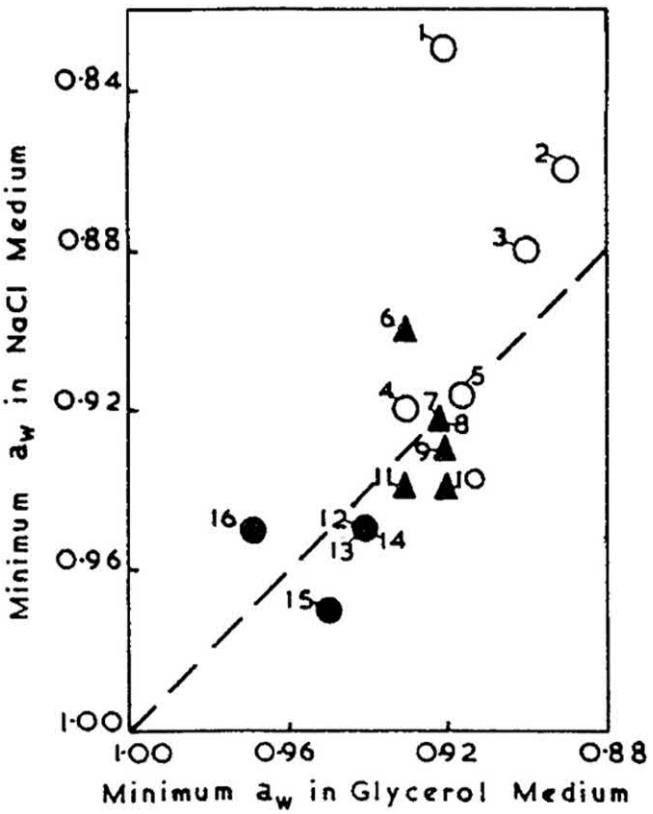

FIGURE 32.8 Relationship between the minimum water activity levels for growth of 16 species of bacteria in NaCl and in glycerol-adjusted medium. (From Christian [132].)

aureus after growing in a medium containing different solutes were analyzed [134]. Microbial cells subjected to sodium chloride and sucrose (a_w = 0.85) did not show any important morphological changes in the cells, thus the inhibitory effects of sucrose and sodium chloride against cells were primarily related to their ability to lower water activity, specific solute effects are not significant. In solutions of propylene glycol (a_w = 0.92), 1,4-butylene glycol (a_w = 0.85), and polyethylene glycol 400 and 1000 (a_w = 0.85) showed that these solutes caused dramatic morphological modifications in the cells. These antibacterial effects may be attributed mainly to the effects of these molecules on the membrane enzymes responsible for peptidoglycan synthesis.

Anand and Brown [135] observed that polyethylene glycol was more inhibitory to yeast growth than were glucose and sucrose at a similar water activity. Marshall et al. [136] evaluated the inhibitory effects of sodium chloride and glycerol at the same water activity on 16 species of bacteria. They found that glycerol was more inhibitory than sodium chloride to relatively salt-tolerant bacteria and less inhibitory than sodium chloride to salt-sensitive species. Lenovich et al. [9] showed that the type of solute influences resistance to sorbate in *Saccharomyces rouxii*, thus indicating an interactive effect of solute type and preservative. Buchanan and Bagi [137] studied the effects of solutes (mannitol, sorbitol, and sucrose) in combination with four pH levels and three incubation temperatures on the growth of *Escherichia coli*. In addition to water activity, the growth kinetics were influenced by temperature and pH, and inhibition order followed as sorbitol > mannitol > sucrose. In addition, at higher water activity levels, particularly when temperature and pH were nonlimiting, the differences between the humectants were minimal. However, as the environment was made more inhospitable, differences due to humectants were observed. Effects of solutes were insensitive to the *Lactobacillus casei* when sodium chloride or sorbitol was used to control the water activity [138]. The time of germination of spores appeared to vary depending on the water activity and solute type during spore production [124]. Resistance or susceptibility of microorganisms to antibiotics depends on the water activity and types of solutes. For example, resistance of *Streptococcus thermophilus* increased when water activity was lowered with glycerol, whereas susceptibility increased when water activity was adjusted with glucose and acid production was higher when sucrose was used. Susceptibility to gentamycin increased in both species (*Streptococcus thermophilus* and *Lactobacillus bulgaricus*) with reduced water activity [139]. Although there are differences in microbial stability when different solutes are used to achieve the same water activity, that does not mean that the concept of water activity is invalid [140]. It has been shown repeatedly in the literature that each microorganism has a critical water activity below which growth cannot occur. For example, pathogenic bacteria cannot grow below a water activity of 0.85–0.86; yeasts and molds are more tolerant of reduced water activity, but usually no growth exists below a water activity of about 0.6 (Table 32.6).

32.11.4 Molecular Mobility and Glass Transition

The water activity concept is mainly based on the binding nature of water and its relationships with the food stability or reactivity. However, molecular and/or matrix mobility also play a significant role in determining food stability, which could not be explained by water activity. The glass transition concept could explain more regarding the molecular or matrix mobility. Recently, Rahman [141–143] reviewed the applications of the glass transition concept in food product stability during storage. Slade and Levine [144] and Franks [145] proposed that water activity can serve as a useful but not the sole indicator of microbial safety. Slade and Levine's [144] hypothesis stated that water dynamics or glass–rubber transition may be used instead of water activity to predict microbial stability.

Slade and Levine [146] also reported that for matched pairs of fructose and glucose at equal solute concentrations, fructose produced a much less stable system in which mold spores germinated much faster, i.e., the solute with lower ratio of melting temperature to glass transition temperature ($\alpha = T_m/T_g$) allowed faster germination. Thus, the following order of antimicrobial stabilization was predicted by Slade and Levine [146]: glycerol (α = 1.62) > glucose (α = 1.42) > mannose (α = 1.36) > fructose (α = 1.06) and sucrose (α = 1.43) > maltose (α = 1.27). The germination of *Aspergillus flavus*, *Aspergillus niger*, and *Eurotium herbariorum* did not follow this sequence

[147]. For example, germination times for all three molds in fructose or glucose were always greater than in glycerol. In all cases, germination time increased when the water activity decreased; the relative effect, however, depended both on the solute type and the mold. None of the molds studied germinated in solution of propylene glycol (at a_w = 0.85 or 0.90; α = 1.27) after 70 days of incubation at 28°C [147]. This is simply because the behavior of propylene glycol cannot be explained on the basis of mobility or water activity effects alone, since this molecule possesses specific antimicrobial effects already recognized in the literature [147]. However, further studies from the microbiology groups could clarify the aforementioned results.

Chirife and Buera [7] also showed evidence that above glass transition, microbial growth is inhibited in prunes, and that below glass transition, microbial growth is possible in wheat flour. Overall, both the water activity and glass transition concepts are not valid in all systems and conditions. Recent trends are to apply multiple concepts, such as water activity, glass transition, and pH together in order to determine the chemical, physical, and microbiological changes in foods. However, a more unified approach including water activity, pH, glass transition, and preservatives needs to be developed. More discussions on glass transition concept and other factors are provided in the chapters on glass transition and state diagram (Chapters 23 and 24, respectively).

32.12 CONCLUSION

Food stability in terms of chemical reaction and microbial growth in foods is very complex due to its multiple factors and their interactions. Water activity could be the first step in determining food stability as different critical limits are developed. However, these critical limits and relationships shifted as other hurdles or factors are involved. This does not invalidate the concept but rather reduces its universality. Therefore, it is necessary to develop and progress a multiconcept theoretical framework, especially linking water activity, molecular mobility, pH, and storage temperature.

33 Surface Treatments and Edible Coatings in Food Preservation

Elizabeth A. Baldwin

CONTENTS

33.1 INTRODUCTION

Consumer interest in health, nutrition, and food safety combined with environmental concerns have renewed efforts in edible coating research. Renewable and abundant resources are available for use as film-forming agents that could potentially reduce the need for synthetic packaging films that add to waste-disposal problems. Alternatives to petroleum-based packaging include naturally occurring lipid, resin, protein, and carbohydrate film formers and their derivatives. In fact, coating techniques had been in use for centuries, before the development of plastic polymers. For example, beeswax was used to coat citrus fruit to retard water loss in China during the 12th and 13th centuries [1], and "larding" (coating food with fat) to prevent desiccation was practiced in 16th-century England [2]. The use of synthetic and natural waxes and resins to coat fresh fruits and vegetables has been researched and practiced in the United States, the United Kingdom, and Australia since the 1930s [3–9]. Development of edible coatings for use on meat products was first reported in the late 1950s [10–14].

Currently, edible coatings and films are commonly used on many commodities, such as candies, fresh fruits and vegetables, and processed meats. New research seeks to expand and improve coating technologies and materials to enhance food stability and quality. Other surface treatments for foods include application of antioxidants, acidulants (or other pH-control agents), fungicides, preservatives, and mineral salts, some of which are more extensively covered in other chapters of this volume.

33.2 RATIONAL FOR USING EDIBLE COATING AND SURFACE TREATMENTS

Edible coatings serve many purposes in food systems. Coatings are used to improve appearance or texture and reduce water loss. Examples include the "waxing" of apples and oranges to add gloss and reduce shrinkage due to water loss or the coating of candies to reduce stickiness [15, 16]. Use of antioxidants and sulfites to preserve fresh appearance in minimally processed fruits and vegetables or processed foods is well-reviewed by Sapers [17] and Sherwin [18]. Antioxidants are used to reduce browning of cut apple and pear [19–22], potato [23, 24], mushrooms [25, 26], and shellfish [17, 27, 28], and to preserve the color of fish [29], which is more extensively reviewed in another chapter. Fungicides are used to reduce decay of whole fruits [30]; and salts, such as calcium, are reported to delay ripening, increase firmness, improve appearance, and enhance the disease resistance of fruits [31–35]. Preservatives, acidulants, and to some extent antioxidants and sulfites reduce surface microbial populations on fresh-cut produce and processed foods [36, 37]. Many of these treatments are covered in more detail in other chapters.

This review concentrates on the use of edible coatings alone and as carriers of antioxidants [38–41], preservatives [41–46], acidulants [40, 41, 47], salts [34], and fungicides [48–55]. Coatings have been shown to increase the efficiency of preservatives [41, 44], but fungicides sometimes have reduced activity in a coating system [51, 52]. Edible coatings can also encapsulate flavor for preservation, storage, or controlled release in food systems [56]. Another advantage is the retention of flavor volatiles in coated fruit [57]. Coatings and films can slow deteriorative changes in coated products by reducing desiccation and oxidation and, in some cases, by creating a modified atmosphere around coated products [15, 16]. Coatings can reduce the migration of lipids (fats and oils) in confectionary products [58] and fried foods [16, 58, 59], or separate components of different water activity [60, 61]. Formulations can be designed to carry desired additives (including antioxidants, acidulants, chelators, preservatives, and fungicides) that help to extend product stability and, therefore, shelf life [62]. Edible films and coatings can also improve mechanical handling properties and structural integrity of various food products by helping fruit slip over packing lines with less injury [63] or by holding toppings in place during product distribution [64].

33.3 MECHANISM OF ACTION

33.3.1 Permeability Properties of Coatings

Permeability of films and coatings to water vapor, gas, solute, or lipids is an important property to consider when selecting film materials or for tailoring coatings for specific commodities. Permeability of a barrier is calculated from a combination of Fick's first law of diffusion and Henry's law of solubility. This is used to determine flux of permeate through a nonporous barrier, assuming that the barrier has no imperfections. Permeance is a measure of flux without accounting for barrier thickness and used for performance evaluation of a film rather than describing its property. Transmission rate describes permeance without accounting for film thickness or the partial pressure gradient of permeate. Resistance describes the ability of a material to serve as a barrier to the diffusion of permeate. A detailed discussion of terms, equations, and theories of permeability are presented by Donhowe and Fennema [64] and McHugh and Krochta [65].

Permeability properties of edible films are often unpredictable due to the absence of a homogeneous structure and the often hydrophilic nature of most formulations [65]. The chemical composition and structure of the film-forming polymer affects film permeability in general. Highly polar materials with a high degree of hydrogen bonding exhibit low gas permeability, especially under conditions of low humidity, but are poor barriers to moisture. Nonpolar materials, such as lipids, provide good moisture barriers but are permeable to gases such as oxygen. The type of functional group on a polymer can also have an effect, depending on the resulting chain interaction, motion, and functional group (i.e., hydrophilic or hydrophobic). Ionic functional groups create strong polymer chain interactions, which restrict chain motion. This usually results in good oxygen barriers, but also hydrogen bonding with water and subsequent water absorption at high relative humidities (RHs), which, in turn, results in high rates of water vapor permeation. In addition, absorption of water disrupts intermolecular chain interaction, which increases permeability in general. This is the reason that films are often more permeable at high RHs [66]. Nonpolar groups result in a much less effective oxygen barrier film when present as the side chain but improve water permeability slightly.

Addition of low molecular weight components, or plasticizers, can affect film permeability and flexibility, often increasing both (especially water vapor permeability) by disruption of polymer chain hydrogen bonding [65, 67]. These components are generally added to decrease film brittleness by increasing elasticity/flexibility, resulting in less cracking and flaking of coatings.

The structure of the film-forming polymer is also important in terms of influencing the permeability properties of a film. Polymer chain packing, whether it is tight or loose due to bulky side chains, results in increased or decreased permeability properties, respectively [65]. The molecular weight and crystalline structure of a polymer can have an effect [67]. Lipids can exist in different crystalline states, which result in different barrier properties, with a higher degree of crystallinity resulting in lower permeability. Temperature affects polymer mobility [68] and thus permeability. Higher temperatures (above the "glass" transition state) result in polymers that are more mobile (plastic amorphous state) and have relatively increased permeability properties compared to when they exist as "glasses" or in brittle form at lower temperatures [65]. Even without going through a structural transition, oxygen transmission through protein films was affected by temperature [68]. Orientation of polymers to the flow of permeate can affect permeability properties. For example, the packed arrangement of wax crystals perpendicular to the direction of gas flow presents a better barrier [69] than when parallel to the direction of flow.

Cross-linking of polymer chains with ions or enzymes can lower permeability values as well as change the pH (depending on the isoelectric point in the case of protein films) [65, 70]. The addition of hydrophobic materials (lipids) to a hydrophilic film former to make a composite coating can sometimes improve the moisture-barrier properties of the hydrophilic film former. This was demonstrated for a matrix of methylcellulose and hydroxypropyl methylcellulose combined with saturated C_{16} and C_{18} fatty acids laminated with beeswax and with a chitosan film containing lauric acid [71–73]. This can also be achieved by forming bilayer films from hydrophilic and hydrophobic materials. An example of this was reported for hydroxypropyl methylcellulose and a blend of stearic and palmitic acids [60, 74].

33.3.1.1 Effect on Water Loss

Water loss usually occurs in the vapor phase. Water vapor permeability describes the movement of water vapor through a film or coating per unit area and thickness, and determines the vapor pressure difference across the film at a specific temperature and humidity [75]. If pores, cracks, or pinholes form on the film surface, then water vapor flows through these areas directly, which is different from the dissolving and diffusion of water vapor through a film barrier [65]. Water vapor transfer through films is dependent on environmental conditions such as temperature and humidity, and thus should be tested under the conditions expected to be encountered by a specific product. Generally, the more hydrophilic the film-forming material, the more permeable the film will be to water vapor.

33.3.1.2 Effect on Gas Exchange of Fresh Fruits and Vegetables

33.3.1.2.1 Creation of a Modified Atmosphere for Coated Fresh Produce and Effect on Ripening

Cells of plant tissues, such as harvested fruits and vegetables, are physiologically active in that they consume oxygen (O_2) and produce carbon dioxide (CO_2) as they respire. When fruits or vegetables are sealed in semipermeable plastic packaging or coating, a modified atmosphere (MA) is created within the packaging or in the internal atmosphere of the fruit, in the case of edible coatings-depending on the permeability of the film or coating. During storage, fruit respiration continues to consume O_2 and release CO_2 [15]. If O_2 levels fall too low (below 1–3%, depending on the produce

and storage temperature), anaerobic reactions can occur, which result in off-flavors, abnormal ripening, and spoilage [76, 77]. Climacteric-type fruits are often harvested immature and ripen off the mother plant with an accelerated respiration pattern and ethylene production [76]. The high rates of respiration and ethylene production, which turn on genes regulating ripening and senescence, contribute to a relatively short shelf life for this type of produce. Ethylene production, like respiration, is a process that requires O_2. Low O_2 (below 8%) and high CO_2 (above 5%) concentrations slow respiration and retard ethylene production and, therefore, ripening [77]. High storage temperatures increase fruit or vegetable respiration [76] and exacerbate the effect of a coating or other packaging on the internal atmosphere of the coated produce. Low temperature, on the other hand, slows fruit ethylene production and respiration, thus minimizing the effect of a film or coating in terms of modifying the atmosphere inside a fruit.

33.3.1.2.2 Retardation of Weight Loss and Surface Desiccation

Fruits and vegetables also lose water to the surrounding air in the form of water vapor in a process called transpiration. This entails the movement of water from fruit cells to the surrounding atmosphere following a gradient of high water concentration (~100% RH in fruit intercellular spaces or internal atmosphere) to low water concentration (% humidity of the storage environment). For this reason, fresh produce is often stored under conditions of high RH (90–98%) to minimize water loss, subsequent weight loss, and shriveling [78]. Edible coatings can help retard this movement of water vapor, but become more permeable to water vapor and gases under conditions of high RH as explained earlier.

33.3.1.3 Effect on Stability of Lightly Processed Fruits and Vegetables

Light or minimal processing of fresh produce indicates cutting, slicing, coring, peeling, trimming, or sectioning of fruits and vegetables. Since fresh-cut produce, like intact products, have an active metabolism, the processing operations result in a series of chemical and biochemical reactions that can lead to deteriorative changes. These reactions include increased respiration, ethylene production, rapid senescence, undesirable color changes, flavor changes, synthesis of secondary metabolites, and increased microbial growth [79–81]. Many of these reactions are plant wound responses [82–84] due to injury incurred by the minimal processing. Methods used to extend the storage life of lightly processed products are the application of antioxidants, acidulants, preservatives, mineral salts, and osmotic agents. Some applications can be made using an edible coating as a carrier of these active compounds that retard browning or discoloration, microbial growth, and softening, etc. In addition, coatings with the appropriate permeability properties and under certain conditions can create a modified atmosphere around the product and retard respiration, oxidation, and desiccation. Several reviews have been published on this subject [79–81, 85]. Reduction of surface water activity can increase product stability. This can be achieved by infiltration of fruit slices or pieces with fruit juices, sucrose syrups, or glycerol with or without a coating made up of a suitable water-soluble polymeric material [79].

33.3.2 Structural Integrity and Appearance of Coated Products

Coatings on fruits and vegetables can act as lubricants to reduce surface injury, scarring, and chafing [1, 86]. With less wounding of fruit, decay due to opportunist wound pathogens is lessened. In addition, the act of applying certain types of coatings reduces surface microbial populations [87]. For these reasons, waxed citrus fruit experience less decay compared to unwaxed fruit [88]. For food consisting of multiple components, a film can be used to secure the components to the product during marketing [64]. Waxes are also used to encase cheeses to prevent surface molding during the ripening and/or aging process [89]. Resins, zein protein, and microemulsions of waxes can impart a high gloss to the coated product [90, 91]. Shellac, polyethylene, and carnauba wax microemulsions are used on fruits [15], and carnauba, shellac, and zein have been applied to candies and confectioneries as well [16, 38, 92]. Zein has been tested on tomato fruit, but thus far has not been used commercially on fruit [93]. Candelilla wax microemulsions impart a glossy appearance, especially when combined with gelatin protein [94]. Carbohydrate coatings, such as cellulose or pectin, result in an attractive nonsticky sheen when applied to products when dry, but often give an undesirable slippery texture when products become wet with condensation, as is often the case after removal from chilled storage. The polysaccharide film formers, however, do not result in the high gloss finish obtained with shellac, carnauba wax, or zein coatings.

33.4 MATERIALS USED IN EDIBLE COATING AND FILM FORMULATIONS

Many and diverse materials are used in coating or film formulations. Descriptions of the most common main ingredients or film formers are given next. The United States is generally considered the leader in worldwide food regulation, thus, when possible, approval rating based on the U.S. Food and Drug Administration Federal Code of Regulations [95] is also given. Generally recognized as safe (GRAS) status covers direct food additives for their intended use at a quantity not to exceed the amount reasonably required to accomplish the intended physical, nutritional, or other technical effect in food; that are of appropriate food grade; and used with good manufacturing practices (GMP) (FDA, 21 CFR, 1996). The GRAS status is shown without differentiating between initial GRAS status (FDA 21 CFR, Part 182) and reaffirmed as safe with minor restrictions and within specified ranges and uses or purposes and under conditions prescribed (Part 184). Part 180 refers to food additives permitted in food on an interim basis or in contact with food pending additional study. Part

172 contains other direct food additives that are not GRAS including food preservatives, coatings, and films, and special dietary and nutritional additives; Part 173 contains secondary direct food additives including polymer substances and adjuvants for food treatment, enzyme preparations, and specific usage additives; and Part 175 contains indirect food additives including adhesives and components of coatings (FDA 21 CFR [95]).

33.4.1 Lipids

Lipids include a group of hydrophobic compounds, which are neutral esters of glycerol and fatty acids. They also include "waxes," which are esters of long-chain monohydric alcohols and fatty acids [69]. A list of lipid components commonly used in coatings, along with their status according to U.S. FDA 21 CFR [95], is given in Table 33.1. Fatty acids and alcohols lack structural integrity and durability in their free form to be good film formers. Due to the fragile nature of these compounds, lipids are often incorporated into a structural matrix of some other compound such as a polysaccharide [64]. Lipid components are, therefore, incorporated in composite coatings made up of a least two materials. The supporting matrix, if made up of hydrophilic polymers, may affect film resistance to water vapor transmission [96]. Generally, oils are not as resistant to gases and water vapor transfer as are the solid-state waxes [60, 74]. Stearyl alcohol was the most resistant to O_2 transmission, probably due to its ability to crystallize as overlapping platelets with an orientation perpendicular to the direction of gas flow [97, 98]. Generally, coatings that include lipid solids up to 75% can be used to improve coating performance without diminishing moisture-barrier properties, but below 25% solids, permeability increase was observed under test conditions [99].

33.4.1.1 Oils

Paraffin oil, mineral oil, castor oil, rapeseed oil, acetylated monoglycerides, and vegetable oils (peanut, corn, soy) have been used alone or in combination with other ingredients to coat food products. White mineral oil is a petroleum-based product, being a mixture of liquid paraffinic and naphthenic hydrocarbons. It is approved for use as a food-release agent and as a protective coating for fresh fruits and vegetables [69]. Fatty acids and polyglycerides are derived from vegetable or tab oils and are considered GRAS [95]. They are commonly used with glycerides as emulsifiers. Among several oils tested, paraffin oil had the greatest resistance to water followed by vegetable oil and light mineral oil [15]. Acetoglycerides are synthetic fats where acetic acid is substituted for a portion of a naturally occurring fat or oil resulting in mono- or diacetotriglycerides or combinations of these compounds. Although acetic acid is a fatty acid, it does not occur as a glyceride in natural fats. Its water vapor permeability was found to decrease with increasing acetylation [100, 101]. Acetoglycerides are highly flexible in polymorphic form and stable in crystalline form. These modified fats have been used as protective coatings and as plasticizers [102]. Most oils used in coatings are considered direct food additives with varying

TABLE 33.1
Common Lipid Components of Coatings

Lipid	Classification	U.S. FDA 21 CFR #
Oils		
Acetylated monoglyceride	Removable hot-melt strippable coating	172.828, 175.230
Castor oil	Component of coatings for candy, tablets	172.876
Fatty acids from edible sources: capric, lauric, myristic, oleic, palmitic, stearic	Release agent; lubricant; protective coating for raw fruits and vegetables	172.86
Lard oil	GRAS, edible oil	182.7
Mineral oil	Removable hot-melt strippable coating	175.23
Peanut oil	GRAS, edible oil	182.7
Rapeseed oil	GRAS, emulsifier, stabilizer	184.1555
Salts of fatty acids	Binder, emulsifier, anticaking agent	172.863
Soy oil	GRAS, edible oil	182.7
Synthetic isoparaffinic petroleum hydrocarbons	Component of coatings on fruits and vegetables	172.884
Tallow	GRAS, edible oil	182.7
White mineral oil	Component of hot-melt coating for frozen meat, acetylated monoglyceride	172.878
Waxes		
Beeswax	GRAS, surface finishing agent	184.1973
Candelilla	GRAS, lubricant, surface finishing agent	184.1976
Carnauba	GRAS, lubricant, surface finishing agent	184.1978
Paraffin wax	Component of coating	175.250, 175.300
Petroleum wax	Component of microcapsules for flavorings, defoamer, protective coating for cheese, and raw fruits and vegetables	172.886

restrictions according to the U.S. FDA [95]. Paraffin and mineral oil are allowed as release agents and lubricants, defoamers, or components of coating, and castor oil is approved as a release agent and component of coatings. Vegetable oils are generally considered GRAS, while acetylated monoglycerides are considered food additives with few restrictions other than that they be made from edible fat [95].

33.4.1.2 Waxes

Paraffin, carnauba, beeswax, candelilla, and polyethylene waxes have been used to coat food products, alone or in combination with other ingredients. Paraffin wax is a distillate fraction of crude petroleum [103]. Synthetic paraffin wax is formed from the catalytic polymerization of ethylene and is allowed for food use in the United States. It is used as a protective coating for raw fruits, vegetables, and cheese; as a chewing gum base and defoamer; and as a component in the microencapsulation of flavorings [69]. Carnauba wax is the exudate of palm tree leaves from the tree of life (*Copernica cerifera*), found in Brazil. Beeswax or "white wax" is secreted by honeybees, and candelilla wax is an exudate of the candelilla plant (*Euphorbia antisyphilitica*), which is a reedlike plant that grows in Mexico and southern Texas. These natural waxes are considered GRAS [95] in the United States and are used in chewing gum, hard candy, and edible coatings. Polyethylene wax is oxidized polyethylene or the basic resin produced by the mild oxidation of polyethylene, a petroleum-based product. This substance is allowed for use in edible coatings for fruits and nuts where the peel or shell is not normally ingested [69, 95, 104]. Coatings made with this wax are more permeable to gases than shellac and most other polymers [104].

33.4.1.3 Emulsions

Emulsion coatings are oil or wax dispersed in water or some other hydrophilic solution. A macroemulsion has dispersed wax particle sizes ranging from 2×10^3 to 1×10^5 Å, and microemulsions from 1×10^3 to 2×10^3 Å. Melted wax disperses in water in a manner similar to oil [105]. Carnauba wax and beeswax form stable microemulsions with the appropriate emulsifiers, forming a glossy coating, while macroemulsions generally impart little shine to the coated product [69].

33.4.2 Resins

Resins are a group of acidic substances that are produced and secreted as a wound response by specialized plant cells of trees and shrubs. Synthetic resins are petroleum-based products [69]. A list of resins commonly used in coatings, along with their status according to U.S. FDA 21 CFR [95], is shown in Table 33.2.

33.4.2.1 Shellac

Shellac resin is secreted by the insect *Laccifer lacca* found in India. Shellac is composed of aleuritic and shelloic acids [106], is compatible with waxes, and gives coated products a high gloss appearance. This compound is permitted as an indirect food additive (FDA 21 CFR 175.300: resinous and polymeric coatings for food contact surfaces), but is nevertheless commonly used in coatings for fresh fruits and candies where the coated surface is consumed. Apparently, this is allowed because a petition has been submitted for GRAS status [69]. Shellac and other resins have relatively low permeability to gases and moderate permeability to water vapor [104, 107].

TABLE 33.2
Common Resin Components of Coatings

Resins	Classification	U.S. FDA 21 CFR #
Copal	Resinous and polymeric coatings	175.300
Coumarone indene	Resinous and polymeric coatings	172.215
Damar	Resinous and polymeric coatings	175.300
Elemi	Resinous and polymeric coatings	175.300
Shellac	Resinous and polymeric coatings	175.300
Terpene	Moisture barrier on soft gelatin capsules or powders of ascorbic acid	172.280
Wood rosin	Coatings on fresh citrus fruit	175.300

33.4.2.2 Wood Rosin

Wood rosin is manufactured from oleoresins of pine trees. The rosin is the residue left after distillation of volatiles from the crude resin [69]. It is less expensive than shellac, and specific esters of maleic-anhydride-modified wood rosin are approved for use in coatings for citrus. Similarly, coumarone–indene resin is approved for use specifically on citrus fruit. Coumarone–indene resin is a petroleum and/or coal tar by-product that is available in several grades. It is most often used as a component of the "solvent waxes" for citrus [69, 108]. These so-called waxes consist mostly of resins with little or no actual wax component and small amounts of petroleum solvent (U.S. FDA 21 CFR 172.250), ethanol (U.S. FDA 21 CFR 184.1293), or isopropanol (U.S. FDA 21 CFR 173.240, 173.340) [3, 69, 95]. They have low viscosity and rapid drying rates. Resin solution waxes contain a small amount of lipid (usually oleic acid), morpholine (U.S. FDA 21 CFR 172.235) or potassium or ammonium hydroxide (U.S. FDA 21 CFR 184.1631 and 184.1139, respectively), and other ingredients [95, 109, 110].

33.4.2.3 Other Resins

Terpene resin is obtained from polymerization of terpene hydrocarbons derived from wood and is approved as a direct food additive [95]. It is allowed for use as a moisture barrier in soft gelatin capsules. Other resins allowed only for food

contact include copal, damar, and elemi, which are used in the pharmaceutical industry [69, 95].

33.4.3 Proteins

Proteins have been used for their film-forming abilities for nonfood applications since ancient times as a component of glue, paint, leather finishes, paper coatings, and inks. More recently protein materials, such as the milk protein casein and corn protein zein, have been used as edible coatings for extruded meats as well as nuts and confectionery items, respectively [111]. A list of proteins commonly used in coatings and films, along with their status according to the U.S. FDA 21 CFR [95], is given in Table 33.3. Film-forming proteins of plant origin include corn zein, wheat gluten, soy protein, peanut protein, and cottonseed protein, of which all but the latter are considered GRAS [95]. Keratin, collagen, gelatin, casein, and milk whey proteins are film formers derived from animal sources, of which casein and whey proteins are GRAS [95]. Adjustment of protein film pH can alter film formation and permeability properties, as was demonstrated for soy protein, wheat gluten [112, 113], and casein [70]. Most protein films are hydrophilic and, therefore, do not present good barriers to moisture. However, dry protein films such as zein, wheat gluten, and soy present relatively low permeabilities to O_2 [112].

TABLE 33.3
Commonly Used Protein Materials in Coatings

Protein Materials	Classification	U.S. FDA 21 CFR #
Casein/Sodium caseinate	GRAS, GMP	182.90, 182.1748
Collagen		
Cottonseed (modified products)	Food additive	172.894
Gelatin	Microcapsules for flavorings (succinylated gelatin)	172.230
Fish protein concentrate	Food supplement	172.385
Fish protein isolate keratin	Food supplement	172.340
Peptones	GRAS, nutrient supplements	184.1553
Soy protein isolate	Migrating to food from paper products	182.90
Wheat gluten	GRAS, stabilizer, thickener, surface finishing agent	184.1322
Whey	GRAS, GMP	184.1979
Zein	GRAS, surface finishing agent	184.1984

Note: GRAS, generally recognized as safe by the U.S. Food and Drug Administration; GMP, good manufacturing practices.

33.4.3.1 Milk Proteins

Milk protein products include casein (80% of total milk protein) and whey (20% of total milk protein) and combinations of both [65, 114]. They can result in films of different properties depending on the commercial source and method of extraction [70, 114].

33.4.3.1.1 Casein

Caseins are soluble in aqueous solutions and form flexible colorless films. The addition of lipid compounds and adjustment of pH reduced the water vapor permeability of casein films [115], while the addition of whole milk, sodium caseinate, and nonfat dry milk or whey into polysaccharide films decreased the water vapor permeability of these hydrophilic films [116]. Lactic-acid-treated casein films retained more sorbic acid preservative, improving the microbial stability of dehydrated apricot and papaya in intermediate-moisture food test systems [117].

33.4.3.1.2 Whey

Whey proteins produce films similar to those produced from caseinates. Heating is required to form intermolecular disulfide bonds, which produces films that are water-insoluble and brittle, requiring plasticizers [111, 114].

33.4.3.2 Collagen and Gelatin

Collagen is the major component of skin, tendon, and connective tissues in animals [111]. This material is partially digested with acid or enzymes to produce edible collagen casings. Collagen casings for meat products were one of the first examples of edible film application in modern times. Gelatin is formed from the partial hydrolysis of collagen [111] and is also allowed as a component of microcapsules for flavorings and for soft capsules in the pharmaceutical industry [95]. It is soluble in aqueous solutions, forming a flexible, clear, oxygen-permeable film.

33.4.3.3 Wheat Gluten

The gluten complex is a combination of gliadin and glutenin polypeptides with some lipid and carbohydrate components [111, 118]. It is soluble in aqueous alcohol, but alkaline or acidic conditions are required for the formation of homogeneous film-forming solutions [112]. This material also requires plasticizers to increase flexibility, for the films are excessively brittle [111, 118]. These films have high water permeability but are good barriers to O_2 and CO_2 [118].

33.4.3.4 Corn Zein

Zein is a prolamine derived from corn gluten and is insoluble in water except at very low or high pH. This is due to its high content of nonpolar amino acids. It is soluble in aqueous alcohol and dries to a glossy grease-resistant surface. The film is, however, brittle, and plasticizers are required to add plasticity [111, 118]. It has been used as a substitute for shellac because of its high-gloss appearance, faster drying rate, and increased stability during storage [118].

33.4.3.5 Soy Protein

Soy protein is available as a concentrate (70% protein) or an isolate (90% protein). Film formation is enhanced by heating, which partially denatures the protein, allowing the formation of disulfide bonds. This was shown to lower water vapor permeability. Enzymatic digestion can increase cross-linking [119]. The pH must be adjusted away from the isoelectric point of the soy protein (~4.6) in order to form films. In Asia, films are formed from heated soy milk and are used for wrapping food products [111].

33.4.3.6 Peanut Protein

Peanut protein films can be formed by two methods. The first is surface film formation, using protein/lipid solutions derived from roasted peanut, partially defatted peanut flour, and protein concentrate. This produces films with rough surface texture and poor mechanical properties. Films can also be produced by the deposition method at pH 9.5 from peanut protein concentrate. This method showed promise for development as an edible film [120].

Zein, casein, and soy proteins have been used on confectionery, fruit, and vegetable products as well as on eggs. Self-supporting sheets of edible proteins have been developed that dissolve in water for microencapsulation of flavorings. Casein, soy [121], peanut, corn protein, and collagen have been used to form free-standing films or sheets for wrapping of foodstuffs [111]. Films made of proteins can add a nutritional component to coated foods especially if formulated to include diet-limiting amino acids [111, 118]. Allergies to food proteins can be a concern when developing coatings and films from these materials. Gluten intolerance and allergic reactions to milk proteins (casein and whey) and associated lactose are common and may require labeling.

33.4.4 Carbohydrates

Polysaccharides are used in food systems as thickeners, stabilizers, gelling agents, and emulsifiers [122]. They comprise an abundant and renewable resource of hydrophilic film-forming agents with a wide range of viscosities, relatively low permeability to gases, but little resistance to water vapor transfer. A list of commonly used polysaccharides in coatings and films, along with their status according to the U.S. FDA 21 CFR [95], is given in Table 33.4.

33.4.4.1 Cellulose

Cellulose is the most abundant polysaccharide on the planet, being a major component of plant cell walls. Cellulose is made up of repeating glucose units in β-1,4-linkage. In its natural form, cellulose is not soluble in water, but derivatized forms such as sodium carboxymethyl cellulose (CMC), methylcellulose (MC), hydroxypropyl cellulose (HPC), and hydroxypropyl methylcellulose (HPMC) are more soluble [102, 122]. These derivatives have different permeabilities to water vapor and gases and are good film formers [102, 105]. The degree of substitution and type of substitution (ionic and nonionic)

TABLE 33.4
Commonly Used Polysaccharides in Coatings

Polysaccharides	Classification	U.S. FDA 21 CFR #
Agar	GRAS, drying and flavoring agent, stabilizer, thickeners, surface finishing	184.1115
Alginate	GRAS, emulsifier, stabilizer, thickener	184.1011
Carrageenan	Emulsifier, stabilizer, thickener, gelling agent	172.620
Salts of carrageenan	Emulsifier, stabilizer, thickener	172.626
Chitosan	Approved in Canada	
Dextrin	GRAS, formulation aid, processing aid, stabilizer, thickener	184.1277
Ethyl cellulose	Binder, filler, component of protective coatings for vitamin and mineral tablets	172.868
Furcellaran	Emulsifier, stabilizer, thickener	172.655
Salts of furcellaran	Emulsifier, stabilizer, thickener	172.660
Gellan gum	Stabilizer, thickener	172.665
Gum Arabic (acacia gum)	GRAS, emulsifier, formulation aid	184.1330
Gum ghatti	GRAS, emulsifier	184.1333
Gum karaya	GRAS, formulation aid, stabilizer, thickener	184.1349
Gum tragacanth	GRAS, emulsifier, formulation aid	184.1351
Locust bean gum	GRAS, stabilizer, thickener	184.1343
Guar gum	GRAS, emulsifier, formulation air, firming agent	184.1339
Hydroxypropyl cellulose	Emulsifier, film former, protective colloid, thickener	172.870
Hydroxypropyl methylcellulose	Emulsifier, film former, protective colloid, thickener	172.874
Methylcellulose	GRAS, GMP	182.1480
Methyl ethyl cellulose	Aerating, emulsifying or foaming agent	172.872
Modified starch	Food additive	172.892
Pectins	GRAS, GMP	184.1588
Sodium carboxymethyl cellulose	GRAS, GMP	182.1745
Xanthan gum	Stabilizer, emulsifier, thickener, suspending agent	172.695

Note: GRAS, generally recognized as safe by the U.S. Food and Drug Administration; GMP, good manufacturing practices.

for functional groups and polymer chain length affect permeability, solubility, and viscometric properties [122, 123]. The derivatives CMC and MC are GRAS, while HPC and HPMC are approved as direct food additives for the purpose of film former, stabilizer, thickener, and suspending agent [95]. The latter two derivatives are not permitted for food use in all countries. However, several commercial coatings were developed from cellulose polymers including TAL Pro-long (Coutaulds Group, London), Semperfresh (United Agri Products, Greeley, Colorado), and Nature Seal (EcoScience Corp., Orlando, Florida). Another cellulose product is called cellulon fiber, which is bacterial cellulose produced by aerobic fermentation of glucose by a strain of *Acetobacter*. It has a fine fiber structure physically but is not chemically different from plant cellulose. It has been applied to surimi to aid in the binding of water [124] but has no reported uses as a coating or surface agent.

33.4.4.2 Pectin

Pectins are a complex mixture of polysaccharides that are also components of plant cell walls [125]. They are commercially obtained from citrus peel and apple pomace [123]. These polymers are mainly long chains of α-1,4-linked galacturonic acid units with varying degrees of esterification with methyl groups. The degree of esterification (DE) affects solubility and gelation properties; pectins with DE above 50% are labeled high-methoxyl and below 50% DE, low-methoxyl pectins [102, 123]. As with cellulose polymers, the chain length also affects solubility and viscosity. When used as a film former in coatings, this polymer gives a somewhat glossy, nonsticky surface, and LM pectins can be cross-linked with calcium ions to form gels [102]. Coatings made with pectin materials generally have high water vapor transmission rates [126] due to their hydrophilic nature [127], which can be improved by the addition of paraffin or beeswax. The tensile strength of pectinic acid films increases with a decrease in methoxyl content [128] because the removal of ester groups leads to increased cross-bonding between residual carboxyl groups. Miers et al. [128] reported that pectin coatings were of acceptable strength with methoxyl contents of 4% or less and intrinsic viscosities of 3.5 or above. Pectins are generally considered GRAS [95].

33.4.4.3 Chitin/Chitosan

Next to cellulose, chitin is the second-most abundant polysaccharide on the planet, being a component of fungal and green algae cell walls and the skeletal substance of invertebrates [129]. It is a β-1,4-linked polymer of 2-acetamido-2-deoxy-D-glucan [125]. Partial deacetylation of chitin results in chitosan, which has been shown to induce plant-defense responses and inhibit the growth of fungi [130, 131]. Use of this polymer as a film former and natural preservative resulted in the commercial coating Nutri-Save (Nova Chem, Halifax, Nova Scotia, Canada). Methylation of the polymer resulted in a twofold resistance to CO_2 [15, 132]. This allows it to retard the ripening of climacteric fruits [133]. It, however, has relatively low resistance to water vapor transfer compared to lipid materials. Chitosan has not yet received approval for food use in the United States (although approved for supplements), but it is approved in Canada. The antimicrobial activity of chitosan was found to increase with ionic strength but decrease with addition of metal ions. The antibacterial activity of chitosan was dependent on its charges and solubility [134].

33.4.4.4 Starch

Amylaceous materials (amylose, amylopectin, and derivatives) have also been used to make coatings. These films have been reported to be semipermeable to CO_2 but highly resistant to O_2 [135]. Most starch consists of 25% amylose and 75% amylopectin, with one notable exception being hybrid corn, which contains 50–80% amylose. Amylose is a polymer of α-1,4-linked glucose, and amylopectin consists of an amylose backbone with side chains of α-1,6-linked glucose. Of the two polymers, amylose is a better film former and amylopectin is more useful as a thickening agent. Some derivatives, such as a hydroxypropyl amylose, showed low permeability to O_2, improved water solubility [102], and increased elongation properties, but no resistance to water vapor. Dextrins (partially hydrolyzed starch molecules, i.e., reduced in size as measured by dextrin equivalent or DE) are used as film formers, encapsulating agents, and flavor carriers. Coatings made from such polymers have lower permeability to water vapor compared to starch films [102, 136] and may have resistance to O_2 [137]. Carboxylated dextrins are used as encapsulating agents [125]. Raw starch and dextrin products are considered GRAS, while modified starch products (modified by acid, bleach, esterification, or oxidized using chlorine) are approved as direct food additives [95].

33.4.4.5 Aloe Vera

Aloe vera gel was used to coat table grapes and extended shelf life by 35 days at 1°C. The gel worked as a barrier to O_2 and CO_2, creating a modified atmosphere, and acted as a moisture barrier and thus reduced weight loss, browning, softening, and growth of yeast and molds. The material reportedly contains antimicrobial compounds and thus prevents decay. This material has been used as a functional ingredient in beverages for years [138]. Aloe vera contains malic-acid-acetylated carbohydrates (including β-1,4-glucomannans) that demonstrated anti-inflammatory activity [139].

33.4.4.6 Konjac Glucomannan

Konjac glucomannan is a polysaccharide derived from the konjac tuber and consists of 1,4-linked β-mannose and β-glucose units with some acetyl groups. It has been used in food, film formers, and biomedical applications. It was combined with chitosan and nisin (used by the food industry as a preservative) and was found to be effective against pathogenic bacteria including *Staphylococcus aureus*, *Listeria monocytogenes*, and *Bacillus cereus* [140].

33.4.4.7 Seaweed and Gum Polymers

33.4.4.7.1 Seaweed Products

Seaweed products such as carrageenan, alginates, and agar make good film formers or gels. Carrageenan consists of sulfate esters of 3,6-anhydro-α-D-galactopyranosyl units

[123, 141], alginates are salts of alginic acid (1,4-polyuronic acid with poly-β-D-mannopyranosylurinic and poly-α-L-gulopyranosyluronic acid blocks) [102, 123, 125], and agar is made up of β-1,4-D-galactopyranosyl linked to 3,6-anhydro-α-L-galactopyranosyl, partially esterified with sulfuric acid. Of these three, agar is more for formation of gels (currently used as a culture medium) and the other two polymers as gel and film formers. Alginate gels are relatively heat-stable [123]. Carrageenan is approved as a direct food additive as an emulsifier, stabilizer, and thickener, while agar is GRAS [95]. In Japan, there is a commercial carrageenan-based coating called Soageena (Mitsubishi International Corp., Tokyo).

33.4.4.7.2 Gum Products

Certain gum products are exudates from plants found mostly in Africa and Asia produced in response to injury [123, 136, 143], some of which are seed and fermentation products. Gums are complex heteropolysaccharides including gum arabic or acacia gum from the tree *Acacia senegal* and related species (*n*-galactopyranosyl, L-rhamnopyranosyl, L-arabinopyranosyl, L-arabinofuranosyl, and D-glucopyranosyluronic acid units with calcium, magnesium, and potassium ions) [144, 145]. Gum arabic forms an aqueous solution of low viscosity and can form stable emulsions with most oils [125]. It is used in the confectionery industry as a stabilizer, adhesive, and flavor fixative. It has also been used to coat pecans [146] and is a good emulsifier [123].

Other less-used gums include gum tragacanth, whose film-forming properties are more useful in nonfood products such as hair and hand lotions and creams [125]. Gum karaya, which forms smooth films that require plasticizers; locust bean gum, whose film-forming properties have been used in the textile industry as a finishing agent and as a common component of cosmetics, sauces, and salad dressings; guar gum, which is also used as a film former in the textile industry (both locust bean and guar gum are galactomannans) [123]; xanthan gum, a fermentation product with a cellulosic backbone [123], used as a thickener in sauces, gravies, frostings, fruit gels, and coatings to prevent moisture migration during frying [125] and in salad dressings with propylene glycol alginate [147]; and gellan gum, another fermentation product developed and patented by Kelco [148], which is also used in glazes, icings, and jams/jellies [125]. Of these gums, gum arabic (acacia gum), gum ghatti, guar gum, and locust bean gum (carob gum) are considered GRAS, while xanthan and gellan gum are approved as direct food additives for use in glazes, icings, frostings, jams, and jellies, and as a stabilizer, emulsifier, thickener, etc. [95].

33.5 AS INDIVIDUAL TREATMENTS OR IN COATING FORMULATIONS

Materials other than film formers are added to edible coatings for two main reasons. One is to improve the structural, mechanical, or handling properties of a coating. The other is to improve the quality, flavor, color, or nutritional properties of the coated product [62]. In the latter case, the coating acts as a carrier of useful compounds that have a desired effect on the coated item.

33.5.1 Plasticizers, Emulsifiers, and Surfactants

33.5.1.1 Plasticizers

Plasticizers are usually low molecular weight compounds that impart increased strength and flexibility to coatings, but also increase coating permeability to water vapor and gases [64, 102]. Commonly used plasticizers, along with their status according to the U.S. FDA 21 CFR [95], are listed in Table 33.5. Common plasticizers include polyols such as glycerol, sorbitol, mannitol, propylene glycol, and polyethylene glycol (molecular weight 200–9500). Sucrose, sucrose fatty acid esters, and acetylated monoglycerides also can be used as plasticizers. Of these, glycerol, sorbitol, and propylene glycol are considered GRAS [95].

33.5.1.2 Emulsifiers and Surfactants

Emulsifiers can be classified as surface-active agents or as macromolecular stabilizers. Macromolecular stabilizers are proteins, gums, and starches that stabilize emulsions [149]. Commonly used emulsifiers and surfactants, along with their status according to the U.S. FDA 21 CFR [95], are listed in Table 33.5. Surface-active agents reduce surface water activity and can affect the rate of moisture loss from a food when used as a coating. This was shown with glycerol monopalmitate and glycerol monostearate and other 16- to 18-carbon fatty alcohols [102]. Reduction of surface water activity at the water/oil interface helps to both form and stabilize emulsions, which is important for shelf-life properties of emulsion coatings. The hydrophilic–lipophilic balance (HLB) of surfactants ranks these compounds according to their hydrophobic and hydrophilic portions, which has an effect on their performance as emulsifiers. For example, sodium lauryl sulfate is a very hydrophilic surfactant with a HLB value of 40. Generally, surfactants with low HLB values are effective for water-in-oil emulsions, and those with high HLB values are more useful for oil-in-water emulsions [69]. Some common emulsifiers are acetylated monoglyceride, lecithin (GRAS) and lecithin derivatives, ethylene glycol monostearate, glycerol monostearate, sorbitan fatty acid esters (TWEENS), and palm and corn oil (GRAS) [95]. Surfactants help coatings adhere to coated surfaces. Most natural waxes also have emulsifying properties since they are comprised of long-chain alcohols and esters [69].

33.5.2 Fungicides and Biocontrol Agents

33.5.2.1 Fungicides

Fresh fruits and vegetables are susceptible to a variety of postharvest decay types that can be reduced by treatment with fungicides with and without a coating or "wax" [150]. About 20 compounds have been developed and tested for use as postharvest pesticides over the last 30 years [62], but

TABLE 33.5
Commonly Used Plasticizers, Emulsifiers, and Surfactants

Compounds	Classification	U.S. FDA 21 CFR #
Acetylated monoglycerides	Emulsifiers, component of coating	172.828
Corn oil	Edible oil	
Ethoxylated mono-, diglycerides	Emulsifiers	172.834
Glycerol	GRAS, GMP	182.1320
Glycerol monopalmitate (ethoxylated mono- and diglycerides)	Emulsifier	172.834
Glycerol monostearate (ethoxylated mono- and diglycerides)	Emulsifier	172.834
Hydroxylated lecithin	Emulsifier	172.814
Lecithin	GRAS, GMP	184.1400
Mannitol	Permitted food additive, component of resinous and polymeric coatings	180.25, 175.300
Oleic acid	Lubricant, binder, defoaming agent	172.862
Palm oil	GRAS, cocoa butter substitute	184.1259
Polyethylene glycol	MW 2200–9500; coating, binder, plasticizer, lubricant	172.820
Polysorbate 60	Emulsifier, foaming agent	172.836
Polysorbate 65	Emulsifier	172.838
Polysorbate 80	Emulsifier, dispersing agent, surfactant, wetting agent	172.840
Propylene glycol	GRAS, solvent, thickener, component of resinous and polymeric coatings	184.1666, 175.300
Propylene glycol alginate	Component of coatings for citrus	172.212
Sodium lauryl sulfate	Emulsifier, whipping agent, surfactant, wetting agent	172.822
Sodium stearoyl lactylate	Surfactant, emulsifier, stabilizer	172.846
Sorbitan monooleate	Emulsifier for clarification of cane or beet sugar juice	173.110
Sorbitan monostearate	Emulsifier	172.842
Sorbitol	Component of resinous and polymeric coatings	175.300
Sucrose	GRAS, GMP	184.1854
Sucrose fatty acid esters	Emulsifiers, texturizers, components of protective coatings for fresh fruit	172.859

Note: GRAS, Generally recognized as safe by the U.S. Food and Drug Administration; GMP, good manufacturing practices.

many have been banned or not reregistered in the United States and other nations. Use of fungicides applied in fruit coatings has been reported for citrus including benomyl, imazalil, and thiabendazole (TBZ), of which only the latter two are currently registered for use on citrus in the United States. These fungicides are applied in solvent or water waxes, and this results in reduced ability to inhibit mold growth compared to application as an aqueous suspension. It is thought that encapsulation of the fungicide in the wax is the reason for its reduced efficiency [53]. Use of fungicides in fruit coatings has been reported for stone fruits (methyl-1-(butylcarb amoyl)-2-benzimidazolecarbamate or benomyl) [49], papayas (TBZ) [54], strawberries (3-(3,5-dichlorophenyl)-*N*-(1-methyl ethyl)-2,4-dioxo-1-imidazolidinecarboxamide, iprodione or Rovral® [55], tomatoes (*N*-[(trichloromethyl)thio]-4-cyclohex ene-1,2-dicarboximide or captan) [151], and apples (Rovral) [152], as well as captan and benomyl on raspberries [153].

33.5.2.2 Biological Control Agents

Antagonistic yeasts and bacteria have been shown to inhibit mold growth and thus prolong the shelf life of fresh fruits and vegetables [154, 155]. The mechanisms of action are reported to be the production of an antibiotic compound, competition for nutrients at wound sites on fresh produce, direct interaction with the pathogen, and induction of host defense responses [155]. These compounds have been successfully applied in fruit coatings and were shown to delay spoilage of citrus fruit by this method [156, 157]. Two commercial products approved and available on the U.S. market are Biosave® (EcoScience Corp., Orlando, Florida), which contains an antagonist bacteria (*Pseudomonas syringae*), and Aspire® (Ecogen Corp., Langhorne, Pennsylvania), which contains an antagonist yeast (*Candida oleophila*) for control of decay on apples and citrus fruits.

33.5.3 Preservatives

Chemical preservatives such as salt, nitrites, and sulfites have long been used to prolong the shelf life of food products [36]. Coatings can also act as carriers of antimicrobial agents for lightly processed and processed food products [62]. Commonly used preservatives, along with their U.S. FDA 21 CFR [95], are listed in Table 33.6.

33.5.3.1 Benzoates, Sorbates, and Other Short-Chain Organic Acids

Preservatives such as benzoic acid and benzoates are most effective at pH 2.5–4.0 with the undissociated form of benzoic acid being most effective (pK_a 4.2), rendering this preservative ineffective above pH 4.5 [36]. This preservative controls yeasts and molds more effectively than bacteria and is considered GRAS to a maximum of 0.1% in the United States and up to 0.15–0.25% in other countries [95]. Sorbic acid and sorbates are also most effective in the undissociated state against fungi and certain bacteria [36]. This preservative is also considered GRAS for most products in accordance

TABLE 33.6
Commonly Used Preservatives

Preservatives	Classification	U.S. FDA 21 CFR #
Acetic acid	GRAS, curing or pickling agent, or in food at levels not to exceed GMP	184.1005
Benzoic acid	GRAS, antimicrobial agent	184.1021
Calcium disodium EDTA	Preservative, color retention	172.120
Citric acid	GRAS, GMP	184.103
Dehydroacetic acid	Preservative for cut or peeled squash	172.130
Fumaric acid	Nutritional additive	172.350
Lactic acid	GRAS, antimicrobial agent	184.1061
Methylparaben	GRAS, antimicrobial agent	184.1490
Natamycin	Mold inhibitor for sliced cheeses	172.155
Potassium sorbate	GRAS, GMP	182.3640
Propionic acid	GRAS, antimicrobial agent	184.1061
Propylparaben	GRAS, antimicrobial agent	184.1670
Sodium benzoate	GRAS, antimicrobial agent	184.1733
Sodium nitrate	Preservative, color fixative for fish and meat	172.170
Sodium nitrite	Preservative, color fixative for fish and meat	172.175
Sorbic acid	GRAS, GMP	182.3089

Note: GRAS, Generally recognized as safe by the U.S. Food and Drug Administration; GMP, good manufacturing practices.

with good manufacturing practices up to a level of 0.1% in the United States [95]. Sorbates are permitted in all countries of the world for preservation of various food products in the range of 0.15–0.25%. Acetic, lactic, propionic, fumaric, and citric acids also can be used in coatings and contribute to antimicrobial activity. Use of coatings as carriers of preservatives such as benzoates and sorbates improved their performance when applied to cut fruit or cheese analogs. This may be due to the prevention of diffusion of preservatives into the food tissue or the fact that more preservative is present on the cut surface due to the thickness of the coating. Use of coatings to establish a surface pH that favors the active form of sorbic acid and other preservatives is also a possibility. This was demonstrated with a zein coating on a cheese analog for sorbate [158]; with MC/fatty acid films with sorbate in a test system [46, 159]; with chitosan, MC, and HPMC films with sorbate in a test system; and with a CMC/soy protein coating on cut apple with sorbate and benzoate [41].

33.5.3.2 Parabens

Alkyl esters of p-hydroxybenzoic acid, or parabens, are effective antimicrobial agents, especially against yeasts and molds. In the United States, methyl and propyl parabens are considered GRAS up to 0.1% [95]. In the United Kingdom, methyl, ethyl, and propyl parabens are permitted in food, while other countries allow butyl ester parabens as well [36].

33.5.3.3 Sulfites

Sulfites or sulfur dioxide and its various salts are effective antimicrobials for the control of yeasts, molds, and especially bacteria, and they prevent enzymatic browning in foods. The effectiveness of this preservative is greatest when the acid is undissociated at pH<4 (pK_a of sulfur dioxide = 1.76 and 7.20). Although sulfur dioxide and various sulfite salts are considered GRAS in the United States, they cannot be used on meats, in food products that are sources of thiamine, or on raw fruits and vegetables [95] due to the elicitation of allergenic responses in a certain segment of the population [36].

33.5.3.4 Sucrose Esters and Chitosan

Sucrose esters are approved as emulsifiers and are an ingredient in edible coatings along with cellulose in Tal Pro-long (Courtaulds Group) and Semperfresh (United Agri Products), or with guar gum in Nu-coat Flo (Surface Systems International Ltd.). Sucrose esterified with palmitic and stearic acids showed some antimicrobial activity against certain molds at levels of 1%. Chitosan, the film former of the edible coating Nutri-Save (Nova Chem. Ltd.), has been shown to inhibit growth of fungi on plants by inducing plant defense responses [130, 131].

33.5.3.5 Other Natural Antifungal Compounds

Unripe fruits are often more resistant to decay possibly due to the presence of some antifungal compounds. Several of these compounds were found in unripe mango including 5,12-cis-heptadecenyl resorcinol and 5-pentadecenyl resorcinol. A similar situation was discovered in unripe avocado with the antifungal compounds 1-acetoxy-2-hydroxy-4-oxohenei cosa-12,15-diene and 1-acetoxy-2,4-dihydroxy-*n*-heptadeca-16-ene. High levels of CO_2-enhanced concentrations of the antifungal avocado diene in treated fruits [160] present a possible explanation for the antimicrobial action of these compounds, at least in the case of avocado fruit.

An antifungal essential oil and a long-chain alcohol, thought to be 17-pentatriacontanol, showed antifungal activity by inhibiting the mycelial growth of *Aspergillus carneus.* This compound was isolated from *Achyranthes aspera,* an herb with reported medicinal properties [161]. Isothiocyanates derived from mustard and horseradish have been shown to have antimicrobial activity [162]. Another compound, pyrrolnitrin, was isolated from the bacteria *Pseudomonas cepacia,* which in turn was isolated from apple leaves. This microbe was found to have antagonistic activity toward *Penicillium expansum*, *Botrytis cinerea*, and *Mucor* species due to the production of the secondary metabolite pyrrolnitrin. This compound was applied to harvested strawberries and was found to retard various storage rots [163]. None of these natural fungicides have been approved for human consumption, but these offer promising alternatives to synthetic fungicides and preservatives.

33.5.4 Antioxidants

Antioxidants are compounds that inhibit or prevent the oxidation reaction caused by free radicals, with or without oxidation enzymes, that cause discoloration or browning of certain

TABLE 33.7
Commonly Used Antioxidants

Antioxidants	Classification	U.S. FDA 21 CFR #
Anoxomer	Antioxidant	172.105
Ascorbic acid	GRAS, GMP	182.8013, 182.5013
Ascorbic acid-2-phosphate		
Ascorbic acid-3-phosphate		
Ascorbyl palmitate	GRAS, GMP	182.3149, 172.110
BHA	GRAS, GMP	182.3169, 172.115
BHT	GRAS, GMP	182.3173
L-Cysteine	GRAS, improved biological quality of total protein in a food	184.1271, 172.320
Diphenylamine (DPA)	Surface treatment of apples for scald disorder	
Erythorbic acid	GRAS, GMP	182.3041
Ethoxyquin	Antioxidant	172.140
4-Hydrocymethyl-2-6-di-tert-butylphenol	Antioxidant	172.150
Lecithin	GRAS, GMP	184.140
Potassium bisulfite	GRAS, GMP, raw fruits and vegetables	182.3616
Potassium metabisulfite	GRAS, GMP, raw fruits and vegetables	182.3637
Propyl gallate	GRAS, antioxidant	184.1660
Rosemary	GRAS, flavoring	182.10, 182.20
Sodium bisulfite	GRAS, GMP, raw fruits and vegetables	182.3739
Sodium metabisulfite	GRAS, GMP, raw fruits and vegetables	182.3766
Sodium sulfite	GRAS, GMP, raw fruits and vegetables	182.3798
TBHP	Antioxidant	172.190
TBHQ	Antioxidant	172.185
Tocopherols	GRAS, GMP	182.8890
α-Tocopherols	GRAS, inhibitors of nitrosamine formation	184.1890
α-Tocopherol acetate	GRAS, GMP	182.8892

Note: GRAS, Generally recognized as safe by the U.S. Food and Drug Administration; GMP, good manufacturing practices.

fruit and vegetable tissues and rancidity of fats [17, 18]. This can affect the color or flavor of meat, fish, mushrooms, fruit, and vegetable products. Commonly used antioxidants, along with their U.S. FDA 21 CFR [95], are listed in Table 33.7.

33.5.4.1 Phenolic Antioxidants

The phenolic structure of certain compounds suppresses free radical formation, which delays the autooxidative process in fat or oil by acting as a proton donor [18]. Approved phenolic antioxidants include butylated hydroxyanisole (BHA), butylated hydroxytoluene (BHT), and esters of gallic acid such as propyl gallate and tertiary butyl hydroquinone (TBHQ). Natural antioxidants are also effective, such as the tocopherols and lecithin. The antioxidants BHA, BHT, tocopherol, and lecithin are GRAS, while TBHQ is approved as a direct food additive and propyl gallate as an indirect food additive component of coatings [95]. These antioxidants are also approved for food use in many countries, especially BHA, BHT, and tocopherol [18]. Coatings have been used as carriers of antioxidants to retard rancidity of meat and nut products, and discoloration of lightly processed fruits and vegetables [16, 39–41]. For whole apples, aqueous dips in the antioxidant diphenylamine (DPA) (300–3000 ppm) or ethoxyquin help to reduce surface discoloration known as scald [152, 164].

33.5.4.2 Other Antioxidants and Antibrowning Agents

Some agents such as cinnamic and benzoic acids (both GRAS) [95] are effective browning inhibitors in combination with ascorbic acid since, like sulfites, they inhibit polyphenol oxidase (PPO) activity [21]. This enzyme is responsible for the browning that occurs when monophenolic compounds of plants or shellfish are hydroxylated to o-diphenols and subsequently to o-quinones in the presence of oxygen and PPO in plants and shellfish. The PPO enzyme requires copper, and thus complexing and chelating agents such as ethylenediaminetetraacetic acid (EDTA) and citric acid can inhibit enzymatic browning [17]. Ascorbic acid and its derivatives, erythorbic acid, and ascorbic acid-2-phosphate and -triphosphate, are effective inhibitors of enzymatic browning for cut apple [21, 165].

Ascorbyl palmitate, cinnamic acid, benzoic acid, and ~3-cyclodextrin were reported to be effective browning inhibitors in juice [21]. Ascorbic acid, erythorbic acid, and ascorbyl palmitate are GRAS [95], but other ascorbic acid derivatives are, so far, not approved. The amino acid cysteine is also an effective inhibitor of PPO [166]. Rosemary extract (and its constituents carnosol, carnosic acid, and rosmarinic acid) is a source of natural antioxidants [167, 168]. Citric acid and EDTA have been incorporated into coatings as browning inhibitors for cut apples, potatoes, and mushrooms [41, 169]. The amino acid cysteine inhibits PPO activity by reacting with quinone intermediates as well as reduced glutathione. Inorganic halides such as sodium or calcium chloride ($CaC1_2$) also inhibit PPO activity [17]. Resorcinol and its derivatives, such as 4-hexyiresorcinol, inhibit browning tyrosinase isozymes in mushrooms and may inhibit PPO by serving as a substrate for this enzyme. These compounds have antimicrobial activity as well [22]. They are not yet approved for food use in the United States.

33.5.5 Mineral and Growth Regulator Treatments

33.5.5.1 Calcium

The mineral calcium has many postharvest uses [31]. Postharvest dips of calcium chloride ($CaC1_2$) can reduce symptoms of bitter pit or small brown lesions that occur on apples as well as scald [152, 170]. Calcium or $CaC1_2$ dips or infiltrations on whole or cut fruit has been reported to increase fruit firmness for apple [32, 171], peach, [172], blueberry [33],

and strawberry [173], and to delay ripening and decay of avocado [174], mango [175, 176], apple [177], pear [178], peach [179], strawberry [173], and potato [34]. The reasons for these benefits range from alleviating disorders resulting from calcium deficiency, to the effect of calcium on cell walls that makes them more resistant to decay [177] and firmer in texture, to adversely affecting conidial germination and germ-tube elongation [180]. The mineral salt $CaC1_2$ is considered GRAS [95]. There is a new compound called Nature Seal that claims to contain vitamins and minerals, likely calcium ascorbate. This product is used to control browning of cut fruits and vegetables like cut apple [181, 182].

33.5.5.2 Growth Regulators

The polyamines putrescine and spermidine altered texture when infiltrated into apples [32], and spermine and spermidine increased firmness in sliced strawberries [183]. Growth regulators such as 2,4-dichlorophenoxyacetic acid (2,4-D) and 2,4,5-trichlorophenoxyacetic acid (2,4,5-T) were added to fruit wax as antisenescent compounds to extend the shelf life of mandarin oranges [184]. Maleic hydrazide (250 ppm) and 2,4,-D were added to wax emulsions to delay ripening of mango fruits [185]. Gibberellic acid (150 ppm) suppressed sprouting of yam tubers for one month [186]. The only approved postharvest growth regulator treatment for fruits in the United States is for lemons destined for long-term storage. These fruit are sometimes treated with 2,4,-D to delay senescence of the button (calyx and residual stem) to reduce infection from *Alternaria* [187].

33.6 FUMIGATION AND GAS TREATMENTS

Hydrogen peroxide is an antibacterial agent based on its oxidative properties [36], effective at concentration ranges of 0.01–0.1% (U.S. FDA 21 CFR 184.1366) [95]. It is especially effective against gram-negative bacteria such as coliforms. There is little information as to its effect on fungi. It is mostly used to extend the shelf life of dairy products and is considered GRAS as an antimicrobial agent for treatment of milk for the making of cheese, whey, and starch [95]. It is reportedly effective as a vapor phase treatment of fumigant for fresh table grapes. Previously, fumigation with sulfur dioxide was used, but there are concerns about adverse effects on some sensitive individuals (U.S. FDA 21 CFR 182.3862) [95, 188]. Acetaldehyde vapor (0.25–0.5%) significantly reduced decay of harvested table grapes [189], while acetic acid vapor fumigation reduced fungal decay of grapes, apples, oranges, tomatoes, and strawberries [190, 191]. Other natural fruit and plant volatiles have been found to exhibit fungistatic activity. Of these volatiles, benzaldehyde, methyl salicylate and ethyl benzoate, 1-hexanol, trans-2-hexenal 2-nonanone, and furan compounds were found to be particularly effective [192–195]. The antimicrobial activity of CO_2 is greatest against molds and gram-negative psychrotrophic bacteria in the concentration range of 10–100% (U.S. FDA 21 CFR 184.1240) [36, 95]. The mechanism of action is not known but may be related to lack of O_2, acidification of intracellular contents, or effect on enzymes. Various concentrations of CO_2 used in modified-atmosphere packaging (MAP) are often within the microbistatic range [196, 197]. It has been shown to reduce brown rot of package cherry fruit [198]. 1-methylcyclopropene (1-MCP) is an ethylene action inhibitor, and thus delays changes caused by the plant hormone ethylene such as ripening, softening, and undesirable color changes such as browning in cut apples [182, 199]. It is currently used by the apple industry to prolong storage life of whole apples and is commercially sold under the name of Smartfresh. However, as ethylene promotes volatile synthesis, use of 1-MCP, by inhibiting ethylene action, can reduce aroma volatiles [200].

33.7 FRUIT QUARANTINE TREATMENTS

Fruit flies are major pests worldwide, and their fruit hosts must be treated to kill 100% of the immatures inside the fruits prior to export to uninfested areas of the world. One of the main treatments currently used is methyl bromide fumigation, which is scheduled to be phased out over the next few years since it is a suspected stratospheric ozone depleter [201]. Other treatments include cold storage, hot air, vapor heat, and hot water treatments [202]. Unfortunately, most of these treatments impart surface or internal quality damage to many fruits. Recently, the use of CA and edible coatings have been investigated as alternative treatments alone or in combination with currently used methods [203–205]. Preliminary findings suggest that lowered O_2 and elevated CO_2 may contribute to fruit fly mortality [204, 205]. Fruit coatings are already approved as a disinfestation treatment for surface mites on cherimoyas and limes from South America [206].

33.8 SURFACE PREPARATION AND COATING TECHNIQUES

Edible coatings can be applied by dipping products in coating materials and then allowing excess coating to drain as it dries and solidifies [64]. This was first reported for the Florida citrus industry [8] where the fruits were submerged into a tank of emulsion coating. Commodities are then generally conveyed to a drier where water or solvent is removed, or coated items can be allowed to air-dry under ambient conditions [207]. Sometimes a porous basket can be used to drain excess coating. Some emulsion coatings are applied with a foam applicator where a foaming agent is added to the coating or compressed air is blown into the applicator tank. The agitated foam is applied to commodities as they move by on rollers and cloth flaps or brushes distribute the emulsion over the surface of the commodity [207]. Excess coating is then removed by squeegees and sometimes recirculated. This type of emulsion contains little water and, therefore, dries quite quickly, but inadequate coverage is often a problem. Edible coating can be sprayed, which is especially useful to obtain a thinner and more uniform coat or if only one part or side of a product is to be coated [64]. This is the most popular method for coating whole fruits and vegetables, especially with the development of high-pressure spray applicators and air-atomizing systems. Overhead drip emitters can also deliver coating to fruit and

brushes below. The fruit tumble over rotating brush beds that become saturated with coating from overhead spray or drip applicators. As the fruit tumble and rotate over the saturated brushes they become uniformly covered with coating [207]. A controlled drop applicator allows drops of coating to be shattered in microdrops through a spray. Free-standing films can be cast such that the thickness can be controlled by spreading or pouring. A spreader with adjustable height can be used to control the thickness of the film, which is then allowed to dry [64]. Pan coating of tablets and candies involves a pan, which is enclosed and perforated along the side panels. The coating is delivered by a pump to a spray gun(s) mounted in various parts of the pan. The coating is atomized by the spray guns [207]. Solutions of antioxidant, preservatives, or other aqueous materials can be applied by dip or spray. In most cases, fruit and vegetable products are sanitized with chlorine and/or o-phenylphenate (SOPP) and dried on brushes or with fans as much as possible prior to coating. Sanitizing solutions are covered in U.S. FDA 21 CFR 178.1010 [95].

Coating of breakfast cereal products usually involves sugar-based materials, which presents a difficult situation since sugar is hydrophilic. With minimal water as a solvent, sugar is heated to a hard candy condition and sprayed on cereal, which is further heated to fuse the sugar. Otherwise, sugar is spun into a blanket on which cereal pieces are placed prior to the application of a second blanket of sugar. The whole sugar/cereal sandwich is then compressed and dried [16].

33.9 REPORTED APPLICATIONS IN FOODS

33.9.1 Fresh Intact Fruits and Vegetables

Edible coatings have been applied to a diverse array of whole fruits and vegetables since the 1930s and 1940s [15]. Coatings of vegetable or mineral oil have been applied to tropical fruits (mango, pineapple, banana, papaya, guava, and avocado) with varying degrees of benefit in terms of extending shelf life [208–211]. Sometimes oils, such as mineral oil, are used alone to coat fruits such as tomatoes or limes, but in such cases, they remain in a liquid state as a thin film on the surface of the fruit. The purpose of coating these fruits with oils is to help them slip over equipment (lubricant), add a slight sheen, delay ripening, delay weight (water) loss, and delay yellowing in the case of limes [15, 86, 212, 213]. Use of a cellulose-based film reduced the number of viable *Salmonella montevideo* cells on the surface of tomatoes in addition to retarding the ripening process [214]. Casein-lipid coatings reduced moisture loss from citrus, apple, and zucchini [65]. Shellac, carnauba wax, and polyethylene wax retard moisture loss and add shine to apples, citrus, and other fruit [15]. Waxing of potatoes with paraffin wax did not adversely affect respiration, but it did reduce sprouting and synthesis of chlorophyll (green pigment) and solanine (toxic glycoalkaloid) [215]. The Tweens lecithin and hydroxylated lecithin surfactants, and applied films were also useful in inhibiting chlorophyll and solanine synthesis in the peel of potato tubers [216, 217]. Creation of a modified atmosphere within the coated potatoes may have inhibited greening due to an effect on the synthesis of these undesirable compounds. In contrast, lipid and hydrocolloid coatings inhibited the degreening of lemons and limes [213] probably by inhibiting chlorophyll breakdown due to a modified atmosphere. The modified atmosphere induced by coatings can also be useful in retarding ripening as demonstrated with zein or chitosan on tomato [93, 133] and cellulose on mango and tomato [169].

33.9.2 Lightly Processed Fruits and Vegetables, Dried Fruit, and Nut Products

Coating of lightly processed fruits and vegetables is a new field [79, 85, 218], whereas coatings have been reported on nut and dried fruit products since the 1940s and 1950s [219]. Casein-lipid coatings reduced moisture loss [65], and a cellulose coating inhibited surface drying and the resulting color change (whitening) of peeled carrots [47, 220, 221]. There have been several reports of coatings applied to cut apple. Dextrin coatings prevented oxidative browning of apple slices [137], while a cellulose coating with antioxidants reduced cut apple discoloration more effectively than a solution of antioxidants alone [41]. A chitosan/lauric acid coating inhibited browning of cut apple [222], a caseinate/lipid coating reduced moisture loss [70], and an alginic acid/casein–lipid coating reduced water loss and browning of cut apple [79]. A bilayer coating of polysaccharide and lipid decreased water loss, respiration, and ethylene production in cut apple [223]. Pectin coatings were used to coat almonds and reportedly held salt and antioxidants on the surface while providing a nonoily texture [39]. Coating nuts with hydrogenated oils or acetylated monoglyceride containing an antioxidant increased their shelf life by retarding development of oxidative rancidity [40, 224]. Gum arabic has also been used to coat pecans [146]. Starch (amylose) and whey protein isolate coatings were used to reduce oxidative rancidity during storage of certain products such as nuts, cereal, beans [224–227], candies, and dried fruits [224]. This can also be controlled with antioxidants such as tertiary butylhydroquinone (TBHQ) alone or in a coating, as was shown for peanuts [40]. For coated candied fruit and dates, pectin coatings reduced stickiness [39]. Acetylated monoglycerides, hydrogenated coconut oil, or confectioner's butter stabilized dried fruit pieces in cake or bread mix [228] and raisins in cereals [229, 230]. Mineral oil, beeswax, vegetable oils, and acetylated monoglycerides have also been used to reduce clumping and stickiness of raisin products [229–233]. Vegetable oil blends as coatings for dried fruit have poor flavor stability [234]. Two commercial products, Spraygum® and Sealgum® (Colloides Naturels, Inc., Bridgewater, New Jersey), are based on gum acacia and gelatin. These products have been used to coat chocolates, nuts, cheese, and pharmaceutical products. In addition, they reduced the darkening of potatoes in combination with $CaC1_2$ [34].

33.9.3 Processed Food and Animal Products

Edible coatings are also applied to processed foods to restrict the movement of moisture and gases, especially O_2. Edible coatings can be used to prevent moisture loss and absorption

or transfer between components of differing water activity [16]. Edible coatings protect some commodities, such as meat and nut products, from oxidative rancidity, fat absorption, breading loss during frying [235, 236], and oil migration from such products as chocolate using hydrocolloids [237]. Amylose coatings provided a nonsticky surface at RH <80%, prevented fat migration from cheese and chocolate products, and retained volatile flavors [224]. Nonedible wax coatings are used to encase some cheese products [89, 238]. Meat fats, vegetable oils, and acetylated monoglycerides; mono-, di-, and triglycerides; waxes; and mixtures of these components have been used to coat meats and meat products including frozen chicken pieces and pork chops [235, 239]. These coatings protected the meat products from dehydration [16]. Cornstarch-alginate coatings reduced moisture loss and improved the juiciness of coated meat products [136], while HPC films reduced moisture loss from chicken [240]. Gelatin coatings have been used to coat or wrap meats [111] and form soft capsules in the pharmaceutical industry. Casein-lipid coatings reduced moisture loss from chicken eggs [65]. Emulsions of oil, water, and sugar have been used to coat cereal products to limit the entrance of water and therefore the amount of drying required [241]. Candies are sometimes coated with chocolate for flavor and reduction of moisture loss [242] or carnauba wax to add shine and reduce stickiness [16]. Corn zein and the derivatives MC and HPMC are oil repellent, and reduced oil absorption for potato balls or meat when included in batters or when applied as coatings [123, 240, 243]. These compounds also improved adhesion of batters or coatings to food products [122]. Coatings can delay the uptake of liquid by dry cereal products so that they last longer in milk before becoming soggy [225]. Such coatings often have a sugar base to impart a sweet flavor [16].

Heterogeneous products of differing water activities, such as ice cream cones with ice cream, or frozen filled pies where a dry material is in contact with a moist filling, have shown benefit from a barrier film between the two components. Such films had a polysaccharide component in a bilayer system with palmitic/stearic acid or saturated C_{16} and C_{18} fatty acids and beeswax [72, 74]. For example, a lipid-cellulose coating showed promise as a barrier to internal moisture migration between two components of a bread and tomato sauce product [71, 72].

33.10 LEGAL ASPECTS

Discussion of the various coating components discussed thus far in this review reflects rulings by the U.S. FDA. The United States allows coating of fresh produce with restrictions as to what can be used as a coating material or ingredient and, in some cases, the type of produce (usually dependent on whether the coated fruit or vegetable peel is normally consumed or not, i.e., apple versus avocado). Other countries, however, do not allow the coating of fruits and vegetables at all. For example, a ban has been reported in Norway on imports of waxed fruit. The Norwegian policy is that foods making significant nutritional contributions to the diet should be as free from additives as possible [244]. The German government tried to ban waxed apples, but the European Commission overruled it with a directive that allows apples, pears, and some other products to be imported from countries where waxing or coating of fruit is legal as long as the formulations contain beeswax, candelilla wax, carnauba wax, and/or shellac. Japan accepts shellac- and carnauba wax-coated citrus from the United States, but will not accept fruit coated with petroleum-based waxes that are legal in the United States for certain fruit, including citrus. The use of the cellulose derivative HPC is allowed in coating formulations in the United States, but not in New Zealand. Other countries such as Thailand and Australia are evaluating the applicability and acceptability of various coating film formers and additives [245, 246].

The U.S. FDA ruled in 1993 that all waxed fruit must be subjected to ingredient labeling regulations at the retail level [247]. Retailers are permitted to use collective names for coating ingredients, however, they should be prominently visible in the retail area where the commodity is displayed. The label or sign should indicate that the commodity is waxed or coated with food-grade animal-, vegetable-, petroleum-, beeswax-, and or shellac-based wax or resin to maintain freshness [246]. The United Kingdom proposed a similar labeling scheme requiring labels indicating all postharvest treatments applied to fresh produce [247]. Processed foods in the United States are required to contain a label on the package listing all additives. Coatings, preservatives, and antioxidants are all considered to be additives and, therefore, must be listed as individual ingredients. Postharvest use of fungicides, however, is not required to be labeled in the United States.

33.11 CONSUMER ATTITUDES

Consumers are becoming increasingly educated about health and nutrition, and are concerned about what goes on or into their food. Some consumer groups are concerned with the waxes and coatings themselves, and others fear that, in the case of fresh produce, harmful pesticide residues may be sealed inside the fruits by the coatings. There is also the issue of the use of animal products in coatings. Although there is a federal law in the United States about labeling coated produce, it is not always enforced. This presents a problem for Muslims, vegetarians, and Orthodox Jews, who have concerns about animal-derived products, and for those with certain protein allergies and intolerances. Enforcement of the regulations described in the previous section requiring a conspicuous sign would allow consumers to make an informed choice. Nevertheless, the main reason for coating produce such as apples and citrus is cosmetic. The fact remains that coated (shiny) fruits sell better than uncoated ones [248]. Some consumer groups want postharvest fungicide treatments to be listed as well as coating types [249].

33.12 CONCLUSION

In conclusion, edible coatings alone or as carriers of useful additives serve many functions for all types of food products.

They improve the external and internal quality characteristics of diverse commodities. Coatings can reduce dehydration and oxidation as well as the resulting undesirable changes in color, flavor, and texture. Waxes and other coatings delay ripening and senescence of fresh produce and can increase the microbial stability of lightly processed fruits, vegetables, and some processed products. Coatings show promise as environmentally friendly quarantine treatments. Most coating materials are produced from renewable, edible resources and can even be manufactured from waste products that represent disposal problems for other industries.

34 Food and Bioactive Encapsulation

Fereidoon Shahidi, Priyatharini Ambigaipalan, Abrehem Abad, and Ronald B. Pegg

CONTENTS

34.1 INTRODUCTION

Encapsulation is an important process for the protection of food components and is widely applicable in all food sectors. At present, encapsulation is of growing interest in food processing and preservation. Various encapsulation techniques (spray drying, spray cooling, freeze drying, electrohydrodynamic techniques, fluidized bed coating, extrusion, coacervation, liposome, and emulsification) address some of the challenges to incorporating food ingredients, antioxidants, lipids, proteins, carbohydrate, minerals, vitamins, and bioactive compounds in powder form in food products. Encapsulation achieves excellent preservation, stabilization, and controlled release of bioactive compounds. Controlled release of bioactive ingredients at the right time and right place could also be provided by encapsulation. Encapsulation improves the effectiveness of food additives and enhances the shelf life of food, in addition to lowering the cost of the food products.

Ingredients are incorporated into the foods we eat for a multitude of reasons. For example, antimicrobial agents are added in an effort to ward off the early onset of microbial growth, antioxidants are used to prolong the shelf life of lipid-containing foods by protecting triacylglycerols and phospholipids against oxidative degradation, flavoring and coloring agents are added for the purpose of enhancing the sensory characteristics of the food, while various carbohydrate-based additives are employed to improve the rheological and textural properties of the product in question [1]. Encapsulation technologies have been increasingly attracting the attention of food ingredient suppliers and food product manufacturers as a means of achieving brand differentiation and enhancing product value. Microencapsulated products can add that extra zing, mask the taste of nutrients, alleviate processing problems, and increase the shelf life of food products [2]. Within the past decade, the explosion of functional foods and nutraceuticals globally and particularly in the North American market has in effect created a new type of additive for foods. These functional food ingredients, that provide a physiological benefit and/or reduce the risk of chronic disease beyond their basic nutritional functions, have led to the development of innovative product lines and functional food products. The ever-increasing health-conscious consumer is very much interested in the beneficial properties of functional food ingredients and nutraceuticals. Hence, the encapsulation (i.e., microencapsulation and nanoencapsulation) and controlled-release technologies, as a means to better deliver bioactives and nutrients in both wet and dry

applications, has grown both in scope and potential. Presently, there is a market interest in omega-3 fatty acids, phytosterols/stanols for cholesterol control, probiotics, prebiotics and synbiotics for gut health, vitamins and minerals for fortification/augmentation of food, bioactive peptides for controlling high blood pressure, amino acids and proteins as key ingredients in sports and energy foods and drinks, polyphenolic antioxidants that are promoted for general health benefits, and a number of lecithin products that are marketed for brain and memory function as well as liver support and cholesterol control [3]. According to the analyst from Frost and Sullivan's Research Service [4], "the growing functional food market is the major driving force behind microencapsulation innovation. Microencapsulation offers food companies a viable means of penetrating this lucrative growth sector because it has the ability to mask the taste associated with some of these ingredients.

Bioactive food components are prone to degradation or inactivation. Numerous bioactive food components can benefit from encapsulation due to protection and/ or prevention of their degradation until the product is delivered to the desired sites. These bioactive components include antioxidants, lipids, fatty acids, peptides, minerals, and vitamins but also live cells such as probiotics [5–8]. Many encapsulation procedures have been proposed but none could be considered as the universal one for all bioactive food components. This is caused by the fact that individual bioactive food components have their own characteristic molecular structures [9]. Nevertheless, they show extraordinary contrasts in solubility, molecular weight, and polarity, among others, which suggest that different encapsulation approaches must be applied in order to meet the specific molecular and physicochemical requirements for a specific bioactive component [9, 10]. Moreover, the compatibility of the bioactives is by all accounts not the only prerequisite an encapsulation procedure needs, but it ought to have characteristics to withstand environmental impacts [9]. The majority of bioactive compounds that have positive effects on human well-being are mostly derived from animal sources and the plant kingdom [11]. Because of the wide availability of encapsulated ingredients, many food products or functional food ingredients, whose development was thought to be technically difficult, are now possible. Such ingredients are products of a process in which the active ingredient is enveloped in a coating or "capsule," thereby conferring many useful properties to or eliminating undesirable properties from the original ingredient.

The real obstacle to the efficacious delivery of bioactive food components is not just hazardous events that occur during passage through the gastrointestinal tract, but the injurious circumstances during storage of the product that may affect the vehicle used for the bioactive components. It is therefore imperative to protect the bioactive component by using encapsulation procedures during the storage, transport, and the entire period of processing [12]. The most important requirement is that the encapsulation system protects the bioactive component from chemical degradation such as hydrolysis and oxidation to keep them fully functional [13]. Protection and controlled delivery of bioactive compounds at the right place and the right time can be achieved by encapsulation [14]. This chapter will focus on the types of bioactive components and highlight the challenges to delivery of bioactives, followed by a detailed explanation for the majority of materials used for encapsulation of food. Subsequently, it discusses different encapsulation techniques. Finally, the use of encapsulation in food applications is considered.

34.1.1 Purpose of Encapsulation

Encapsulation is a procedure that entraps one material (active agent) into another (wall material) in order to create particles in the micrometer (microencapsulation), millimeter, or nanometer (nanoencapsulation) scale [15, 16]. The encapsulated material (packaged) may also be called the fill, active core, payload phase, or internal material. On the other hand, the substance that encapsulates the active agent (packaging) is known as the coating, shell, membrane, capsule, external phase, carrier material, or matrix, and can be made of proteins, sugars, gums, natural and modified polysaccharides, synthetic polymers, or lipids [12, 17, 18]. Encapsulation technology has been used in food processing to provide an effective barrier against natural environmental parameters such as light, oxygen, and free radicals, among others [19]. Several types of encapsulants (matrix, reservoir, and coated matrix) have been characterized (Figure 34.1) as specified by Ray, Raychaudhuri, and Chakraborty [20].

The science of encapsulation deals with the manufacture, analytical evaluation, and application of encapsulated products. Despite the passage of time, the technology that has been developed for the food industry remains relatively unsophisticated compared to many other fields of application. This is a consequence of the limitations imposed on the food industry for the use of edible, low-cost ingredients and processing. Nevertheless, due to health-conscious consumers and the fashionable trend toward functional foods and nutraceuticals/natural health products, it is only now that manufacturers have been exploring new encapsulation delivery methods to ensure the bioavailability of efficacious quantities of desired functional food ingredients. Nanotechnology is one of the recent developments in which, for example, liquid designed for clear beverages, using small particle size nanocapsules has been considered. In nanoencapsulation, products can be reduced to a size of 30 nm and encapsulated in food compounds; the process is essentially self-assembly once the base encapsulation

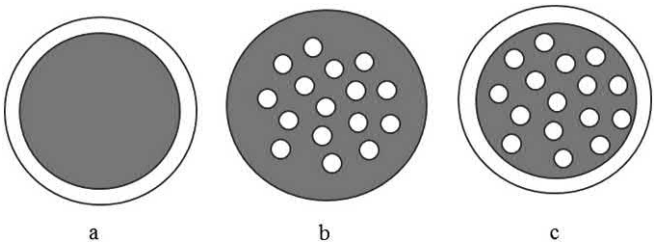

FIGURE 34.1 Types of encapsulates: (a) reservoir, (b) matrix, (c) coated matrix. (From Ray et al. [20].)

material is finalized. In effect, nanotechnology provides an improved activity level and solubilized ingredients, for example, for clear beverages, that previously could not be used.

King [21] notes that it is important for food scientists to distinguish between encapsulation versus entrapment of food ingredients. He states that encapsulation may be defined as a process of forming a continuous thin coating around encapsulants (i.e., solid particles, droplets of liquids or gas cells), which are wholly contained within the capsule wall as a core of encapsulated material. On the other hand, entrapment refers to the trapping of encapsulants within or throughout a matrix (e.g., gel, crystal), but a small percentage of the entrapped ingredients will normally be exposed at the particle surface, whereas this would not be so for the encapsulated product. As mentioned, the entrapped material is commonly a liquid but could be a solid particle or gas, and is referred to by various names such as core material, payload, actives, fill, or internal phase [22]. The material that forms the coating is referred to as the wall material, capsule, membrane, carrier, shell, or coating.

The food industry applies encapsulation for a number of reasons [23–25]:

(i) Encapsulation/entrapment can protect the core material from degradation by reducing its reactivity toward the outside environment (e.g., heat, moisture, air, and light).
(ii) Evaporation or transfer rate of the core material to the outside environment is decreased/retarded.
(iii) The physical characteristics of the original material can be modified and made easier to handle. For example, (a) a liquid component can be converted into solid particles; (b) lumping can be prevented; (c) the core material can be distributed more uniformly throughout a mix by giving it a size and outside surface; (d) hygroscopicity can be reduced; (e) flow and compression properties can be improved; (f) dustiness can be reduced; and (g) density can be modified.
(iv) The product can be designed to either release slowly over time or to release at a certain point (i.e., to control the release of the core material so as to achieve the proper delay until the right stimulus).
(v) The taste of the core material can be masked.
(vi) Encapsulation can dilute the core material when it is needed only in very small amounts, but to achieve uniform dispersion in the host material.
(vii) Encapsulation can be used to separate reactive components within a mixture, which would react with one another.

34.1.2 Challenges to Delivery of Bioactive Compounds

Most food bioactives, especially lipids, have very low water-solubility. For example, ω-3 oils, oil-soluble vitamins, phytosterols, and the like are difficult to directly incorporate in aqueous-based foods, such as sauces, beverages, yogurts, desserts, and dressings. Instead, they should be incorporated into delivery systems via encapsulation or emulsification [26]. Some bioactive lipids, such as carotenoids and phytosterols as well as the compound curcumin, are crystalline at room temperature and therefore difficult to be directly incorporated into foods. This is because they tend to form sediments or give an unpleasant appearance that might be overcome by using high temperatures; however, heating may adversely impact the stability or sensory properties of products [8, 27].

A number of important lipophilic bioactives such as carotenoids, curcumin, and ω-3 oils are prone to chemical degradation during storage or after ingestion [28–31]. The rate and the extent of chemical degradation depend on the nature of the bioactive compound being considered and environmental conditions such as temperature, pH, oxygen, light, and the presence of prooxidants. Therefore, it is necessary to develop delivery systems that can protect these bioactives from chemical degradation [8, 26]. Many of the lipophilic bioactive components have variable and/or low bioavailability within the human gastrointestinal tract. This might occur for a number of reasons, including transformation in the gastrointestinal fluids, poor absorption, or low bioaccessibility [26, 32]. In this case, nanoscale delivery systems might be prepared in order to modulate these processes and to increase bioavailability [26]. Some of the lipophilic bioactives might physically interact with other components in the system leading to instability. Therefore, it might be necessary to use a nanoscale delivery system to isolate one component from others in the system in order to make them unavailable for interaction with each other [26]. Furthermore, lipids must maintain their bioactivity within the human body before being delivered to the desired site. For instance, they might have to resist enzyme activity and high acidity of the stomach [8].

Bioactive proteins are also quite sensitive to degradation. These proteins have to reach the small bowel in an intact conformation in order to exert a beneficial health impact and to inhibit their biodegradation in the gastrointestinal tract. However, it must not always be interpreted that all food proteins should be encapsulated. Most of the proteins and peptides also require hydrolysis in the small intestine and stomach in order to release specific amino acids or bioactive peptides [7, 8, 33, 34].

In the case of bioactive carbohydrates, the main classes that need to be delivered into foods are dietary fibers. Soluble, nondigestible carbohydrates isolated from their natural environment and converted to food ingredients are added into food products, instead of fibers that are naturally present in whole foods, such as fruits, vegetables, and grains. This is because some isolated soluble fibers are bioactive food components and, as such, might need to be encapsulated in delivery systems. A well-designed structured delivery system might be capable of increasing the total amount of dietary fiber in a food without impacting its physicochemical or organoleptic properties [8].

Probiotic bacteria are at present the driving force in the design of functional foods and maintaining their functional impact for supporting health. Probiotic bacteria are defined as live microorganisms that when administered in sufficient quantities confer a beneficial physiological impact in the host,

as is their use in dairy products [13]. Application of encapsulation to living probiotics is limited; the size of probiotics (1–5 μm) excludes some of their nanotechnological use in encapsulation. Hence, we usually refer to microencapsulation, rather than nanoencapsulation, when discussing the encapsulation of probiotics [7, 8, 10]. Microencapsulation of many types of probiotics might be mandatory for achieving their promised health benefits [8]. Though several health benefits of probiotics in dairy products have been described, it is not easy to allow long-term survival of probiotics in traditional dairy and fermented products [35]. Probiotics are influenced by several factors such as difference in pH including the postacidification in some fermented products [10, 35]. In addition, the oxygen toxicity during processing and packaging has been shown to be detrimental for the survival of probiotics [10].

34.1.3 Benefits and Types of Microcapsules

Microencapsulation is defined as the technology of packaging solids, liquids, or gaseous materials into miniature, sealed capsules that can release their contents at controlled rates under specific conditions [4, 36, 37]. The small packages, called "microcapsules," may range from submicron to several millimeters in size and have a multitude of different shapes, depending on the materials and methods employed to prepare them. Generally speaking, the microcapsule has the ability to modify and improve the apparent shape and properties of a substance. More specifically, the microcapsule has the capacity to preserve a substance in the finely divided state and to release it when the occasion demands.

Microcapsules offer the food processor a means to protect sensitive food components, ensure against nutritional/nutrient loss of functional food ingredients, utilize otherwise sensitive food-grade materials, incorporate unusual or time-release mechanisms to a formulation, mask or preserve flavors and aromas, and transform liquids into easily handleable solid ingredients [38]. The unusual properties afforded by encapsulated ingredients offer the food technologist greater flexibility and control in developing functional foods that are more flavorful, nutritious, and may offer physiological benefits, such as a reduction in the likelihood of developing a chronic disease, beyond basic nutritional functions, in order to meet the expectations of today's health-conscious consumers. Microencapsulation technology, however, is sometimes considered more of an art than science. In *Microcapsule Processing and Technology*, Asajo Kondo [39] states, "Microencapsulation is like the work of a clothing designer. He selects the pattern, cuts the cloth, and sews the garment in due consideration of the desires and age of his customer, plus the locale and climate where the garment is to be worn. By analogy, in microencapsulation, capsules are designed and prepared to meet all the requirements in due consideration of the core material, intended use of the product, and the environment of storage."

Various properties of microcapsules may be changed to suit specific ingredient applications, and these include composition, mechanism of release, particle size, final physical form, cost, and regulations. Before considering the properties desired in encapsulated products, the purpose of encapsulation must be clear. In designing the encapsulation process, the following questions should be taken into consideration: (i) What functionality should the encapsulated ingredients provide to the final product? (ii) What type of food-grade coating material should be selected? (iii) What processing conditions must the encapsulated ingredient survive before releasing its content? (iv) What is the optimum concentration of the active material in the microcapsule? (v) By what mechanism will the ingredient be released from the microcapsule? (vi) What are the particle size, density, and stability requirements for the encapsulated ingredient? (vii) What are the cost constraints of the encapsulated ingredient? (viii) Will the encapsulated ingredient meet regulations/standards to be considered as a functional food ingredient?

The architecture of microcapsules is generally divided into several arbitrary and overlapping classifications. One such classification is known as matrix encapsulation. This is the simplest structure in which a sphere is surrounded by a wall or membrane of uniform thickness, resembling that of a hen's egg. In this design, the core material is buried to varying depths inside the shell. This microcapsule has been termed as a single-particle structure. In addition to this structure, it is also possible to design microcapsules that have several distinct cores within the same capsule, or more commonly, numerous core particles embedded in a continuous matrix of wall material. This type of design is termed the aggregate structure. The particles in the aggregate structure need not be all of the same material. In the case of aggregate capsule structures, a degree of particle size control can be achieved. This technique has been accomplished with numerous materials to improve size distribution properties [40]. Another well-known design for a microcapsule is to form a multiwalled structure, in which the different concentric wall layers can have the same or quite different compositions. In this case, the multiple walls are placed around a core to achieve multiple purposes related to the manufacture of the capsules, their subsequent storage, and controlled release. This design is particularly important for controlled-release encapsulation systems using nanospheres containing an active ingredient. These nanospheres can be encapsulated with other ingredients, such as flavors, cooling or heating agents, or sweeteners, within a microsphere. Upon exposure to water or pH the microsphere releases its contents, and over an extended period of time the nanosphere releases the encapsulated active ingredient via molecular diffusion and possibly by enzymatic degradation. The surface properties of the nanospheres can be altered to be bioadhesive or charged negatively or positively depending on the intended target site [41].

The theory and application of microcapsular delivery systems encompass a variety of engineering techniques and scientific disciplines, thus making it difficult to present a systematic view of the total effort being dispensed in this field. This contribution summarizes the art of microencapsulation as it relates to the food industry and presents current information on the process of encapsulation. To accomplish this, a comprehensive examination of various encapsulating matrices currently utilized by the food industry is included. In

addition to their general description, the advantages and disadvantages they offer as an encapsulating agent when forming microcapsules is discussed. An in-depth examination of the various microencapsulation techniques follows. This includes the processes of spray drying, spray cooling and spray chilling, fluidized bed coating, extrusion, centrifugal extrusion, lyophilization, coacervation, centrifugal suspension separation, cocrystallization, liposome entrapment, interfacial polymerization, inclusion complexation, and nanoencapsulation. Afterward, encapsulated ingredients and their application to various food systems are considered with reference to some of their common uses and growing importance to the functional food and nutraceutical arena. Finally, an examination of what is meant by controlled release and some of the mechanisms surrounding it are discussed.

34.2 ENCAPSULATION MATRIX

In order to encapsulate a functional food ingredient, the first requirement is the selection of an appropriate coating material referred to as the encapsulating matrix. As indicated earlier, many researchers have referred to the coating material as the shell, wall material, or encapsulating agent [42]. Coating substances, which are basically film-forming materials, can be selected from a wide variety of natural or synthetic polymers, depending upon the material to be coated and the characteristics desired in the final microcapsules. It is the composition of the coating material that is the main determinant of the functional properties of the microcapsule and of how it may be used to improve the performance of a particular ingredient. An ideal coating material should have the following properties: (i) good rheological properties at high concentrations and be easy to work with during the process of encapsulation; (ii) a capability to disperse or emulsify the active material and to stabilize the emulsion so produced; (iii) nonreactivity with the material to be encapsulated both during processing and upon prolonged storage; (iv) a capability to seal and hold the active material within its structure during processing and storage; (v) a complete release of the solvent or other materials, which are used during the process of encapsulation, under drying, or other desolventization conditions; (vi) a capability to offer maximum protection to the active material against environmental conditions (e.g., oxygen, heat, light, and humidity); (vii) solubility in solvents acceptable by the food industry (e.g., water, ethanol); (viii) chemical nonreactivity with the active material; (ix) standards that meet specified or desired solubility properties of the capsules, and release properties of the active material from the capsule; and (x) low cost. Because no single coating material meets all of the aforementioned criteria, in practice, coating materials are employed either in combination or with modifiers such as oxygen scavengers, antioxidants, chelating agents, and surfactants. Many substances can be encapsulated such as liquids, solids, or gases of different origins, types, and properties. However, only a limited number of substances have been certified for food applications as generally recognized as safe (GRAS) materials. It is worth noting that the regulations for food additives are stricter than for pharmaceuticals or cosmetics. As a result, some compounds that are widely accepted for drug encapsulation are not approved for use in the food industry [43]. Some commonly used coating materials are presented in Table 34.1 and discussed in detail next.

TABLE 34.1
Coating Materials for Encapsulation of Food

Origin	Carbohydrate Polymer	Protein	Lipid
Plant	Starch – Derivatives (maltodextrins, corn syrup solids, dextran, modified starch, sucrose) Cellulose – Derivatives Plant extracts – Galactomannans – Soluble soybean Plant exudates – Gum arabic – Gum karaya – Mesquite gum Polysaccharide	Gluten (corn)	Fatty acids/ alcohols Glycerides Waxes Phospholipids
Microbial/ animal	Xanthan Dextran Gellan Chitosan	Whey proteins Caseins Gelatin	Fatty acids/ alcohols Waxes Glycerides Phospholipids
Marine	Alginate Carrageenan

34.2.1 Carbohydrates

Carbohydrates comprise about 90% of the dry mass of all biomass and about 90% thereof are polysaccharide polymers. These natural and copolymers are composed of sugar derivatives and/or residues. Many of the native polysaccharides contain a small percentage of peptides and proteins remaining from their biosynthesis. However, these are generally removed during the processing [43]. The ability of carbohydrates to absorb and adsorb volatiles from the environment or to retain them tenaciously during the drying process has important implications and applications for flavor encapsulation. In fact, carbohydrates are the most commonly used coating material in flavor encapsulation processes.

The mechanisms by which carbohydrates retain volatiles during processing such as freeze drying and spray drying as well as extrusion are not fully understood but most probably involve physical interactions [44]. It has been postulated that the formation of microregions during freeze drying, which contain highly concentrated solutions of carbohydrate and volatiles, results in molecular association of the carbohydrate through hydrogen bonding. This in turn creates a stable network and traps the volatiles [45]. For example, it has been

reported that loss of volatiles from lactose during freeze drying increases when the material changes from an amorphous solid to a crystalline one [46]. Formation of cracks in the microregion structure might have accounted for this [44].

The two major processes used for encapsulation of food flavorings are spray drying and extrusion [47], both of which depend primarily on carbohydrates used for the encapsulation matrix [48]. While one can find examples of encapsulation of fats (e.g., spray chilling), proteins (gelatine), and inorganics (fused silica), carbohydrates constitute the majority of the market of encapsulation matrices. While many compounds are classified as carbohydrates, the discussion here does not include all such compounds. Some are discussed under other headings and classifications. Figure 34.2 presents the classification of natural food-grade materials with their origin and Figure 34.3 presents the relevant structural information [43].

34.2.1.1 Modified Starch

Starch, the reserve polysaccharide of most plants, is one of the most naturally abundant polymers found on earth. It is extracted from numerous food sources including tubers (potato, tapioca, arrowroot, and sweet potato) and cereals (corn, waxy maize, wheat, and rice). It is the most commonly used food hydrocolloid and this is partly because of the wide range of functional properties it can provide in its native and modified forms, and partly because of its low cost relative to alternatives [49].

Starch comprises polymers of glucose units linked together primarily by α-(1⟶4) bonds and secondarily by α-(1⟶6) bonds. In the native state, starch exists as granules that are insoluble in cold water due to hydrogen bonding of the polymer chains. The two polymer types found within the granules are amylose, a straight-chain polymer, and amylopectin, a branched-chain polymer. With its long, straight chains, amylose is known for forming strong, flexible films. On the other hand, due to its extensive branching, amylopectin is not a strong film former, but is noted for clarity and stability when forming gels and may show a slightly greater tendency toward absorption or binding of flavors. The content of amylose and amylopectin in starch granules varies depending upon the source: typically starch contains 18% to 30% amylose, except for waxy corn types, which are virtually all amylopectin [49]. When mixed with water and provided with enough heat, starch granules swell sufficiently as hydrogen bonds are broken to form pastes that can produce strong films. For most encapsulation processes, however, the viscosity of native starch is too high.

Starch presents an interesting situation with regard to flavor binding. Because the amylose fraction forms helical structures, starch can entrap flavor molecules, thereby producing

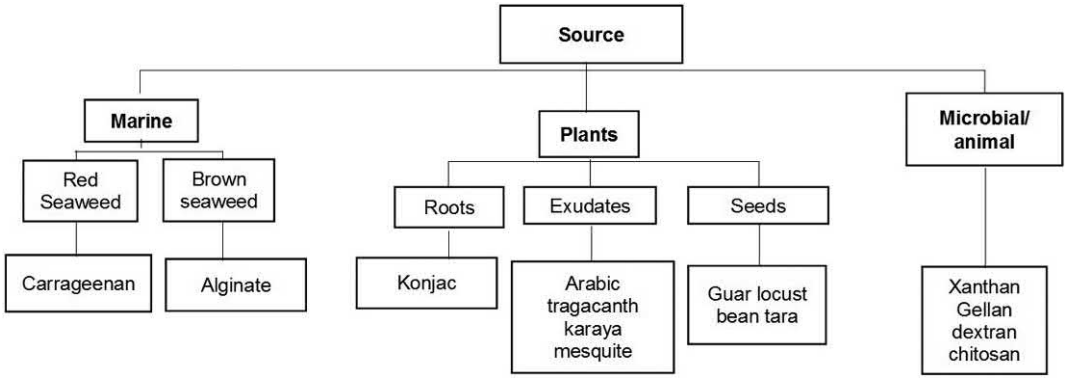

FIGURE 34.2 Classification of natural carbohydrate polymers.

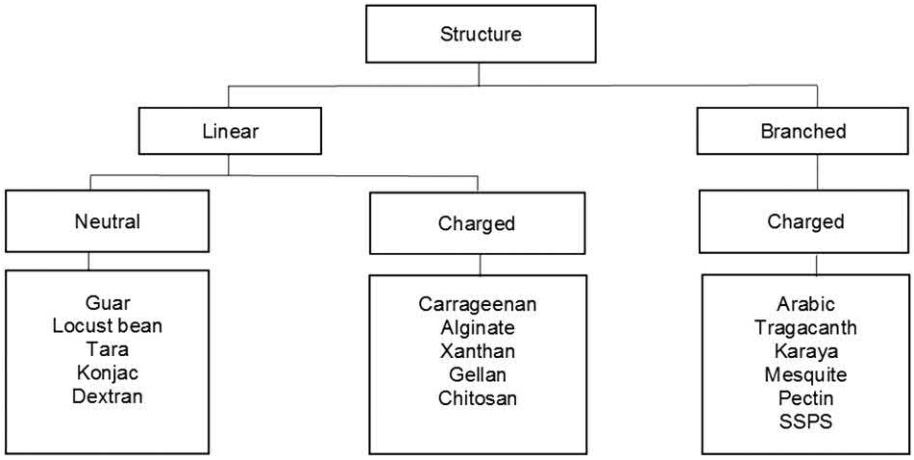

FIGURE 34.3 Classification of carbohydrate polymers related to structural characteristics. (From Wandrey et al. [43].)

very stable complexes [50–52]. However, starch is hydrophilic and hydrolysates derived from it afford virtually no emulsification properties to the compound being encapsulated.

Both physical and chemical modifications of starch are known. Many functional derivatives of starch are marketed, including oxidized, cross-linked, acetylated, partially hydrolyzed, and hydroxypropylated starch. The main reason for starch modification is to change the structure and impact the hydrogen bonding in a controllable manner in order to promote and extend the industrial applicability of such commodities [53]. Cross-linking replaces a few hydrogen bonds between chains in starch by covalent bonds, thus swelling is inhibited. The shelf life can be improved and retrogradation can be prevented. The starches modified in this way show better tolerance to temperature fluctuations [43]. In its natural state, starch is cold-water insoluble [49]. In dextrinization, starch is heated in the dry granular form with agitation, generally in the presence of an acid such as hydrochloric or sulphuric. The term *dextrinization* refers to the reduction in size of the starch molecule to smaller fractions or dextrins. Partial hydrolysis of starch granules ensues as well as repolymerization to form more highly branched polymers. The extent of this process can be varied based on time, temperature and pH conditions to yield products with different solubility and viscosity characteristics. Dextrins have increased cold-water solubility and lower solution viscosity than gelatinized native starch. If heated too long the products become darker and stronger reaction flavors are noted. Unfortunately, these strong color and flavor characteristics and a lack of lipophilic emulsifying qualities make dextrins less than ideal for encapsulation, especially for oil-based products. Dextrin formulations could be prepared at higher concentrations than the unmodified starch yielding films with higher proportions of solids that dry faster and are thicker. For example, yellow corn dextrin is used to encapsulate oils and water-insoluble flavors by spray drying [43].

The lack of emulsification properties of native starch creates two major problems. The first is that poor flavor retention results. The fineness of the infeed emulsion has a strong influence on determining the extent of flavor retention during drying. The second problem relates to the stability of the flavor emulsion once reconstituted in the final product. If the carrier provides no emulsification to the flavor, then the flavor rapidly separates from the product and forms a ring at the top. For a compound to function as an emulsifier, it must contain both lipophilic and hydrophilic groups. To overcome this problem, starches can be modified chemically to change their functional characteristics. For example, the US Food and Drug Administration has approved the reaction of starch with 1-octenylsuccinic anhydride to form a modified starch containing both hydrophobic and hydrophilic groups. The level of substitution, usually in the range of 0.02%, results in a product that is vastly different from that of the native starch. The addition of lipophilic moieties along the starch polymer permits the formation of emulsions with tight alignment of the polymer around an oil droplet. This stabilization is extremely important for encapsulation of lipids and lipid-containing products. Modified starch provides excellent retention of volatiles during spray drying and can be used at a higher infeed solids level than gum acacia (also known as gum arabic). While gum acacia is generally limited to use at about 35% level of infeed solids, modified starch can typically be used at levels approaching 50% [48]. The high solids level helps to reduce the loss of encapsulated ingredients and increases spray dryer throughput.

The emulsification properties of lipophilic starches, as well as oil retention in the spray dried powders, are reported to be equal to or greater than that of gum acacia [54, 55]. Modified starch also excels in promoting emulsion stability. One means of doing so is to produce small particle size droplets. Solutions of gum acacia produced an average emulsion droplet size of about 3 μm, and modified starch gave droplets of less than 2 μm. The emulsions made with modified starch were physically more stable than those made with the standard gum acacia [47]. Reineccius [48] pointed out some disadvantages of modified starches. For example, they are not considered natural for labeling purposes and often have an undesirable off-flavor and may not afford good protection to oxidizable flavorings.

34.2.1.2 Maltodextrins and Corn Syrup Solids

Maltodextrins, $(C_6H_{12}O_5)_nH_2O$, are nonsweet nutritive polysaccharides consisting of α-(1⟶β4)-linked D-glucose units. However, in order to be termed maltodextrin, they must possess a reducing sugar content or dextrose equivalence (DE) of less than 20. Maltodextrins are prepared as white powders or concentrated solutions by partial hydrolysis of corn starch with safe and suitable acids or enzymes. If the DE equals or exceeds 20, they are referred to as corn syrup solids. The DE, which is a percentage, is a measure of the reducing power of a sample compared to an equal weight of dextrose. Common designations of maltodextrins are 5, 10, 15, and 18 DE, while commercial corn syrup solids have 20, 25, 36, and 42 DE [56]. Products with a DE greater than 42 cannot be easily dried and hence are sold only as concentrates/syrups. Because maltodextrins and corn syrup solids are so closely related to one another in terms of their physical and chemical properties, as well as their applicability to food ingredient encapsulation, they will be discussed jointly. A flow diagram for the production of maltodextrins and corn syrup solids from corn starch is presented in Figure 34.4.

In the production of maltodextrins and corn syrup solids, starch is only partially hydrolyzed by acid or enzymes; thus, the resulting products are heterogeneous mixtures of various chain-length glucose polymers. The higher the DE, the higher the concentration of product that can be put into solution. In spray dried encapsulations, increased levels of soluble solids at a low viscosity is a major factor in the efficiency of production. In spray dried encapsulation of citrus oils, Anandaraman and Reineccius [57] reported that the higher the DE of the corn syrup solids used, the longer the stability of the encapsulated oil. Bangs and Reineccius [58] found intermediate or lower DE products to be more efficient for spray dried encapsulation of volatile artificial flavor compounds. It was postulated that a

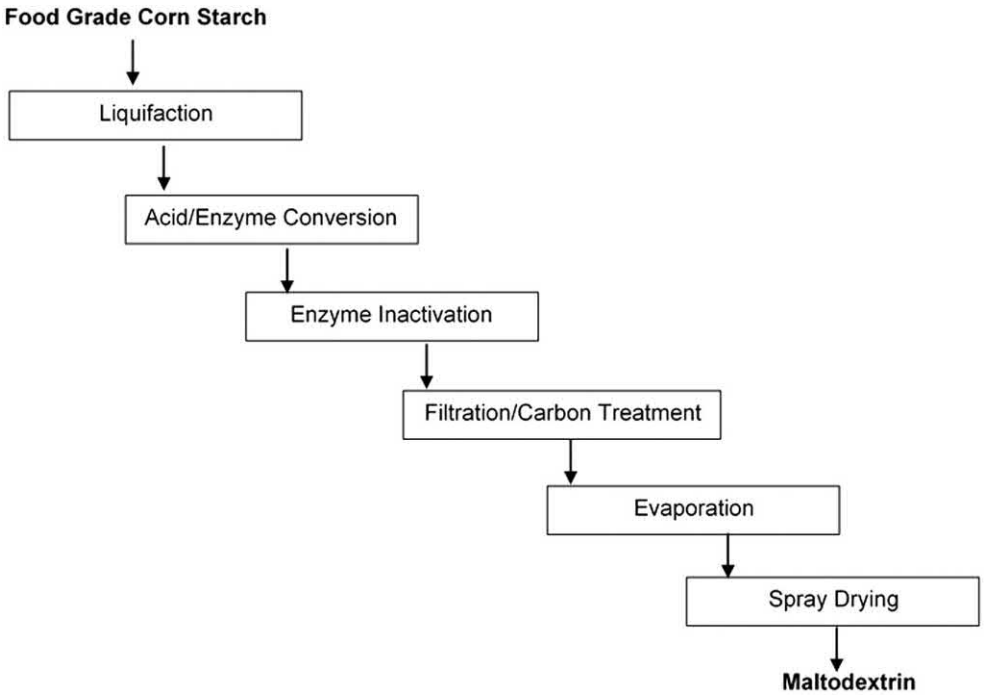

FIGURE 34.4 Flow diagram for the production of maltodextrin and corn syrup solids from corn starch.

balanced polymer length might aid in trapping the volatiles as the surface of the droplet dries.

These hydrolyzed starches offer the advantages of being relatively inexpensive (approximately one third that of modified starches), bland in flavor, and low in viscosity at high solids content. However, the major problem with these products is the lack of emulsification properties [59]. Since most active materials (especially the flavors) are insoluble in aqueous solutions and thus exist as emulsions, emulsion stability is viewed as an important consideration when selecting a coating material. Maltodextrins and corn syrup solids lack lipophilic characteristics and have virtually no emulsion-stabilizing effect on water-insoluble components [48]. It is also found that maltodextrins and corn syrup solids do not result in good retention of volatile compounds during the spray drying process. Corn syrup solids typically perform more poorly. Retention often ranges between 65% and 80% [48]. The retention capacity changes significantly with the difference of the DE values. Raja et al. [60] investigated the use of maltodextrins with varying DE values for encapsulating cardamom oil. The reason for the poor retention of volatiles by maltodextrins and corn syrup solids was believed to be due to their poor film-forming capabilities (*nota bene*, this is why they are sometimes referred to as carriers and not encapsulators). The wet encapsulation matrix must form a film around the droplets of active material in order to effectively retain them during the drying process and water removal. It is considered that since maltodextrins and corn syrup solids have no emulsification properties, they produce coarse emulsions and therefore result in poor flavor retention during drying [61].

Maltodextrins and corn syrup solids vary greatly in protecting encapsulated ingredients from oxidation. There is a strong dependence of associative stability on DE of the hydrolyzed starch. The encapsulated product with the highest DE is extremely stable and would have a shelf life of years without use of an antioxidant [57]. Several factors have been attributed to the outstanding protection afforded by high-DE coating materials. It has been considered that the higher-DE systems are less permeable to oxygen and therefore offer better protection to encapsulated ingredients [48]. One should also keep in mind that the presence of glucose in the encapsulation system has a considerable effect on the antioxidative properties.

34.2.1.3 Cyclodextrins

Cyclodextrins are chemically and physically stable molecules formed by enzymatic modification of starch. They have the ability to form complexes with a wide variety of organic compounds within their ringed structure, most notably flavor compounds [62]. The ability of these unusual molecules to form inclusion complexes, which can change the physical and chemical properties of guest molecules, offers a variety of potential uses to the food industry. Although cyclodextrins have been studied for a century, and their ability to form inclusion complexes has been recognized for at least 50 years, they were not utilized for food applications until the 1970s when Japan and Hungary began producing them commercially.

Cyclodextrins were discovered in 1891 when Villiers reported their appearance in rotting potatoes. In 1904, Schardinger characterized them as cyclic oligosaccharides and identified *Bacillus macerans* as the bacterium that produced cyclodextrin glycosyltransferase (CGTase), the enzyme responsible for the generation of cyclodextrins from starch. Because of Schardinger's studies, cyclodextrins were initially referred to as Schardinger dextrins, but of more significance

was the fact that his work set the direction for future research, pointing it toward a study of the structure of cyclodextrins and their commercial production. French [63] has provided a detailed history of the development of cyclodextrins up to 1956. Cyclodextrins are completely metabolized by colon microflora because they are not absorbed in the upper gastrointestinal tract [64].

Today, cyclodextrins are produced from starch by selected microorganisms such as *Bacillus macerans* and *Bacillus circulans*, which have CGTase activity. After cleavage of starch by the enzyme, the ends are joined to form circular entities with α-(1⟶4) linkages. Because cyclodextrins are closed circular molecules, glucoamylases and beta amylases cannot hydrolyze them, as there is no reducing end group, which is necessary to initiate hydrolysis. The cyclic dextrins formed contain six, seven, or eight glucose monomers; these are referred to as alpha-, beta-, and gamma-cyclodextrin, respectively. The glucose monomers are joined to one another in a doublenut-shaped ring, giving the cyclodextrin is a molecular structure that is relatively rigid and has a hollow cavity of specific diameter and volume. Depending upon the enzyme used and the conditions under which the reaction is performed, the ratio of cyclodextrins can vary from various mixtures to a single cyclodextrin being formed.

Figure 34.5 shows the chemical structure of α-, β-, and γ-cyclodextrins. β-Cyclodextrin is the predominant

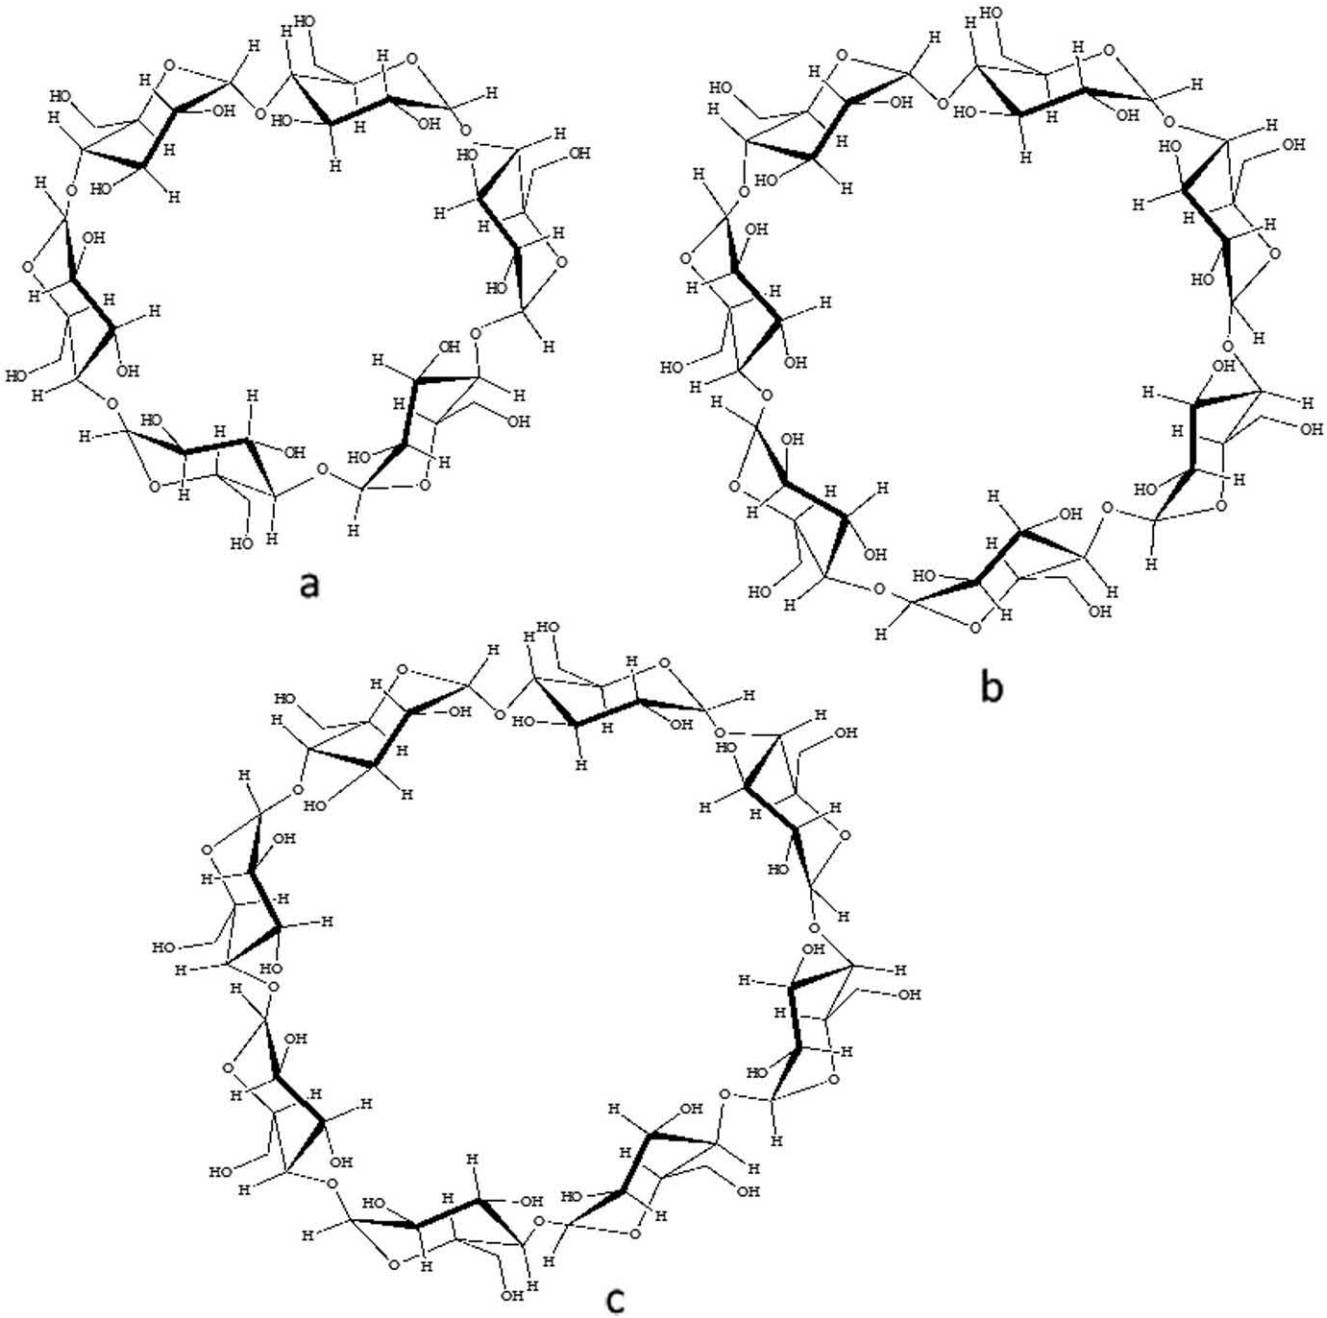

FIGURE 34.5 Chemical structures of (a) α-cyclodextrin, (b) β-cyclodextrin, and (c) γ-cyclodextrin.

cyclodextrin produced by CGTase enzymes. Polar hydroxyl groups of the glucose monomers are located on the rim of the molecule and are directed away from the cavity. These groups interact with water giving cyclodextrins their aqueous solubility properties and will interact with polar groups of some molecules to form hydrogen bonds. While the outer surfaces (top and bottom) are hydrophilic, the internal cavity has a relatively high electron density and is hydrophobic in nature due to the hydrogen and glycosidic oxygen atoms being oriented to the interior of the cavity.

Organic molecules of suitable size, shape, and hydrophobicity are able to interact noncovalently with cyclodextrins to form stable complexes. Several forces, such as van der Waals forces, hydrophobic interaction, and dipole–dipole interaction, are involved in the binding of guest molecules to the cyclodextrin cavity. These forces are sufficiently efficacious to form a stable complex but are not so secure that the guest molecule can be released from the complex to become available for the intended effect of the guest molecule [65].

The dimensions of the cyclodextrin's cavity allow some selectivity for the complexation of guest molecules. Strong binding results if more interaction occurs between the walls of the cyclodextrin and the guest molecule. If the molecule to be encapsulated is small compared to the cavity, only part of its surface is in contact with the walls and the full potential of the guest molecule to interact with the cyclodextrin is not realized. For molecules containing five or fewer carbon atoms, the smaller cavity of α-cyclodextrin affords more interaction between the molecule and the cavity walls. Better complexation results than if β- or γ- cyclodextrin were used. On the other hand, large bulky molecules, such as anthracene, fit into the cavity of the γ-cyclodextrin better than that of α- or β-cyclodextrin. In fact, sometimes, molecules are too large to fit into the cavity of one or more of these. Thus, the guest molecule might be totally excluded from the cavity, or only a portion of it would fit. As more of the molecule can fit into the cavity, a stronger binding results. Some of the physical properties of cyclodextrins are summarized in Table 34.2 [66].

β-Cyclodextrin deserves special attention because it is the most readily available cyclodextrin. In preliminary studies, it is generally used and is known to be able to form inclusion complexes with flavor ingredients of molecular masses ranging between 80 and 250 Da. Lindner [67] reported that the molecules of nearly all natural spices and flavors fit into this range. Much research has focused on the ability of cyclodextrins to prevent the volatilization of flavors and essences from spices, flavor extracts, and lipids. Nagatomo [68] reported that cyclodextrins improve the stability of spices for use in sausages and other meat products. Spices that have been included in cyclodextrins have demonstrated controlled flavor release. In addition, thermal stability is improved when fats are added to them. Nagatomo [68] also noted that cyclodextrins preserved the flavor of cookies, vegetable pastes, biscuits, citrus fruits, Japanese onions, garlic, celery, and a variety of other products. Pagington [69] reported that the strong odor of onion oil, garlic oil, and pyrazines was restricted by cyclodextrin use, but complexing with cyclodextrins prevented their flavor from being lessened in processing, and released their flavor directly into the mouth.

Natural pigments, such as carotenoids and anthocyanins, can also be stabilized by a cyclodextrin complex [68]. Pigments can be masked, or their color tones intensified. It has been reported that the colors can be changed through the inclusion complexation process. Cyclodextrin complexes can protect ingredients from oxidation, light-induced reactions, thermal decomposition, and evaporation loss. Crystalline complexes are stable and improve processing conditions, handling, and storage of food ingredients.

34.2.1.4 Modified Cyclodextrins

Although β-cyclodextrin forms a stable microcapsular structure, water solubility of β-cyclodextrin complexes is generally a problem. The solubility of α- and γ- cyclodextrin at room temperature is 12.8 and 25.6 g/100 mL water, respectively; whereas for β-cyclodextrin it is only 1.8 g/100 mL. As temperature increases, the solubility of cyclodextrins also increases, but their solubility can change when a guest is complexed. If the guest molecule is highly soluble in water, then the inclusion complex is more soluble than the cyclodextrin itself. The polar or ionic moiety of the guest molecule projects out of the cavity and contributes to the solubility of the complex along with the interaction of the hydroxyl groups of the cyclodextrin. On the other hand, complexation of the cyclodextrin with a guest molecule that is not soluble or only partially soluble in water generally results in a decrease in the solubility of the cyclodextrin. Although solubility of the complex is generally

TABLE 34.2
Physical Properties of Cyclodextrins

	Physical Properties						
			Molecular Dimensions (Å)

less than that of the cyclodextrin, it is greater than that of the guest molecule.

The solubility of cyclodextrins can be improved by substituting various hydroxyl groups of the rims of the cyclodextrin molecule [70]. By chemical modification, cyclodextrins may attain some characteristics very different from those of the original material. Cyclodextrins can be incorporated into polymer structures. One such polymer can be produced by linking cyclodextrin rings with suitable agents such as epichlorohydrin in order to obtain insoluble copolymers in the form of water-swelling beads. Some of these polymers retain the ability of the cyclodextrin to form complexes with various compounds, especially those with hydrophobic groups.

It has been reported that if cyclodextrins are linked to polyethers, water-soluble polymers are produced [71]. Initial studies have shown that heptamino-β-cyclodextrin can be cross-linked by hexamethylene diisocyanate. If the degree of polymerization is high enough, the cyclodextrins bound within the matrix become insoluble. The chemical structure of an experimental polymer produced from maize is shown in Figure 34.6.

Polydextrose also designated as poly-D-glucose, a synthetic, highly branched polymer with many glycosidic linkages is produced by heating dextrose with acid and purifying the resulting water-soluble polymer. For instance, melt-condensation of 89% (D-glycose), and 1% citric acid 10%, sorbitol (D-glucitol) results in branched polydextrose with primarily 1→6 linkages and a molar mass of about 22,000 g/mol that is water-soluble [72]. Polydextrose is used as a bulking agent because it is similar to fiber in terms of its resistance to digestion and being tasteless.

34.2.1.5 Sucrose

The most commonly used ingredient in the food industry is sucrose (β-D-fructofuranosyl-α-D-glucopyranoside), which

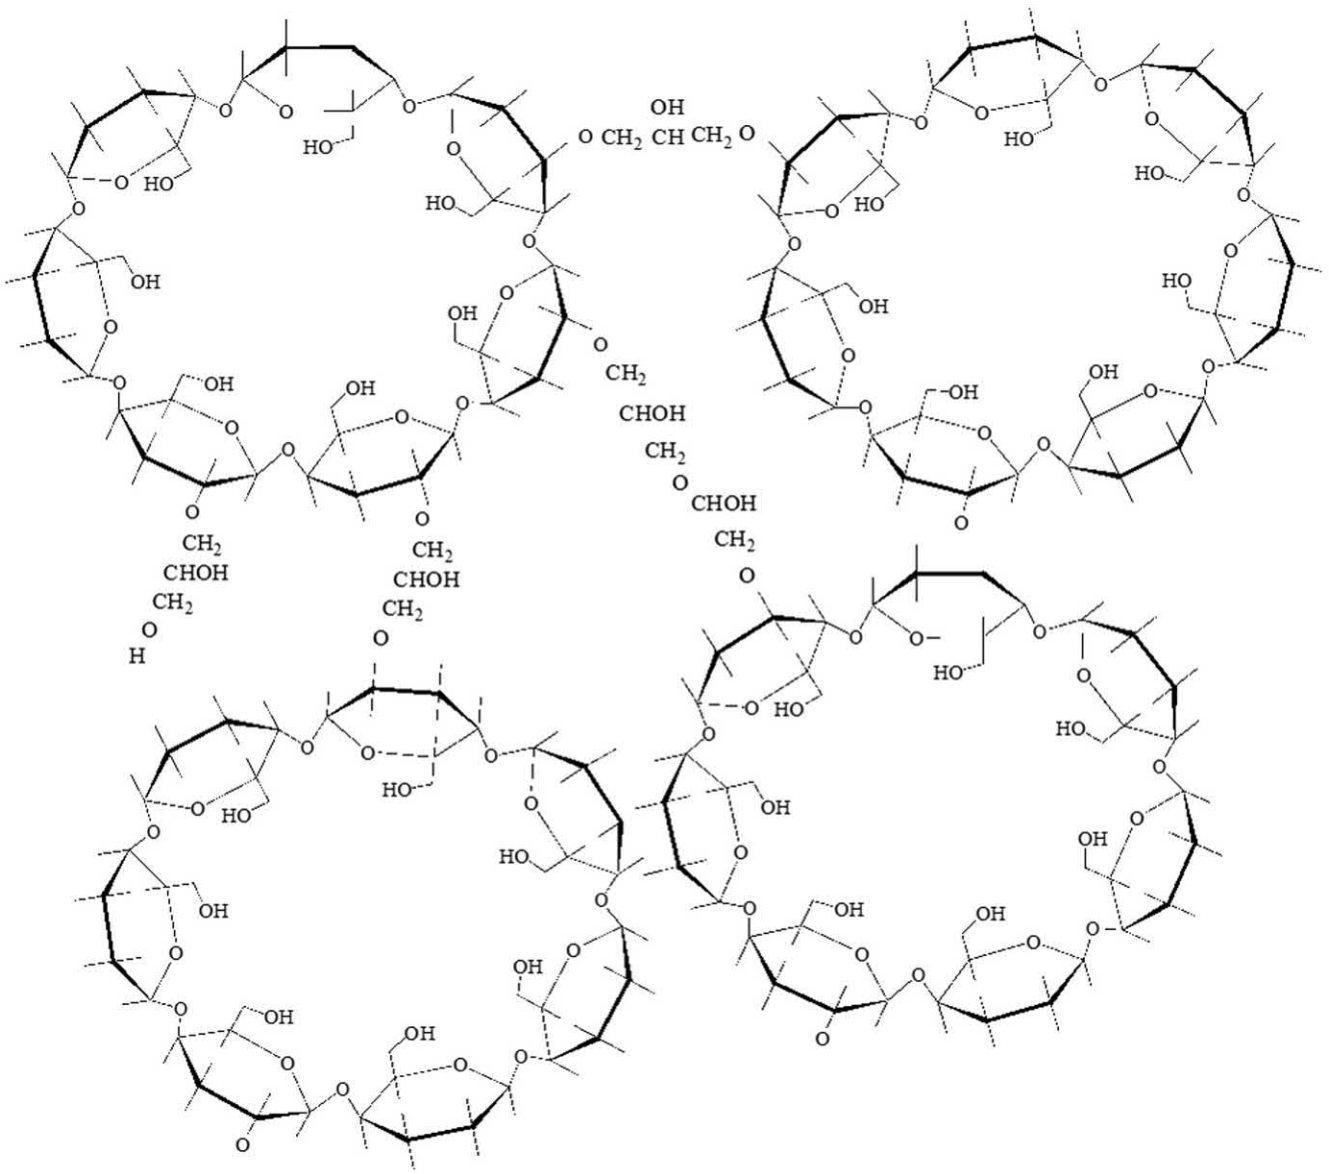

FIGURE 34.6 Structure of a polymeric, modified β-cyclodextrin. (From Pszzcola [497].)

provides sweetness, and acts as a bulking agent, texture modifier, preserving agent, and fermentation substrate in food applications [73]. Sucrose is also useful as a carrier for food ingredient encapsulation because of its (i) quick dissolution in water producing a clear solution, (ii) heat stability, (iii) nonhygroscopicity, (iv) indefinite shelf life under ambient conditions, and (v) inexpensive nature [74].

In extrusion processing, sucrose and other mono- and disaccharides provide flavor, sweetness, energy, texture, stabilization, and control of water activity as well as color [75]. Mixtures of sucrose and maltodextrin are the most commonly used coatings for extrusion encapsulation [76, 77]. Flink and Karel [45] reported that retention of volatiles by carbohydrates during lyophilization was roughly in the order of sucrose > maltose ≥ lactose > glucose >> dextran T-10. In the case of lactose, its crystal form as well as the structure of the volatiles were found to influence the amount of absorption [78]. Sucrose is used for encapsulating food flavors by a process known as cocrystallization [74, 79–81]. However, before it can be used, its chemical structure needs to be modified from a single perfect crystal to that of a microsized, irregular, agglomerated form, prior to cocrystallization occurrence. This modified structure has an increased void space and surface area that provides a porous bed or base for the incorporation of active ingredients.

34.2.1.6 Chitin and Chitosan

Chitin is a β-1,4–linked linear polymer of 2-acetamido-2-deoxy-D-glucopyranosyl residues, and is a main constituent of the exoskeleton of crustaceans such as crab, shrimp, lobster, and crayfish. Chitosan is the principal product from the alkaline hydrolysis of chitin and consists of 2-deoxy-2-aminoglucopyranosyl residues joined by β-(1⟶ 4) linkages. Complex coacervate capsule formation can occur between chitosan, a cationic polyglucosamine, and carrageenan or alginic acid, which are anionic in nature.

Gel bead formation can be achieved by interaction of chitosans with low molecular weight negatively charged counterions such as polyphosphates. The gelling properties of chitosans allow their use in a wide range of applications, the most attractive being coating of foods and pharmaceuticals, and gel entrapment of biochemicals, plant embryos, and whole cells, microorganisms, or algae [82, 83]. Such entrapment offers diverse uses including microencapsulation and controlled release of flavors, nutrients, or drugs. Because chitosan has been shown to be an effective agent, concurrent cell permeabilization and immobilization using chitosan-containing complex coacervate capsules have been explored [82, 83].

Polycationic chitosan molecules can be incorporated with oppositely charged polymers to form coacervate capsules of good mechanical strength. The permeability of these coacervate capsules can be controlled by either altering the type of chitosan and/or the counterion [84].

34.2.1.7 Cellulose and Cellulose Derivatives

Cellulose is the main constituent of plant cell walls and consists of β-(1⟶ 4)-linked glucopyranosyl residues. It is a solid polymer with extended rodlike conformation. In contrast to starch, cellulose is more crystalline. While starch undergoes a crystalline to amorphous transition between 60°C and 70°C in water, cellulose requires about 320°C to become amorphous in water [43]. The primary cell wall of all green plants is made of cellulose and some of its important natural sources include hemp, flax, straw, and jute, among others. In addition, acetic acid bacteria and some forms of algae are known to synthesize cellulose [43].

Together with some other inert polysaccharides (e.g., lignin), cellulose constitutes the indigestible carbohydrate fraction of plant foods, referred to as dietary fiber. Until recently the importance of dietary fibers in human nutrition was considered to be mostly the maintenance of intestinal mobility (peristalsis). However, "functional fiber" refers to isolated, nondigestible carbohydrates that have beneficial physiological effects in humans. Functional fiber may bind bile acids or cholesterol in the intestine, thus preventing their reabsorption into the body. The liver responds by taking up more low-density lipoprotein (LDL) cholesterol from the bloodstream, thereby lowering the concentration of LDL cholesterol in the blood. Short-chain fatty acids, products of fermentation from functional fiber in the gut, may inhibit synthesis of cholesterol by the liver, reducing the concentration of blood cholesterol. The high viscosity of soluble fiber may slow the rate of digestion and absorption of carbohydrates, affecting insulin activity, which is implicated in the removal of LDL cholesterol from the blood.

Cellulose as an edible film for food preservation and other functional ingredients in food processing has attracted much research interest [85–87]. Native cellulose is insoluble in water due to the high level of intramolecular hydrogen bonding in the cellulose polymer [49]. As an edible film for food coatings, the permeability of cellulose coatings can be modified by combining them with other coating materials via etherification [88]; that is, reacting cellulose with aqueous caustic and then with methyl chloride, propylene oxide, or sodium monochloroacetate to yield methylcellulose, hydroxypropyl methylcellulose, hydroxypropyl cellulose, and sodium carboxymethylcellulose [49]. Methyl- and hydroxypropyl methylcellulose mixed with lauric, palmitic, stearic, and arachidic acids were found to significantly lower the permeation rate relative to cellulose ether films containing no fatty acids [89]. Cellulose may also be used in the encapsulation of water-soluble food ingredients such as sweeteners and acids as well as for encapsulating enzymes and cells [90].

Methylcellulose (MC) is a hydrophilic white powder that dissolves in water to form a viscous solution. Higher degrees of substitution (DS) and degrees of polymerization (DP) result in lower solubility (Figure 34.7a). Viscosity of MC solutions is stable over pH range of 3–11. Three-dimensional gel formation appears upon heating above 50°C. Methylcellulose has good film-forming properties, but it is not digestible. Synthesis steps contain heating of raw cellulose with sodium hydroxide and treatment with methyl chloride [43].

Hydroxypropyl methylcellulose (HPMC) is similar to methylcellulose and is a white powder or granule that dissolves in water and forms a viscous, nonionic colloidal solution.

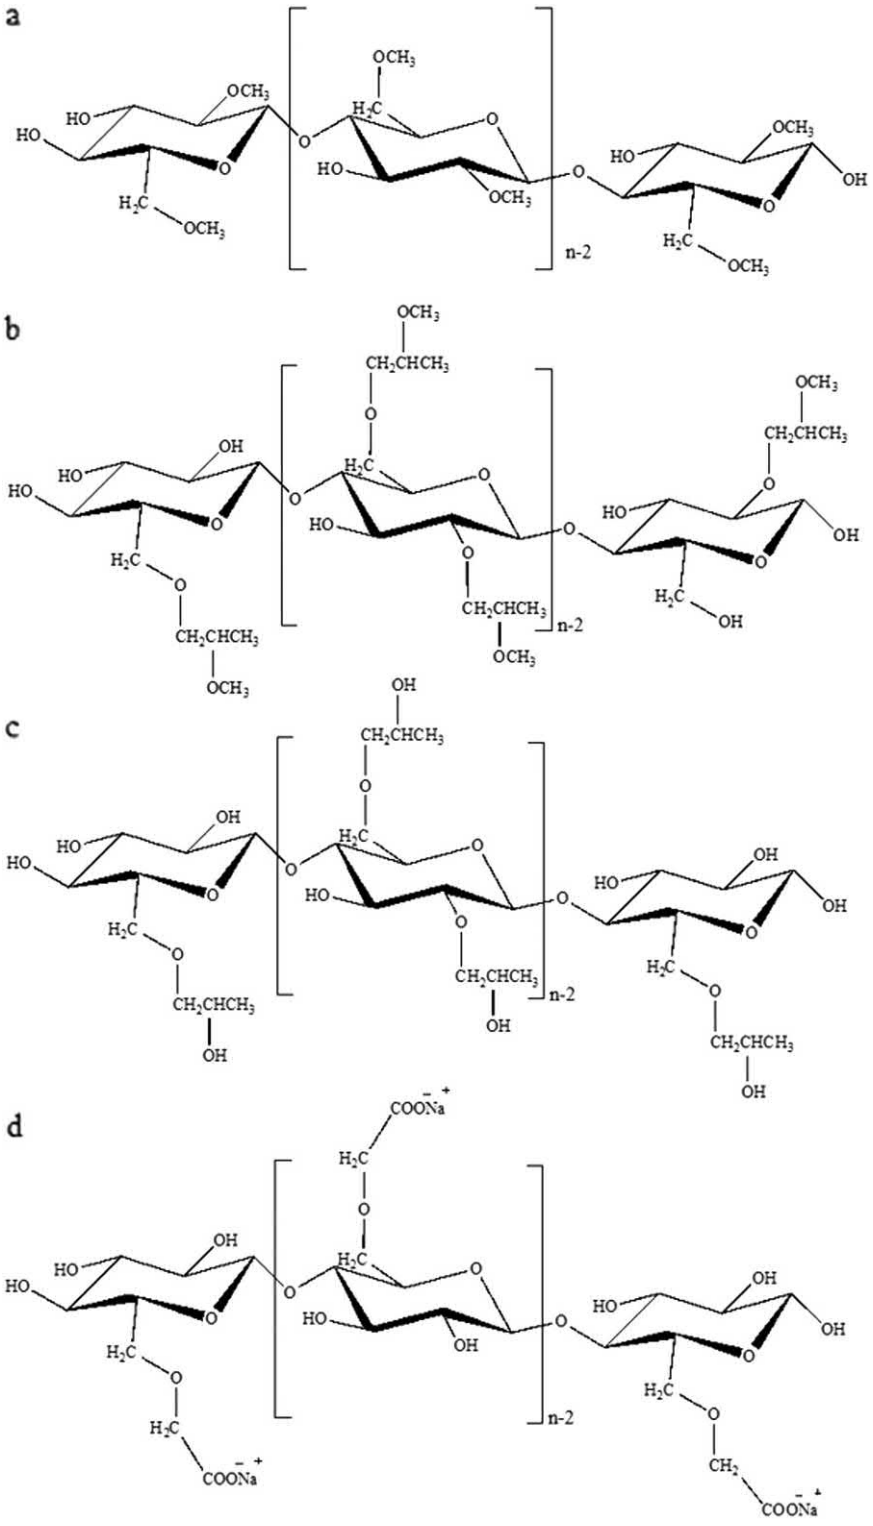

FIGURE 34.7 Chemical structures of (a) methylcellulose (MC), (b) hydroxypropyl methyl cellulose (HPMC), (c) hydroxypropyl cellulose (HPC), and (d) ethyl methylcellulose (EMC). (From Wandrey et al. [43].)

In addition, HPMC is soluble in most polar solvents. They undergo transformation from solution to gel upon heating and cooling. The gel transition temperature usually depends on the ratio of methyl to hydroxypropyl derivatization. The molar mass of HPMC is higher than 10,000 g/mol, with a density of 1.6 g/ml (Figure 34.7b) [91].

Hydroxypropyl cellulose (HPC; Figure 34.7c) is soluble in cold water. Viscosity of the solution could be adjusted by the degree of polymerization. Because of the presence of hydrophilic and hydrophobic groups, it becomes insoluble at temperatures above 45°C and no gel is formed [92, 93]. Advantageous features of HPC include its solubility in ethanol

and mixtures of ethanol and water, and good film-forming ability [43]. The films are glossy, flexible, and nontacky [92].

Ethyl methylcellulose (EMC) behaves like HPMC and MC. EMC is soluble in cold water and forms gels upon heating. Meanwhile, ethylcellulose (EC) is a water-insoluble commercial thermoplast used for coating [43]. Sodium carboxymethylcellulose (CMC) is produced by the reaction of chloroacetic acid and cellulose with alkali. The degree of polymerization decreases a bit during the modification. Modification produces areas of low and high substitution. The product is white to off-white, odorless, and tasteless [94]. CMC dissolves very rapidly in cold water and affords clear and colorless solutions with its viscosity decreasing after heating. The solution behavior of CMC strongly depends on the degree of polymerization and the molar mass. At low pH, CMC might form cross-links between free hydroxyl groups and carboxylic acid (Figure 34.7d) [95].

34.2.2 Plant Exudates and Extracts

Polysaccharide exudates of plants and their extracts are complex macromolecules that are mostly mixtures consisting of oligomers and polymers of different chemical structures. Some of the materials used for food encapsulation are products of gummosis, which are also known as plant gums. Gummosis is a result of stress conditions like heat, wound, and drought. The gums are produced in response to injury of the plant and form the barrier at the lesion hindering the invasion by the microorganisms. Some plant species are cultivated at present to provide the gums for the food industry. Some examples of common plant gums that are harvested include the following: *Acacia senegal* – gum arabic (gum Senegal), *Cyamopsis tetragonolobos* – guar gum, *Astragalus* spp. – gum tragacanth, and *Ceratonia siliqua* – locust bean gum.

Several other tree exudates such as mesquite gum are harvested and consumed [96]. One class of material often exploited for its encapsulating capabilities is that of hydrocolloids, or more commonly, gums. These compounds are long-chain polymers that dissolve or disperse in water to render a thickening or viscosity-building effect [97]. Gums are generally used as texturing ingredients, but their secondary effects include encapsulation capabilities [98], stabilization of emulsions, suspension of particulates, control of crystallization, and inhibition of syneresis (i.e., the release of water from fabricated foods) [99, 100]. Additionally, a few gums are capable of forming gels.

Food gums are obtained from a variety of sources. Although most gums are obtained from plant materials such as seaweed (e.g., carrageenans and alginates), seeds (e.g., locust bean gum and guar gum), and tree exudates (e.g., gum acacia), others are products of microbial biosynthesis (e.g., xanthan gum and gellan gum), and still others are produced by chemical modification of natural polysaccharides. Some commonly used gums as coating materials for food ingredient encapsulation are discussed next.

34.2.2.1 Seaweed Extracts

Alginates, agar, and carrageenan are extracts from red (*Rhodophyceae*) and brown (*Phaeophyceae*) algae, which are collectively referred to as seaweeds [101]. Their use in encapsulation processes is well documented. A major source of industrially produced alginates is the giant kelp, *Macrocystis pyrifera*, which is harvested mechanically off the coast of California. Other seaweed species of alginates include *Laminaria hyberborea*, *Laminaria digitata*, and *Ascophyllum nodosum*. Algae are extracted with alkali from seaweed, and the polysaccharide is usually precipitated from the extract by addition of an acid or calcium salts.

34.2.2.1.1 Alginates

Alginates are salts of alginic acid and include a variety of products made up of poly-β-D-mannopyranosyluronic and poly-α-L-gulopyranosyluronic acids joined in a linear fashion by α -(1⟶ 4) linkages [102]. They are arranged either in regions composed solely of one unit or the other, referred to as M-blocks and G-blocks, or in regions where the two units alternate [101]. In alginates, both the ratio of mannuronic acid to guluronic acid and the structure of the polymer govern how effectively the chains associate during gel formation. Figure 34.8 shows part of the sodium alginate chain. The weight average molar mass of the commercial sodium alginates usually varies between 4×10^4 and 5×10^5 g/mol. However, some alginates have a molar mass higher than 10^6 g/mol. Alginate is available as a dry powder as well as a solution. Degradation of alginate leads to a fast decrease in chain length, which is detectable by a decrease in viscosity. A number of microorganisms are able to digest alginate. Sodium alginate can be kept for years in a deep freezer without any significant degradation. Alginates are found abundantly in nature and are commercially produced mainly from marine brown algae but may also be synthesized as an exocellular material by several bacteria [103].

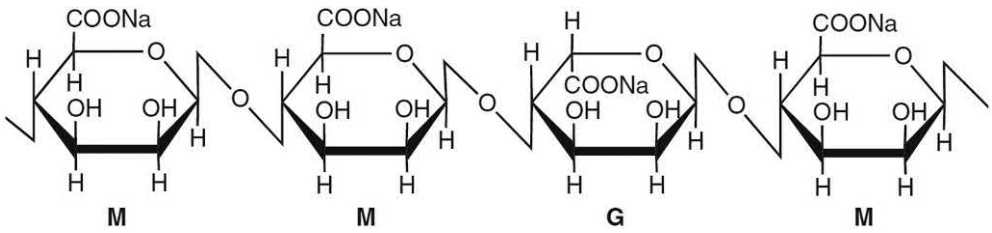

FIGURE 34.8 Chemical structural units of a sodium alginate polymer chain. (From Wandrey et al. [43].)

Alginates are powerful thickening, stabilizing, and gel-forming agents and are utilized in a variety of foods. At a level of 0.25–0.5%, they improve and stabilize the consistency of fillings for baked products, salad dressings, and milk chocolate, and prevent the formation of large ice crystals in ice cream during storage. They are also used as an encapsulating agent. Water-soluble alginate is capable of forming liquid capsules [104]. Alginate films tend to be quite brittle when dry but may be plasticized by inclusion of glycerol [105]. Viscous high-fat food can also be encapsulated with calcium alginate [106].

34.2.2.1.2 Agar

Agar is a heterogeneous complex mixture of related polysaccharides having the same backbone chain structure. Its main components are β-D-galactopyranosyl linked (1⟶4) to a 3,6-anhydro-α-L-galactopyranosyl unit, and partially esterified with sulfuric acid. Deemed as one of the most potent gel-forming agents, agar produces perceptible gelation at concentrations as low as 0.04%. The gelling properties of the gum, the heat resistance of its gels, and the differential between the gel-forming and melting temperatures are the primary reasons for selecting agar. Agar is best known as a culture medium and is not employed to any great extent in foods. Nevertheless, chlorella agar has been used for the encapsulation of flavors [107].

34.2.2.1.3 Carrageenan

Carrageenan is extracted mainly from the red seaweed species, *Chondrus crispus*, with water and a small amount of alkali, followed by filtration and recovery by alcohol precipitation [49]. It is composed of β-D-galactose and 3,6-anhydro-α-D-galactose, which is partially sulfated as 2-, 4-, and 6-sulphates and 2,6-disulphates. The galactose residues are alternatively linked by 1–3 and 1–4 linkages. There are three principal carrageenan fractions known as iota (ι), kappa (κ), and lambda (λ) (Figure 34.9). κ-Carrageenan fraction contains the lowest number of sulfate groups and the highest concentrations of the 3,6-anhydro-α-D-galactopyranosyl units. ι-Carrageenan differs from κ-carrageenan with an additional sulfate group at the 2 position. Meanwhile, λ-carrageenan differs from κ- and ι-carrageenans by having variable amounts of sulfate groups and no 3,6-anhydro-α-D-galactopyranosyl residues [49].

Carrageenan utilization in food processing is based on the ability of the polymer to gel, to increase solution viscosity, and to stabilize emulsions and various dispersions. Gels from carrageenan are thermoreversible. Because of its reactivity with certain proteins, the gum has found use at low concentrations (typically 0.01% to 0.03%) in a number of food products. Locust bean gum is compatible with carrageenan, forming a cooperative association with the double helix structure, and increasing the elasticity of the resultant gels. A process for producing capsules containing meat soup or juice with agar-agar, carrageenan, or pectin coatings has been developed by Hoashi [108].

Carrageenans have typical weight average molar mass in the range of 3×10^5 to 6×10^5 g/mol and are highly polydisperse with a typical number average molar mass of 1×10^5 to 2×10^5 g/mol [109]. Because of the variation in their chemical structures, carrageenans show a wide spectrum of rheological behavior [110]. Depending on the type of carrageenan used, they could form viscous solutions and thermally reversible gels with a texture varying from soft and elastic to brittle. Both ι- and κ-carrageenans have the ability to form elastic gels with some of the cations like K^+ and Ca^{2+} and might be used as adjuncts in encapsulation processes (Table 34.3).

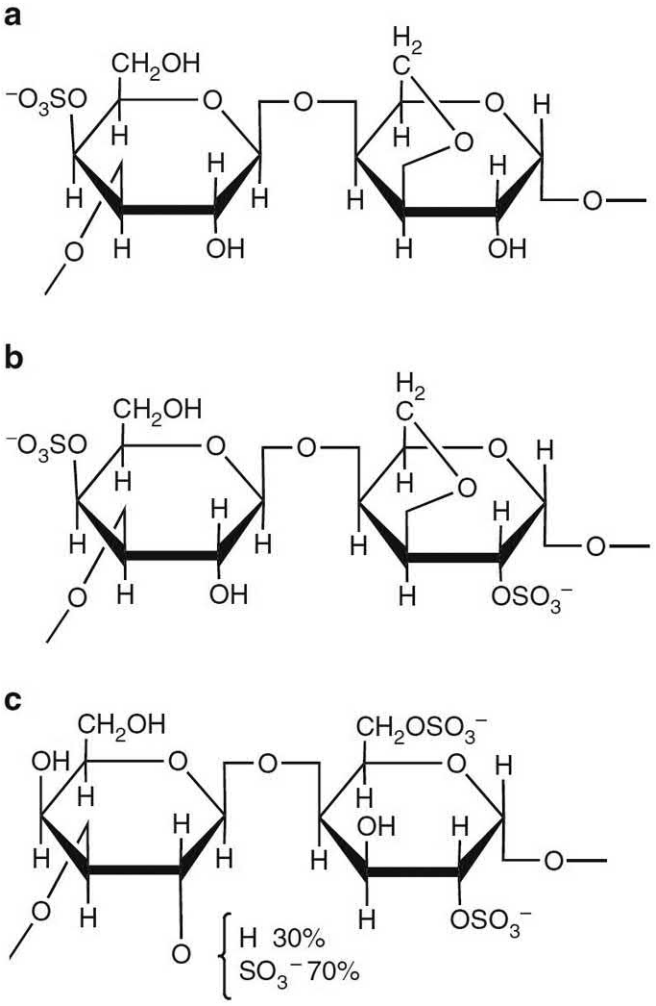

FIGURE 34.9 Repeating dimer units of limit carrageenans: (a) κ-carrageenan, (b) ι-carrageenan; and (c) λ-carrageenan. (From Wandrey et al. [43].)

34.2.2.2 Exudate Gums

Gum arabic (acacia), gum ghatti, gum karaya, and gum tragacanth are referred to as exudate gums. Exudate gums are structurally complex heteropolysaccharides obtained from certain shrubs and small trees that grow predominantly in Africa and Asia [111]. The term *exudate* refers to the fact that gums are secreted or exuded in response to plant tissue injury. Upon exposure to the atmosphere, they form extremely hard, glossy nodules or flakes, which can be harvested [49].

TABLE 34.3
Molecular Structural Properties of Carrageenans

Property	Carrageenan Type		
	Lambda	**Kappa**	**Iota**
Solubility in cold water	All salts soluble; viscous solutions	Na-salts soluble; from limited to high swelling of K^+, Ca^{2+}	Na-salts soluble, Ca-salts give thixotropic dispersions
Solubility in hot water	Soluble	T >70°C	T >70°C
Gelation		Strongest with K^+	Strongest with Ca^{2+}
pH stability	Hydrolysis below pH 4.3	Stable at neutral alkaline pH	pH = 3.5
Salt tolerance	Good	Poor	Good

Source: Davidson (1980).

34.2.2.2.1 Gum Arabic

Gum arabic (GA), which is a natural vegetable colloid obtained by exudation from the trunk and branches of leguminous plants of the Acacia family, primarily *Acacia Senegal*, is the most commonly used encapsulation coating material [112, 113]. Although there are several hundred species of Acacia, only a few are gum producers, and these are located in the subdesert region of Africa. GA is a complex mixture of arabinogalactan oligosaccharides, glycoproteins, and polysaccharides. Its chemical composition could vary depending on the source, climate, age of the tree, season rainfall, time of exudation, and other factors. GA consists of β-(1→3)–linked D-galactopyranosyl units. Side chains are composed of 2-5 β-(1→3)–linked D-galactopyranosyl units and joined to the main chain by 1, 6-linkages. Both the main and side chain contain units of α-larabinofuranosyl, β-D-glucuronopyranosyl, α-L-rhamnopyranosyl, and 4-*O*-methyl β-D-glucuronopyranosyl [114]. GA has a complicated molar mass distribution and some studies have shown that it includes a mixture of higher molar mass hydroxyproline-rich glycoprotein ($M_{w:}$ 2.5×10^6 for the minor component) and lower molar mass polysaccharide (M_w: 2.5×10^5 for the major component) [115, 116].

GA is tasteless, colorless, and odorless, and thus does not affect the color, odor, and taste of the system to which it is added. GA is soluble in both hot and cold water with concentrations of up to 50% (w/w). Viscosity of its solutions varies with the GA type, ionic strength, and pH. Its maximum viscosity is around pH 6 to 7. GA acts as an excellent emulsifier [43] and has the ability to create a strong protective film around oil droplets [117].

34.2.2.2.2 Gum Acacia

Gum acacia is a neutral or slightly acidic salt of a complex polysaccharide with an average molecular weight range of 260–1160 kDa. Gum acacia primarily consists of D-galactopyranosyl, L-rhamnnopyranosyl, L-arabinopyranosyl, L-arabinofuranosyl and D-glucopyranosyluronic acid. It contains ca. 2–3% protein with an arabinogalactan-protein complex and is rich in hydroxyproline, serine, and proline. This protein fraction is responsible for the emulsification properties of the gum. The gum also exists as a mixed salt of sodium, calcium, magnesium, and potassium ions. Owing to the complex character of this polymer, the stereochemical organization of the molecule is not completely understood even though the qualitative and quantitative analysis of the sugars is.

Gum acacia is the traditional gum of choice for flavor encapsulation via spray drying. It dissolves readily in hot or cold water, is an outstanding natural emulsifier, is the least viscous and the most soluble of the hydrocolloids, is stable in acidic media, and rates well based on criteria used in evaluating a flavor carrier. Because beverage applications account for a large proportion of dry flavorings used, emulsion stability in the finished product is one of the most important criteria in carrier selection. Gum acacia has the advantage of being considered natural in virtually all countries. An interesting and unique property of gum acacia is its low viscosity in aqueous solutions. Although solutions containing up to 50% gum can be prepared, the solution viscosity starts to rise steeply at concentrations of greater than 35%. Most other gums yield solutions with high viscosity at concentrations as low as 1%. It would be impossible to effectively atomize these very viscous emulsions, and thus these other gums are not useful, especially as flavor encapsulants.

Gum acacia is also applied as a flavor fixative in the production of powdered aroma concentrates. Although modified food starches are superior to traditional gum acacia in emulsion stability, gum acacia produces quite stable emulsions. The emulsions are then spray dried. In this process, the polysaccharide forms a film surrounding the oil droplet, which then protects the oil against oxidative degradation. Compared to maltodextrins, gum acacia gives superior aroma retention during drying and very little aroma is lost during storage at humidities below the water monolayer level [118]. A new generation gums (blends of West Africa gums) are superior even to modified starches for stabilizing flavor emulsions [48]. Protection of oxidizable flavorings by gum acacia varies with the source of the gum. The traditional gum acacia is not quite as good as the modified food starch/corn syrup solids blend

and quite inferior to the blends of West African gums [48]. Blends of gum acacia with maltodextrins and the new West African gum acacia can be used to encapsulate flavors and offer excellent stability to oxidation [119].

34.2.2.2.3 Gum Ghatti

Gum ghatti is an amorphous translucent exudate of the *Anogeissus latifolia* tree of the family Combretaceae, which is native to India [105]. It is a water-soluble, complex polysaccharide consisting of L-arabinofuranosyl, D-galactopyranosyl, D-mannopyranosyl, D-xylopyranosyl, and D-glucopyranosyluronic acid units. As a whole, it is nongelling but can be dispersed in hot or cold water to give a colloidal sol that develops due to a soluble fraction. The gum closely resembles the viscosity and emulsifying properties of gum acacia and has been effectively used in food systems as an emulsifier and a stabilizer. Gum ghatti is seldom used because of its limited supply [101].

34.2.2.2.4 Gum Karaya

Gum karaya is the dried exudate of the *Sterculia* tree, which grows in central and northern India, hence it is routinely referred to as Indian gum. It occurs naturally as a complex, partially acetylated branched polysaccharide containing about 37% uronic acid residues and approximately 8% acetyl groups. Gum karaya comprises a central chain of D-galactopyranosyl, L-rhamnopyranosyl, and D-galactopyranosyluronic acid units, with some side chains containing D-glucopyranosyluronic acid [105]. It swells very easily in water and absorbs water very rapidly to form viscous colloidal dispersions at low concentrations. The gum forms smooth films that can be plasticized with compounds such as glycols to reduce brittleness [49].

Gum karaya has a molar mass of up to 1.6×10^7 g/mol, and a branched structure [120]. It consists of α-L-rhamnose residues and α-D-galacturonic acid. The side chains are attached by (1→2)- or (1→3)-linkages of β-D-galactose and/or β-D-guluronic acid to the galacturonic acid of the main chain. Moreover, half of the rhamnose residues of the chain are (1→4)-linked to β-D-galactose units [121]. Powdered gum karaya is white to grayish-white, and it is one of the least soluble of the gums. About 10% of the native gum is soluble in cold water and this percentage increases to about 30% in hot water. However, after deacetylation, 90% of it dissolves in water [114]. India is the largest producer of gum Karaya, so it is sometimes known as Sterculia gum, which is a dried exudate from the branches and stems of *Sterculia urens Roxbourg* and other species of *Stericula* [122].

34.2.2.2.5 Gum Tragacanth

Gum tragacanth is the dried gum exuded from the stems of *Astragalus gummifer* and other Asiatic species of *Astragulus*. The plants grow wild in certain areas of Asia Minor and in the arid and mountainous regions of Iran, Syria, and Turkey. Gum tragacanth has a complex structure and upon hydrolysis yields D-galacturonic acid, L-fucose, D-galactose, D-xylose, and L-arabinose. According to Glicksman [105], it consists of a mixture of a water-insoluble component, tragacanthic acid that constitutes 60–70% of the gum and a water-soluble component, tragacanthin or arabinogalactan, in which L-arabinose is the predominant sugar. The water-soluble to water-swellable ratio varies, being, for example, 35:65 and 60:40. The tragacanthic acid fraction has a rodlike molecular shape and a very high molar mass [123]. The major chain is formed by (1→4)-linked D-galactose residues and side chains of D-xylose units attached to the main chain via (1→3)-linkages. Water-soluble tragacanthin is a neutral, very highly branched arabinogalactan with a spherical molecular shape. Its structure might consist of a core composed of (1→6)- and (1→3)-linked D-galactose and attached chains of (1→2)-, (1→3)-, and (1→5)-linked L-arabinose [114, 122].

Gum tragacanth is an acid-resistant gum and does not degrade at low pH. It is also considered as a bifunctional emulsifier for two reasons: its ability to lower the interfacial tension between the oil-in-water emulsion and to increase the viscosity of the aqueous phase. Gum tragacanth forms viscous aqueous solutions even though at low concentrations [124]. It swells rapidly in either cold or hot water to form highly viscous colloidal sols or semigels, which act as protective colloids and stabilizing agents. The gum is generally used as a thickener and stabilizer in salad dressings, sauces, bakery emulsions, toppings, ice cream, and confectioneries.

34.2.2.2.6 Mesquite Gum

Mesquite gum is a neutral salt of a complex acidic branched polysaccharide. It is formed by (1→3)-linked β-D-galactose residues with (1→6)-linked branches, L-rhamnose, β-D-glucuronate, and 4-*O*-methyl β-D-glucuronate. It also contains a small amount of a protein (0.7–5.8%) [125–129]. Solubility of Mesquite gum is similar to GA and has a dark brown color compared to GA. Its molar mass is 3.5×10^4 to 9.3×10^5 g/mol with a protein content of about 0.04% to 30%. Solutions of up to 50% concentration may be prepared, however, an increase of viscosity with increasing concentration is very high for mesquite gum compared to GA [130]. Mesquite gum has perfect film-forming properties [131] and is obtained from the mesquite tree *Prosopis* spp. or shrub that grows in the southwest of Mexico, the United States, and other areas in the world [96].

34.2.2.2.7 Galactomannans or Locust Bean Gum

Galactomannan or locust bean gum (LBG), also called guar gum or carob bean gum, are galactomannans [132]. They consist of linearly (1→4)-linked β-D-mannopyranosyl units and with single α-D-galactopyranosyl units connected by (1→6) linkages. Three gum types, namely, tara gum, LBG, and guar gum, vary in the ratio of D-mannosyl to D-galactosyl. In tara gum, every third main chain unit bears a side unit, whereas in LBG it is every fourth, and in guar gum it is every second main chain unit (Figure 34.10). The actual ratios differ slightly and vary from the average for LBG of between about 3.9:1 and 3.5:1 [133].

The three gum types have different in solubilities. Solubility increases with increasing the number of side units. Solubility of tara gum is about 70% under these conditions but

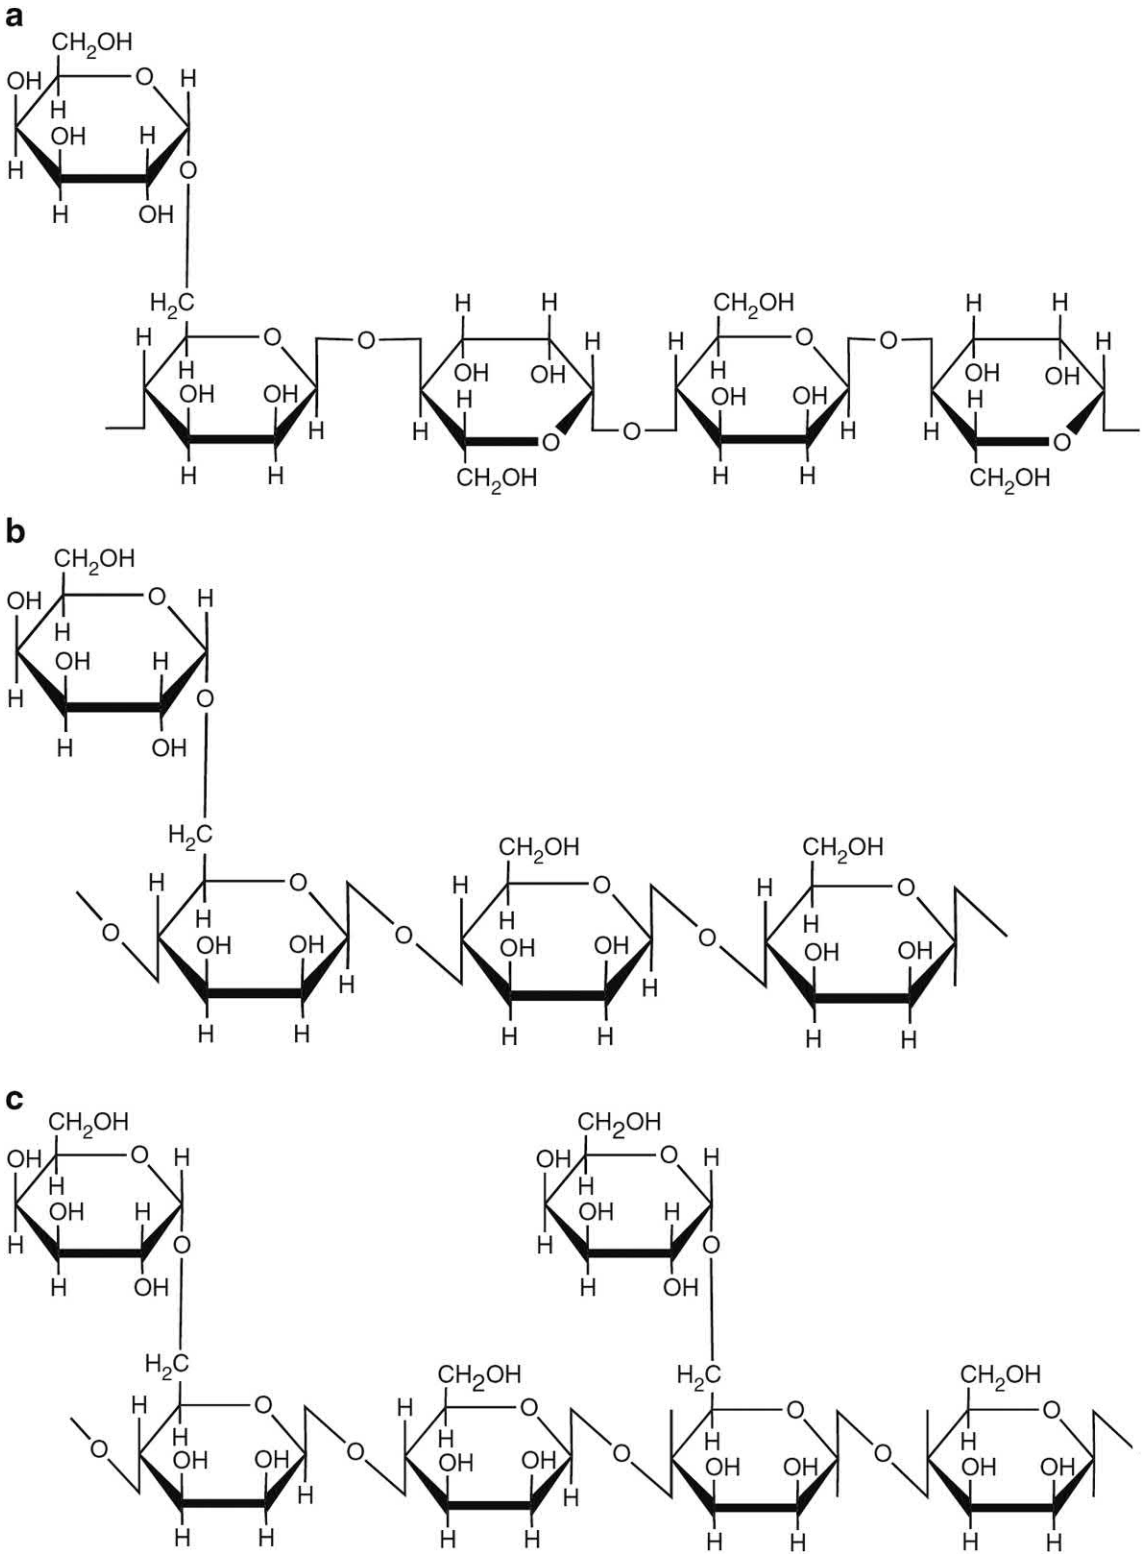

FIGURE 34.10 Chemical structures of (a) locust bean gum, (b) tara gum, and (c) guar gum. (From Wandrey et al. [43].)

is fully soluble above 70°C. However, guar gum is completely water-soluble at room temperature, and LBG has a limited water solubility at ambient temperature and swells below 60°C but becomes soluble above 60°C and fully hydrated if heated for 10 min at 80°C [133]. The range of molar mass for guar gum varies from 1.5×10^5 to 1.5×10^6 g/mol, having a higher molar mass as well as producing higher viscosities of solutions than LBG. Moreover, purification, isolation, solution preparation, and characterization method could have an impact on their molar mass [134–136].

34.2.2.3 Pectins

Pectin is a high molar mass heteropolysaccharide of about 65% (wt) of a-(1→4)-linked D-galacturonic acid-based units. All units are present as free acid (potassium calcium, sodium, ammonium), as acid amide in amidated pectins, or esterified with methanol. In addition, some of the neutral sugars like L-arabinose L-rhamnose, D-galactose, D-xylose, as well as small amounts of others are part of this polymeric chain. L-Rhamnose units exist as (1→2)-linked in the main chain, while other neutral sugar residues are bonded preferably to the rhamnose [72].

Pectins may have different degrees of esterification of the carboxyl groups of galacturonic acid, generally between 20% and 80%. Pectins with low esterification or low methoxylation (LM) have less than 50% ester groups. However, pectins with more than 50% esterification are high-esterified or highly methoxylated (HM). The molar mass depends on the source of pectin as well as the processing and varies from 10^4 to 2×10^5 g/mol [137]. Pectins are insoluble in most organic solvents but soluble in water. Solutions could be obtained up to concentrations varying from 6% to 12%, depending on the type, and have a low viscosity compared to other plant gums [43].

34.2.3 Microbial and Animal Polysaccharides

Polysaccharides that are produced biotechnologically by bacteria are biopolymers with partially unique functional properties such as xanthan and gellan. A brief description of xanthan and gellan polysaccharides is provided in the following sections.

34.2.3.1 Xanthan

Xanthan is a high molar mass anionic polyelectrolyte that occurs as a mixed salt of sodium, calcium, and potassium. The chemical structure of xanthan consists of β-(1→4)-D-glucopyranosyl units with every second unit having a trisaccharide side chain attached at the C-3 position, one D-glucuronosyl unit between two D-mannosyl units (Figure 34.11). Approximately 40% to 50% of the terminal mannosyl units are 4, 6-pyruvated and the nonterminal mannosyl units are 6-acetylated. Their molar mass varies from 1.5×10^5 g/mol to several millions. Association phenomena observed for xanthan gum could explain these differences [138, 139]. Xanthan is soluble in cold water and hydrates quickly in it without lumping. Generally, its solution viscosity is retained at pH 2 to 12 [140].

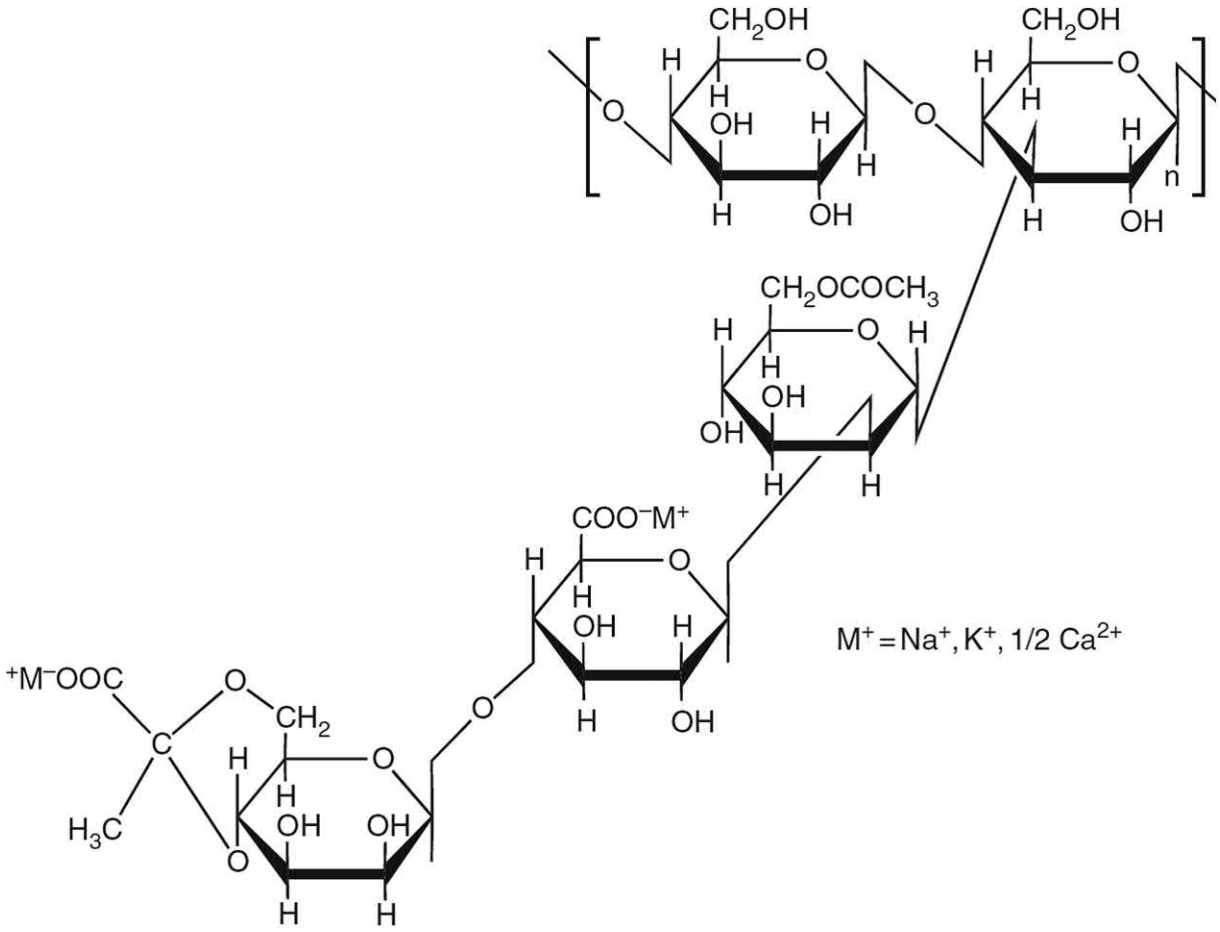

FIGURE 34.11 Chemical structural of xanthan gum. (From García-Ochoa et al. [498].)

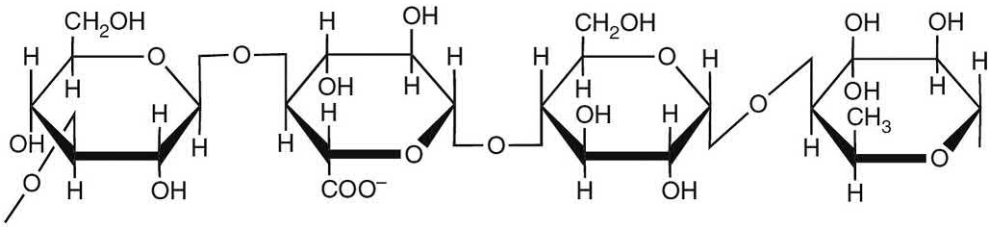

FIGURE 34.12 Chemical structural of gellan gum. (From Wandrey et al. [43].)

34.2.3.2 Dextran

Dextrans are linear polymers of α-D-glucose linked by α-(1→6) glycosidic bonds and can have variable amounts of α-(1→3) branches. The links in the main chain can be α-(1→2) links or α-(1→4) instead of α-(1→6) links. The molar mass of dextrans is in the range of 3×10^3 to 2×10^5 g/mol and they are freely soluble in water. Dextran produced from sucrose by microbial fermentation processes can be easily isolated. The bacteria used in the fermentation process determine the chain architecture and products so prepared are available commercially as a powder or solution [72].

34.2.3.3 Gellan

Gellan consists of one glucuronic acid, one rhamnose, and two glucose units. The 3-linked glucose unit is substituted with glyceryl at O 2 and with acetyl at O 6 (Figure 34.12). Thus, it can be designated as (1→4)-L-rhamnopyranosyl-α-(1→3)-D-glucopyranosyl-β-(1→4)-D-glucurono-pyranosyl-β-(1→4)-D-glucopyranosyl-β-(1→ 4) [43]. Molar mass of gellan is up to 5×10^5 g/mol. Solubility and solution properties of gellans depend on both the degree of substitution and concentration of ions present in the solution [43].

34.2.4 Lipids

Lipids include edible oils, waxes, fats, and phospholipids. These are widely distributed in nature and are water-insoluble. A cursory discussion of this topic is provided in the following sections.

34.2.4.1 Fatty Acids and Fatty Alcohols

There are two types of fatty acids that might be distinguished: saturated and unsaturated. Saturated fatty acids are linear monocarboxylic acids with the general formula of $CH_3(CH_2)_nCOOH$, while unsaturated fatty acids have one or more double bonds in their chain. They differ in the number of carbons in the aliphatic chain and the number of double bonds present [43, 141].

In general, short-chain aliphatic acids are miscible in water; furthermore, the water solubility rapidly decreases with increasing chain length. Melting points of fatty acids differ over a wide range. For example, for the saturated acids, which have much higher melting point, stearic acid (n = 16) is 69.4°C and palmitic acid is (n = 14) 62.6°C. Fatty acids tend to undergo autoxidation at room temperature [142]. Fatty acids are produced by the hydrolysis of the ester linkage of naturally occurring oils and fats. In addition, the glycerol is obtained as the by-product of this process [43].

34.2.4.2 Acylglycerols (Glycerides)

Monoglyceride (monoacylglycerol), diglyceride (diacylglycerol), and triglyceride (triacylglycerol) belong to the family of acylglycerols (Figure 34.13). Only one, two, or three fatty acid chains are covalently bound to a glycerol molecule by ester linkages. The fatty acids may be unsaturated or saturated. Glycerides are generally insoluble in water. Monoglycerides and diglycerides have emulsifying properties. The melting points of the glycerides depend strongly on the symmetry of the fatty acid residues and their chemical nature [143].

Acetylation of glycerol monostearate, by its reaction with acetic anhydride, yields 1-stearodiacetin. This acetylated monoacylglycerol displays the unique characteristic of solidifying from the molten state into a flexible, waxlike solid. It is found that the barrier properties of acetoacylglycerol improve as the degree of acetylation increases. This is due to the removal of free hydroxyl groups, which would otherwise interact directly with migrating water or other small polar molecules. The lower permeability through the acetoacylglycerol film prepared from technical grade monoacylglycerols might be a consequence of difference in crystal packing or the number of free hydroxyl groups [144]. Although the water vapor permeability of acetylated monoacylglycerol films is considerably less than that of most polysaccharide films, it is greater than the permeability values of ethyl- and methylcellulose [145].

34.2.4.3 Waxes: Beeswax, Candelilla Wax, Carnauba Wax

Waxes are important derivatives of higher alcohols, such as C_{12}–C_{28}, which are esterified to long-chain fatty acids.

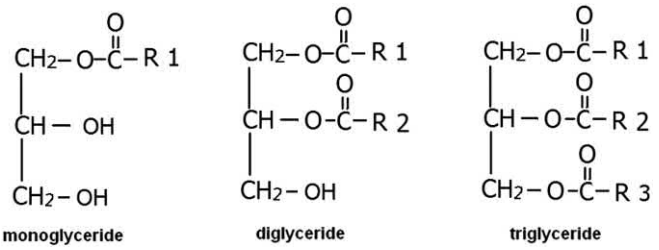

FIGURE 34.13 Acylglycerols (monoacylglycerol or monoglyceride; diacylglycerol or diglyceride; and triacylglycerol or triglyceride), also known as glycerides.

Traditionally, wax coatings have been applied to fresh fruits and vegetables to extend their postharvest storage life. Edible waxes are significantly more resistant to moisture transport than most other lipid or nonlipid coatings. It has been reported that waxes are most effective in blocking moisture migration; paraffin wax being the most resistant followed by beeswax [144, 146, 147]. For this reason, waxes are commonly used as lipid coatings for encapsulation of food ingredients, particularly for the encapsulation of water-soluble ingredients. In 1980, Petroleum wax was permitted for use by the US Food and Drug Administration (USFDA) in formulating microcapsules for encapsulation of spice-flavoring substances in frozen pizza [148].

The great resistance of paraffin and beeswax coatings to diffusion of water is related to their molecular compositions. Paraffin wax consists of a mixture of long-chain saturated hydrocarbons, whereas beeswax comprises 71% hydrophobic, long-chain ester compounds, 15% long-chain hydrocarbons, 8% long-chain fatty acids, and 6% other compounds [149, 150]. The absence of polar groups in paraffin and the relatively low level in beeswax account for their significant resistance to moisture transport. Main components of beeswax are paraffin (about 15%), triacontylcerotinate (approximately 10%), and triacontylpalmitate (about 75%) [142]. In general, waxes are practically insoluble in water. Beeswax melts in the range of 62°C to 64°C, and the color of beeswax varies from nearly white to brownish [43].

Candelilla wax is soluble in several organic solvents and melts in the range of 67–79°C. The color of candelilla wax is light brown to light yellow. It is compatible with all animal and vegetable waxes, fatty acids, and a large variety of natural and synthetic resins. Carnauba wax is one of the hardest natural waxes and has a melting point (about 83°C) higher than that of candelilla wax [43]. Waxes are isolated from plant and animal products. Candelilla wax is derived from leaves of the Candelilla shrub that grows in northern Mexico. Meanwhile, carnauba wax is obtained from leaves of palm trees in Brazil. Beeswax is secreted by young honey bees to construct the honeycomb [43].

34.2.4.4 Lecithins

Lecithin plays a significant role as a surface-active substance in the production of emulsions. Pure lecithin is a water-in-oil (W/O) emulsifier with a hydrophile–lipophile balance (HLB) value of about 3. Because commercially used lecithins are complex mixtures of lipids, their HLB values vary considerably.

Major phospholipids of raw soybean lecithin are listed in Table 34.4 [151]. The ethanol-insoluble fraction is suitable for stabilization of W/O emulsions and the ethanol-soluble fraction for O/W (oil-in-water) emulsions. To increase the HLB value, "hydroxylated lecithins" are prepared by controlled partial oxidation of unsaturated acyl residues with hydrogen peroxide or benzoyl peroxide [151].

Lecithin vesicles have recently been used for encapsulation of food enzymes since the formation of lecithin capsules can be achieved under a relatively low temperature. Using lecithin vesicles to encapsulate lysozyme and pepsin, it was found that the encapsulating efficiency was best when the pH was close to the isoelectric point of each enzyme [152].

TABLE 34.4
Percentage of Phosphatidyl Compounds in Unfractionated and Fractionated Soy Lecithin

Type	Unfractionated	Ethanol-Soluble Fraction	Ethanol-Insoluble Fraction
Phosphatidylethanolamine	32.6	32.5	32.6
Phosphatidylcholine	32.6	65.1	4.6
Phosphatidylinositol	34.8	2.4	62.8

If blended with other coating materials, lecithin changes the structure of microcapsules formed. Studies by Matsuzki et al. [153] on the encapsulation of β-galactosidase in lecithin-cholesterol liposomes prepared by dehydration–rehydration (DR) and reverse-phase evaporation (RE) revealed that encapsulation efficiency decreased as cholesterol content increased. A mixture of lecithin and polyethylene has been used for encapsulating active ingredients such as sweeteners and flavor compounds [154]. Furthermore, lecithin itself has also been encapsulated as a dietary supplement [155].

34.2.4.5 Liposomes

A liposome (or lipid vesicle) is defined as a structure compound of lipid bilayers that encloses a number of aqueous or liquid compartments [156]. Prepared by a variety of techniques, liposomes consist of one, a few, or many concentric bilayer membranes whose diameter size varies from about 25 nm to several micrometers (Figure 34.14). Figure 34.15 shows the general chemical structure of one of the main phospholipids/phosphodiacylglycerols, namely, phosphatidylcholine. Phospholipids contain two long-chain fatty acids. The third hydroxyl group of the basic glycerol is modified with the phosphoric acid linked to a base such as an ethanolamine or choline [142]. As with triacylglycerols [43], numerous species are possible by variation of the different head groups and fatty acyl substitution at the second and first position of the glycerol backbone.

The most abundant phospholipid is lecithin [157], where the base is choline. The fatty acid components may be unsaturated or saturated, such as stearic, palmitic, oleic, linoleic, or linolenic acid. Other polar lipids are cephalins where the base is ethanolamine (phosphatidylethanolamine). Over the past few decades, liposomes have been studied extensively in the medical and pharmaceutical areas because of their potential use as targetable carriers of drugs and bioactive macromolecules [158]. Liposome microencapsulation technologies have been developed almost to the point where they can be employed in a variety of commercial applications. Recently, there has been interest in use of liposomes in the food industry for development of new food products with improved

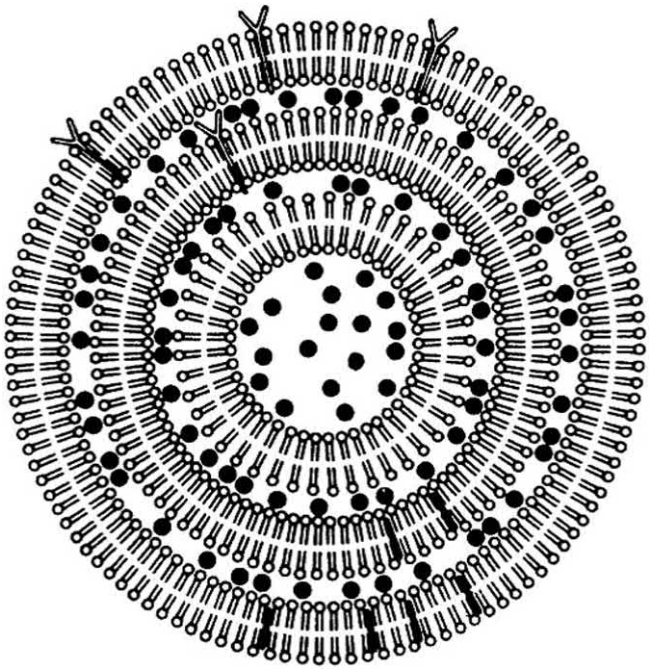

FIGURE 34.14 Schematic structure of a liposome. (Adapted from Shahidi and Han [499].)

characteristics, especially for encapsulation or immobilization of enzymes.

Phospholipids generally form liquid crystalline suspensions as long as the temperature is held at above the phase transition. Because of the amphiphilic character, they function well as emulsifying and dispersing agents. Thus, when mixed with water, they self-assemble or aggregate into well organized and defined bilayers and structures [157]. Liposomes are prepared from phospholipids such as those from egg yolk or soybean lecithin. Semisynthetic phospholipids with fatty acid chains of defined length and saturation as well as cholesterol are also used for specific purposes. The choice of the type of phospholipid and the amount of cholesterol play important roles in determining liposomal stability upon storage and their fate in injected animals [158]. Virtually any substance regardless of solubility, electrical charge, molecular size or other structural characteristics can be incorporated into liposomes, provided that the substance does not interfere with liposome formation [158]. Water-soluble materials may be entrapped in the aqueous phase of liposomes, whereas lipid-soluble materials will be incorporated into the lipid phase. Liposome structure is determined by its method of preparation. Although various techniques exist for preparing liposomes [159, 160], they are generally divided into three classes, namely, multilamellar vesicles (MLV), small unilamellar vesicles (SUV), and large unilamellar vesicles (LUV).

Multilamellar vesicles were first prepared by Bangham et al. [161]. In a typical preparation, a solution of phospholipids in chloroform is evaporated producing a thin film, which is then hydrated with an aqueous solution. The main advantage of MLVs is that the lipid and the aqueous solution to be encapsulated are not subjected to harsh treatments such as exposure to organic solvents or to high-intensity ultrasound. However, a major disadvantage of MLVs is their heterogeneous size distribution (diameters in the range 0.2–2.0 μm) and their low encapsulation efficiency (5–14%) [162].

Small unilamellar vesicles were first prepared from MLVs by sonication. High-intensity ultrasound results in MLVs of a much smaller size (25–50 nm in diameter). A second method for producing SUVs involves injection of lipids, dissolved in ethanol into the desired aqueous phase. The resulting vesicles had diameters in the range of 30–110 nm, while a third technique involves pumping of MLVs through a French pressure cell to produce liposomes with diameters in the range of 30–50 nm [160]. The main disadvantage of SUVs is their small diameter and consequently their low capture volume.

Several methods are available for production of LUVs whose size range from 100–500 nm; these are often the most useful liposomes. The three common methods of preparing LUVs are infusion, reverse-phase evaporation, and detergent dilution. In general, LUVs are more homogeneous than MLVs and have a higher encapsulation efficiency than SUV.

The gel-to-liquid-crystalline transition temperature is one of the key parameters for liposomal systems, where the bilayer loses a considerable amount of its ordered packing structure because of the melting of hydrocarbon chains of the lipids. Liposomal content might leak out fast, especially above the gel-to-liquid-crystalline temperature. Furthermore, liposomal functionality and properties depend on external parameters such as ionic strength and pH of the medium [157]. Phospholipids are present in almost all plant and animal cells. Commercially, they are isolated from several sources such as soybean oil and egg yolk [163]; however, they are also produced from milk fat globules isolated from buttermilk [164].

A serious drawback of the aforementioned liposome preparations for their application in foods has been the use of organic solvents. Liposome microencapsulation using a microfluidizer eliminates this problem because the method does not utilize any organic solvent or detergent. The two most common microencapsulation techniques, spray drying and extrusion, encounter major problems with flavor encapsulation, the

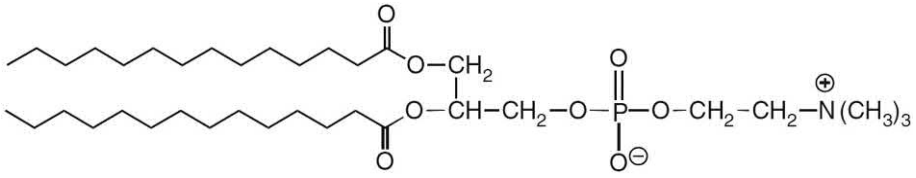

FIGURE 34.15 Phospholipid (e.g., phosphatidylcholine).

occurrence of oxidative reactions, and inability to implement procedures for intermediate-moisture foods [156]. A limitation of the use of liposomes in some food applications may be their lack of stability in the presence of moderate levels of oils or hydrophobic proteins.

34.2.5 Proteins

As an important nutrient in food, proteins possess many desirable functional properties. These properties allow them to be good candidates as coating material for the encapsulation of food ingredients, even though food hydrocolloids are mostly used for this purpose. Gelatine is the most commonly used protein for this purpose, but other proteins such as sodium caseinate, whey protein and soy concentrate, and soy protein isolates have been utilized [165]. Protein-encapsulated tallow and vegetable oils have been applied to produce animal feed [166]. Proteins can also be used, together with other coating materials, to form microcapsules. A mixture of protein and carbohydrate has been applied to an encapsulation process of oily substances [167, 168].

34.2.5.1 Gelatine

Gelatines are water-soluble molecules that vary widely in their size and charge distribution. Nevertheless, they generally have a characteristic primary structure determined by the parent collagen [169]. Gelatine derived from pig skin consists of 33 glycine, 11 alanine, 13 proline, 9 hydroxyproline, 3.5 serine, 5 arginine, 3 aspartic acid, 2.5 glutamic acid, 3 lysine, and also leucine, valine, threonine, phenylalanine, isoleucin, hydroxylysine, histidine, tyrosine, and methionine. However, this can vary depending on the source of raw material as well as the processing technique employed. In type B gelatines, glutamine and aspargine are missing due to their conversion into glutamic acid and aspartic acid. The molar mass of gelatine is less than 5×10^4 g/mol [169]. Gelatines do not occur naturally but are manufactured from collagens by destroying the secondary and higher structures of collagen. Higher structures of collagen are the major constituent of all white fibrous connective tissue occurring in animals such as cartilage, skin, and sinews. The manufacturing process of gelatine is complex and uses skin, bone, or hide from all domesticated cattle, pigs, and horses as preferred sources; fish skin may also be used as a starting material source [43].

Gelatine that is derived from collagen is a valuable coating material partly because it is nontoxic, inexpensive, and commercially available in nature. In addition to good film-forming properties, gelatine has other ideal chemical and physicochemical characteristics that lend themselves to microencapsulation. For example, gelatine forms thermally reversible gels when warm aqueous suspensions of polypeptides are cooled. Fish skin gelatine has a lower gelation temperature of about 5°C for cold-water fish skin gelatine, while mammalian gelatines dissolve in hot water, thus forming solutions of high viscosity [170]. With an aqueous solution of gelatine, the change between the gel and solid state is quite definite. However, when the gelatine concentration in the aqueous solution is lower than about 1%, definite gelation cannot be observed even by cooling. These characteristic properties are effectively used for formation of capsules. The isoelectric point of gelatine and its derivatives can be changed depending upon the method of preparation [171]. By changing the pH of the aqueous solution, either polycationic or polyanionic effects are exhibited by gelatine. This property is used for coacervation formation.

Gelatine is often used in combination with gum acacia to form coating films. Gum acacia, a hydrocolloid derived from plant sources, consists mainly of carboxylic acid functional groups. When the pH is lower than its isoelectric point, gelatine becomes polycationic, and hence, there is an interaction between polycationic gelatine and polyanionic gum acacia, resulting in the formation of a coacervation. As an example, if pigskin gelatine (isoelectric point pH 8–8.5) in aqueous solution is mixed with gum acacia at pH 4.0–4.5, a complex coacervation will form because of the charge attraction between the negatively charged acacia gum and the positively charged gelatine [171]. Fixing (insolubilization) of this structure can be achieved by the use of cross-linking agents such as ionized calcium. The type of gelatine and gum acacia selected, and the formation and fixing procedures employed ultimately influence coating permeability [171]. Coating formation can also be achieved by a solvent evaporation technique.

34.2.5.2 Gluten

Gluten is a complex mixture of gliadins (monomeric gluten) with a molar mass of about 3×10^4 to 8×10^4 g/mol [172] and glutenins (polymeric gluten) with a molar mass of approximately 8×10^4 to several million g/mol [173]. Gliadin is a highly heterogeneous mixture of monomeric gluten. There are three groups of gliadins: α-, γ-, and ω-type. The ω-type gliadins are classified as sulfur-poor prolamins, whereas the α- and γ-types are classified as sulfur-rich prolamins [174].

Wheat glutenin is a heterogeneous mixture of disulfide-stabilized polymers of low-molar-mass glutenin subunits (LMM-GS) and high-molar-mass glutenin subunits (HMM-GS). Recently, more than 19 different HMM-GS have been identified [175]. Glutenin has low solubility in water because of its higher content of nonpolar amino acids and glutamine, lower content of amino acids with ionizable groups, and their high molar mass [176]. Both glutenin and gliadin exist conjoined with starch, in the endosperm of several grass-related grains such as wheat, barley, and rye [177].

34.2.5.3 Milk Protein

Bovine milk consists of water, lactose, fat, other minor components, and nearly 3.0% to 3.6% proteins (caseins and whey proteins are the two major fractions) [178–181]. These can be used in different ways in a variety of food formulations.

34.2.5.3.1 Caseins

The most predominant phosphoprotein found in milk is casein. Four principal primary proteins of the highly heterogeneous casein fractions are αs_1-, αs_2-, β-, and κ-casein (Table 34.5). Caseins may differ in their net charge, metal binding,

TABLE 34.5
Typical Characteristics of Casein Fractions of Bovine Milk

and hydrophilicity. Caseins do not coagulate by heat since they are very heat-stable proteins. Caseins are insoluble at their isoelectric point around pH 4.6. Furthermore, the solubility behavior of casein fractions isolated from milk is different. Generally, caseins are manufactured from skim milk by destabilizing the micelles [43].

34.2.5.3.2 Whey Proteins

Whey is a by-product of cheese or casein production and has some commercial uses. Whey proteins primarily include α-lactalbumin, β-lactoglobulin, serum albumin, and immunoglobulins (Table 34.6). Whey proteins are globular proteins and soluble in the ionic environment of milk, almost independent of pH [182]. However, they become insoluble at their isoelectric point and at low ionic strength (pH of about 5). Whey proteins become insoluble and denature at temperatures above 70°C and form thermally irreversible gels [183].

The remains after removal of caseins and fat from milk are whey proteins. There are different whey protein products that can be isolated, namely, whey powders of different quality (delactosed, demineralized, and demineralized–delactosed), whey protein isolate (WPI), whey protein concentrate (WPC), lactalbumin, and individual whey protein fractions. WPC typically contains 35–80% protein and a low level of fat. During the isolation of WPI, fat and lactose are removed yielding a higher protein content of >90%. The most important whey protein is β-lactoglobulin [183]. Proteins recovered from milk are becoming increasingly important, especially when considering emerging technologies, such as the microencapsulation of ingredients [184], and manufacture of edible films [185], which may benefit from further developments in this area [181].

34.2.6 Others

34.2.6.1 Polyvinylpyrrolidone (PVP)

Polyvinylpyrrolidone (PVP), 1-ethenyl-2-pyrrolidoinone homopolymer (Figure 34.16) is a synthetic neutral polymer, with a molar mass of about 1×10^4 to 5×10^5 g/mol. Powder of PVP is well soluble in both organic solvents and water. The good film-forming ability makes it a better polymer for coatings that requires temperature stability [186].

34.2.6.2 Shellac

Shellac is secreted by the lac insect *Laccifer lacca* found in some of the forests of northeast India, China, Bangladesh, and Thailand. Shellac is soluble in alkaline media such as sodium hydroxide, sodium carbonate, and ammonia as well as in several organic solvents. The chemical composition of shellac is still unknown, and its physical properties and composition depend on source and time of the harvest. For instance, its melting point ranges from 77°C to 120°C. Shellac is soluble in methanol, ethanol, glycol ethers, and glycols [187].

Isoionic point	4.2–4.5	5.2	5.3	

Source: Adopted from Ennis et al. [181].

34.2.6.3 Paraffin

Paraffin is the family of linear hydrocarbons with the general formula of C_nH_{2n+2}. It is dependent on the number of carbon atoms that could differ from 1 to 40. Paraffin is edible but not digestible, and is a white, tasteless, and odorless waxy material with a melting point ranging from 48°C to 95°C [43].

34.2.6.4 Inorganic Materials

There are some food-grade inorganic materials that have been described as being useful for microencapsulation or coatings in food applications, which include aluminum oxides, tripolyphosphate, or silicon oxides. They can be utilized alone or in combination with other materials [188, 189].

34.3 ENCAPSULATION

The food industry employs the encapsulation process for different reasons [190]; these include the following.

1) Encapsulation can protect the material from degradation and reduce interaction with the outside environment such as moisture, heat, light, and air, which may influence the ingredients and lead to loss of their functionality [20, 191].
2) Encapsulation can be used as a delivery system whereby the ingredient is released at the required time and at a certain point such as releasing of the leavening agent at a certain temperature during baking [20, 191].
3) The physical characteristics of the original material could be modified in order to allow its easy handling [20].
4) It could be used to separate components within a mixture that may react with one another [20].

34.3.1 Microencapsulation

Nearly 80 years ago microencapsulation was developed as a technology for packaging liquids, solids, or gaseous materials that are miniature or smaller than the normal size of the package [19, 192]. Designing of a microencapsulated ingredient requires knowledge of several factors: the core, the encapsulation material, interaction between the matrix or the wall material, the core and the environment, and the stability of the microencapsulated ingredient during storage. Although many ingredients are suitable to be encapsulated, processing costs are expensive and scaling up of the process might not always be feasible [193, 194]. The different methods for microencapsulation are described in the following sections.

34.3.1.1 Spray Drying

Spray drying is a low-cost technology commonly used at the industrial level. It offers the advantage of producing microcapsules in a fairly simple and economical way compared to other techniques [195]. Encapsulation by spray drying starts with homogenizing the active substance with the carrier material in a liquid medium (Figure 34.17). The emulsion is pumped into the drying chamber through a nozzle. At the exit of the nozzle tip, the droplets are allowed to come into contact with the drying fluid (hot gas) inside the drying chamber. Water is evaporated by hot air and a dry crust is formed on the droplet surface when the droplet water content reaches a critical value, and based on this process the wall material covers the active material. Finally, the dry microcapsules are collected at the powder collector of the cyclone or at the bottom of the dryer [196, 197].

Spray drying accounts for the majority of commercial encapsulated materials in food products [41]. It is typically used for the preparation of dry, stable food additives and flavors. At first, it is by no means obvious that spray drying is suitable for encapsulating flavors, because in principle the volatile flavor compounds evaporate faster than water. It is only a question of finding suitable carriers that prevent the volatile flavor compounds from being lost during the drying process, yet simultaneously allow water to evaporate unhindered [197]. Spray drying is economical, flexible in that it offers substantial variation in the encapsulation matrix, adaptable to commonly used processing equipment, and produces particles of good quality [198–200]. In fact, spray drying production costs are lower than those associated with most other

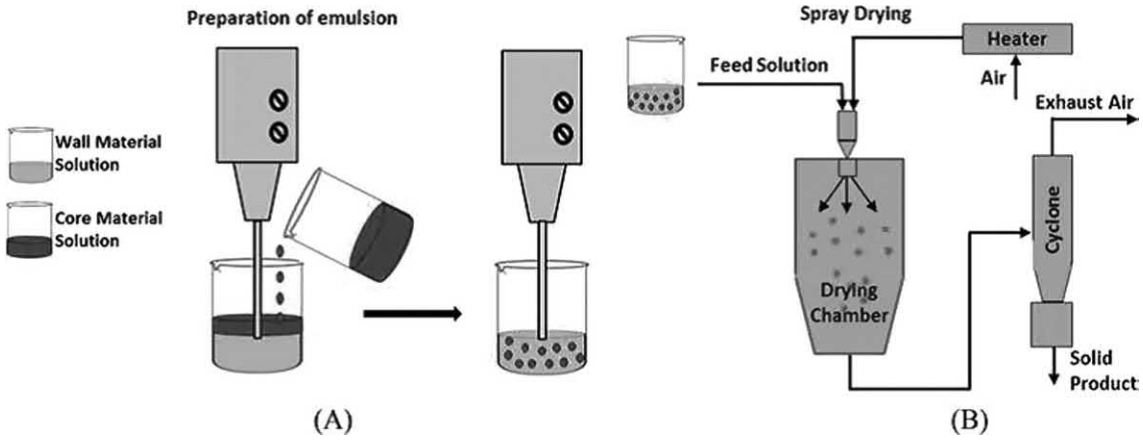

FIGURE 34.17 (A) Preparation. (B) Spray drying apparatus. (Adapted from Drosou et al. [197].)

methods of encapsulation. It is also one of the oldest and well-known encapsulation techniques—the C.E. Rogers Co. has been manufacturing spray dryers since the early 1900s— and is a standard technology in the food industry, especially the dairy industry [201]. In the 1930s spray drying was employed to prepare the first encapsulated flavors using gum acacia as the coating [202].

Although spray drying is most often considered as a dehydration process and is used in the preparation of dried materials such as powdered milk, it can be used as an encapsulation process when it entraps "active" materials within a protective matrix formed from a polymer or melt. In most cases, the encapsulated actives are released upon contact of the product with water, which dissolves the spray dried capsules [41]. The process is conducted in a spray dryer such as the one shown in Figure 34.17 and involves the following basic steps.

34.3.1.1.1 Preparation of the Dispersion or Emulsion

The initial step in spray drying an encapsulated food ingredient is the selection of a suitable wall material or encapsulating agent. The ideal choice should have adequate emulsifying properties; be a good film former; have low viscosity at high solids levels (<500 cps at ≥45% solids levels); exhibit low hygroscopicity; release the coated ingredients when reconstituted in a finished food product; be low in cost, bland in taste, and stable in supply; and afford good protection to the encapsulated ingredients [59, 203]. A food-grade hydrocolloid such as a gelatine, vegetable gum, modified starch, dextrin, or nongelling protein [38] is generally used as an encapsulating agent.

Once a wall material or combination has been selected, it must be hydrated. It is desirable to use a particular infeed solids level, which is optimum for each encapsulating agent or the combination chosen. Research has shown that the infeed solids level is the most important determinant of flavor retention during the spray drying process [48]. Increasing the solids level up to the point that the additional solids are no longer soluble benefits flavor retention by decreasing the required drying time to form a high solids surface film around the drying droplets. Once the droplet surface reaches about 10% moisture, flavor molecules cannot diffuse through this surface film, while the relatively smaller water molecules continue to do so and are lost to the drying air [204–207].

A high infeed solid means that this semipermeable membrane forms quickly and thus assists flavor retention. It is possible to pump and atomize infeed materials that contain encapsulating agent solids in excess of the solubility limits. Insoluble solids offer no barrier to the diffusion of flavor molecules and therefore do not improve flavor retention during drying. It has been found that there is an optimum infeed solids level that is unique for each wall material [203, 208, 209].

Once the encapsulating agent or mixture has been solubilized (with or without heating), the flavor or ingredient to be encapsulated is added to the mixture and then thoroughly dispersed into the system. A typical ratio of encapsulating agent to core material is 4:1, but in some applications higher flavor loads are used. Brenner et al. [210] have obtained a patent for a process that produces high-load spray dried flavorings. They claim that high surface oils and poor flavor retention during drying are largely due to particle shrinkage and cracking during the dehydration process. A cracked particle surface results in substantial flavor loss during drying. Brenner et al. [210] used a combination of polysaccharides (e.g., gum arabic, starch derivatives, and dextrinized and hydrolyzed starches) and polyhydroxy compounds (e.g., sugar alcohols, lactones, monoethers, and acetals) to form an encapsulating mixture, which remained in plastic during spray drying. Using this plastic encapsulating agent, Brenner et al. [210] reported to have spray dried infeed materials with a flavor load of up to 75% (based on dry solids). Mass balance data showed oil recoveries of 80% at this high loading. However, higher flavor loads typically result in an unacceptable loss of flavors in the dryer. For example, Emberger [211] has shown that compared to a 10% loading only 33% to 50% of the flavor was retained during drying when a 25% flavor load was used.

34.3.1.1.2 Homogenization of the Dispersion

Prior to spray drying, the mixture is homogenized in order to create small droplets of flavor or ingredient within the encapsulating solution. The creation of a finer emulsion increases the retention of flavor during the drying process [23]. Sometimes the addition of an emulsifier is required, and the dispersion is then homogenized prior to spray drying. However, considerable process variation exists within the industry in this respect. Risch and Reineccius [212] reported a direct relationship between the degree of homogenization and the retention of orange peel oil during spray drying. Therefore, it appears advantageous to efficiently homogenize the dryer infeed material. Water-soluble materials may also be encapsulated by the treatment of homogenization. Instead of having a clearly defined core and coating, the product consists of a homogeneously blended matrix of the polymer entrapping the core. These products are sometimes described as matrix particles or entrapped ingredients. They are also said to be covered with a very fine film of coating.

34.3.1.1.3 Atomization of the Infeed Emulsion

The core/wall material mixture is fed into a spray dryer where it is atomized through a nozzle or spinning wheel. The single-fluid, high-pressure spray nozzle and the centrifugal wheel are two types of atomizers that are widely used; the industry is nearly equally divided between their use. While each type of atomizer has its advantages and disadvantages, there is nothing in the literature that suggests that one type is superior to the other.

Atomization parameters have a significant effect upon the particle size distribution of the resultant powders. Several researchers have reported that larger particles result in improved flavor retention, but Reineccius and Coulter [46] found that particle size had no effect on flavor retention. On the other hand, studies by Chang et al. [213] indicated that there is an optimum particle size for flavor retention. Part of the controversy was cleared up by Bomben et al. [207] who showed that particle size was insignificant if high infeed solids were used. This might explain why some authors found a

relationship between particle size and flavor retention while others did not. Although particle size may have a minimal influence on flavor retention during drying, it is often desirable to produce large particles to aid in dispersion upon reconstitution. Small particles are often difficult to disperse and tend to float on liquid surfaces. Larger particles can be obtained by using a large orifice, low atomization pressure (pressure nozzle only), high infeed solids, high infeed viscosity, low wheel speed (centrifugal wheel atomization only), or some type of agglomeration technique [214].

34.3.1.1.4 Dehydration of the Atomized Particles

When hot air flowing in either a cocurrent or countercurrent direction contacts the atomized particles, water is evaporated and a dried product consisting of starch or an encapsulating matrix containing small droplets of flavor or core is formed. As the atomized particles fall through the gaseous medium, they assume a spherical shape with the oil encased in the aqueous phase. This explains why most spray dried particles are water-soluble. The rapid evaporation of water from the coating during its solidification keeps the core temperature below 100°C in spite of the high temperatures used in the process [215]. The particles' exposure to heat is in the range of a few seconds at most [38]. Thus, the main advantage to this method is its ability to handle many heat-labile materials. Because a flavor may contain as many as 20 to 30 different components (alcohols, aldehydes, esters, ketones, etc.) with boiling points ranging from 38°C to 180°C, it is therefore possible to lose certain low-boiling point aromatics during the drying process [199]. The dried particles fall to the bottom of the dryer and are collected, or they may be separated by a gas–solid separation unit such as a dust cyclone. Spray dried ingredients typically have a very small particle size (generally less than 100 μm), which makes them highly soluble but may present separation problems in dry blends. Separation can be prevented, and fluidity improved by a separate compacting or agglomeration step; in the latter, encapsulated particles are treated with steam to induce their cohesion and form large particles. Factors such as the coating structure may also affect the solubility of the spray dried microcapsules [216].

The processes of compacting and agglomeration complement spray drying. In both processes the objective, as stated above, is to obtain larger particles. Compacting gives a compressed product with lower porosity (strength). For example, spray dried flavors are compressed under high pressure into lumps and then crushed into small pieces ranging in size from 0.7 to 3.0 mm. This process is useful for applications where a grainy structure is required to assure that flavors will not separate (e.g., in tea bags). Agglomeration products, on the other hand, are loose products with high porosity (instant properties). Spray dried product is fluidized in hot air. The fluidization singles out powder particulates and allows them to be sprayed from all sides. By spraying onto a binder, such as water, the powder particles gradually stick to one another forming larger particles [198].

Feed temperature is one of the main factors that affect encapsulation efficiency and particle morphology. Feed temperature modifies the viscosity and homogeneity, therefore if feed temperature increases to a certain level, the droplet size and viscosity will decrease. However, extremely high temperatures could cause degradation or volatilization of some ingredients [217]. Shu et al. [218] encapsulated lycopene by using a gelatin–sucrose system and found that encapsulation efficiency increased through increasing feed temperature from 35°C to 55°C, while at 65°C encapsulation efficiency decreased. Brückner et al. [219] reported that the ideal feed temperature for microencapsulation of food ingredients was about 40°C because of the higher drying rate and the lower feed viscosity; however, a feed temperature of around 60°C was disadvantageous because it lowered the viscosity of the carrier material. Moreover, Yamamoto et al. [220] investigated the influence of feed temperature on encapsulation efficiency of D-limonene by using a mixture of gum arabic and maltodextrin. The results presented showed that the powder prepared at a higher temperature had better stability against the oxidation and release of D-limonene was higher than that of the powder obtained at a lower temperature. The findings might be partly attributed to an increase in shell thickness of the particle at higher temperatures, which creates a stronger barrier against the diffusion of oxygen as well as moisture from the surrounding environment. Furthermore, another study reported that the encapsulation efficiency of D-limonene was not significantly dependent on the feed temperature [221].

Another important parameter in spray drying is air inlet temperature and flow rate during the process, therefore these variables must be adjusted so that the liquid sprayed evaporates before it reaches the drying chamber. According to a recent study, powders with higher content of bioactive compounds are produced at lower inlet drying temperatures as well as a higher feed rate [222]. The encapsulation efficiency of lycopene, with maltodextrin as wall material, increased when inlet air temperature was increased from 110°C to 150°C, while the efficiency became almost constant when the temperature reached 160°C [223]. With an inlet temperature increasing from 170°C to 210°C, the encapsulation efficiency of lycopene increased at the beginning; however, it decreased dramatically when temperature reached 210°C [218]. Microencapsulation of vitamin C by using gum arabic as the wall material was studied at air temperatures varying from 140°C to 200°C and the wall material concentration of 10–20% [218]. Paramita et al. [221] found a reduction in flavor of spray dried powder product after increasing the inlet air temperature from 120°C to 150°C. In addition, they reported that higher inlet air temperature enhanced the vaporization of flavor compounds during the drying process.

The concentration of wall material in the solution can be increased in order to obtain a high microencapsulation efficiency, which could be related to the formation of a shell around the core material [224]. Rubilar et al. [225] reported that the microencapsulation efficiency of flaxseed oil increased from 54.6% to 90.7% after using a high concentration of 30% wall material that was composed of maltodextrin mixed with gum arabic instead of 25% wall material. Lewandowski et al. [226] spray dried nonfoamed and foamed emulsions of sunflower

oil and showed that the foaming process reduced the powder density by 50% compared to the powder produced from a nonfoamed emulsion in addition to increasing the microencapsulation efficiency.

Generally, wall materials have to be soluble in water in all spray drying processes in the food industry and must also have good emulsification properties, film forming around liquid droplets, and solutions of concentrated wall material should be of low viscosity [227, 228]. Flaxseed oil, one of the richest sources of plant-derived omega-3 fatty acids, has been successfully stabilized by spray drying. Sodium caseinate and whey proteins as wall materials improved the oxidative stability during storage of flaxseed oil [229].

In a recent study, the potential of a maltodextrin combination with different wall materials such as whey protein, gum arabic, and starch was examined for microencapsulation of flaxseed oil by using spray drying. The results showed that maltodextrin in combination with modified starches gave better encapsulation efficiency compared to a whey protein and gum arabic combination. Moreover, better emulsion stability and oxidation protection were found in the maltodextrin and whey protein combination [230].

There are certain factors that limit the use of spray drying. Firstly, the variety and number of wall materials available are limited, as they should have good water solubility. Secondly, the product considered as microcapsule powder needs additional processing like agglomeration. Another consideration is lower oxidative stability caused by the high temperatures used during the atomization process; this may limit the use of this technique [195]. For additional details about the spray drying process, the reader may view the reference by Drosou et al. [197].

34.3.1.2 Electrohydrodynamic Techniques

In these processes, electrostatic forces are used to produce electrically charged jets from viscoelastic solutions that on drying produce ultrathin structures by evaporating the solvent [231]. This technique is referred to as electrospinning when ultrathin continuous fibers are generated. Electrospraying consists of four main components: (i) a high-voltage source (1–30 kV), which is commonly operated in direct current mode, even though using alternating current mode is also possible; (ii) blunt-ended capillary or stainless-steel needle; (iii) a syringe pump; and (iv) a grounded collector (Figure 34.18) [232].

Both electrospinning and electrospraying work on the same principle with minor differences. The electrospinning process involves the application of a strong electrostatic field by the high voltage across a conductive capillary attached to a reservoir containing a polymeric liquid. Upon increasing the electrostatic field strength to a critical value, the solvent evaporates [233]. The difference between electrospraying and electrospinning, which might be considered as "sister" technologies, is based on viscosity and concentration of the polymer solution [234, 235]. The particle diameter or fiber and morphology in the electrospinning process are strongly dependent on several parameters [231] that include intrinsic properties of the polymer solution such as elasticity, viscosity, electrical conductivity, and type of polymer as well as operational conditions such as the strength of the applied electric field [236].

34.3.1.3 Spray Cooling and Spray Chilling

Spray cooling and chilling are two commercially practiced encapsulation processes similar to spray drying in that both involve dispersing the core material into a liquefied coating material and spraying through heated nozzles into a controlled environment [237]. Unlike spray drying, however, there is no water to be evaporated since the coating material is a fat. Other principal differences between these processes and spray drying lie firstly in the temperature of the air used in the drying chamber and secondly on the type of coating applied. Spray drying employs hot air to volatilize the solvent from a coating dispersion; in contrast, spray cooling and spray chilling use air-cooled to ambient or refrigerated temperatures. The core and lipid wall mixtures are atomized into the chilled air, which causes the fat to solidify around the core, thereby forming a crude encapsulated product. Spray cooling uses ambient or chilled air in order to solidify molten droplets, whereas spray drying uses heating of the feed line

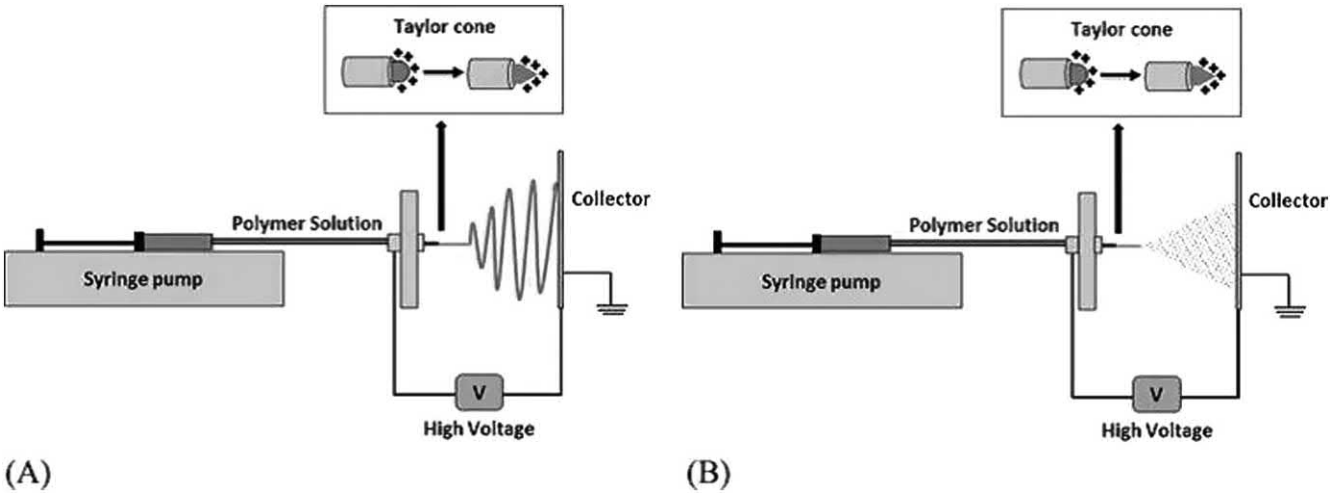

FIGURE 34.18 (A) Electrospinning. (B) Electrospraying. (From Drosou et al. [197].)

[238]. Spray cooling/chilling is a safe, rapid, and reproducible physical process. In addition, it is an environmentally friendly technique compared to other methods, such as spray drying. The most important aspect is the ease to scale up the production since this technique can be operated continuously [239].

In using this technique, the bioactive compound is dispersed or dissolved in a solution of the coating material. Furthermore, the vessel contains the cold medium, and as a result, the wall material solidifies forming a film coating. These techniques take place in one-step rapid process [240]. Spray cooling microencapsulation is considered the cheapest technology, uses lower temperatures and has a high potential for scale-up. It has been used to encapsulate both vitamins and minerals [241].

The particles produced are usually matrix type, and since this process does not include solvent evaporation, the particles produced by spray chilling are dense and mechanically resistant [242]. The spray cooling/chilling technique is cost-effective for probiotics [5] and also benefits from other advantages, as it does not include use of organic solvents that are lethal in the case of probiotics. Moreover, since the matrix is composed of fats, the release of bacteria occurs in the intestine due to the action of lipases [243].

Microcapsules produced by spray chilling and spray cooling are insoluble in water due to the hydrophobic coating. Consequently, these techniques tend to be utilized for encapsulating water-soluble core materials such as minerals, water-soluble vitamins, enzymes, acidulants, and some flavors. The major drawbacks of spray chilling include interactions between the fat and the active ingredient, volatilization of lipid-soluble materials over time, and loss of volatile materials during processing [41].

In spray cooling, the coating substance is typically a vegetable oil or one of its derivatives. Yet, a wide variety of other encapsulating materials can also be employed. These include fat and stearin with melting points of 45°C to 122°C as well as hard mono- and diacyl-glycerols with melting points of 45°C to 65°C. Taylor [199] indicated that mono- and diacylglycerols facilitate dispersion of the encapsulate in the finished, reconstituted food products and may also be considered as part of the overall emulsification system.

In spray chilling, the coating is typically a fractionated or hydrogenated vegetable oil with a melting point in the range of 32°C to 42°C. Coating materials with even lower melting points can be utilized, but their end products may require specialized handling and storage conditions [199]. Furthermore, in spray chilling there is no mass transfer, i.e., evaporation from the atomized droplets, and therefore the droplets solidify into almost perfect spheres to give free-flowing powders. Through atomization, it gives an enormous surface area, and an immediate and intimate mixing of these droplets with the cooling medium.

Spray chilling is used primarily for the encapsulation of solid food additives such as ferrous sulfate, acidulants, vitamins, minerals, and solid flavors, as well as for heat-sensitive materials or those that are not soluble in typical solvents [199]. With the functional food revolution, the importance of spray chilling has increased, particularly in the production of functional food ingredients for the primary purpose of fortification. Liquids may also be encapsulated following their conversion to a solid form, perhaps by freezing. The end products of the process, resembling fine beadlets of a large particle size, are water-soluble but release their contents at or around the melting point of the wall material. With the ability to select the melting point of the wall, this method of encapsulation can be used for controlled release. The process is thus suitable for protecting many water-soluble materials such as spray dried flavors that may otherwise be volatilized from a product during thermal processing. Spray chilled products have applications in bakery products, dry soup mixes, and foods containing high levels of fat [202].

Lamb [244] pointed out the importance of maintaining optimum temperatures during processing, as this can affect the fat's polymorphism, a phenomenon that describes the capability of a substance to exist in more than one crystalline form. He also noted that if a fat, say a powdered triacylglycerol, is permitted to exit from a chiller at a too high temperature, heat generated by polymorphism tends to reverse the encapsulating process and return the powder to a melt or perhaps a pasty mass.

De Lara Pedroso et al. [245] encapsulated probiotics using interesterified palm kernel and palm fat and found that the solid lipid microparticles provide protection for *Lactobacillus acidophilus* and *Bifidobacterium lactis* against the simulated gastric as well as intestinal fluids. Furthermore, promising results for viability during storage in both refrigerators and freezers were obtained. Okuro et al. [243] found similar results when encapsulating probiotics (*Lactobacillus acidophilus*) by using spray chilling with prebiotics in polydextrose within the lipid matrix. Solid lipid particles, prepared by spray chilling, are water insoluble because of the lipid carrier, which could limit some applications in food [190]. In general, these techniques are used for dry products in order to conserve all thermosensitive components such as vitamins, proteins, flavors, and minerals [246, 247].

34.3.1.4 Fluidized Bed Coating

Fluidized bed coating, also referred to as air suspension coating or the Wurster process, is a common technique used for commercial production of encapsulated ingredients for the food industry. It was developed by D.E. Wurster in the 1950s. In general, it has been found that dense particles with narrow particle size distribution and good flowability are most suitable for encapsulation by fluid bed. Ideally a particle size distribution between 50 and 500 μm is best, although it is possible to encapsulate particles ranging from 35 to 5000 μm [25].

Fluidized bed coating is considered as one of the most efficient coating methods with growing applications in the food as well as pharmaceutical industries. In this process, ingredients could be mixed, granulated, and also dried in the same vessel, therefore reducing the processing time and material handling compared to other processes [248]. Furthermore, fluidized bed coating is a powerful tool that produces microparticles in order to promote functionality of food products [249]. The

particles are suspended using an air stream at a specific temperature and sprayed with coating material. Evaporation of water can be controlled by some factors such as airflow, temperature, spraying rate, humidity of the air inlet, and water content [250].

Fluidized bed coating of food ingredients was once viewed as the last choice by a formulator on account of the costs involved. Today, however, high production volumes and well-developed technologies have made a number of encapsulated food products standard items and available at cost-effective prices [251]. Solid particles to be sprayed are suspended in an upward-moving column of air in a fluidized bed chamber at a controlled temperature and humidity. Depending upon the specific application, the airflow may be heated or cooled [237]. Once the moving fluid bed of particles has reached the prescribed temperature, the encapsulation coating material is introduced to the system. Great variations exist as to the type of wall material chosen. Cellulose derivatives, dextrins, emulsifiers, lipids, protein derivatives, and starch derivatives are examples of typical coating systems, and they may be used in a molten state or dissolved in an evaporable solvent. The coating is atomized through binary or pneumatic spray nozzles at the top of the chamber, whose droplets are of smaller size than the substrate being coated. The atomized particles travel down into the particle stream and deposit as a thin layer on the surface of suspended core material. The turbulence of the air column is sufficient to keep the coated particles suspended, thereby allowing them to tumble and become uniformly coated. Upon reaching the top of the air stream, the particles move into the outer, downward-moving column of air, which returns them to the fluidized bed with their coating nearly dried (Figure 34.19). The particles pass through the coating cycle many times per minute [37]. With each successive pass, the random orientation of the particles further ensures their uniform coating. In the case of hot melts, the coating hardens by solidification in cool air. In the case of solvent-based coatings, the coating is hardened by evaporation of the solvent in hot air. The amount of coating applied can be regulated by controlling the length of time (i.e., residence time) that the particles are in the chamber. In order to achieve a good degree of coating, the process takes anywhere from 2 to 12 h to complete. After this period, only 0.2–1.5% of the particles remains uncoated.

The amount of material that coats the particles depends on the length of time that the particles are in a chamber. The different methods of fluid bed include top spray, tangential spray, and bottom spray (Figure 34.19). In the top spray system, the coating solution is sprayed downward with air into the fluid bed that when porous particles move to the coating region they become microencapsulated. Opposing flows of the particles and coating materials lead to increased encapsulation efficiency as well as prevention of cluster formation. This system has been used successfully for obtaining very small microcapsules ranging between 2 and 100 μm. In addition, higher yields of microencapsulated particles were obtained compared to both tangential and bottom spray fluidized bed coaters [195].

Uncontrolled agglomeration of particles is the main problem in the fluidized bed process. In fact, the coalescence of the wet coated material occurs with the formation of liquid bridges between some particles [252]. The liquid bridges become solidified after evaporation of the solvent, thus forming agglomerates. Studies have shown that atomization must be controlled using some variables such as pressure, coating solution concentration, and inlet temperature in order to reduce agglomerations [253–255].

Fluidized bed spray granulation is a more recent technology that allows specific particle size distributions from 0.2 mm to 1.2 mm with low porosities to be designed into the product. As with spray drying, continuous spray granulation starts off with an aqueous emulsion. Repeatedly spraying, applying, and drying drops in a fluidized bed forms granules with an onion-like structure. A particular advantage offered by granulation technology is the possibility of producing large flavored particles of uniform particle size and shape without the need for any additional production steps [198].

The fluidized bed coating technique has been in use for a long time for the encapsulation of vitamins C and B and some minerals. Furthermore, encapsulates of calcium propionate and potassium sorbate produced by fluid bed coating

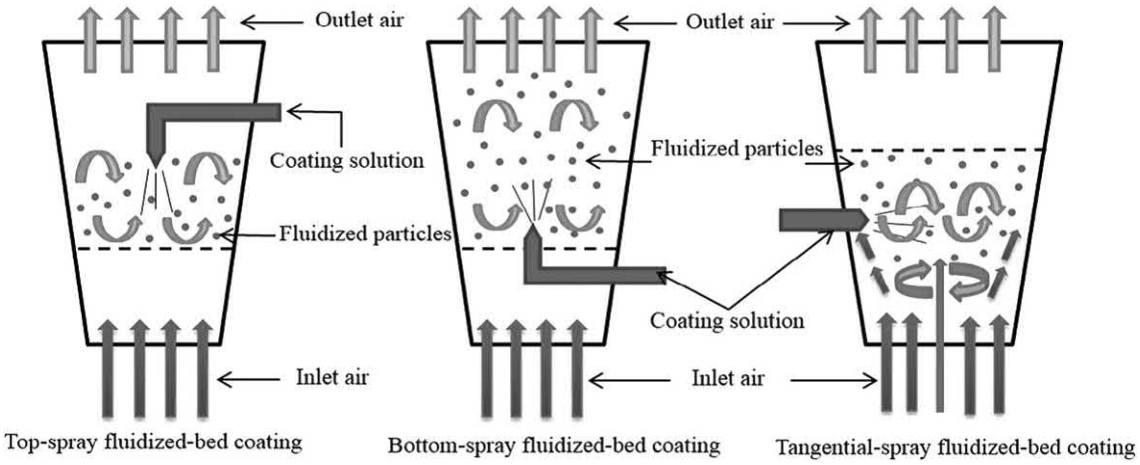

FIGURE 34.19 Diagram to show top, bottom, and tangential-spray fluidized bed coating. (From Bakry et al. [195].)

have wide applications in bakery products. In addition, some flavors and pigments are coated and used in the meat industry [251]. Because of equal temperature distribution, the fluidized bed technique could be carried out at significantly lower temperatures compared to other techniques such as spray drying. This is appropriate for the encapsulation of bacteria, where higher survival rates can be achieved [256, 257].

Schell and Beermann [258] found that the shellac coating of whey-encapsulated probiotic bacteria *Lactobacillus reuteri* might stabilize probiotics during both processing as well as storage. The coating also protects bacteria from acid conditions in the gastrointestinal tract and also improves the physiological effects of probiotics. The main point of selecting the right coating material (gelatine coating) between different types is to control release of fluidized-bed-coated menthol powder. Sixty percent of the menthol powder was released after about 11 min in water at 37°C [259]. Currently, the fluidized bed coating technique is used to encapsulate fish oil by spraying into the fluidized bed chamber followed by film-coating of the granules [248].

34.3.1.5 Extrusion

Encapsulation of food ingredients by extrusion is a newer process than spray drying. Extrusion, used in this context, is not the same as that used for cooking and texturizing of cereal-based products. The extrusion technologies for microencapsulation have been achieved using ram extrusion (melt injection) and screw extrusion (melt extrusion) [260–262]. Actually, extrusion, as applied to flavor encapsulation, is a relatively low-temperature entrapping method that involves forcing a core material dispersed in a molten carbohydrate mass through a series of dies into a bath of dehydrating liquid. The pressures and temperatures employed are typically <100 psi and seldom exceed 115°C, respectively [59]. Upon contact with the liquid, the coating material, which forms the encapsulating matrix, hardens and entraps the core material. Isopropyl alcohol is the most common liquid employed for the dehydration and hardening process. The extruded filaments or strands are then broken into small pieces, dried to mitigate hygroscopicity (an anticaking agent such as calcium triphosphate can facilitate this), and sized.

The main advantage of screw extrusion is its variation in terms of operating conditions, while the major disadvantage is the difficulty of accurately controlling the parameters of this complex setup [262, 263]. Co-extrusion comprises of a dual fluid stream of immiscible liquid core as well as shell materials. Both core and coating materials are pumped separately through the concentric feed tubes. Due to the action of surface tension, the wall material entraps the core material [264, 265].

Schultz et al. [266] were pioneers in the extrusion/encapsulation process. They emulsified orange peel oil in a molten dextrose mass, poured it on stainless steel sheets, and let it cool. The pulverized product exhibited good stability and flavor retention over a 6-month period. Combining the basic formulation of Schultz et al. [266] with extrusion, Swisher [267] created a novel encapsulating process that is similar to the one currently employed today by the flavor industry. The primary benefit claimed in his patent [268] was the maintenance of fresh flavor in encapsulated citrus oils, which otherwise would readily oxidize and yield objectionable off-flavors during storage. He conducted an accelerated shelf-life test on encapsulated orange peel oil that contained an antioxidant and found that its shelf life was about one year. Figure 34.20 shows the key steps for flavor encapsulation by extrusion.

In general, extrusion microencapsulation includes three processes: (i) melt injection, (ii) melt extrusion, and (iii) centrifugal extrusion (co-extrusion) (Figure 34.21). In the melt injection process, the core material is dispersed in molten carbohydrate and after that pressed through either one or more dies orifices to a bath of cold dehydrating liquid such as liquid nitrogen and isopropanol. The wall material solidifies with liquid forming an encapsulating matrix to entrap the core material. The granules are then recovered by centrifugation followed by using vacuum or air drying to remove any residual solvent. The melt extrusion process is also similar to the melt injection. However, the main differences are that melt injection is a vertical screwless process with surface-washed particles, whereas melt extrusion is a horizontal screw process with particles that are not surface-washed. Extruders used in melt extrusion are in a cylinder that contains thermomechanical mixers that consist of either one or more screws [195].

Centrifugal extrusion (co-extrusion) consists of a concentric feed tube through which core materials and wall materials are pumped separately to multinozzles mounted on the outer surface of the device. While wall material flows through the outer tube, the core material flows through the center tube [19]. There are several reasons extrusion encapsulation is popular in the food industry. It is easy to control the inlet temperature, which prevents degradation of heat-sensitive ingredients in addition to controlling the shape of the extruded product. The flexibility to control the processing conditions like moisture content, temperature, and screw speed is another advantage. Finally, extrusion is economical [15].

Swisher [268] added an essential oil such as orange peel oil, containing an antioxidant and a dispersing agent, to an aqueous melt of corn syrup solids (42 DE) and glycerine. The core syrup melt contained 3% to 8.5% moisture and was held at a temperature ranging from 85°C to 125°C, typically 120°C. The flavor/core syrup mixture was vigorously agitated while blanketed under nitrogen to form an oxygen-free emulsion. This emulsion was forced through a die into a hot immiscible liquid (e.g., vegetable or mineral oils), which was then rapidly cooled or extruded into pellets and allowed to solidify. The hardened pellets or solid globules were ground to a desired particle size, washed with isopropanol to remove surface oil and then dried under vacuum to yield a free-flowing granular material containing 8–10% flavoring.

The extrusion process of encapsulation has remained largely unchanged since Swisher's patent [268]. Most research developments to date concern the composition of the material that forms the encapsulating matrix. For example, Beck [269] replaced the high-DE corn syrup solids with a combination of sucrose and maltodextrin; a melt consisting of about 55% sucrose and 41% maltodextrin (10–13 DE). Even though the

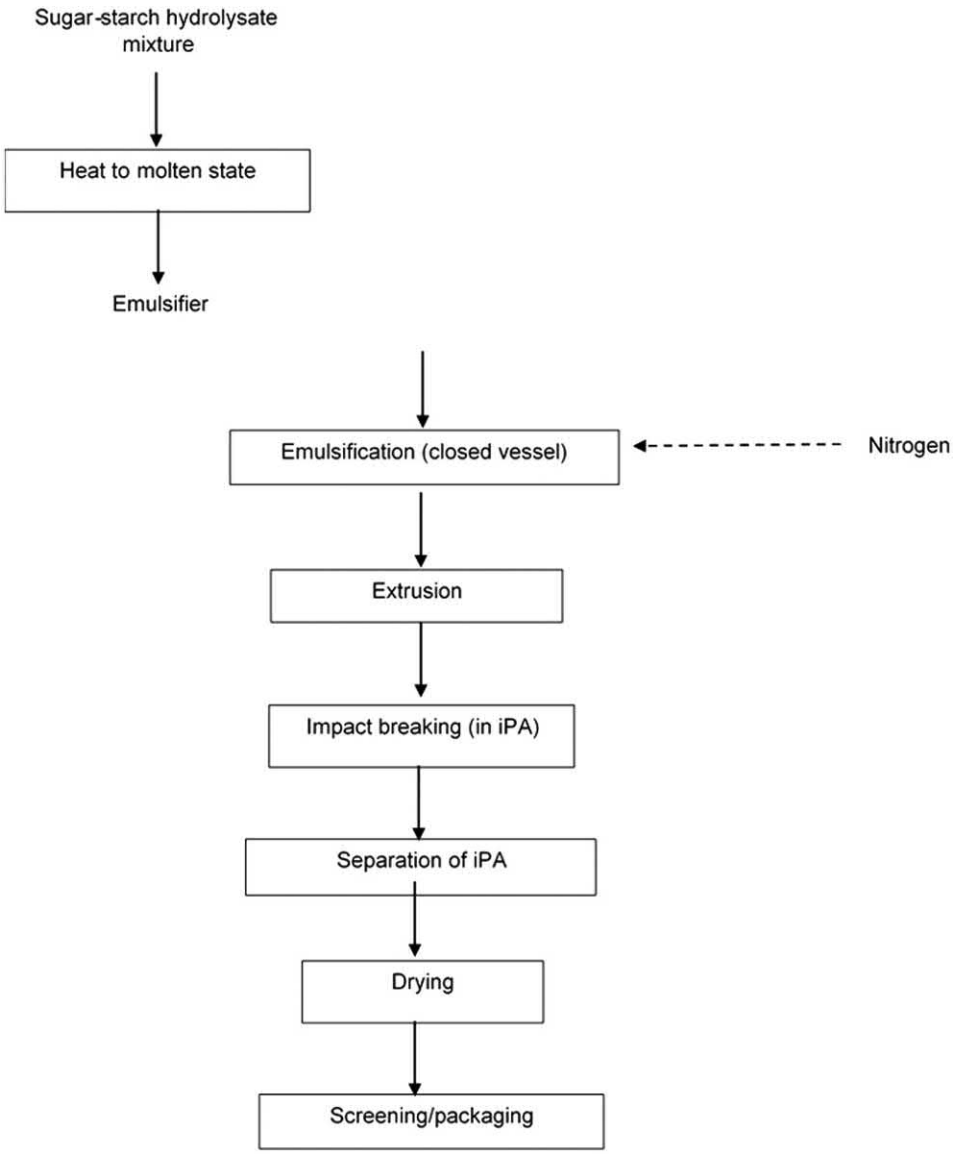

FIGURE 34.20 Flow diagram of encapsulation of food flavors via extrusion processing. (From Reineccius [47].)

low DE maltodextrin/sucrose matrix was considerably less hygroscopic than that used by some researchers [267, 268], Beck [269] continued to employ an anticaking agent, and even recommended pyrogenic silica rather than tricalcium phosphate. The flavor load obtained by Beck [269] ranged from 8% to 10%, with 12% considered as a practical maximum.

Barnes and Steinke [270] were awarded a patent for developing a modified food starch in place of sucrose in a similar process. Because chemically modified starches can possess good emulsification properties, the authors hypothesized that an emulsifying starch, with its lipophilic characteristics, would absorb the flavor oils into the matrix. The maltodextrin was, therefore, used primarily to provide bulk and some viscosity control. Barnes and Steinke [270] claimed that the use of emulsifying starches in the encapsulation matrix would permit increasing the loading capacity up to 40% flavoring.

Another benefit cited by the authors was that the total replacement of sucrose with emulsifying starches resulted in a product that was "sugar-free." This might have some advantages in the marketing of a final food product. Sucrose substituted with modified starches also provided greater flexibility to manufacturers. Because sucrose will invert to glucose and fructose at low pHs and high temperatures, the resulting product would be more hygroscopic and readily participate in nonenzymatic browning reactions. Therefore, the replacement of sucrose permitted longer cooking times, larger bath sizes, and higher cooking temperatures. Barnes and Steinke [270] also claimed that fruit juices, fruit essences, volatile substances, and propylene glycol could be encapsulated in this way using their encapsulation matrix. In order to successfully encapsulate fruit essences, it was first necessary to remove water and low-molecular-weight alcohols from the essence. The essence was then incorporated into an edible oil so that it would form an emulsion with the encapsulation matrix. For example, orange juice concentrate (42% water) could be encapsulated at 10–15% loading levels with their process. This was a

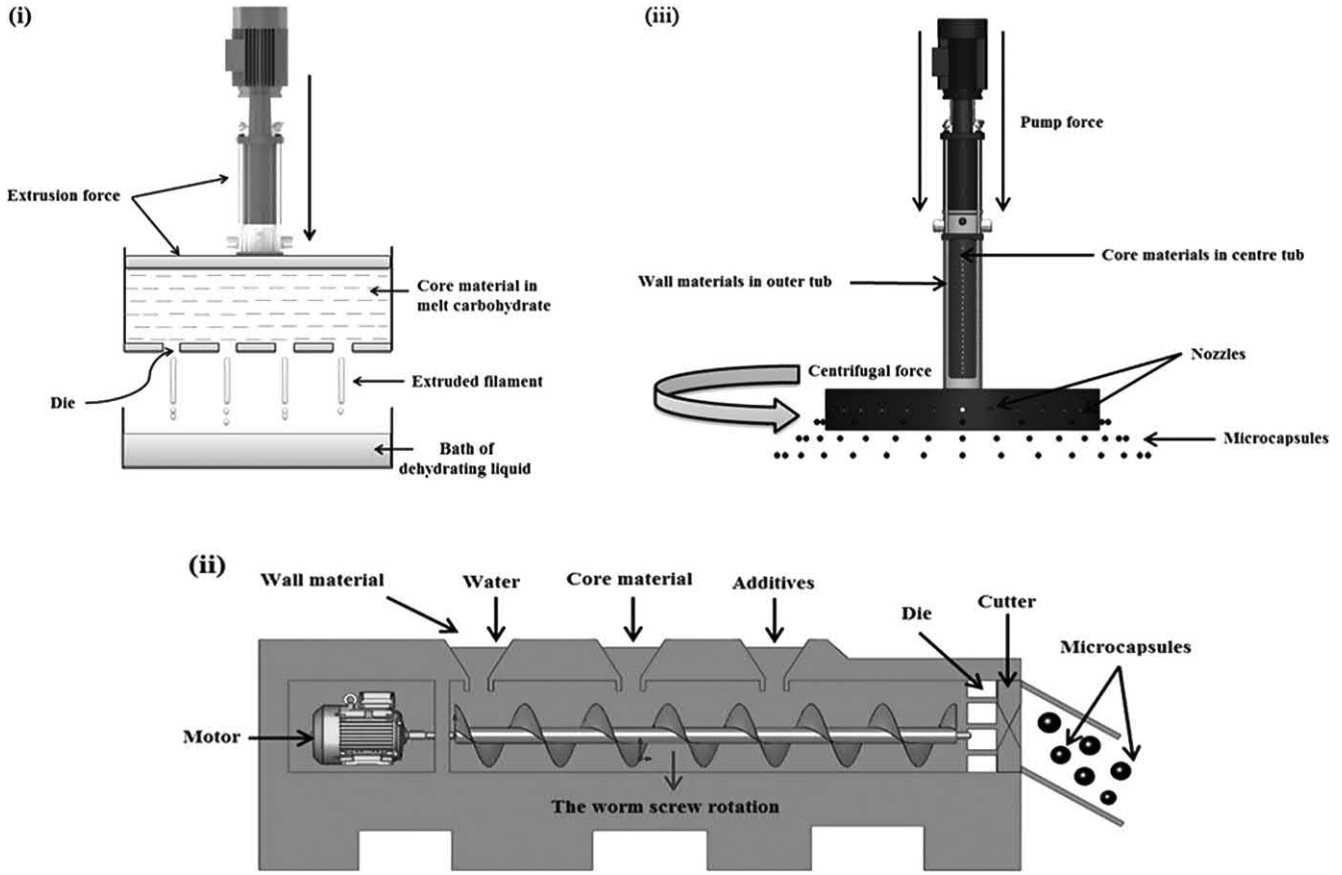

FIGURE 34.21 Diagram of microencapsulation by (i) melt injection, (ii) melt extrusion, and (iii) centrifugal extrusion (coextrusion) process. (From Bakry et al. [195].)

substantial improvement considering that prior formulations using sucrose were limited to 5–6% juice solids loading and could only be used with concentrates containing <20% water.

Miller and Mutka [271, 272] were awarded two patents for flavor encapsulation via extrusion. The first patent [271] involved a process for the encapsulation of orange juice solids, while the second dealt primarily with optimization of the extrusion process. It was their intent to improve the flavor load and encapsulation efficiency. A study of the effect of cooking temperature on flavor load and encapsulation efficiency indicated that high-load products (greater than 22%) had an optimum cooking temperature of about 123°C. As shown in Table 34.7, temperatures above or below this value yielded poorer encapsulation efficiencies. Because the cooking temperature is basically determined by moisture content, Miller and Mutka [272] postulated that too little moisture reduced emulsification effectiveness, while too much moisture hindered encapsulation. A cooking temperature of 123°C corresponded to ~5% moisture.

From the work of Miller and Mutka [272], optimization of cooking temperature, emulsifier concentration, and pressurization of the cooking vessel resulted in an improved encapsulation efficiency at high flavor loadings. Although their patent claims loadings of up to 35% can be used, only one example with loading as high as 27.6% was cited. The majority of examples demonstrated feasibility at flavor loadings from 15% to 20%, but still such levels are well over the traditional 8–10% flavor loadings achieved in commercial applications.

The extrusion process is particularly useful for heat-labile substances and has been used to encapsulate flavors, vitamin C, and colorants. According to Risch [22], extrusion provides true encapsulation in that the core material is completely surrounded by the wall material. When the material contacts the isopropanol and the wall is hardened, all residual oil or core material is removed from the surface. The absence of residual surface oil and the complete encapsulation gives products manufactured in this manner an excellent shelf life. This

TABLE 34.7
Influence of Cooking Temperature on Encapsulation Efficiency

Oil Encapsulated (%)	Encapsulation Efficiency (%)	Cooking Temperature (°C)
20.5	63.5	118
22.9	70.9	122
21.1	65.3	126
19.3	59.8	130
19.2	59.4	134

Source: Reineccius [47].

technique produces larger particles that can be used when visible flavor pieces are desirable. The primary advantage of extrusion is unquestionably its outstanding protection of the flavor against oxidation. For example, an accelerated shelf-life test on encapsulated orange peel oil containing no antioxidants was reported to be in excess of 4 years [267]. In terms of its weaknesses, extrusion is considerably more expensive than spray drying; process costs are estimated to be nearly double those of spray drying. Twenty percent flavor loading is standard for spray drying, while extrusion delivers less flavor per unit weight because its loading is currently running in the 8–12% range. Finally, one must realize that extrusion is a high-temperature batch process. The flavorings must be able to tolerate 110–120°C temperatures for a substantial period of time without deterioration.

Centrifugal extrusion is another encapsulation technique that has been investigated and used by some manufacturers. A number of food-approved coating systems have been formulated to encapsulate products such as flavorings, seasonings, and vitamins. These shell materials include gelatine, sodium alginate, carrageenan, starches, cellulose derivatives, gum acacia, fats/fatty acids, waxes, and polyethylene glycol.

Developed by scientists in the United States, centrifugal extrusion is a liquid co-extrusion process utilizing nozzles consisting of concentric orifices located on the outer circumference of a rotating cylinder (i.e., head) [273]. The encapsulating cylinder or head consists of a concentric feed tube through which coating and core materials are pumped separately to the many nozzles mounted on the outer surface of the device. While the core material passes through the center tube, coating material flows through the outer tube. The entire device is attached to a rotating shaft such that the head rotates around its vertical axis. As the head rotates, the core and coating materials are co-extruded through the concentric orifices of the nozzles as a fluid rod of core sheathed in coating material. Centrifugal force impels the rod outward, causing it to break into tiny particles. By the action of surface tension, the coating material envelops the core material, thus accomplishing encapsulation. The capsules are collected on a moving bed of fine-grained starch that cushions their impact and absorbs unwanted coating moisture. Particles produced by this method have diameters ranging from 150 to 2000 μm [274].

Another extrusion-based development is a process for encapsulating water-soluble lipids as particles of 1 to 15 mm. In this process, a core material is fed down a vertical tube while the coating material, a viscous solution of sodium alginate, simultaneously flows through a ring-shaped opening around the base of the tube, forming a membrane across the bottom of the device. The extruding core material pushes against the membrane until it eventually breaks off and carries a portion of the membrane with it. Upon spinning, the particles assume a spherical shape and become encapsulated. Passage through a bath of aqueous calcium acetate, calcium glutamate, or calcium lactate finishes this film-forming process by converting the coating to a water-insoluble calcium salt.

Chopde et al. [275] reported that the extrusion technique is an economical and simple method that is safe and does not cause damage to the probiotic cells and also affords high probiotic viability. Gouin [190] reported that the extrusion technique is primarily used for the encapsulation of unstable flavor and volatile compounds. Furthermore, this method is efficient for the encapsulation of phenolic compounds [276, 277].

Microencapsulation by extrusion is less used compared to spray drying. However, extrusion techniques have been used to encapsulate several essential oils including those of clove, olive, cinnamon, and thyme, for food industries, as well as pesticide industries [278, 279]. Sun-Waterhouse et al. [278] used this method to encapsulate olive oil by using alginate microspheres, and the study found that oil encapsulated by the co-extrusion technique was more stable during storage than unencapsulated oil.

34.3.1.6 Lyophilization or Freeze Drying

Lyophilization or the freeze drying method is a process for the dehydration of almost all heat-sensitive materials and aromas. It has been used to encapsulate water-soluble essences and natural aromas [280, 281] as well as drugs [282]. Except for the long dehydration period required (commonly 20 h), freeze drying is a simple technique that is particularly suitable for the encapsulation of aromatic materials.

Because the entire dehydration process is carried out at low temperature and low pressure, it is believed that the process should have a high retention of volatile compounds. Model system investigations by Thijssen and coworkers [206, 283] and Flink and Karel [45, 284] indicated that the retention of volatile compounds during lyophilization was dependent upon the chemical nature of the system; flavor retention increased when the molecular weight of the carbohydrate wall materials decreased and the level of total soluble solids increased (up to about 20%).

Freeze drying has long been known as the best drying method for maintaining the original properties of the product. It maintains the biological activity of aromas of food, flavors, and pharmaceuticals. Nevertheless, it is also an expensive method, about 4–7 times more expensive than spray drying [285], due to its long drying time and operation complexity [286]. There are three stages in the complete freeze drying process: freezing, primary drying, and secondary drying. First, the active compound is frozen and after that dried by sublimation under high vacuum [287]. The conditions such as low temperature and vacuum avoid oxidation and chemical modification of the products. This is the main reason that makes freeze drying an appropriate technology for products that are sensitive to heat [288]. For more details about these steps, see the reference by Liapis and Bruttini [289].

Many food and pharmaceutical companies use the freeze drying process in order to obtain dry products such as vaccines [290], viruses [291], proteins, peptides [292], and colloidal carriers [293]. Freeze drying can be used for dehydration of saffron with minimum crocin and safranal loss [294]. The same authors reported that the crocin and sarfanal contents of freeze dried samples were 5 times higher than the crocin and safranal contents of sun dried samples, which means that high cost of freeze drying could be compensated with a recovery of crocin and safranal.

For the production of citrus aroma powders to be used as natural flavor ingredients in soft drink dry mix formulations, Kopelman et al. [280] proposed the use of a freeze drying method. By simply dissolving various blends of corn syrup solids and sugars (mono- and disaccharides) in an aroma solution at a 25% (w/w) level followed by lyophilization, these authors claimed that approximately 75% of the initial aroma volatiles could be retained in the optimal maltodextrin sucrose mixture [280].

Freeze drying methods can also be used for other encapsulation processes. For example, Kirby and Gregoriadis [282] used freeze drying in the development of a technique known as dehydration–rehydration vesicles (DRV) for liposome entrapment. Upon the controlled addition of water, up to 70% of the water-soluble drugs present were entrapped into the formed liposomes. It has been reported that preparation of coatings only entrapped drugs that could be freeze dried again, and the liposomal structural integrity was apparently preserved. Intact liposomes with most of their contents still entrapped were obtained upon rehydration [158].

Indrawati et al. [295] encapsulated brown seaweed pigments using maltodextrin and Tween 80 by the freeze drying technique. The objective was to determine the stability of the active compounds that exist in the product upon encapsulation. In another study freeze drying was used successfully for microencapsulating several oils such as fish, walnut, flaxseed, and olive oils. The highest encapsulation yield (99.79%) was achieved for olive oil when carboxymethylcellulose, lecithin, and maltodextrin were used as encapsulants [296–299]. Furthermore, freeze drying has high consumption of energy (6–8 times) and requires longer times than spray drying. In addition, freeze drying renders a lower encapsulation efficiency [300].

34.3.1.7 Coacervation

The term *coacervation* originally originated from the Latin word *acervus*, which means "heap" [301]. Complex coacervation is a process that uses more than one encapsulating agent. In complex coacervation, electrostatic attraction is caused between at least two oppositely charged macromolecules. Furthermore, other weak interactions like hydrophobic interactions and hydrogen bonding may also play a role or contribute to the complex formation [302]. This technique is used to encapsulate different types of compounds such as vitamins, flavors, antioxidants, sweeteners, minerals, enzymes, fatty acids, and pre- and probiotics [303–305].

Coacervation is a phase separation phenomenon in which a homogeneous polymer solution is converted into two phases. One is a polymer-rich phase, called a coacervate, and the other is a polymer-poor phase, i.e., solvent [306]. Coacervation was developed and patented in the 1950s by the National Cash Register Company in the US and was used as a means of producing a two-component ink system for carbonless copy papers. Because of the very small particle sizes attainable with this process (ranging from a few submicrons to 6 mm), coacervation is regarded by many as the original and true microencapsulation technique [307].

The coacervation method is a commonly used encapsulation technique for some food applications for two reasons. First, it provides high encapsulation efficiency, and, second, because of the triggered controlled release that could be based on the temperature as well as providing the needed versatility to support many food products [190]. Jamekhorshid et al. [308] reported that the advantage of this method is its effectiveness in controlling particle size and its versatility. However, the disadvantages are high wall permeability and agglomeration. Figure 34.22 shows the flow diagram of a model complex coacervation technique that is commonly used for encapsulation of phase change materials (PCMs).

An example of a simple coacervation process could be described as follows: a gelling protein is dissolved in water, the core material is emulsified into the protein solution, and formation of the coacervate wall is initiated by changing either the temperature, pH, or by adding a concentrated salt solution. The resultant microcapsules are isolated by centrifugation or filtration. In effect, coacervation involves the separation of a liquid phase of coating material from a polymeric solution followed by the coating of that phase as a uniform layer around suspended core particles. The coating is then solidified. In general, batch-type simple coacervation processes consist of three steps, as summarised next, and are carried out under continuous agitation [36].

34.3.1.7.1 Formation of Three Immiscible Chemical Phase

In the first step, a three-phase system consisting of a liquid manufacturing vehicle phase, a core material phase, and a coating material phase is formed by either a direct addition or *in situ* separation technique. In the direct addition approach,

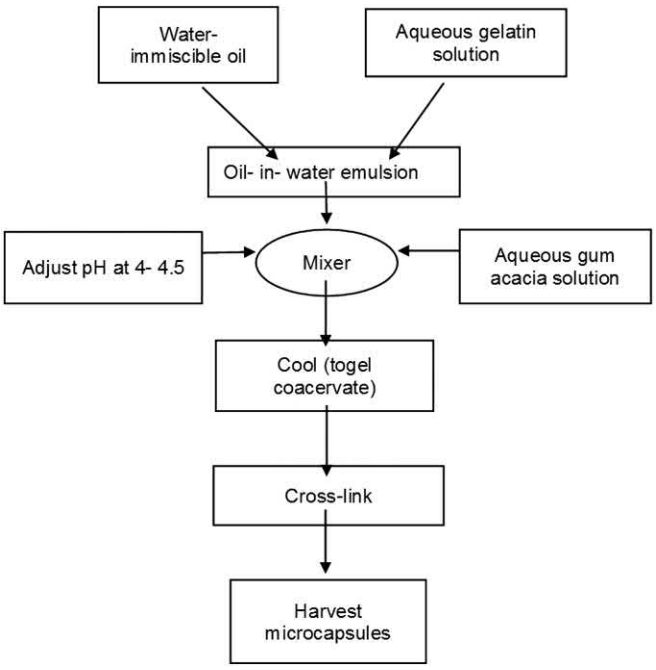

FIGURE 34.22 Flow diagram of a typical complex coacervation encapsulation process. (From Jamekhorshid et al. [308].)

the coating-insoluble waxes, immiscible polymer solutions, and insoluble liquid polymers are added directly to the liquid manufacturing vehicle, provided that it is immiscible with the other two phases and is capable of being liquefied. In the *in situ* separation technique, a monomer is dissolved in the liquid vehicle and then subsequently polymerized at the interface.

34.3.1.7.2 Deposition of the Coating

Deposition of the liquid polymer coating around the core material is accomplished by controlled physical mixing of the coating material (while liquid) and the core material in the manufacturing vehicle. Deposition of the liquid polymer coating around the core material occurs if the polymer is sorbed at the interface formed between the core material and the liquid vehicle phase; this sorption phenomenon is a prerequisite to effective coating. Continued deposition of the coating is promoted by a reduction in the total free interfacial energy of the system brought about by a decrease of the coating material surface area during coalescence of the liquid polymer droplets.

34.3.1.7.3 Solidification of the Coating

Solidification of the coating is achieved either by thermal, cross-linking, or desolventization techniques, and forms a self-sustaining microcapsule entity. The microcapsules are usually collected by filtration or centrifugation, washed with an appropriate solvent, and subsequently dried by standard techniques such as spray or fluidized bed drying to yield free-flowing, discrete particles.

Simple coacervation deals with systems containing only one colloidal solute (e.g., gelatine), while complex coacervation deals with systems containing more than one solute (e.g., gelatine and gum acacia [309] or gelatine and polysaccharide [310]). By strict definition, however, complex coacervation involves two biopolymers with opposite charges forming a complex coacervate as a result of ionic interaction at the interface. For example, positively charged type A gelatine (component A) forms complex coacervates with negatively charged polyphosphate (component B). Other systems that have been studied are gelatine/gum acacia, gelatine/pectin, gelatine/carboxymethyl guar gum, and whey protein/gum Arabic [306]. This technology has been used in flavor encapsulation as well as for the storage and delivery of additives [311]. The relatively high processing costs, sensitive multistep batch process, regulations limiting the number of polymeric agents that can be used in food preparations, and the difficulty in dealing with encapsulates having both aqueous and lipid solubility properties—as well as the sensitivity of these systems to high shear—have limited the application of coacervation for flavor encapsulation in the food industry [41].

Coacervation may also be subdivided into nonaqueous phase separation and aqueous phase separation techniques. Aqueous phase separation has been used to encapsulate citrus oils, vegetable oils, and vitamin A. It requires a hydrophilic coating, such as gelatine or gelatine–gum acacia, and water-insoluble core particles. The resulting microcapsules may contain payloads of 85% to 90% and can release their contents by pressure, hot water, or chemical reaction. For nonaqueous phase separation, the coating is usually hydrophobic, and the core may be water-soluble or water-immiscible. This process has been investigated for the encapsulation of solid food additives such as ferrous sulfate [38].

Although coacervation is very efficient, it can be an expensive process. It has found limited use in flavor encapsulation [24, 312], because of the high costs associated with the technology and difficulties encountered with the level of flavor that can be incorporated into the microcapsules [199]. Another reason cited by various industries for the limited use of coacervation is the problems associated with developing suitable encapsulating materials that are food approved. According to Blenford [202], the technology has been basically restricted to encapsulated ink systems used in carbonless office forms and to encapsulated fragrances that are applied in the form of scratch-and-sniff strips in promotional literature. Arneodo et al. [313] and King [314] observed that research into this technology was in progress and proposed that commercial applications would be available in the near future.

Ocean Nutrition Canada (ONC), now DSM, uses a proprietary microencapsulation technology based on a complex coacervation process to encapsulate fish oil concentrates rich in eicosahexenoic acid (EPA) and docosahexaenoic acid (DHA). The technology is based on the patent of Yan and Jin [306]. Research has suggested that a diet containing omega-3 fatty acids, such as EPA and DHA, may have a beneficial effect in lowering the incidence of cardiovascular disease [315]. Although there is no established daily requirement for the omega-3 fatty acids, recommendations range from 250 to 500 mg EPA/DHA per day. ONC's patented process involves preparing an emulsion comprised of fish oil and a gelatine-based polymer. The emulsion has a particle size of <100 mm. Two oppositely charged polymer colloids—one an amphoteric polymer and the other a polyanionic polymer—interact with each other to cause phase separation. The product is introduced into a spray drier and a dried microcapsule results. MEG-3™ powder is a patented microencapsulated fish oil product comprising a 60% payload of fish oil; this represents one of the highest, if not the highest, concentrations of bioavailable omega-3 in the market place. MEG-3™ powder is manufactured to withstand shear and high temperature and other food processing operations such as pasteurization and homogenization. Studies conducted by ONC have shown that there is no loss of omega-3 EPA/DHA during processing or via shelf-life deterioration. This functional food ingredient has been used to develop an omega-3 yogurt product. Delivering 50–100 mg of EPA/DHA per serving in a variety of functional foods will help consumers reach the recommended daily intake levels.

This method was found to be especially suitable for high-valued as well as sensitive functional ingredients such as polyphenols [18]. In another study, Zheng et al. [316] encapsulated anthocyanins using this method, which can be used to encapsulate heat-sensitive ingredients because it is done at room temperature.

34.3.1.8 Centrifugal Suspension Separation

Centrifugal suspension separation is a more recent microencapsulation process. The process has been patented [317,

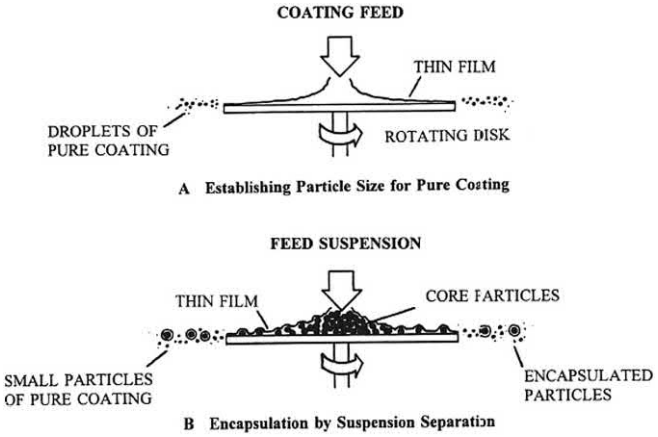

FIGURE 34.23 Representation of rotational suspension separating system. (From Sparks and Mason [317].)

318] and was first applied commercially in February 1987 to a chemical produced in Europe. The process, in principle, involves suspending core particles in a pure, liquefied coating material, and then pouring the suspension over a rotating disk apparatus under such conditions that excess liquid between the core particles spreads into a film thinner than the core's particle diameter. The excess liquid is atomized into tiny droplets, separated from the coated product and recycled. The core particles leave the disk with residual liquid still around them, which forms the coating. The particles are hardened by chilling and drying [319]. The principle behind this process is illustrated in Figure 34.23.

Centrifugal suspension separation is a continuous, high-capacity process that takes seconds to minutes to coat core particles. The process can handle a wide variety of core materials, including those that are temperature sensitive, and coating materials, in solid, liquid, or suspension states, without presenting aggregation problems. Furthermore, the process handles each particle only once and, under most conditions, produces no uncoated particles. The process has been used successfully to coat particles ranging from 30 μm to 2 mm. Coatings have been produced with thicknesses ranging from 1 to 200 μm. Microcapsules have been prepared with payloads ranging from 1% to 97%, depending on diameter size of the particle. Another advantage associated with centrifugal suspension separation is that the size distribution of the encapsulated particles resembles that of the uncoated particles.

34.3.1.9 Cocrystallization

Cocrystallization is an encapsulation process utilizing sucrose as a matrix for the incorporation of core materials. Although granulated sugar is composed of solid, dense, monoclinic spherical crystals with a limited surface area, it is not suitable as an encapsulating agent for flavor encapsulation. In order for flavors to be incorporated into the matrix, the structure of sucrose must be modified from a single perfect crystal to a microsized, irregular, agglomerated form, to increase void space and surface area [74, 320]. It involves spontaneous crystallization, which produces aggregates of micro- or fondant-size crystals ranging from 3 to 30 μm, while causing the inclusion of entrapment of all nonsucrose materials within or between sucrose crystals [321]. Use of the cocrystallization process allows many types of food ingredients, either single ingredients or combinations of ingredients, to be incorporated permanently into a crystalline sucrose aggregate, thus providing interesting and useful characteristics.

Sucrose syrup is concentrated to the supersaturated state and maintained at a temperature high enough to prevent crystallization. A predetermined amount of core material is then added to the concentrated syrup with vigorous mechanical agitation, thus providing nucleation for the sucrose/ingredient mixture to crystallize. As the syrup reaches the temperature at which transformation and crystallization begin, a substantial amount of heat is emitted. Agitation is continued in order to promote and extend transformation/crystallization until the agglomerates are discharged from the vessel. The encapsulated products are then dried to a desirable moisture (if necessary) and screened to a uniform size [80, 81]. It is very important to properly control the rates of nucleation and crystallization, as well as thermal balance during the various phases. The essential steps for the preparation of cocrystallized flavor are presented in Figure 34.24.

The agglomerates form a loose network, bonded together by point contacts. The encapsulated materials are located primarily in the interstices between crystals. Due to the porosity of the agglomerates, it is easy for an aqueous solution to rapidly penetrate the agglomerate and release the core materials for dispersion and/or dissolution.

The cocrystallization process offers several advantages, for example, it can also be employed to achieve particle drying. In the highly saturated solution, nucleation and crystallization proceed at a rapid rate and the resulting heat of crystallization can be used to affect particle dehydration by evaporation. By means of the cocrystallization process, core materials in a liquid form can be converted to a dry powdered form without additional drying. Because the flavor or core material is well entrenched in the modified sucrose matrix, there is no tendency for flavor material to separate from or settle out during handling, packaging, or storage. Additionally, all cocrystallized sugar/flavor products offer direct tableting characteristics because of their agglomerated structure, and thus offers significant advantages to the candy and pharmaceutical industries [322].

34.3.1.10 Liposome Entrapment

Liposomes provide an attractive encapsulation system for the delivery of both hydrophilic and lipophilic functional compounds. They are spherical-shell structures consisting of one or more phospholipid bilayers enclosing a liquid core [323]. Liposomes can be classified based on their lamellarity into three types, namely, oligolamellar vesicles (OLV), unilamellar vesicles (ULV), and multilamellar vesicles (MLV). Vesicles can likewise be categorized by their size as giant unilamellar vesicles (GUV), large unilamellar vesicles (LUV), and small unilamellar vesicles (SUV) (Figure 34.25) [324, 325]. A number of methods for liposome preparation are presently

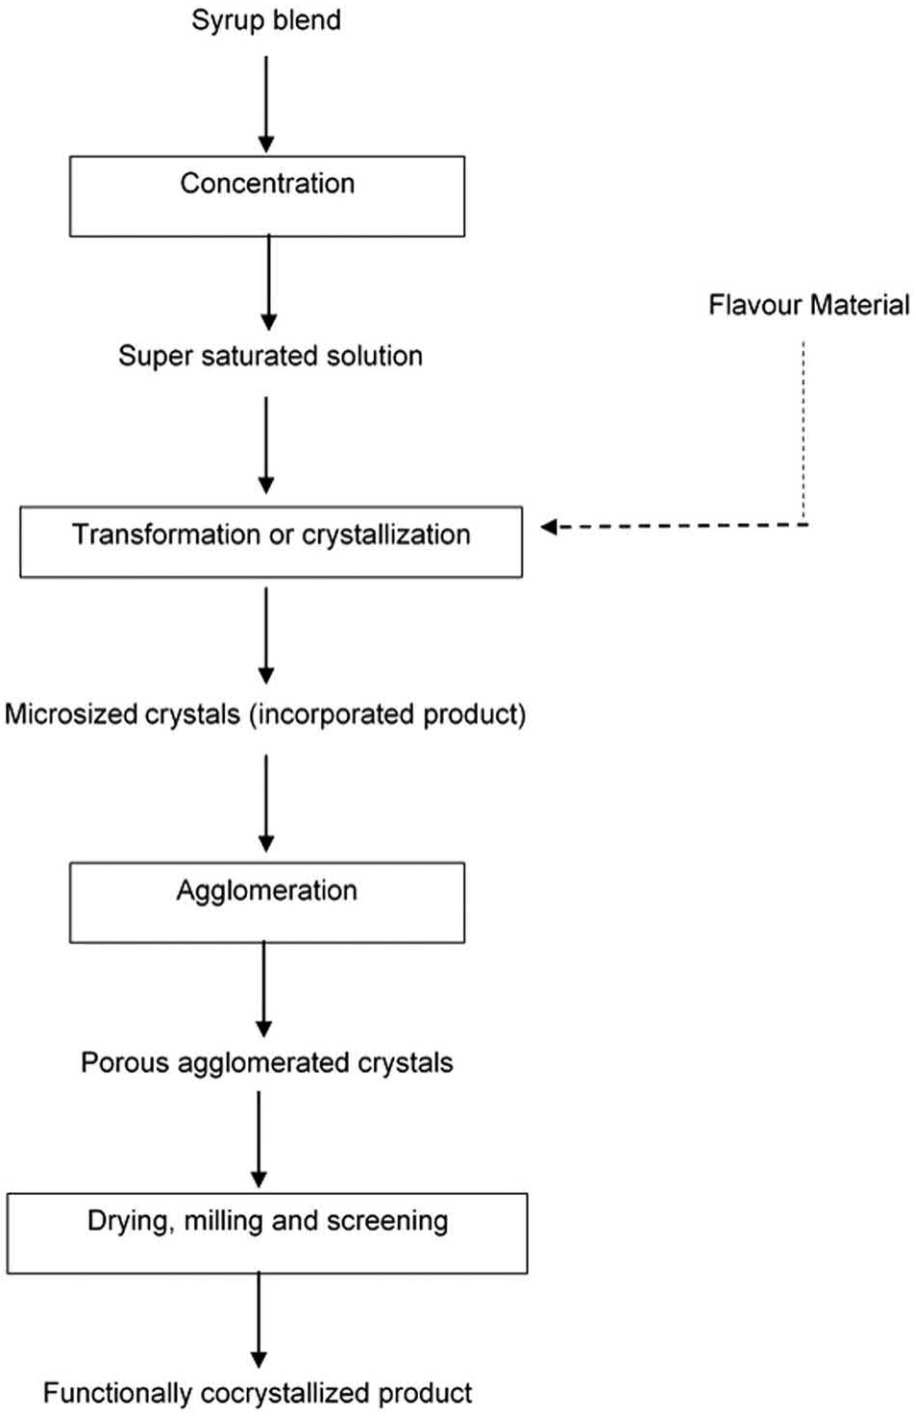

FIGURE 34.24 Essential steps for the preparation of a cocrystallized flavor. (From Chen et al. [74].)

available such as the solvent injection method, heating-based method, and thin-film hydration method [326].

Liposomes are usually used to deliver proteins [327], enzymes [328], vitamins [329], minerals [330], flavors [331], antioxidants [332, 333], and antimicrobials [334] in food products. A number of strategies are used for the preparation of liposomes. Further details about these preparation methods have been described elsewhere [323].

Liposomes provide a promising solution for protecting vitamins from degradation. Wechtersbach, Ulrih, and Cigić [335] reported that increased half-life of liposomal vitamin C was about 300 times in a model system and it also decreased the rate of oxidation in apple juice. However, liposomal stabilization of vitamins in fermented milk products was lower due to the integration of the lipids in the product into the membrane, therefore increasing liposome permeability and milk lipoprotein lipase, which may lead to hydrolysis of membrane phospholipids.

Numerous methods of liposome entrapment have been developed [156, 158, 336]. Preparations may vary widely

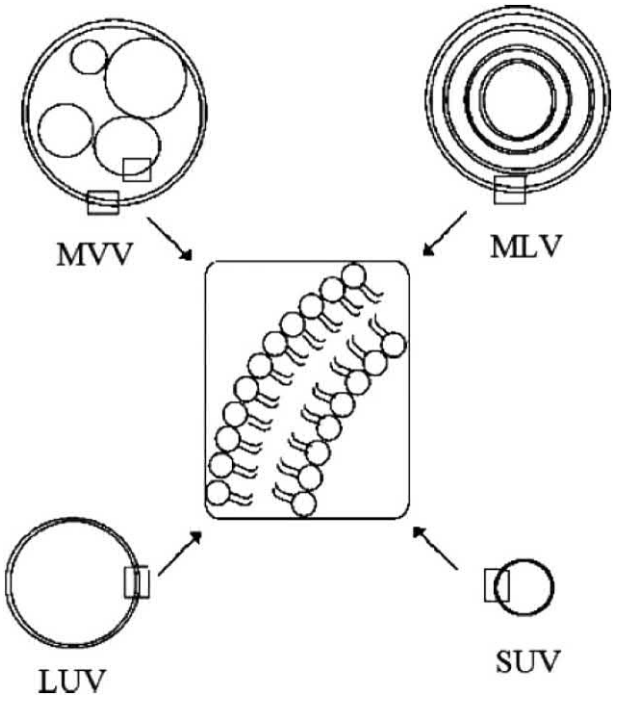

FIGURE 34.25 Liposome classification based on lamellarity and size. (From Emami et al. [323].).

in vesicle size distribution, number of bilayers per vesicle, and encapsulation efficiency. Liposomes consist of an aqueous phase that is completely surrounded by a phospholipid-based membrane. When phospholipids, such as lecithin, are dispersed in an aqueous phase, the liposomes form spontaneously. One can have either aqueous or lipid-soluble material enclosed in the liposome. However, liposome entrapment for many flavor compounds is not possible because liposomes will not form with materials that are soluble in both the aqueous and lipid phases [22]. From a physicochemical point of view, the formation of liposome structures may be illustrated by phase diagrams. A simplified phase diagram of the 1,2-dipalmitoyl phosphatidylcholine–water system is shown in Figure 34.26 [337]. The addition of water decreases the transition temperature of the phospholipid to a limiting value (T_c), which is the minimum temperature required for water to penetrate between the layers of lipid molecules. When the system is cooled below T_c, the hydrocarbon chains adopt an ordered packing. The structure of this phase, known as the gel, is lamellar and the hydrocarbon chains extended [337]. Each type of phospholipid molecule is characterized by a phase transition temperature. Below T_c, its fatty acyl chains are in a quasicrystalline array, while above T_c, the chains are in a fluid-like state.

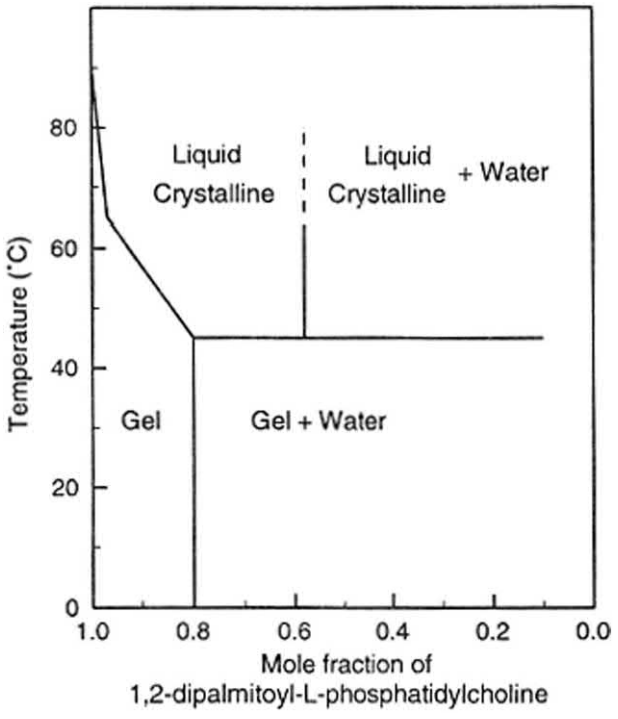

FIGURE 34.26 Phase diagram of the 1,2-dipalmitoyl-L-phospha tidylcholine-water system. (From Shahidi and Han [499].)

There are two principal requirements for liposome microencapsulation. Firstly, the lipid of choice must have a negative Gibb's free energy value (ΔG) for bilayer structure formation, because a negative ΔG value between two states of the system indicates a favorable reaction. Secondly, sufficient energy must be put into the system to overcome the energy barrier. Close to room temperature, the value of ΔG for the formation of liposomes is always negative and, therefore, favorable. Even though thermodynamics are favorable, this does not mean that the reaction will proceed automatically; it is usually necessary to overcome an energy barrier in order to initiate a reaction. Different lipids and types of energy input may be used to produce different varieties of liposomes for specific purposes. Some methods commonly employed are described next.

34.3.1.10.1 Microfluidization

The microfluidization technique is based on the dynamic in specially designed microchannels. The resulting momentum and turbulence allow the lipid emulsion to overcome the energy barrier ($\Delta G^{\ddagger}$). An air-driven microfluidizer operates at pressures of up to 10,000 psi. A pump driven by compressed air is used to pump the aqueous emulsion of lipids, and the single-feed stream is split into two fluidized ones. The two flows interact with one another at ultrahigh velocities and in precisely defined microchannels.

Mayhew et al. [338, 339] found that small (0.1 μm in diameter) liposomes with high solute-capture efficiency could be easily formed by microfluidization technology. At an initial lipid concentration of 300 mM, up to 75% of cytosine arabinoside was captured in the aqueous space of these liposomes. Advantages of microfluidization include (i) a large volume of liposomes can be formed in a continuous and reproducible manner; (ii) the average size of the liposomes can be adjusted; (iii) very high capture efficiencies (larger than 75%) can be obtained; (iv) the solutes to be encapsulated are not exposed to sonication, detergents, or organic solvents; and (v) the resulting liposomes appear to be stable, and do not aggregate or fuse.

34.3.1.10.2 Ultrasonication

Ultrasonic dispersion is often used for the preparation of SUV; the lipid emulsion overcomes the energy barrier through ultrasound absorption. In one approach, phospholipids are sonicated by immersing a metal probe directly into a suspension of large liposomes. In a second method, the lipid dispersion is sealed in a glass vial, which is then suspended in an ultrasonic cleaning bath. Bath sonication requires longer periods (up to 2 h) than probe sonication (only a few minutes), but it has the advantage that it can be carried out in a closed container under nitrogen or argon and does not contaminate the lipid with metal from the probe tip [160].

34.3.1.10.3 Reverse-Phase Evaporation

The reverse-phase evaporation technique has been developed for the preparation of LUV in which lipids in mixed aqueous-nonpolar solvents form inverted micelles (i.e., the lipid tails are inserted into the nonpolar phase and the head groups surround water droplets). When the nonpolar solvent is removed by rotary evaporation under vacuum, the gel-like intermediate phase changes into large unilamellar and oligolamellar vesicles. This procedure produces liposomes of quite uniform size, ranging from 0.1 to 1.0 μm in diameter, with high encapsulation efficiency of up to 65% in low ionic strength media. However, its disadvantage is that components are exposed to both organic solvents and sonication. This may result in the denaturation of proteins and other molecules of similar stability [159].

34.3.1.11 Interfacial Polymerization

Interfacial polymerization happens when two different polymeric solutions are brought together. These two reactive polymeric species, each solubilized in a different liquid, react with one another when one liquid is dispersed in the other. The polymerization reaction takes place at the interface between the two polymeric liquids.

The interfacial polymerization process can be used to encapsulate solutions or dispersions of hydrophobic materials. It can also be used to encapsulate aqueous solutions or dispersions of hydrophilic substances. In the interfacial polymerization microencapsulation process, both the dispersed and continuous phases serve as a source of reactive polymeric species. In general, an interfacial polymerization reaction proceeds at a rapid rate that results in the formation of a very thin film having physical property characteristics of a semipermeable membrane. Properties of the film are markedly influenced by the reaction time [340].

The ultimate capsule size of interfacial polymerization is determined by the size of the first monomer. In general, the capsule size ranges from about 1 μm to several millimeters. This capsule size is a direct function of the agitation rate [340]. It was found that an increase in the concentration of the emulsifier yields a narrow size distribution range and a reduction of the average particle size. The patent application for the microencapsulation process utilizing the principle of interfacial polymerization was filed by IBM (serial no. 813,425) in 1959 [340]. However, use of interfacial polymerization for food systems is limited since most coatings are not food grade.

34.3.1.12 Inclusion Complexation: Molecular Inclusion

Molecular inclusion is another means of achieving encapsulation. Unlike other processes discussed to this point, this technique takes place at a molecular level and β-cyclodextrin is typically used as the encapsulating medium [61]. As previously noted, β-cyclodextrin is a cyclic glucose oligomer, consisting of seven β-D-glucopyranosyl units linked by α-(1⟶4) bonds. Due to its molecular structure, β-cyclodextrin has limited solubility, a hydrophobic center, and a relatively hydrophilic outer surface, all of which affect the compound's formation of complexes.

The β-cyclodextrin molecule forms inclusion complexes with compounds that can fit dimensionally into its central cavity. These complexes are formed in a reaction that takes place only in the presence of water. Molecules that are less polar than water (i.e., most flavor substances) and have suitable molecular dimensions to fit inside the cyclodextrin interior can be incorporated into the molecule. In aqueous solutions, the slightly nonpolar cyclodextrin interior is occupied by water molecules. This situation is energetically unfavorable and, therefore, the sites occupied by water are readily substituted by the less polar guest molecules. Cyclodextrin complexes are relatively stable and their solubility in aqueous solutions is reduced compared to the uncomplexed cyclodextrin. Therefore, the complexed cyclodextrins readily precipitate out of solution and can be recovered simply by filtration.

The complexing of a cyclodextrin with a guest compound can be accomplished by three methods [69]:

(i) Stirring or shaking the cyclodextrin and guest molecules to form a complex that then canbe easily filtered and dried. Although in some cases, complexation of an insoluble guest can only be accomplished through dissolution of the guest in a water-soluble solvent.
(ii) Blending of solid β-cyclodextrin and guest with water to form a paste. Solvent should not be used. This method is particularly applicable for oleoresins.
(iii) Forcing a gas through the solution for complexation to occur. This method is seldom used.

However, it should be emphasized that there are several variations to these basic techniques, but still in all methods both the cyclodextrin and the guest molecules must be solubilized. If the guest material is insoluble in water, it is necessary to dissolve it in another solvent such as alcohol.

The composition of the cyclodextrin complex formed depends greatly upon the molecular weight of the guest molecule in question. Because one molecule of cyclodextrin will normally include only one guest molecule, the loading depends upon the compounds included. It should be noted that the theoretical maximum loading is not always obtained. For example, Pagington [341] stated that dimethyl sulfide should be complexed at 5.5% but only 2% loading has been observed.

It has been reported that cyclodextrins have a variable affinity for different guest compounds. This may be used to the advantage, or it can be disadvantageous. Some researchers have made use of the variable-binding properties offered by β-cyclodextrin to selectively remove bitter compounds from orange and grapefruit juices [342]. Variable binding properties can also be a disadvantage when it comes to the encapsulation of flavor compounds. Reineccius and Risch [61] formed 0% (isoeugenol) to 100% inclusions (ethyl hexamoate and linalool) when they added a model flavor system to β-cyclodextrin in an ethanol:water mixture. The losses of flavor compounds were due to the lack of inclusion rather than a loss during the subsequent complex recovery and/or drying steps. Once the complex was formed, it was quite stable to evaporation.

The variable inclusion properties of cyclodextrins would result in a dry flavor quite different from that of the original flavor when the flavor is comprised of a broad range of flavor molecules (e.g., an artificial flavor that contains short-chain esters and longer-chain character impact compounds). However, flavors such as orange, which have been included in β-cyclodextrin, may not be distinguishable from fresh orange even by trained taste panels [343].

There are substantial data in the literature that document excellent protection for substances that have been treated with cyclodextrins [24, 343–345]. As previously mentioned, the cyclodextrin–guest complex formed is very stable to evaporation. Szente and Szejtli reported [345] only about a 5% loss of included volatiles after 2 years of storage at room temperature. However, more important is the oxidative stability of the included guest compounds. Many reports have demonstrated that inclusion complexes are quite stable to oxidation [343, 345].

As with all processes, there are limits to the application of cyclodextrin complexation in the formation of flavors [346]:

(i) There is a limited amount of flavor content in formulations (average 9% to 14% by weight).
(ii) The size and polarity of flavors to be complexed limits the usefulness of the process.
(iii) Cyclodextrin can act as an artificial enzyme, sometimes enhancing the rate of hydrolysis of some ester-type flavor components. This can result in the undesirable adulteration of the flavor.
(iv) The water solubility of β-cyclodextrin flavor complexes is generally much lower than that of spray dried and other microencapsulated samples.

34.3.2 Nanoencapsulation

The encapsulation of bioactive compounds at a size of 100–500 nm or less, usually at lower than 100 nm is known as "nanoencapulation" and also the material is called "nanomaterial" [347]. Nanoencapsulation is one of the most promising technologies that have the ability to protect and entrap bioactive compounds [14]. The two main reasons behind high and slow release and water solubility of nanoencapsulated materials compared to native counterparts are firstly due to the reduction in size of the particles to become nano, leading to increased surface area and hence bringing maximum active sites on the surface and augmenting their penetration. Secondly, the tailor-made carrier material controls the gradual release of bioactive compound and therefore allows maximum absorption in the digestive system [348–351]. With the employment of nanoencapsulation, deliveries of multiple active ingredients that do not normally mix well, such as water-soluble and lipid-soluble vitamins, can be released consecutively. The role of nanotechnology in delivery systems for bioactives and specialty gradients has advanced considerably in recent years [182].

34.3.2.1 Classification of Food Nanodelivery Systems

Recently, different types of nanodelivery systems have been developed and reviewed in the literature. These include nanostructured lipid carriers (NLCs); nanoemulsions; solid lipid nanoparticles (SLN); nanosuspensions; liposomes and nanoliposomes; polysaccharides; and combinations with lipid or mineral components, nanoparticles (NPs), and micelles made of proteins [352–355].

Nanoemulsions are colloidal dispersions of small liquid droplets, less than 100 nm (Figure 34.27a) [355, 356] and might be water-in-oil (W/O) or oil-in-water (O/W), and either liquid-in-liquid or liquid-in-solid such as butter and a W/O solid emulsion. The interface might be stabilized by different types of emulsifiers, in which their structure and amphiphilicity determine the size droplet curvature. In addition, the oil type and composition as well as the surfactant-to-oil ratio might affect emulsion stability and droplet size [357].

The major types of amphiphiles used for nanoemulsion formation include high molecular weight biopolymeric amphiphiles [358], either natural (such as milk proteins [359], milk protein peptides [360], whey proteins, mainly beta-lactoglobulin [361], and particularly caseins [362]) or synthetic (such as octenyl succinate modified starch [363]); and low molecular weight surfactants, either natural surfactants (such as saponins [364] and phospholipids [365]) or synthetic surfactants (such as Tween 20 [366], Tween 80 [367] and sucrose palmitate [368]).

Generally, nanoemulsions are made by using low-energy or high-shear/high-energy homogenization methods. In addition, spontaneous self-emulsification methods may be used [357, 369]. Nanostructured lipid carriers (NLCs) include partially crystallized lipid nanovehicle particles with a mean size of about 100 nm, which are dispersed in an aqueous phase containing emulsifiers (Figure 34.27c). The partially solid material creates nanostructures that promote stability of entrapped bioactives and increase loading capacity [370]. Another type of NLC is pickering emulsions (Figure 34.27d) in which solid NPs are adsorbed or sintered to the oil–water interface and also provide much higher stability to emulsions [354, 371]. Nanosuspensions are systems in which solid NPs are dispersed in a liquid medium (Figure 34.27e). The noanosuspension is normally made of nanoemulsions and is composed of a solid carrier lipid–bioactive ingredient mixture [372].

Protein/peptide nanovehicles may also be used. As an example, curcumin was encapsulated in casein NPs by spray drying their aqueous ethanol solution. This inhibited curcumin

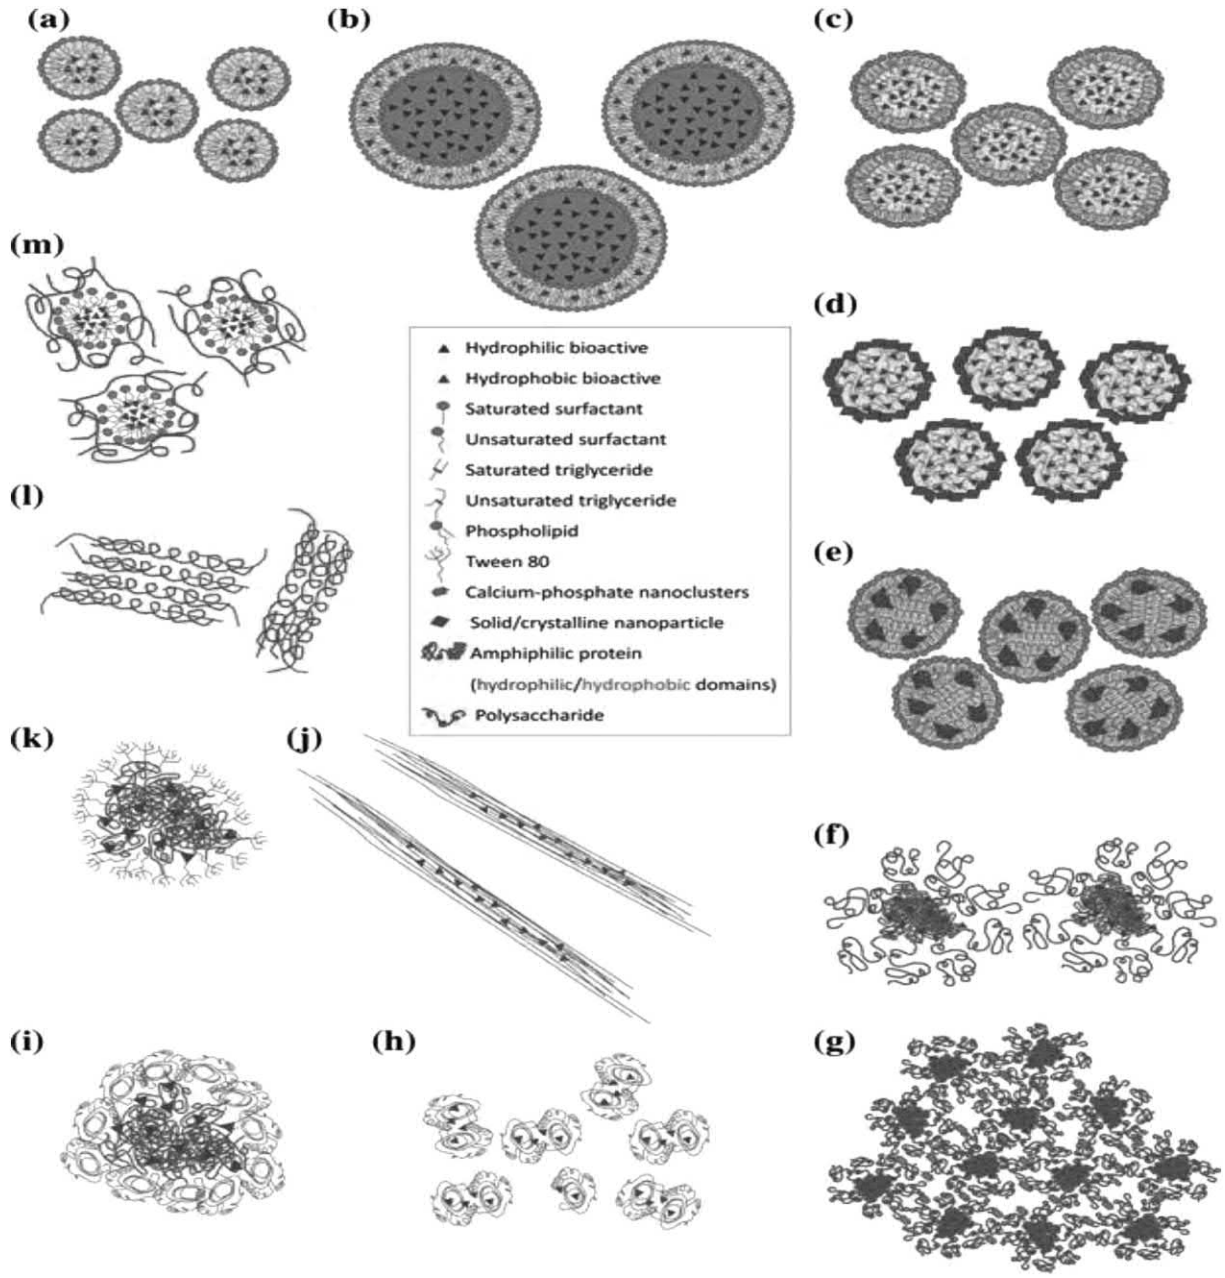

FIGURE 34.27 Types of nanostructured delivery systems recently studied: (a) nanoemulsion, (b) liposomes, (c) nanostructured lipid carriers (NLCs), (d) pickering emulsion, (e) solid–lipid NPs (SLN), (g) reassembled casein micelle, (h) protein-bioactive nanocomplexes, (i) hydrophobic protein, (j) electrospun protein nanofibers, (k) hydrophilic protein, (l) amylose inclusion complexes entrapping fatty acids, (m) polysaccharide-lipid NPs. (From [373].)

crystallinity (Figure 34.27f) [374]. Benzaria et al. [375] reported encapsulation of curcumin in native-like phosphocasein micelles improved by ultrahigh-pressure homogenization (Figure 34.27g). Shpigelman et al. [376] studied nanovehicles for nutraceuticals. They recently formed β-Lg-naringenin nanocomplexes that suppressed naringenin crystallization, in order to promote its bioavailability and increase its effective solubility (Figure 34.27h). Ghasemi and Abbasi [377] encapsulated fish and vegetable oils in casein micelles by use of pH modification.

Chen et al. [378] encapsulated the tangeretin, a hydrophobic flavonoid, in protein. This was achieved by mixing tangeretin and an organic phase containing zein with an aqueous phase containing β-lactoglobulin (Figure 34.27i). Protein–surfactant NPs of Zein–Tween 80 NPs (Figure 34.27k) were proposed as food-grade delivery systems. The NPs had a Tween 80 shell with a thickness around 4 nm and a zein core of 78 nm diameter [379].

The polysaccharide-based NPs could also be prepared by using enzymatically synthesized dextran NPs of 100–450 nm. This was developed in order to entrap hydrophobic nutraceuticals. Generally, dextransucrase generated spherical dextran NPs from sucrose [380]. Mogol et al. [381] used high amylose

corn starch (HACS) for encapsulating omega-3 fatty acids for enriching bread as a functional food as well as for improving thermal stability (Figure 34.27l). Polysaccharide-lipid NPs were prepared for encapsulating quercetin in lecithin/chitosan NPs of about 170 nm size (Figure 34.27 m). The encapsulated product had improved antioxidant properties compared to free quercetin.

34.3.3 Emulsions (Micro- and Nanoemulsions)

Emulsions could be in the form of either water drops in oil or oil drops in water, but in both cases, the droplets must be stabilized to prevent them from recoalescing. Stabilization of the emulsion droplet is usually achieved by the addition of amphiphilic molecules such as emulsifiers that act by decreasing the interfacial tension between the phases as well as increasing the steric hindrances [382]. Food-grade nanoemulsions could be prepared by high-energy methods such as high-pressure homogenization or sonication, or low-energy methods such as maintaining temperature above phase inversion so that nanoemulsions maintain good stability against droplet aggregation [356, 383].

Mehmood [384] developed the delivery of ω-3 fatty acids and vitamin D_3 in cheddar cheese. The study recovery level of vitamin D_3 in cheese was 84%. The fortification of foods by using encapsulated vitamins and other bioactive molecules might have a positive impact on the chemical stability and possibly composition of the resultant products. Vitamin E acetate (tocopheryl acetate) nanoemulsion was produced by using mustard oil and no flocculation was observed during the first 15 days. The nanoemulsion showed improved antimicrobial and antioxidant activity and could potentially be used to increase the shelf life of beverages such as fruit juices [385].

Nanoemulsions of oregano essential oils and clove bud were incorporated into methylcellulose films, and their antimicrobial activity was tested in sliced bread. The study showed that antimicrobial films reduced the counts of molds and yeasts in bread for 15 days [386]. Sari et al. [387] studied both the preparation and physicochemical characterization as well as *in vitro* digestion kinetics of curcumin nanoemulsions. They prepared coarse emulsions by using magnetic stirring at room temperature for different time periods, and fine emulsions were prepared by ultrasound processing of the coarse emulsions. Because curcumin is highly unstable in aqueous food systems, it was encapsulated in a carrier oil as an emulsion form and with an efficiency of 90%; this was found to be more stable than the unencapsulated curcumin for 27 days of storage at 25°C.

34.4 ENCAPSULATED INGREDIENTS AND THEIR APPLICATIONS

Microencapsulation can potentially offer numerous benefits to the materials being encapsulated, particularly in the case of functional food ingredients and nutraceuticals. Various properties of active materials may be changed/modified by encapsulation. For example, handling and flow properties can be improved by converting a liquid to a solid encapsulated form. Hygroscopic materials can be protected from moisture. The stability of functional ingredients that are volatile or sensitive to heat, light, or oxidation can be protected, thereby extending their shelf life. Materials that are otherwise incompatible can be mixed and utilized safely together. Using food fortification as an example, microencapsulation can mask the undesirable taste of some nutrients (i.e., minerals) that may be imparted by the free forms, thus enabling the production of functional foods, say, a nutraceutical beverage, with desirable sensory properties [388]. Currently, several hundred types of microcapsules are being utilized as food additives or as ingredients in functional food formulations throughout North America and elsewhere around the world [24], some of which are described next.

34.4.1 Acidulants

Acidulants are added to foods for a variety of reasons. They can be used as flavor enhancers and modifiers as well as preservation and processing acids. In addition, they facilitate the development of a wide variety of textural effects in foods because of their interaction with other macro- and micromolecules such as proteins, starches, pectins, and gums [389].

Unencapsulated food acids can react with food ingredients to produce many undesirable effects. These include decreased shelf life of citrus-flavored and starch-containing foods (e.g., pudding and pie fillings, in which the acid hydrolyzes the starch), loss of flavor, degradation of color, and separation of ingredients. Encapsulated food acids overcome these and other problems because they preclude oxidation and provide controlled release under specific conditions. Moreover, encapsulated acids reduce hygroscopicity, reduce dusting, and provide a high degree of flowability without clumping.

Encapsulation of acids in a time-release matrix is suggested as a means of avoiding undesirable reactions of acidulants with other food ingredients. The matrix used for forming the encapsulating coat in the acid products is generally a partially hydrogenated vegetable oil, although maltodextrin and emulsifiers are also available for this purpose. The encapsulated acids can be released at the appropriate time in the processing operation either by heating to the melting point of the coating material or by contact with water or a combination of these methods. Several applications of encapsulated acidulants are given next.

34.4.1.1 Meat Processing Aids

In the meat industry, encapsulated acids, such as lactic acid and citric acid, as well as glucono-δ-lactone (GDL) are used to assist in the development of color and flavor in meat emulsions, dry sausage products, restructured meat products, uncooked processed meats and meat-containing products, such as pasta meals. Fat encapsulation allows the acid to survive the blending process, giving a uniform dispersion within the meat formulation. Later, the encapsulated acid controls the drop in pH and prevents the meat from prematurely setting [25]. In a meat preparation, encapsulated acids need to

be released after the later processing stages such as cooking. Early release causes protein binding and the final texture of the product will become brittle and unacceptable.

Cured meat products, especially dry and semidry sausages (e.g., summer sausages, pepperoni, and salami), have historically been prepared using lactic-acid-producing bacterial cultures to develop flavor and lower the pH. Bacteria are added to the meat emulsions and allowed to proliferate until a sufficient amount of lactic acid is generated. Upon its production, the pH drops, binding occurs, and flavor develops. However, such products often tend to have inconsistent flavor, color, and textural characteristics from batch to batch. Uncoated lactic acid and citric acid cannot be added to meat during curing because they react almost instantly with meat proteins, rendering it unsuitable for further processing. Contamination is especially troublesome when the meat processor uses fermented raw meat as the source of bacteria rather than frozen cultures. An encapsulated acid, which is formulated for delayed release under smokehouse temperatures, can be employed as an alternative to the cultures. Acidification by encapsulated acids can improve emulsification and protein binding of emulsified meat and poultry products and impart the "tangy" flavor associated with fermented sausages without the complicated use of lactic acid starter cultures. In effect, encapsulation permits addition of the acidulants prior to stuffing without premature denaturation/binding of meat.

Nearly 50 years ago, encapsulated acids in a heat-rupturable inert vehicle such as ethyl cellulose were developed [390]. The prepared encapsules were mixed with nitrite-treated comminuted meats, and upon thermal processing, the encapsulated acid was released and brought about a lowering of the pH in the meat product and gave rise to rapid development and stabilization of the c.ured meat color. The more acidic conditions within the meat matrix assisted the production of nitrous acid and/or dinitrogen trioxide from the exogenous sodium nitrite. Both nitrous acid and dinitrogen trioxide are potent nitrosating species that interact with the prosthetic heme group of myoglobin, the main haemoprotein pigment of muscle tissue, to form the cooked cured-meat pigment (CCMP), nitorsyl ferrohemochrome.

The effect of encapsulated food acids on restructured pork from prerigor sow meat was studied by Cordray and Huffman [391]. Results from sensory panels indicated that sodium acid pyrophosphate and encapsulated GDL treatments yielded products with a more intense flavor than that of the control sample. Objective analysis revealed no significant ($P > 0.05$) difference in shear value, tensile strength, water-holding capacity, cooked yield, or chilled yield. However, significantly more of the total meat pigment was converted to CCMP in the GLD treatment than that of the control. Lactic acid can also be encapsulated by plating it onto a particle calcium lactate carrier and then encapsulating the carrier and acid with a molten edible lipid [392].

34.4.1.2 Dough Conditioners

The baking industry has long been aware of the need for stable acids and baking soda for use in wet and dry mixes to control the release of carbon dioxide during processing and subsequent baking. Products commonly encapsulated for bakery applications include a variety of leavening system ingredients, as well as vitamin C, acetic acid, lactic acid, potassium sorbate, sorbic acid, calcium propionate, and sodium chloride.

Use of ascorbic acid (vitamin C) for the strengthening and conditioning of bread and roll doughs provides many positive effects to the finished products. Examples of these are stronger sidewalls, uniform crust color, and improved slicing, in addition to a stronger structure that supports the addition of other protein-rich ingredients (such as soybean flour, nonfat milk powder, and wheat germ). However, because ascorbic acid degrades rapidly in the presence of water and oxygen, most of the acid is destroyed before it is needed. Encapsulated in an edible coating, ascorbic acid imparts some of the effect of an oxidizing agent when used alone in natural breads. In combination with bromate, it enables higher amounts of protein-rich ingredients to be utilized without disturbing the grain of the bread to any great extent [393].

For yeast-raised dough, encapsulated salt, potassium sorbate, and sorbic acid are employed because they do not allow the pH to drop too early in the baking process and therefore the yeast can grow. Once baked, however, the mold-inhibiting properties of these ingredients are released into the dough [25].

34.4.1.3 Other Encapsulated Acidulants

Acids are frequently used as liquids but would be easier to handle if they could be supplied in solid forms. Seighman [394] developed a method for encapsulation of food-grade phosphoric acid in a dispersion containing a film-forming agent (hydrogen octenylbutane-dioate-amylodextrin) and a matrix-forming ingredient (modified and hydrolyzed starches). The dispersion is thermally processed and then extruded into a cold aqueous alcohol to solidify the matrix-forming ingredients and to allow the film-forming agent to harden to a vitreous structure.

34.4.2 Flavoring Agents

The development and production of artificial or natural flavors and spices is an ever-expanding field in the food industry. The vast majority of flavor compounds used are a liquid at room temperature and constituents of the flavors tend to show sensitivity toward air, light, irradiation, and elevated temperatures. Moreover, these flavor concentrates are oily and lipophilic materials that can be difficult to work with. Therefore, it is necessary to employ a process to convert these flavor compounds into a more useable form. One of the purposes behind encapsulation in the food industry is the conversion of liquid flavors to dry powders. Microencapsulated flavors provide the convenience of a solid form over a liquid one, with reduced volatility and less oxidation [47, 200, 341]. Microencapsulation has become an attractive option to transform liquid food flavorings into stable and free-flowing powders that are easier to handle and incorporate into a dry food system.

The flavor industry depends heavily on encapsulation as a means of providing solid flavor compounds, which offer them protection until consumption. Flavoring agents and spices are encapsulated by a variety of processes and provide numerous advantages to food processors. Examples of commonly used encapsulated flavors are citrus oils, mint oils, onion and garlic oils, spice oleoresins, and whole spices. Citrus oils are very susceptible to oxidation due to sites of unsaturation in their mono- and sesquiterpenoid structures. Oxidative deterioration results in the development of off-flavors described as painty or turpentine-like. Encapsulated citrus oil, prepared by spray drying in a maltodextrin matrix, has a greater stability than unprotected oil [57].

Because flavors are often volatile materials, the stability of the dry microcapsules is an important consideration. Microcapsules must be stable for an extended period of time. Many volatile liquids can be encapsulated and subsequently dried to form free-flowing powders with minimal loss of activity during storage. Table 34.8 illustrates the stability of encapsulated flavors as a function of storage time in microcapsules of various particle sizes under ambient conditions [40].

Flavors encapsulated by inclusion complexation in β-cyclodextrin were protected against volatilization and attack by oxidation [341, 345]. Storage stability of flavors encapsulated in β-cyclodextrin under "non-stress" conditions at room temperature showed that molecular encapsulation, in most cases, provides an almost perfect preservation of flavors for up to 10 years [345] (Table 34.9).

There has been a great expansion in the development of techniques to encapsulate flavors. A spray dried composition comprising a volatile and/or a liable component in a carrier can be further encapsulated in an extruded glassy matrix. Such a procedure of double encapsulation has recently been developed by Levine et al. [395]. Excellent reviews of microencapsulation technology as it applies to food flavors have previously been written [36, 47, 199, 215, 396–398]. However, it should be noted that details about these techniques are difficult to obtain since they are often trade secrets.

TABLE 34.8
Stability of Microencapsulated Flavors

Encapsulated Flavor	Average Capsule Size (μm)	Storage Period (Days)	Flavor Content in Microcapsules (%) Initial	(%) Final
Cassia	750	730	87.8	86.1
	20	730	63.1	59.2
	600	400	90.2	89.9
	250	500	70.5	76.3
Lemon	40	730	74.0	67.9
	20	730	60.1	59.9
Lime	1000	409	92.5	89.6
Peppermint	50	732	75.3	74.6
	20	730	58.5	56.3

34.4.3 Sweeteners

Sweeteners are often subjected to the effects of moisture and/or temperature. Encapsulation of sweeteners, namely, sugars and other nutritive or artificial sweeteners, reduces their hygroscopicity, improves their flowability, and prolongs their sweetness perception. Sugar that has been encapsulated with fat and incorporated into chewing gum requires more shear and higher temperatures to release its sweetness than uncoated sugar, which dissolves more rapidly in the mouth.

Patents awarded to the encapsulation of sweeteners emerged mainly in the 1980s, as the technical development of encapsulation allowed their commercial manufacture. Among these, aspartame is the most widely studied sweetener. Aspartame is the methyl ester of a dipeptide made from two amino acids, phenylalanine and aspartic acid (aspartate). Although this white, odorless, and crystalline powder has a very intense sweetness, approximately 180 to 220 times sweeter than sucrose, the potential for its use in food has, in the past, been limited. At high temperatures, aspartame degrades into its amino acids, aspartic acid and phenylalanine, which is accompanied by a loss of sweetness. This internationally marketed sweetener has now been encapsulated by many methods.

Patents awarded to Cea et al. [399, 400] are mainly on the encapsulation of APM (L-aspartyl-L-phenylalanine methyl ester) as a chewing gum composition. It has been claimed that the encapsulated APM overcomes difficulties experienced in the use of APM with respect to its stability in the presence of water or elevated temperature [399, 400]. Yang and coworkers

developed a process for encapsulating aspartame in a film composed of high molecular weight polyvinyl acetate and a hydrophobic plasticizer (mono- or diacylglycerol with fatty acid chains of 16–22 carbon atoms) [401–403]. In this process, active ingredients, including soluble dietary fibers, flavoring agents, and drugs, can also be encapsulated. The product can be used to give chewing gum an extended shelf life, with highly controlled release of active ingredients [401].

A process developed by Cherukuri and coworkers can be used to produce a stable delivery system. It comprises a dipeptide or amino acid sweetener or flavorant or mixture thereof encapsulated in a mixture of fat and high-melting-point polyethylene wax [404–406]. Gas chromatographic analyses were used to measure the retention of orange, synthetic peppermint, and natural lemon flavors that had been cocrystallized and then stored in polyethylene bags under ambient conditions. Data indicated that there was no significant change in flavor retention for up to 15 weeks of storage. Results from oxidation studies [407] showed that peanut-butter-flavored products had a very good shelf life, even after storage for an appreciable period of time. Chen et al. [80, 81, 407, 408] have published a number of patents in this area. Some typical examples of products encapsulated by cocrystallization are listed in Table 34.10.

34.4.4 Colorants

Natural colors such as annatto, β-carotene, and turmeric present solubility problems during their use and may create dust clouds. Encapsulated colors are easier to handle and offer improved solubility, stability to oxidation, and control over stratification from dry blends. Synthetic colors, together with other food ingredients, can also be encapsulated for improving their stabilities [409].

A technique for solubilizing oily substances in micellar solutions of protein and carbohydrates was applied by Ono [167] in order to achieve encapsulation of two oil-soluble pigments, namely, paprika oleoresin and β-carotene. The pigment in oil was solubilized in an aqueous solution containing 60% (w/w) corn syrup solids and 1% (w/w) polypeptone. The solubilized mixture so obtained was solidified by vacuum drying at 60°C and formed into granules by crusting and sieving. These granules containing approximately 12% pigment-containing oil underwent virtually no discoloration during storage for 20 days at 60°C or when subjected to irradiation under a fluorescent lamp. Dispersibility of the pigments in water was improved by their encapsulation in a protein–carbohydrate matrix [167].

Ciliberto and Kramer [410] developed an encapsulation process for producing granular water-soluble food ingredients that otherwise deteriorated on exposure to the atmosphere (such as coloring agent). It was claimed that the resulting coated particles had a long shelf-life and were still substantially instantaneously soluble in water. Studies on encapsulation of preformed cooked cured-meat pigment (CCMP) showed that the CCMP may be stabilized effectively by its encapsulation in food-grade starch-based wall materials. The color stability of the treated meat products was found similar to their nitrite-cured analog [411].

TABLE 34.10
Examples of Products Encapsulated by Cocrystallization

Flavored sugar crystals	Brown sugar, chocolate, honey, molasses, and peanut butter granules
Fruit juice crystals	Cranberry, grape, orange, raspberry, and strawberry juices
Essential oil powders	Cinnamon, lemon, orange, and peppermint oils
Dry flavors	Barbecue, beef fat, butterscotch, chocolate, maple, and smoke flavors
Volatile substances	Acetaldehyde and diacetyl

34.4.5 Lipids

Lipids contribute to more than 30% of the dietary energy of North Americans, and similar figures apply to many other affluent societies. Use of lipids/fats are commonplace in food processing practices, but the susceptibility of lipids to oxidative degradation during processing and storage is always a concern; particular attention must be paid to foodstuffs containing higher proportions of polyunsaturated fatty acids (PUFA). One possible way to protect lipids against oxidative deterioration is via encapsulation. Early research in this area was mainly focused on production of encapsulated lipids for animal feed [412–415], but more recently, encapsulated high-fat powders or shortenings have become available in human food formulations [416].

Because of the pro-health benefits of fish oils, encapsulated oils have been available in health food stores, pharmacies, and supermarkets for a number of years. These fish oils contain long-chain omega-3 PUFA, such as eicosapentaenoic acid (EPA), docosahexaenoic acid (DHA), and docosapentaenoic acid (DPA), whose beneficial effects have been ascribed to their ability to lower blood serum triacylglycerol and cholesterol levels [417, 418]. Whereas DHA is essential for proper functioning of the eye and may have a structural role in the brain, EPA serves as a precursor to eicosanoid compounds [419] and has therapeutic benefits in human cardiovascular diseases [141, 420, 421]. It should be noted that fish oils are exceptionally susceptible to autoxidation and can form complex mixtures of high molecular weight oxidation products. Shukla and Perkins [422] reported that because of the unknown health effects of the oxidative polymeric materials and their high level in some encapsulated oils, caution should be exercised when ingesting fish oil capsules on a regular basis. However, encapsulation can enhance the oxidative stability of these oils.

Gejl-Hansen and Flink [423] freeze dried an aqueous emulsion of linoleic acid in a maltodextrin coating in the presence of detergents. The microencapsulated linoleic acid was not susceptible to oxidative deterioration even though more effective encapsulating wall materials could have been used. Ono and Aoyama [168] reported that vacuum dried rice brain oil embedded in granules containing corn syrup solids and

pork polypeptone did not undergo much oxidation upon exposure to air at a high temperature for a few weeks. Taguchi et al. [424] reported the oxidative stability of sardine oil embedded in spray dried egg white powder and use of the product as a source of omega-3 PUFA for fortification of cookies. These authors reported that use of microencapsulated sardine oil in fortified cookies did not affect their sensory quality.

The antioxidative effects of spray dried powders, at various water activities, prepared from alcoholic solutions of gliadin, linoleic acid, and palmitic acid, were compared against powders prepared by simple mixing of these components in the same portions and against gelatine or starch powders substituted for gliadin by Iwami et al. [425]. It is reported that the microcapsules obtained from the experiment were highly resistant to oxidative deterioration during long-term storage at various A_w's [425]. Shahidi and Wanasundara [426] spray dried an emulsion of seal blubber oil, which contained 21–26% long-chain omega-3 PUFA, with either β-cyclodextrin, corn syrup solids, or maltodextrins. They found that β-cyclodextrin was the most effective entrapping agent and prevented oxidative deterioration of seal blubber oil.

34.4.6 Vitamins and Minerals

Most vitamins cannot be synthesized by the body and must be supplied by the diet [427]. Because vitamins are such important nutritional and dietary factors, processed foods are often enriched or fortified with vitamins. Table 34.11 presents the recommended daily allowances for vitamins A, D, E, K, C, B_6, B_{12}, folic acid, thiamine, riboflavin, and niacin as compiled by the National Academy of Sciences' Food Nutrition Board [428]. Vitamins and minerals are often added to dry mixes to fortify a variety of foods.

Encapsulation of vitamins and minerals offers many advantages as it reduces off-flavors contributed by certain vitamins and minerals, permits time release of the nutrients, enhances stability of vitamins to extremes in temperature and moisture, and reduces each nutrient's reaction with other ingredients. Encapsulation also improves flow properties and reduces dusting when nutrients are added to dry mixes. Both fat- and water-soluble vitamins may be encapsulated with a variety of coatings to provide many advantages. Hall and Pondell [429] developed a process to encapsulate vitamin or mineral particles. The coating matrix for this process was chiefly ethyl cellulose together with propylene glycol monoester and acetylated monoglycerol. Vitamins and minerals can also be encapsulated in fat [430] or in starch matrices [431].

For encapsulation of water-soluble vitamins, ethylcellulose is useful because it is water-insoluble, and coatings with increased thickness reduce the water permeability of the prepared capsules. Thiamine enrichment of some bakery products such as devil's food cake, ginger snaps, and soda crackers, has always been unsuccessful due to the vitamin destruction in the neutral or alkaline pH. A procedure for microencapsulating thiamine in an ethylcellulose coating to protect it from alkaline conditions experienced in bakery products, and to mask its undesirable bitter taste, has been developed [432].

Riboflavin, thiamine, and niacin are partially destroyed during processing and cooking of pasta products. Studies on unprotected versus encapsulated thiamine, riboflavin, and niacin in cooked enriched spaghetti showed that concentrations of the three B vitamins tested were higher in cooked pasta that contained encapsulated vitamins [433].

Lipid-soluble vitamins lose their activity due to isomerism, anhydrovitamin formation, oxidation, and photochemical reactions [341]. Losses of vitamins in fortified foods can be minimized if they are added as cyclodextrin complexes [341] or gelatine-encapsulated beadlets [434]. It was found that the stability of vitamin A in skim milk was substantially increased by encapsulation in gelatine. Loss of the vitamin in fortified milk powder was minimal even when heated at 100°C for 9 min or stored at 28°C for 40 weeks [434]. Table 34.12 presents the stability data of vitamin A palmitate, of 325,000 units per gram potency, encapsulated in a modified gelatine film [40]. The data indicate that the rate of vitamin A degradation under the test conditions is significantly reduced by microencapsulation.

TABLE 34.11
Recommended Dietary Allowances

Vitamin	Men	Women	Children to Age 11
Fat-soluble			
Vitamin A (retinol, μg)	1000	800	400–700
Vitamin D (cholecalciferol, μg)	5–10	5–10	10
Vitamin E (α-tocopherol, mg)	10	8	6–7
Vitamin K (μg)	45–80	45–65	15–30
Water-soluble			
Vitamin C (mg)	60	60	40–45
Vitamin B_1 (thiamine, mg)	1.5	1.1	0.7–1.0
Vitamin B_2 (riboflavin, mg)	1.7	1.3	0.8–1.2
Niacin (mg)	19	15	9–13
Vitamin B_6 (pyridoxine, mg)	2.0	1.6	1.0–1.4
Vitamin B_{12} (μg)	2.0	2.0	0.7–1.4
Folic acid (μg)	200	180	50–100

TABLE 34.12
Stability of Vitamin A Palmitate at 45°C and 75% Relative Humidity

	Percentage of Potency Retained	
Time (Days)	Raw Oil	Microencapsulated
5	86.1	98.3
15	84.2	97.8
42	76.2	94.2
56	69.9	94.1

Source: Shahidi and Han [499].

A well-designed phase-separation technique for encapsulation of vitamin A has been developed by Markus and Peleh [435]. The matrix components used consisted of substituted cellulosic materials, fatty acids, or a variety of proteins. Antioxidants such as butylated hydroxytoluene (BHT) and ethoxyquin were incorporated in the formulations. It has been claimed that the capsules prepared with substituted cellulosic materials gave the best protection to vitamin A from degradation [435].

Iron compounds have been encapsulated to improve the color, odor, and shelf life of fortified products. Encapsulation reduced the ability of iron to react with other food ingredients and also lightened the color of an unspecified type of electrolytic iron [436]. The process for encapsulation of ferrous sulfate was developed by Jackel and Belshaw [437] in the 1970s. It is reported that the encapsulated $FeSO_4$, a fine, white, free-flowing powder, can withstand 6 months of storage without any deteriorative change. Harrison et al. [438] examined the effect of iron in various forms on the oxidation of lipids in white flour. When subjected to an accelerated stability test (stored at 50°C), flours enriched with ferrous sulfate, fat enriched with ferrous sulfate, electrolytic iron powder, and carbonyl iron powder, developed an unacceptable oxidized flavor after 8 days. However, oxidation was not detected in flour stored at room temperature for 2 years [438].

Soy milk beverages have gained attention as possible alternatives to cow's milk. However, soy milk is nutritionally inferior to cow's milk with respect to its calcium content. Attempts to fortify soy milk with calcium have been unsuccessful since soy protein is coagulated and precipitated by calcium [439, 440]. Hirotsuka et al. [440] found that calcium coated with lecithin to form liposomes could be added to soy milk without undesirable calcium–protein interactions. The technology was successful in fortifying 100 g of soy milk with an additional 120 mg of calcium.

34.4.7 Enzymes

Enzymes are being used increasingly in the food industry for a wide variety of applications. Encapsulation of enzymes could enhance their properties in different ways. The first and foremost of these concerns stability. The complex biochemical structure of the enzyme can make it highly vulnerable to inactivation by other components or conditions within the food system. By segregating it inside a microcapsule, it can be maintained in conditions that could otherwise be very harmful to it. A variety of other stabilizing materials can be encapsulated alongside the enzyme to protect them from different antagonistic effects. Inhibitory agents and harmful ions will be excluded from the capsule. Penetrating ions can be removed by buffers or chelating agents, and oxidative damage may be prevented by the use of antioxidants. Thermostabilizers such as sugars will protect against extreme processing conditions such as dehydration or freezing. Further stabilization may be achieved by simply maintaining the enzyme in a concentrated form rather than allowing it to become diluted into the bulk-food phase.

As long as it remains encapsulated, the enzyme will be isolated from its substrate and therefore latent and passive within the food matrix. By selecting a capsule with appropriate properties, we can choose when, where, and how to interact it with its intended substrate. By altering the surface properties of the microcapsules, they can often be made to accumulate at a particular microscopic location within the food. When they eventually break down, the enzyme activity will be concentrated at the intended target site rather than nonspecifically dispersed throughout the food. In this way, enzymes can be used much more selectively and with far greater efficiency than their normal usage would allow.

The timing of enzyme release can be controlled by selecting a microcapsule according to its stability properties within a particular food system. A low stability will lead to early release in the food process, whereas a more stable one will allow postponement of its release. This is very useful when early release is undesirable and enzyme action is not needed until a later step of a multistage process.

Considerable progress in research for the control of cheese ripening using encapsulated enzymes has been achieved [441–449]. The principles involved in this application provide a good illustration of how encapsulation can be generally applied in the food industry, as it has been reviewed by Kirby and Law [450]. Other enzymes such as lipase [451, 452] and invertase [453, 454] have also been encapsulated for applications in food processing.

34.4.8 Microorganisms

Encapsulation of viable bacterial cells has several advantages over encapsulation of isolated enzymes such as those in cheese ripening. The stability of enzymes in intact cells is greater than in extracts. Production achieved by cells is also easily manipulated by controlling substrate concentration in the microcapsules [448].

Kim and Olson [449] reported that cells of *Brevibacterium linens* were successfully entrapped in milk-fat-coated microcapsules. It is believed that the bacteria using methionine to produce methanethiol and other sulfur compounds make a major contribution to the cheddar cheese flavor of low-fat cheese products. Microencapsulated microorganisms may be helpful in reducing the ripening time of blue cheese or in imparting blue cheese flavor to other foods. Spores of *Penicillium roqueforti* were encapsulated in a milk fat coating matrix [455]. The microenvironment provided by the microcapsules enhanced methyl ketone production by spore enzymes.

Recently, intensive research efforts have been focused on protecting the viability of bacterial cultures, which demonstrate probiotic activity, during a product's manufacture, storage, and gastric transit. Studies have demonstrated that probiotic cultures can be significantly protected via encapsulation using a variety of carriers. In essence, microencapsulation has been at the forefront of the functional foods and nutraceuticals revolution, as it relates to probiotics.

Probiotics are described as "live microorganisms which when administered in adequate numbers confer a health benefit to the host" [456]. These supplements contain beneficial,

friendly bacteria of the *Lactobacillus* and *Bifidobacterium* species, and are formulated to reflect the composition of healthy gut flora; they have a direct impact on both the host's metabolism and physiology. In order for a microorganism to be classified as a probiotic, it must be (i) isolated from humans, (ii) compatible with humans, (iii) safe for humans, (iv) able to survive the acid conditions in the stomach, (v) able to grow and colonize in the gut, (vi) antagonistic to pathogenic bacteria, and (vii) have scientifically proven efficacy. Moreover, probiotics share a number of common traits such as a generally regarded as safe (GRAS) status, acid and bile tolerance, and an ability to adhere to intestinal cells [457]. Though probiotics are commonly added to fermented milks, yogurts, and cheeses (i.e., as functional foods), they are also available as dietary supplements, where the probiotic is in the form of a dried encapsulated product or capsule [458]. Clinical studies have shown beneficial health effects from the consumption of probiotics of the *Lactobacillus* and *Bifidobacterium* species, and these include reduction of rotavirus diarrhea, alleviation of lactose-intolerance symptoms, reduction of harmful intestinal microbial enzyme activity, decrease in fecal mutagenicity, aid in digestion, prevention of illness by inhibiting the growth of pathogenic and putrefactive bacteria in the gastrointestinal (GI) tract, and possibly assistance in the reduction of cholesterol [459–462].

In Japan, there is a long tradition of believing that health is dependent on food and in particular that the maintenance of a population of beneficial bacteria is important. The addition of probiotics to foods is seen as an effective means of restoring some of the initial beneficial food-associated microflora that may be destroyed during microbial reduction treatments such as pasteurization. The Japanese have long believed that probiotic bacteria must arrive at the site of action in large enough numbers to exert their effect and this might most easily be achieved by using resistant bacteria or by providing large numbers of live bacteria when consumed to compensate for losses during passage through the upper GI tract. The Fermented Milks and Lactic Acid Bacteria Beverages Association in Japan has set a minimum of 10^7 bifidobacteria or CFU/mL of product [463, 464]. Furthermore, the probiotic food product must be consumed regularly to ensure that a sufficient "dose" of live bacteria is delivered to the gut. Consequently, technological issues relating to the development of foods containing these bacteria in sufficient numbers throughout shelf life need to be overcome as well as a means of stabilization following ingestion, that is, during exposure to the adverse conditions of the human GI tract [458]. This is where encapsulation technology has stepped in to give a helping hand. The probiotic food industry has been increasingly utilizing encapsulation as a means of protecting live cells from extremes of heat or moisture, such as those experienced during drying and storage [465, 466].

Spray dried powders possessing high numbers of viable probiotics is a convenient means of storage and transport of probiotic cultures and their subsequent application to functional foods. Most probiotic lactobacilli, however, do not survive well during the temperature and osmotic stresses they face when spray dried [467, 468]. Thermal and dehydration damage to cell membranes and proteins leads to bacterial cell injury and eventually death. To overcome this problem one approach has been the addition of thermoprotectants to the media prior to drying. Desmond et al. [469] reported that the incorporation of soluble fiber (as a prebiotic, an energy source for the probiotic) and gum acacia to a milk-based medium prior to spray drying of the probiotic, *Lactobacillus paracasei* NFBC 338, increased the culture's viability during drying and powder storage compared with milk powder alone. In this situation the encapsulated product not only had better probiotic viability, but it can also be regarded as a synbiotic given the presence of both probiotics and prebiotics. Other investigated prebiotics such as inulin and polydextrose did not enhance probiotic viability during drying or powder storage [470].

Several methods of microencapsulation of probiotic bacteria have been reported; these include spray drying, extrusion, emulsion, and phase separation [10, 471]. In a study by Guerin et al. [472] *Bifidobacterium bifidum* cells encapsulated in gel beads composed of alginate, pectin, and whey proteins, and surrounded by two membranes exhibited good survival at pH 2.5 for up to 2 h, while free cells did not survive under these conditions. Furthermore, protection was afforded by this system when the cells were exposed to bile salt solutions. Selmer-Olsen et al. [473] reported that encapsulated lactobacilli in calcium-alginate beads had improved heat tolerance, and O'Riordan et al. [466] demonstrated that this technology also prolonged the viability of spray dried *Bifidobacterium ruminatium* during storage. Probiotic bacteria have also been microencapsulated in a matrix of vegetable fatty acids. This technique broadens the range of ingredients with which probiotics can be blended and formulated. Moreover, the passage through the GI tract is very stressful for probiotics, especially on an empty stomach where the pH can be as low as 1.5; thus, the hydrophobic coating surrounding the microencapsulated bacteria protects the fragile microbial cells and allows them to pass into the intestine. According to Frost and Sullivan [4] the future for probiotics is bright because their encapsulation in hydrocolloid beads is helping to improve their survival rate right through both processing and digestion. As the technology matures and improves, it is hoped in time that a mechanism for targeting the release of beneficial bacteria in specific sites of the human GI tract will be provided.

34.4.9 Gases

Some hard candies can be made with entrapped carbon dioxide gas [451]. Confections made with encapsulated carbon dioxide produce a sizzling effect on the tongue as the candy melts in the mouth. The candy is produced by incorporating gas at a pressure of 50 to 1000 psi into the molten sugar. Concentrations of carbon dioxide in the candy range from 0.5 to 15 ml per g sugar [451]. Gas can also be injected into the encapsulation system and be coated together with the foaming and aromatic core mixtures [474].

34.4.10 Other Food Additives

Almost all food additives can theoretically and technically be encapsulated. However, only some encapsulated additives

are commercially available since there are many factors that have to be taken into consideration before the process leads to commercial manufacture. Research has been done to encapsulate food preservatives such as monocapric acid [475] and oleic acid [476]. The process for preparing a coated-particle salt substitute composition was described by Meyer [477]. Other studies suggested that encapsulated antioxidants could be beneficial to food preservation [478]. It could be expected that there are many new encapsulated food ingredients that will be produced, and these could contribute greatly to further development of food processing and preservation.

34.5 CONTROLLED-RELEASE MECHANISMS AND THEIR EFFECTS

Encapsulation allows reactive ingredients to be separated from the environment until their release is desired. Though separation is the goal of encapsulation, release mechanisms of the core material must also be considered. In fact, when designing a custom encapsulated food ingredient, one must determine the desired release mechanism and a method for ensuring quality control. For example, in home-baked pizza products, sodium bicarbonate can be encapsulated to prevent early release of the bicarbonate and delay the reaction of the leavening phosphate until the crust reaches a particular temperature in the oven. Controlled release technology can help a wide variety of nutritional supplements deliver their payloads more effectively while heightening produce resale frequency for brands and retailers. In essence, a well-controlled release of core material is a very important property of microcapsules. For example, a substance in formulated food may be released upon consumption but prevented from diffusing throughout the product during processing operations (e.g., flavors, nutrients). Similarly, an additive may be released in a specific processing step, but protected in preceding operations (e.g., acids, leavening agents, cross-linking agents) [479].

Because the physical and chemical properties of volatile compounds are governed by their structures and cannot be changed, one has to manipulate the choice of the encapsulation matrix as well as the formulation of the flavor itself if the flavor is a compound flavor. By picking a capsule matrix with limited selectivity, which may in fact be chosen to discriminate against vapor pressure differences and the desired flux rate (to release slowly or quickly but uniformly), flavor imbalances can be minimized. Additionally, if the flavor is a formulated one, there may be some opportunity to choose flavor compounds that will have similar release rates. Such well-controlled release delivery systems present the food technologist with exciting opportunities for improving the performance of existing food processes, as well as for the development of entirely new ones [479, 480]. However, in order to address the issue of controlled release, one needs to examine the basic principles of controlling the release of encapsulated materials and then consider which technologies can be applied in the food industry. The various mechanisms of release from controlled-release delivery systems in consumer products are provided in Table 34.13 [481].

TABLE 34.13
Mechanisms of Release from Controlled-Release Delivery Systems in Consumer Products

Diffusion-controlled release	Membrane-controlled release
Pressure-activated release	Tearing or peeling release
Solvent-activated release	Osmotic-controlled release
pH-sensitive release	Temperature-sensitive release
Melting-activated release	Hybrid release

34.5.1 Release Rate

Release rates that are achievable from a single microcapsule are generally zero, half, or first order. Zero-order release occurs when the core is a pure material that may be released through the wall of a microcapsule as a pure material. Half-order release generally occurs with matrix particles, whereas first-order release occurs when the core material is actually a solution trapped within a solid matrix [479]. As the solute material releases from the capsule, a desired concentration of solute is reached.

A mixture of microcapsules will include a distribution of capsules varying in size and wall thickness. The effect, therefore, is to produce a release rate different from zero-, half-, or first-order because of the ensemble of microcapsules. Thus, it is desirable to carefully examine the experimental basis of the release rate from an ensemble of microcapsules, and to recognize the deviation from theory due to the distribution in size and wall thickness [24]. Numerous factors affecting the release rate of core materials are summarized in Table 34.14.

34.5.2 Release Mechanisms

The coating not only protects the core material from moisture, light, oxygen, other food ingredients, and additional external agents [307], but it allows/assists in controlling the release of core materials. Thus, the release of the core material is dependent upon the type and geometry of the particle and the wall material used to form the microcapsule. These factors dictate the mechanism of release for the capsule, which may be based on solvent effects, diffusion, degradation, or particle fracture

TABLE 34.14
Parameters Affecting the Release Rate of Core Materials

[482]. A variety of release mechanisms, which have been proposed for microcapsules, are summarized next.

34.5.2.1 Fracturation or Pressure-Activated Release

A number of controlled-release systems prepared primarily by coacervation technology depend on pressure for release of the active core [483]. The coating can be fractured or broken open by external forces, such as pressure, shearing, ultrasonics, or by internal forces, as would occur in a microcapsule having a permeation-selective coating. Both fracturation and diffusion involve the controlled release of volatile materials; however, a slow release of core material from the capsule in the case of fracturation is a detriment rather than an attribute. A completely impermeable capsule is needed that releases only on rupture. For example, capsules made from hardened fats or waxes are insoluble in water but can be made to release their contents by mechanical breakage, e.g., shear, or by increasing the temperature to the melting point of the fat (see Section 34.5.2.4). The act of chewing is the most commonly used mechanical release means. It is also possible to get release of the core substance by incorporation of a swelling agent into the core substance or by an electromagnetic method using discharge or magnetic force. The force-fractured release is accomplished in a relatively shorter duration beginning at certain controlled conditions compared to the other release mechanisms.

34.5.2.2 Diffusion

The mechanism involved in diffusion is to limit the release of core material from within the capsule to the surface of the particle by controlling the rate of diffusion of the active compound. The bulk of the capsule material itself may control the release (i.e., matrix-controlled release) or a membrane may be added to the capsule for doing so (i.e., membrane-controlled release). Most microcapsules have thin walls that may function as a semipermeable membrane. Furthermore, because microcapsules are very small in size, they have a very large surface area per unit weight. Hence, controlled release is frequently accomplished through a diffusion-controlled process [484].

Diffusion release depends upon the kinetic relationship between the core and wall materials and the rate at which the core material is able to pass through the outer wall. It is strictly governed by the chemical properties of the microcapsule and by the physical properties of the wall material such as the matrix structure and pore sizes [482]. Diffusion is a permeation process driven by a concentration gradient or interchain attractive forces [485]. In other words, it is controlled by the solubility of a component in the matrix (this establishes a concentration gradient in the matrix for driving diffusion) and the permeability of the component through the matrix. In the absence of cracks, pinholes, or other flaws, the primary mechanism for core materials to flow through a wall or coating is activated by diffusion, i.e., the penetrant dissolves in the film matrix at the high concentration side, diffuses through the film driven by a concentration gradient (i.e., Fick's law, $I_A = -D_{AB}\, dC_A/dy$, where I_A is the flux of the core material in the y direction, D_{AB} is the diffusivity, and dC_A/dy is the concentration gradient), and evaporates from the other surface. It should be noted that if the food components were not soluble in the matrix, it would not enter the matrix to diffuse through, irrespective of the matrix's pore size.

Diffusion also depends upon the size, shape, vapor pressure, and polarity of the penetrating molecules as well as the segmental motion of polymer chains [485, 486]. This also includes interchain attractive forces such as hydrogen bonding and van der Waals' interactions, degree of cross-linking, and the amount of crystallinity [487]. In general, cross-linking of a matrix has little meaning in most food applications. This is because very few situations exist where the matrix can be cross-linked considering the limitations imposed by having food-approved materials [484]. However, cross-linking of proteins as a consequence of Maillard reactions can occur and possibly influence the diffusion of solutes in heated protein-based encapsulation matrices (e.g., gelatine). Thus, the greater the degree of cross-linking, the lesser the rate of diffusion through the matrix (hence, a readily controllable process of making a controlled-release capsule).

The problem of uniform releasing of the aroma of an encapsulated flavor into food should be noted. Because a flavor consists of aroma compounds with a range of volatility, their release, for example, into the headspace of a food package will not be uniform and therefore a balanced characteristic food aroma may not be achieved [488]. The volatility or vapor pressure of these different compounds and their resistances to diffusion will affect their rate. Thus, aromas could become imbalanced as the constituents diffuse through the capsule.

For most physical methods, it is known that the success of encapsulation depends on the formation of a metastable amorphous structure, a glass, with a very low permeability to the organic compounds that are encapsulated within it. In drying processes, the presence of sugar and/or polymers in the encapsulation system reduces the water content. Reducing the water content lowers the glass transition temperature and the resulting amorphous matrix is impermeable to organic compounds as well as to oxygen. However, permeability to water remains finite. This phenomenon, also known as the selective diffusion theory of Thijssen and Rulken [489], is the basis for encapsulation using spray drying and freeze drying [479]. In spray drying, upon droplet formation, rapid evaporation from the surface produces a surface layer in which the selective diffusion mechanism operates. In freeze drying, upon water crystallization, the nonfrozen solution is viscous, and the diffusion of core materials is retarded. At the beginning of freeze drying, the surface of this solution becomes an amorphous solid in which selective diffusion comes into play.

The permeability of the coating structure can be changed by controlled conditions. The physical state of the food polymer has a considerable role in influencing diffusion and thus release of the core material. The physicochemical principles governing the softening or glass transition of the encapsulating materials have been studied by several researchers [490–493]. These investigations have shown that the release occurs when the glassy, impermeable structure undergoes a transition to a more mobile rubbery state (Figure 34.28). Thus, the

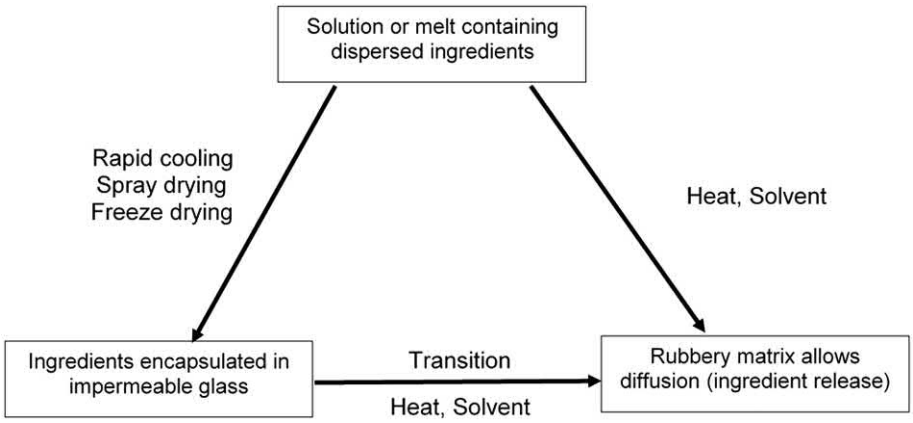

FIGURE 34.28 Preparation and release of core ingredients from microcapsules. (From Karel and Langer [478].)

glass–rubber transition of a matrix material is a relevant consideration when evaluating release properties. The relation of transition temperature to the composition of encapsulating formulations has been studied by To and Flink [494] and Levine and Slade [491] for the case of starch-derived encapsulating agents. It must be noted, however, that even after the critical moisture content or the critical temperature is exceeded, the rate of release is also a function of water content, temperature, and time [495]. This fact allows the generation of controlled-release systems. The maltodextrins and similar materials with controlled collapse temperatures are important not only as encapsulating agents but are also extremely useful in protecting enzymes and other sensitive biological materials during dehydration and subsequent storage. The principles are similar in that the sensitive materials are placed in a medium in which their mobility is restricted.

34.5.2.3 Solvent-Activated Release

Solvent-activated release is the most common controlled-release mechanism used in the food industry. Since most encapsulating matrices are water-soluble, the water in the food product dissolves away the microcapsule thereby liberating its content to the food, or it causes the capsule to swell to either begin or enhance the release of the core material. However, water-insoluble coatings can also be dissolved by selecting an appropriate solvent. Encapsulated agents are often added to dry food products such as dry beverages, and cake and soup mixes. The encapsulated flavors in these products are released upon rehydration [484]. Their release may be a sudden burst, or a continued or delayed delivery regulated by controlling the rate of wall solubility, the swelling of the wall material, pH effects, or changes in the ionic strength of the surrounding medium [482].

Although most traditional wall materials will rapidly release the core material once they are rehydrated, microcapsule matrices may be modified to release the active material at a desired point in time. Osmotic-controlled release is similar to solvent-activated release in that the core of the particle adsorbs a solvent (usually water) over time and swells until the capsule bursts [481]. For any food ingredient that is first encapsulated in a hydrophilic matrix and then coated with a lipophilic once, osmotic-controlled release functions to a limited extent. The encapsulated product will eventually swell and either expand the surface coating causing cracks or fractures, or rupture entirely.

34.5.2.4 Melting-Activated Release

The integrity of the coating can be destroyed by thermal means. This mechanism of release involves the melting of the capsule wall (or a protective coating that has been placed on the capsule wall) to release the active material. Because there are numerous meltable materials that are approved for food use (e.g., lipids, waxes, and modified lipids), this method of release is easily accomplished, but its applications are limited. In general, salts, nutrients, leavening agents, and some water-soluble flavoring agents have been protected by hydrophobic coatings to curtail release of the active ingredient into the food until the baking process. The hydrophobic coating and core material must be immiscible with one another in order to avoid migration of the active ingredient through the wall material. This limits the usefulness of the technique for many flavor applications. On the other hand, an already encapsulated flavor prepared by spray drying can be coated with a hydrophobic matrix via centrifugal coating or the fluidized bed technique. In this manner, the secondary coating on the flavor provides melt release properties [496]. The major problem in this approach, however, is the dilution of the flavoring by additional wall material and the extra cost involved.

34.5.2.5 Biodegradation and pH-Sensitive Release

Release from microcapsules can be accomplished by biodegradation processes if the coatings lend themselves to such degradative mechanisms. Lipid coatings may be degraded by the action of lipases [497]. Karel and Langer [479] released enzymes from liposomes using pH as a stimulant to initiate release. They postulated that pH changes destabilized the phospholipid-based liposomal structure, thereby releasing the enzymes from the liposome core.

34.6 CONCLUSION

Encapsulation is an effective preservation method for different food components as well as for bioactive compounds, including

antioxidants, lipids, peptides, vitamins, minerals, fatty acids, and probiotics. The main goal consideration should be to choose the appropriate encapsulation technique as well as the proper encapsulating material. Microencapsulation and nanoencapsulation have shown greater potential in improving the effectiveness of the delivery of bioactive compounds, which contribute to improved health. Different techniques of encapsulation are still emerging with their own advantages and disadvantages. Techniques such as spray drying, electrohydrodynamic techniques, spray cooling and spray chilling, freeze drying, fluidized bed coating, extrusion, coacervation, liposome, and emulsification are useful techniques for encapsulation of food ingredients. Furthermore, freeze drying and extrusion remain unique techniques for encapsulation of heat-sensitive ingredients. However, all encapsulation techniques ultimately depend on how to produce encapsulates in the powder form. Currently, freeze drying and spray drying are widely used drying techniques in the encapsulation process. Nevertheless, freeze drying is still 4–7 times more expensive than spray drying. Each encapsulation technique has several unique operating variables and factors that affect the quality of the final encapsulates; these factors need to be considered and carefully optimized. However, possible risks of encapsulation materials to human health are still unknown. Thus, regulatory national bodies may need to move ahead with initiatives to control and monitor proper development of encapsulated food products and ingredients.

34.7 FUTURE DIRECTIONS

Many encapsulation techniques can be developed with high efficacy. Further studies that investigate techniques other than microencapsulation, nanoencapsulation, and emulsions with different combinations are needed in order to develop reliable methods for efficiently producing stable products that can be easily delivered to food and protect sensitive ingredients from the environment as well as reacting with one another. It is also important to develop standard methods that can better compare different encapsulation techniques. Development of encapsulation specifics for food processing, proper delivery of nutraceuticals, and quality control of products is of utmost global interest and must be researched. In addition, proper packaging of encapsulated ingredients may benefit from novel ideas and further research.

Part V

Preservation Using Heat and Energy

35 Pasteurization and Food Preservation

M. N. Ramesh

CONTENTS

35.1 INTRODUCTION

Pasteurization is one of the most important steps in preservation and is essential for food safety. It greatly improves a product's "keeping" quality by effectively destroying virtually all disease-producing and most other bacteria (source: www.fao.org). Pasteurization is a process of heat treatment to inactivate enzymes and to kill relatively heat-sensitive microorganisms that cause spoilage, with minimal changes in food properties, for example, sensory and nutritional characteristics. It is also defined as a "mild heat treatment" for avoiding microbial and enzymatic spoilage. It is used to extend the shelf life of food at low temperatures, usually 4°C, for several days (e.g. milk) or for several months (e.g. bottled fruit juice). The heating of liquid foods to 100°C is employed to destroy heat-labile spoilage organisms such as non-spore forming bacteria, yeast, and molds.

35.2 PURPOSE OF PASTEURIZATION

The primary object of pasteurization is to free the food of any microorganism that might cause deterioration or endanger the health of the consumer. The severity of the heat treatment and the resulting extension of shelf life are determined mostly by the pH of the food. In low-acid foods (pH >4.5), the main purpose is the destruction of pathogenic bacteria, whereas, below pH 4.5, the destruction of spoilage microorganisms or enzyme inactivation is usually more important. Table 35.1 shows different pasteurization conditions for food. Pasteurization does not aim to kill the spore-bearing organisms, such as thermophilic *Bacillus subtilis*, but these organisms and most other spore-bearing bacteria cannot grow in acidic fruit juices, and consequently, their presence is of no practical significance. The pasteurization of carbonated juices need only be conducted at such a temperature and for such

TABLE 35.1
Purpose of Pasteurization for Different Foods

Food	Main Purpose	Subsidiary Purpose	Minimum Processing Conditions
pH < 4.5			
Fruit juice	Enzyme inactivation (*pectinesterase* and *polygalacturonase*) (yeasts, fungi)	Destruction of spoilage microorganisms	65°C for 30 min; 77°C for 1 min; 88°C for 15 s
Beer	Destruction of spoilage microorganisms (wild yeasts, *Lactobacillus* species) and residual yeasts (*Saccharomyces* species)	--	65–68°C for 20 min (in bottle); 72–75°C for 1–4 min at 900–1000 kPa
pH > 4.5			
Milk	Destruction of pathogens; *Brucellaabortis*, *Mycobacterium tuberculosis*, (*Coxiella burnetti*)	Destruction of spoilage microorganisms and enzymes	63°C for 30 min; 71.5°C for 15s
Liquid egg	Destruction of pathogens Salmonella seftenburg	Destruction of spoilage microorganisms	64.4°C for 2.5 min; 60°C for 3.5 min
Ice cream	Destruction of spoilage microorganisms	Destruction of pathogens	65°C for 30 min; 71°C for 10 min; 80°C for 15 s

a time that yeasts and molds are destroyed. Yeast is killed by heating at 60–65°C, and the resistant mold spores, negative in most cases, are heated up to 80°C for 20 minutes. But molds require oxygen for growth, and for this reason, heavily carbonated juice can be pasteurized safely at 65°C, which destroys yeast cells. Most still (non-carbonated) juices must be pasteurized at 80°C. Juices of high acidity may be pasteurized at lower temperatures of 60–65°C.

The processing of containers of food that have a naturally low pH (e.g. fruit pieces) or in which the pH is artificially lowered (e.g. pickles) is similar to canning. In acidic products like tomatoes, mangoes, bananas, etc. (pH 4.0 to 4.4), yeast, molds, and bacteria (both thermophilic and mesophilic) grow. The main risk of spoilage is from spore-forming species other than *Clostridium botulinum* especially *B. coagulans* among the aerobes and *Clostridium pasteurianum* and *Clostridium thermosaccharolyticum* among the anaerobes. In high-acid food (pH <3.9) like pineapple juice, spoilage is generally caused by non-spore-forming bacteria (*Lactobacillus* and *Leuconostoc*), yeast, or molds. Fruits with a pH lower than 4.5 contain enzyme systems such as catalase, peroxidase, polyphenol oxidase, pectinesterase, etc., in addition to spoilage organisms. Unless inactivated, these enzymes are likely to cause undesirable changes in the canned products. Some of these enzymes, particularly peroxidases, have higher heat resistance than the spoilage organisms and have been used in evaluating the thermal processing of canned fruits.

35.3 TYPES OF PASTEURIZATION

There are several types of pasteurization: (i) In-package pasteurization: Inside packages, heating to the level of sterility is not required. A gradual change in temperatures is preferred in some containers. (ii) Pasteurization prior to packaging: Preheating is good for foods that are sensitive to high=temperature gradients. (iii) Batch pasteurization: This is also called the low-temperature-short-time process. Here fluid foods like milk are held in a tank where they are heated to 62.8˚C for 30 minutes. A batch pasteurizer consists of a steam jacket kettle or a tank equipped with steam coils in which juice or milk is heated to the desired temperature. (iv) Continuous pasteurization: This is also called the high-temperature-short-time process. Foods like milk are subjected to 71.7˚C for about 15 seconds or more by flowing through different heat exchangers. In continuous pasteurization generally plate heat exchangers, tubular heat exchangers, and scraped surface heat exchangers are used depending on the viscosity of the fluid food material. The heating medium is usually steam or water.

35.4 PASTEURIZATION TESTING

Over the past 60 years, the industry has used colorimetric tests to determine proper pasteurization. This manual inspection method is based primarily on a technician's subjective interpretation of the results. In 1990, a new rapid enzymatic assay (test) was designed to confirm pasteurization. This test involves the use of an automated instrument and a fluorometric assay. Alkaline phosphatase (ALP) is an enzyme naturally present in raw milk, which is used as an indicator for proper milk pasteurization. Non-pasteurized or raw milk contains ALP, which causes intra-abdominal bacterial infection after drinking the milk, whereas after pasteurization**,** ALP is denatured. Therefore, milk companies test the milk after pasteurization by ALP testing wherein the instrument interprets the results instead of a technician, dramatically reducing the evaluation process from 90 minutes to 3 minutes. ALP testing, unlike the colorimetric method, can be used to confirm pasteurization of many different products including bovine, sheep, and goat milk, flavored and cultured products, and cheeses. This test is revolutionizing the way the industry checks for pasteurization. Dairy processors enjoy higher precision and reproducibility and a tenfold sensitivity improvement. This enhances process improvement and troubleshooting while allowing immediate

process validation following maintenance. The ALP method has been accepted in Europe as a reference method, and dairy producers are beginning to implement the equipment. In the U.S., the test's accuracy and sensitivity resulted in the FDA lowering its pasteurization acceptance criteria from 500 to 350 mU/L of ALP activity. By lowering the criteria with better technology, plants are able to improve HACCP programs and advance the cause of food safety to protect consumers.

Biostrips have become more popular for testing of different chemical and biochemical parameters. A quick, simple, and economical test using dry-reagent strips for the detection of ALP activity in milk has also been developed [1]. It is based on ALP reaction with *p*-nitrophenyl phosphate in the presence of water to liberate *p*-nitrophenol and inorganic phosphate. *p*-Nitrophenol on reacting with a specific chromogen changes the color of the strip from light blue to green, which is visible to the naked eye. The strip has a sensitivity of >0.5 units/L. The strips may be used in dairy companies and remote areas where expensive instruments are not available. The strip is stable for more than a year at room temperature.

Processing methods have different effects on the nutritional and sensorial qualities of juices. Thermally treated juices produced by full or flash pasteurization are still the most widely marketed product. Acidophilic microorganisms have been shown to be the major contaminants of citrus juices, especially lactic acid bacteria and yeasts [2]. The redox potential (Eh) is a physiochemical parameter that determines the oxidizing or reducing properties of the medium, and it depends on the composition of the food (thiol-containing amino acids, peptides, proteins, and reducing sugars), the pH, the temperature, and for a large part the concentration of dissolved oxygen [3]. This parameter plays an important role in the cellular physiology of microorganisms such as growth capacity [4, 5] enzyme expression [6], and thermal resistance [7–9].

35.5 ACHIEVING DESIRED PASTEURIZATION

Broadly, pasteurization can be achieved by a combination of time and temperature such as (i) heating foods to a relatively lower temperature and maintaining that temperature for a longer time, e.g. holding pasteurization and pasteurization by overflow method, and (ii) heating foods to a high temperature and holding this temperature for a short time only. Pasteurization can be performed in two ways: (i) by first filling sterile containers with the product and then pasteurizing or (ii) by pasteurizing the product first and then filling in sterile containers.

35.6 PASTEURIZATION EQUIPMENT

35.6.1 Pasteurization of Packaged Foods

In packaged foods like beers and fruit juices, in-container processing is applied. When the container is glass, generally hot-water processing is used to reduce any damage due to thermal shock. After processing, the container is cooled to 40˚C, which also facilitates evaporation of the surface water. This minimizes external corrosion of metal containers or caps and accelerates the setting of adhesives used in labels. Hot-water pasteurizers may be batch or continuous in operation. The simplest batch equipment consists of a water bath in which crates of packaged food are heated to a pre-set temperature and held for the required length of time. Cold water is then pumped in to cool the product. A continuous version consists of a long trough fitted with a conveyer belt to carry containers through the heating and cooling stages [10].

35.6.1.1 Water Bath Pasteurization

For acidic food products that can be adequately pasteurized at temperatures of 100˚C or below and for non-sterile meat items, a water bath is one of the simplest methods of heating for pasteurization. The water bath may be either a rectangular steel tank or a 1-m diameter vertical retort. The product is packed in retort crates or in racks and immersed in the bath for pasteurization. Cooling may be carried out in the same tank used for heating, or the containers may be moved from the heating tank to a cooling tank. Heating and cooling may be carried out in steps. Essentially, the same procedure is followed in the processing of meats, pickles, apple sauce, and other acidic food products [11]. The continuous water bath is an improvement over batch operation and is in use by both pickle processors and fruit canners for pasteurization where high production rates are required. A conveyer belt moves through the tank at a selected speed to provide adequate time in the bath to accomplish pasteurization. The tank is usually divided into sections, each of which is heated and controlled separately. In continuous water bath pasteurizers, the jars and cans must proceed down an incline into the tank and up an incline when they come out of the tank. Since there is considerable hazard in conveying glass containers up or down an incline, plants that pasteurize glass-packed products have switched to water-spray or steam pasteurizers.

35.6.1.2 Continuous Steam or Water-Spray Pasteurizer

The continuous water-spray pasteurizer is extensively used for pasteurizing beer and acidic food products. In this type of unit, the bottles or cans are conveyed through the pasteurizer either by a walking beam or by a continuous belt conveyor. It is common practice to have as many as six different temperature zones or sections through the pasteurizer to obtain maximum efficiency. The sections are first preheat, second preheat, pasteurizing zone, pre-cooling, cooling, and final cooling zone. Water-spray units are designed so the water in the first preheat zone is the water that drains off the jars in the pre-cooling zone, and the water that is sprayed in the pre-cooling zone is used in the first preheat zone. In this way, a considerable amount of heat is recovered and reused, and a reduced amount of cooling water is required. Cooling water is also recirculated [11].

Glass containers should not be subjected to excessive "thermal shock"; when heating products in glass containers it is recommended that the thermal shock temperature difference be kept below 20˚C and under no condition to exceed 40˚C. When cooling a hot product in a glass container, temperatures

are more critical; 10°C is a desirable maximum, and under no conditions should the temperature change exceed 20°C. Several sections are necessary in both continuous-steam and water-spray pasteurizers to heat glass containers efficiently; however, metal containers may be pasteurized in the same equipment. Through the use of sectionalized equipment, it is possible to have high-temperature heating and low-temperature cooling of glass containers with a minimum amount of "thermal shock" breakage. The water-spray-type unit has been very successful in the pasteurization of beer and similar products where the operation proceeds under ideal conditions.

The steam pasteurizer is simply a tunnel that is open at both ends with a conveyer along the bottom. Cloth baffles are hung between each section, but these are not adequate to hold the steam in the pasteurizer against strong air currents. The rate of heat transfer from the steam–air mixture to the food container is not constant in the steam pasteurizer, but varies with steam temperature and steam velocity.

35.6.1.3 Tunnel Pasteurization

Hot-water sprays are used to heat containers as they pass through the different heating zones of the tunnel and provide an incremental rise in temperature until pasteurization is achieved. Cold water sprayed then cools the containers as they continue through the tunnel. Steam tunnels have the advantage of faster heating, giving shorter residence time and smaller equipment. Savings in energy and water are achieved from heat recovery from the hot products and re-circulating water. Temperatures in the heating zone are gradually increased by reducing the amount of air in the steam–air mixtures, and cooling takes place using water sprays or by immersion in a water bath [10].

35.6.2 Pasteurization of Unpacked Liquids

35.6.2.1 Long-Hold or Vat Pasteurizing

Vat or tank-type heat exchangers are used for the long-hold method of pasteurization. Here the raw product is pumped into the vat, heated to the pasteurizing temperature, held for the required time, and pumped from the vat through cooling equipment. With most vat pasteurizers, circulation of the heating medium can be started as soon as the filling of the vat is begun. In this way, some heating of the product takes place during filling so that the heating time can be shortened. With some designs of pasteurizing vats, cold water can be circulated over the outside of the inner liner as soon as the holding period is completed, thus doing part of the cooling in the vat [12]. It is considered good practice with all heat-exchange equipment for dairy products to use a heating medium (hot water or steam vapor) only a few degrees warmer than the milk, for then there is less accumulation of milkstone on heating surfaces and less danger of injury to cream line or flavor.

35.6.2.1.1 Advantages

Vat pasteurizers are well-suited for small plants and for low-volume products in larger operations. They can handle a variety of products with a wide range of physical characteristics. They are especially well-adapted to the processing of cultured products such as buttermilk and sour cream, which, in addition to being pasteurized and cooled, require mixing for the incorporation of starter, several hours of quiescent holding for incubation, agitation for breaking the curd, and final cooling in the tank.

35.6.2.1.2 Disadvantages

There are several disadvantages to consider. Vat pasteurization is normally a batch operation, and is inherently slow, although the flow can be made continuous by the use of three or more vats (depending upon the holding, heating, filling, and emptying times). The operation may even be made automatic by the use of complex and expensive controls. In the great majority of batch operations, manual controls are used, and constant attention must be given by the operator to prevent overheating, over-holding, and burning. Another disadvantage is that regenerative heating is not possible in the vat, so both heating and cooling is relatively expensive.

35.6.2.2 Heat Exchanger Pasteurizer

Small-scale batch pasteurization is carried out in open boiling pans or in scraped surface heat exchangers which are used for some liquid foods with high viscosity. Generally, less viscous liquids are pasteurized by a plate heat exchanger. Some products, such as fruit juices and wines, require deaeration before pasteurization to prevent oxidative changes during storage. This can be achieved by spraying liquids into the vacuum chamber after which dissolved air is removed [13]. The plate heat exchanger consists of a series of thin vertical stainless-steel plates. The plates form parallel channels held tightly together in a metal frame and separated by rubber gaskets to produce a watertight system. The plates are corrugated to induce turbulence for a high heat transfer rate. The advantages of heat exchangers over in-bottle processing include (i) more uniform heat treatment, (ii) simpler equipment and lower maintenance costs, (iii) reduced space requirements and labor costs, (iv) greater flexibility for different products, and (v) greater control over pasteurization conditions.

A number of systems for pasteurizing milk have been used commercially. The first were batch systems employing holding tanks. The milk was heated in a jacketed tank to a temperature of 65°C and held for 30 min. This type of system is rarely found, but it can be suitable for small operations. Improvements on the batch system came with the advent of the continuous-holding or retarding systems. Holding times and temperatures are the same; however, the tanks automatically fill, hold, and empty in a timed cycle. The system of choice in most modern dairies is now the high-temperature-short-time (HTST) process.

The heat exchanger has the following advantages over the batch and continuous-holding systems: (i) lower initial cost due to elimination of holding tanks, (ii) less labor required as the system incorporates mechanized circulation cleaning, (iii) saved space (about 10,000 liters/hr can be pasteurized in 4.5 m^2), (iv) increased flexibility (capacity of the plant and processing rate can be easily controlled), (v) ease of recording

and safeguarding the pasteurization temperature requirements (milk can be readily diverted if it does not reach minimum safe pasteurized temperatures), and (vi) lower operating costs (plant can be almost entirely automatically controlled).

The capacity of the equipment varies according to the size and number of plates—up to 80,000 liters/hr. Other types of heat exchangers are also used for pasteurization. In particular, the concentric tube heat exchanger is suitable for more viscous food and is used with dairy products, mayonnaise, tomato ketchup, and baby food. It consists of a number of concentric stainless-steel coils, each made from double- or triple-walled tubes. Food passes through the tube, and heating and cooling water are recirculated through the tube walls. Liquid food is passed from one coil to the next for heating and cooling, and the heat is regenerated to reduce energy costs. Pasteurized food is immediately deposited into cartons or bottles. Care with cleaning and hygiene is therefore necessary.

35.6.2.3 High-Temperature-Short-Time Pasteurizers

HTST pasteurizers are continuous-flow systems using tubes, plates, swept surfaces, and direct steam, in conjunction with a timing pump, a holder, and controls for temperature and flow rate. The great majority of HTST pasteurizers use plate-type heat exchangers with sections for regenerative heating and cooling. A schematic of a plate-type HTST pasteurizer is shown in Figure 35.1. This is also referred to as a flash pasteurizer [12]. Continuous pasteurizers assure that all the product of an entire run receives uniform treatment. HTST pasteurizers employing regenerative heating are much more economical to operate than batch pasteurizers. In the application of controls, the general requirements for flow rate, temperature, and pressure must be considered; these are the factors that govern proper operation and public health safety.

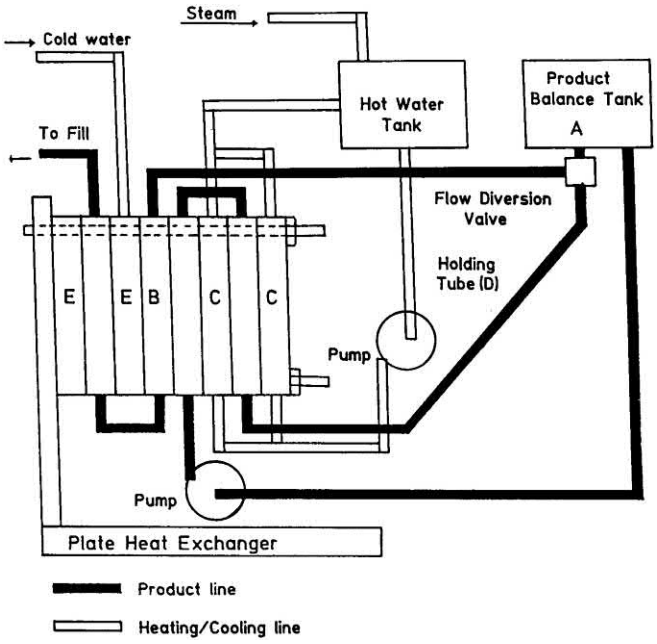

FIGURE 35.1 Plate heat exchanger pasteurizer.

The flow rate through a continuous pasteurizer is regulated by metering or a timing pump. A positive displacement pump of the rotary or piston type is used almost exclusively for milk and milk products. Often variable speed drives are employed so that the flow rate can be changed when desired. A continuous pasteurizer must include synchronization of holding time and flow rate. Controlling temperature includes maintaining a uniform product temperature at some set value at or above the legal minimum, and diverting the flow, directing it back through the system if, at the end of the holder, it is below the legal minimum temperature. Usually, a safety thermal limit-recording controller is used which keeps a continuous record of the temperature.

The pressure is especially important in two areas of continuous pasteurizers—the regenerator and the flow-diversion valve. Where product-to-product regeneration is used, it is necessary, for public health reasons, to maintain at least 7 kPa more pressure on the pasteurized side than on the raw side so that any leakage through the heat-exchange can be identified, thus eliminating the possibility of contaminating the pasteurized product. In order to prevent the mixing of air into the product and inefficiency of the pump due to air leakage into the system, the entire system is operated at a positive pressure (above atmospheric pressure). A centrifugal booster pump is employed between the product storage and the regenerator. This will ensure that the pasteurized product is always under higher pressure than the raw product.

To facilitate this, it is necessary to (i) size the booster pump correctly to deliver the rated capacity at a predetermined pressure and (ii) equip the booster pump with a pressure-actuated switch located at the outlet of the pasteurized regenerator set so that the pump can run only when the pressure is at least 7 kPa greater than that on the raw-product side. If the cooler section does not produce enough back pressure on the pasteurized regenerator to satisfy the minimum 7 kPa or greater difference, it may be necessary to install a restrictor in the line. The other pressure requirement is that which is needed on the diverted milk line, since it may affect the holding time during diversion. If, upon testing, the holding time during diverted flow is shorter than that in forward flow, a restricting orifice should be placed in the diverted line.

35.6.2.4 Flash Pasteurization

The process of heating fruit juices for only a short time at a temperature a few degrees higher than the pasteurization temperature of the juice is called flash pasteurization. In this method, the juice is heated rapidly for about 1 minute to a temperature about 5°C higher than the pasteurization temperature, and filled into containers, which are sealed airtight under cover of steam to sterilize the seal and then cooled. This process can also be used for orange juice, apple juice, grape juice, etc. The advantages of this process are that it (i) minimizes flavor loss, (ii) aids in the retention of vitamins, (iii) effects economy in time and space, (iv) helps to keep the juice uniformly cloudy, (v) heats juice uniformly, reducing cooked taste to a minimum, and (vi) by this beneficial enzyme inactivation is obtained in addition to the destruction of viable microorganisms.

35.6.2.5 Deaerator and Flash Pasteurizer

Freshly extracted and screened juices contain an appreciable quantity of oxygen, which should be removed before packing. The special equipment used for this purpose is called a deaerator. The deaerated juice is then heated in flash pasteurization equipment. Commercial deaerators and flash pasteurizers differ greatly in design, construction, and capacity. The deaerator and flash pasteurizer have been used successfully in the case of fruit juices, like tomato and pineapple and orange.

35.6.2.6 Ultra-High-Temperature Pasteurizers

The equipment for ultra-high-temperature (UHT) pasteurizers is much the same as for HTST units. The controls are similar, but the operating temperature points are higher. The holder is, of course, much smaller for minimum pasteurizing time. Generally, with a holding time in the order of 3 seconds, it is impossible to determine the holding time accurately by tests similar to those used with HTST pasteurizers, and calculated holding times are preferred [12]. Ultra-high-temperature treatment is desired because of its greater bacterial destruction and its beneficial effects on body and texture in ice cream, and where confusion exists regarding requirements for UHT pasteurization, a UHT treatment may be given following regular pasteurization. This may be accomplished with a direct-steam heater installed downstream from the flow diversion valve or with steam-vacuum flavor treating equipment.

35.6.2.7 Vacreator

The vacreator is a special type of pasteurizing apparatus used particularly in the butter industry. The product is fed into a steam-heated chamber where it is flashed at a temperature of 90–96°C under 13.5–30 kPa of vacuum. It then passes into a second chamber of higher vacuum (50–67 kPa) and is reduced to a temperature of 72–82°C. From here, it passes into a third chamber of high vacuum, 91–95 kPa of vacuum, and is reduced to a temperature of 38–46°C. This process is claimed to be very effective in pasteurization and at the same time removes undesirable odors and flavors. It also employs a continuous-type machine and is especially adapted for use on high-viscosity material, although it will also operate on plain fluid milk [12].

35.7 QUALITY OF PASTEURIZED FOODS

Pasteurization is a relatively mild heat treatment, and even when combined with other unit operations (for example irradiation and chilling) there are only minor changes to the nutritional and sensory characteristics of most foods. However, the shelf life of pasteurized foods is usually only extended by a few days or weeks compared with several months with the more severe heat sterilization methods.

In fruit juices, the main cause of color deterioration is enzymatic browning by polyphenoloxidase. This is promoted by the presence of oxygen, and fruit juices are therefore routinely deaerated prior to pasteurization. The difference between the whiteness of raw milk and that of pasteurized milk is due to homogenization, and pasteurization has no measurable effect. Other pigments in plant and animal products are also unaffected by pasteurization. A small loss of volatile aroma compounds during pasteurization of juices causes a reduction in quality and may unmask other cooked flavors. Volatile recovery may be used to produce high-quality juices, but this is not routinely used. The loss of volatiles from raw milk removes a hay-like aroma and produces a blander product.

In fruit juices, losses of vitamin C and carotene are minimized by deaeration. Changes to milk are confined to a 5% loss of serum proteins and small changes to the vitamin content (Table 35.2). Most of the pasteurized food products have a low pH either due to the low natural pH of the system or because the product has been fermented to produce an acidic environment. Since most of the heat-labile nutrients are relatively stable in acidic conditions, nutrient losses in those products are relatively minor. Although thermal losses during pasteurization may be small, oxidative losses can be high. Thus pasteurization of liquid foods such as fruit juices, beer, and wine is generally accomplished in indirect heat exchangers like plate or double tune rather than open film-type pasteurizers. Often fluids are deaerated prior to pasteurization. The most important nonacid liquid food is milk. The effect of pasteurization on the nutrients of milk has received considerable attention.

Ascorbic acid degradation of single-strength orange juice was lower than that of fully pasteurized orange juice under aerobic conditions with ca. 23% and 83%, respectively, after 7 weeks of storage. It is reported that unpasteurized orange juice exhibited significantly higher ascorbic acid retention than fully or lightly pasteurized juice during storage at 4°C for 36 days [14]. Similar results have also been reported that long-life commercial orange juice, when stored in open containers in the refrigerator for 1 month, lost 60–67% of its ascorbic acid, whereas fresh orange juice lost 7–13% [15]. These differences in the destruction rates of ascorbic acid during storage between single-strength and fully pasteurized orange juice may be due to (i) oxygen consumption by natural background flora in single-strength juice, (ii) the thermal oxidative destruction of several protectors of ascorbic acid such as bioflavonoids (anthocyanins, flavonols, etc.), vitamins P1 and P2, vitamin E, and phenols, and (iii) the production of oxidative molecules during the first steps of the Maillard reaction. The ascorbic acid content of single-strength orange juice was found to be 41 mg/100 ml, and this decreased during

TABLE 35.2
Vitamin Losses during Pasteurization of Milk

	Method of Pasteurization

pasteurization at 90°C/1 min to 38 mg/100 ml. The ascorbic acid degradation rates of single-strength and fully pasteurized orange juice were high for the first 3 weeks of storage; they then stabilized up to the 7th week.

The ungassed juice sample exhibited higher browning than both other conditions (nitrogen and gas mixture) for $P \leq 0.35$. Fully pasteurized orange juice, gassed by nitrogen or the gas mixture, then stored under the same gas, showed a significantly lower browning index than that of un-gassed juice (control) ($P \leq 0.25$). Oxygen elimination in the gassed samples (nitrogen and gas mixture) could decrease the evolution of browning because browning is considered as an oxidative reaction [16]. Furfural formation, which is due to the decomposition of ascorbic acid, has a similar effect to sugar and may combine with amino acids and contribute to juice browning. Storage temperature can also affect the evolution of browning. It is reported that 12°C was the critical storage temperature for furfural accumulation [17].

The pH levels of different samples of orange juice (uninoculated with the test microorganisms) were monitored during ascorbic acid and browning experiments. The pH value significantly decreased for control-unheated samples. The consumption of oxygen by natural background flora and the production of acidic metabolites may account for this decrease in pH values. Storage under both oxygen-free and reducing conditions improves the microbial and organoleptic quality of pasteurized orange juice. Consequently, it might be proposed to adjust the redox potential by gas just after heat treatment in order to maximize thermal destruction of microorganisms and to stabilize the product during storage [18].

A comparative study between the aromatic profile in fresh orange juice versus deaerated and pasteurized juices, respectively, was conducted in order to understand the evolution of volatile components after deaeration and pasteurization processes. The aromatic fractions isolated by simultaneous distillation and extraction are analyzed by capillary gas chromatography–mass spectrometry. At the qualitative level, all the volatile components in fresh orange juice were also found in the counterparts after deaeration and pasteurization processes. According to statistical analyses, significant losses in the concentration of volatile components occurred during the deaeration process, while there were no statistically significant differences determined among concentrations of volatile components in deaerated and pasteurized juices. These results show that during the industrial processing of orange juice the biggest losses in the concentration of volatile components occur during deaeration. The pasteurization process does not change the analytical composition of deaerated orange juice in a significant way for any of the 42 quantitated compounds [19].

Changes in carotenoid pigment content and juice color due to thermal pasteurization of Valencia orange juices have been studied [20]. Total carotenoid pigment content loss was significant ($P < 0.05$) after thermal pasteurization at 90°C for 30 s. Thermal effects on carotenoid pigment contents, especially on violaxanthin (–46.4%) and antheraxanthin (–24.8%), were clearly observed. With the loss of violaxanthin and antheraxanthin, lutein became the major carotenoid, followed by zeaxanthin, in pasteurized Valencia orange juice. There was perceptible color change after orange juice pasteurization, which led the juice color to become lighter and more saturated. Decreases in CIE a* value and increases in CIE L*, b*, h*, and C* are the major color changes after pasteurization. Overall increases in reflected light might also influence the perception of color to a great extent in pasteurized orange juice. Total color difference (DE*) compared to the fresh juice was 2.92 ± 0.97 ($P < 0.05$).

35.8 PACKAGING OF PASTEURIZED FOODS

Both bottles and cartons take into account the properties of milk and provide packaging acceptable to consumers worldwide. Glass bottles have the advantage of being easily cleaned, transparent, and rigid, but have the great disadvantage of high weight and fragility. Increasingly, milk is also packaged in gable-top (PurePak, Elopak) or other carton types (TetraBrik). Even though the equipment may be expensive to install, the advantages include a lower price per unit of milk and a lower risk of contamination from the air during filling [21]. Smaller quantities have been packaged in plastic pouches. A cylindrical milk carton with a reclosable pouring lid has been introduced [22]. While suitable for sterilized milk, glass bottles are a problem for "long-life" milk. The question of the container is therefore of vital interest to the dairy industry, as about 50% of all milk produced is sold in liquid form [22]. Sunlight can destroy riboflavin and vitamin C in milk, producing a taint by the oxidation of the fat [22] and protein. This led to the use of brown glass bottles, which hold back the light rays responsible. However, taint is very rare, brown bottles are not very attractive, and it has also been found that milk becomes sour faster in brown than in colorless bottles [23].

35.8.1 Returnable Bottles

For economic reasons, the use of returnable glass bottles has continued over many years. The glass bottle will take a long time to disappear because of its economic advantage, the traditions of the industry, and the attitude of the consumer. Other factors such as transport costs have led to the use of non-returnable packaging, although more recently, "green" considerations have led to the re-introduction of returnable bottles [22–24]. The advantages of non-returnable containers are (i) elimination of returned empties, (ii) elimination of collecting, sorting, and washing, (iii) elimination of the foreign object problem, (iv) elimination of the glass fragment problem, and (v) reduction in transport costs. The disadvantages are (i) possible increases in costs of packages, (ii) lack of consumer acceptance, (iii) delivery problems resulting in lower total sales, (iv) hygiene problems, and (v) environmental considerations. Plastic containers and plastic-coated cartons are nearly sterile by virtue of their method of manufacture. No sterilizing process is necessary for pasteurized milk, but for the aseptic filling of milk, sterilization is essential. So far, TetraBrik has proved the most effective. Containers for this purpose must be sterilized immediately before filling.

35.8.2 Glass Bottles

The traditional glass bottles used for fruit juices and fruit juice beverages provide many advantages. Glass is not susceptible to mold growth and is impermeable to odorous vapors and liquids. Hot-filling and in-bottle pasteurization are generally employed for pure fruit juices or products that do not contain preservatives. Hot-filling is achieved by passing the liquid product through a heat exchanger and then filling above 70˚C. The closure is then applied. Any microbiological contamination on the inner surfaces of the bottle and the closure is destroyed by hot liquid, and adequate sterility is obtained without heating the container [22]. Glass bottles can also be covered with a polystyrene shield, which enables bottles to be reduced in weight without risking breakage of bottles. Sleeves give protection, and graphics can be added easily. Some bottles are shrink-wrapped with plastic sleeves.

35.8.3 PET Bottle and Other Plastic Containers

PET bottles are displacing those made from PVC for products such as edible oils and mineral waters, as well as glass bottles for carbonated products. Improvements in processing technology have resulted in the appearance of stretch-blown PVC bottles. PET bottles have also become even lighter than before (a 2 L bottle usually weighs less than 40 g) and can be coated externally with PVC to provide improved resistance to gas permeability. Polyethylene and PVC bottles are being used for squashes and cordials, but shelf life is restricted compared to glass [25]. Unlike glass, the PET bottle will lose carbon dioxide with time, about 15% over 4 months [26, 27]. Hence PET is preferable for drinks with high carbon dioxide content in large bottles, whereas for lower carbonation levels, and small- or medium-sized bottles, other materials may be better. Other forms of plastic container have also been used [25, 28], for example, the Plasto-can, a coextruded plastic container with conventional aluminum easy-open can ends, or the the Rigello container, a multilayered polypropylene foil extrusion with a spherical bottom and tear-off cap assembled in a paperboard cylinder. New combinations of materials in can form are also being developed. Coca Cola has patented a PET/aluminum can with easy open top [29]. High barrier plastics cans, which can be recycled, are under investigation. Orange juice has also been packed in clear oriented polypropylene bottles, which provide good oxygen and moisture barrier properties [30]. Tamper-evident pull-tab closures are used on this container. Paperboard basket carriers, plastic clips (on bottlenecks) and shrink films are used to provide multipacks holding three, four, or six units.

35.8.4 Cans

Fruit juices and fruit juice concentrates are frequently distributed in cans [31]. The most common are standard tinplate containers, but specially lacquered and coated cans are also used, especially for high-acid products. Cans are usually hot-filled, but sometimes are aseptically filled. Cold-filling after pasteurization is occasionally employed, but refrigerated or frozen storage is then advisable. Products preserved with benzoic acid can also be filled cold after pasteurizing, but sulfated products are incompatible with cans. The juice tends to deteriorate in the cans due to corrosion and an increasing amount of tin and iron in the product.

In the normal hot canning process, the juice is first deaerated to improve its flavor stability and then pasteurized to destroy microorganisms and to inactivate enzymes. After hot-filling into the cans, the lids are applied and sealed immediately before cooling, which forms a slight vacuum in the headspace as the liquid contracts. This is desirable as the presence of oxygen encourages corrosion (cold-filling operations usually involve undercover gassing, in which the headspace is replaced by carbon dioxide immediately before sealing the lid).

Carbonated beverages are susceptible to metal pick-up and are therefore packaged in lacquered two-piece aluminum cans or three-piece tin-plate with side seams having a special tab design to withstand the internal pressure. Warming the filled cans immediately before packaging is important; otherwise, the cans when filled with cold carbonated liquid attract a layer of condensation from the atmosphere and may corrode on the outside. Frozen orange juice concentrate has been distributed in composite paperboard or plastics canisters of approximately 170 ml capacity [25]. There are many pack variations, including canisters with tear-off ends or, frequently, leaving the product unpasteurized to provide maximum freshness of flavor. Spoilage may result if it is left unfrozen.

Bulk frozen orange juice is packed in 200 L polyethylene drums or polyethylene-lined steel drums or transported in tankers. However, aseptically produced juice (e.g. in bag-in-box systems) is replacing bulk frozen juice. Beverage cans are also sold in [32] multipacks of four, six, or more. The most common form of over wrapping which assists handling and distribution is a plastic ring carrier which slips underneath the rim of the can and grips tightly throughout distribution. Paperboard multi-packs are also popular as well as shrink films.

35.8.5 Cartons

Pasteurized fruit juice and soft drinks can be packaged very successfully in cartons with a polyethylene coating or in plastic containers [32]. These products have a limited shelf life when stored in a refrigerator. Materials selected must not absorb flavor components from the juice. In addition, acid diffusion into the plastics material can delaminate the package. Polyethylene is the most common surface-contact material and is regarded as chemically stable with most food products. Packaging materials must also provide the best possible barrier to light as light affects the color and nutritive value of fruit juices. Aseptic filling of fruit juices and other drinks into TetraPaks and other systems (e.g. Combibloc, PurePak, Elopak) has also become popular, giving the product an extended shelf life. Such products have advantages over hot-filled products or non-aseptically packaged products, which need a chilled distribution chain [33].

35.9 ENERGY ASPECTS OF PASTEURIZATION

Indirect heating through a heat exchanger involves much more energy than direct heating with infusion heating. To reduce the energy input and hence improve the efficiency of the system, a regenerative method is adopted. For example, total energy difference between the 90 and 80% regeneration capacity of a system processing milk is about 62, 131 kcal/hr. This shows that even a 10% increase in regenerative efficiency can save considerable energy [34]. Regeneration of heating and cooling streams is now an accepted conservation technique.

The heat energy consumption for pasteurization will be about 30 MJ per 1000 L milk, and correspondingly the cooling energy is about 4 kWh per 1000 L. Normally, pasteurizers will have the facility of regeneration, with an efficiency of 75 to 92%. Efficiency can be increased by increasing the number of plates in the regeneration section. But this increases the pumping pressure and hence the electrical energy. Hence, the maximum regeneration is about 90%. Table 35.3 gives the steam and electrical requirements of a large-size pasteurization unit [35, 36]. Increasing regeneration decreases the steam and refrigeration requirement but increases the electricity required for pumping. These energy requirements have also been converted into their primary fuel equivalents. This facilitates the checking of the processes on a uniform energy basis. The processing, storage, and distribution of pasteurized milk requires an estimated 2200 kJ/kg of milk [37, 38].

36 Canning and Sterilization of Foods

M. N. Ramesh

CONTENTS

36.1 INTRODUCTION

Sterilization is the complete destruction or elimination of all viable organisms in/on a food product being sterilized. Sterilization destroys yeasts, molds, vegetative bacteria, and spore formers and allows the food processor to store and distribute the products at ambient temperatures, with extended shelf life. Sterilization procedures involve the use of heat, radiation, or chemicals, or physical removal of cells. The sterilization process consists of four distinct stages. First, the product must be heated to a temperature of 110 to 125°C to ensure sterilization. After this, the product requires a few minutes to equilibrate, since the surface will be hotter than the central portion of the container causing a temperature gradient. The equilibration stage allows a reduction in the temperature gradient. Next, the product must be held at this temperature for a certain period of time to ensure a predetermined sterilization value designated by F_o. Finally, the product has to be cooled, mainly to arrest further heat treatment and to avoid overcooking [1]. The basic principles of sterilization technology as applied to food processing are [2]:

- The processed product must be free from microorganisms capable of producing food poisoning toxins and those microorganisms which cause food spoilage during product shelf life, until it is consumed.
- *Clostridium botulinum* spores are capable of growing in low-acid (pH >4.6) products during storage and hence must be heat treated to the equivalent of at least 121.1°C for 3 minutes (an F_o value of 3) to achieve a 12-decimal reduction of the microorganism.
- The processing conditions should be applied to the slowest-heating point referred to as "cold point." This facilitates the assumption that, when the slowest-heating part is sterilized, by exposing it to the required time–temperature profile, the rest of the product will be sterilized.

Practically, complete sterilization will lead to deteriorations in product quality and nutrients [3]. Hence, in practice, commercial sterility is targeted. Commercial sterility is defined as a product that has been optimally processed so that under normal conditions, the product will neither spoil nor endanger the health of the consumer and also retain its organoleptic properties and nutrients [4]. The pH of the product is an important factor in determining the severity of the sterilization process.

36.2 THEORY OF STERILIZATION

Thermal treatment of food products to render them free of pathogenic microorganisms has been practiced for several years. However, a method to quantify the microbial destruction that takes place during a thermal treatment has only been understood for the last 75 years. To determine the amount of microbial destruction that a thermal treatment delivers to a process requires an understanding of both the amount of heat delivered to every portion of the food product and the destruction kinetics of the microorganisms of interest. The amount of heat delivered by the sterilization process is dependent on the way in which the product is heated and on its physical nature. Process-dependent factors include processing equipment design, type of heating media, container, or food size and shape, product composition, and viscosity (conduction or convection heated). The thermal destruction kinetics of microorganisms or their ability to be killed within the food matrix is dependent on a number of factors. These factors include pH of the product, levels and types of preservatives, water activity, the previous growth conditions of the microorganisms of concern, product composition, and competitive microorganisms [5].

The two types of bacteria of concern in food preservation are organisms of public health significance and spoilage-causing bacteria. In low-acid foods with a pH greater than 4.6, the organism of public health significance is *Clostridium botulinum*. Canned foods are processed based on the survival probability for *C. botulinum* of 10^{-12} or one survivor in 10^{12} cans. The organism most frequently used to characterize low-acid food spoilage by mesophilic spore-formers is PA 3679, a strain of *C. sporogenes*. Most food companies accept thermal inactivation of 10^{-5} for mesophilic spore-formers and 10^{-2} for thermophilic spore-formers. The processing time depends on the bioburden of the most resistant bacteria in a particular food, the spoilage risk involved, and whether food can support the growth of potential contaminating bacteria [6]. Although a lot of research work has been carried out on the influence of different factors on the processing time and the corresponding sterilization value, a number of uncertainties still exist on the application of these factors to scientifically arrive at the exact processing conditions. These uncertainties have been discussed in detail [7]. To avoid any risk due to these uncertainties, a safety factor is added to increase the processing time to completely sterilize the food product, which invariably reduces the nutrient content and increases the energy cost.

36.3 METHODS OF STERILIZATION

The food sterilization methods are divided into two categories: sterilization by heating (thermal processing) and sterilization without heating (non-thermal processing). Thermal processing is widely practiced in spite of some problems such as that the process of heating might reduce nutrition or deteriorate the quality of foods and that it is ineffective against certain types of bacteria. Thermal processing is further divided into two categories: in-container sterilization (bulk canning) and aseptic

sterilization (processing). The principles involved in the thermal sterilization of foods remain the same for both methods.

36.4 BULK CANNING

36.4.1 Introduction

The thermal processing operation requires the heating of food products. For a low-acid food product (pH >4.6), the product is heated to temperatures above 100°C usually in the range 115–130°C for a time sufficient to achieve a 12-log reduction of the spores of *Clostridium botulinum* as defined in Department of Health Code of Practice No.10. Current practice is, however, to move to even higher temperatures and consequently shorter process times to maximize the organoleptic and nutrient retention within the product. The time–temperature procedure required to render a product commercially sterile must be carefully determined using established procedures. Canned foods might be described as full-moisture, ambient-temperature stable food products regardless of the package form employed.

36.4.2 Processing Equipment

The food processing industry produces a wide range of products in a variety of containers. This requires an equally wide range of processing techniques, retort designs, and operating procedures. Retorting systems can be subdivided in several ways.

36.4.2.1 Methods of Processing the Containers

Two types of retorts are batch retorts and continuous retorts. In batch systems, the retort is filled with product, closed, and then put through a processing cycle. In continuous retorting systems, containers are continuously fed into and out of the retort. Batch retorts are available in a number of configurations for various applications including static, rotary, steam heated, and water heated with or without air overpressure. The air overpressure is necessary to maintain the integrity of the containers during retort operating cycles for glass and flexible containers.

36.4.2.2 Methods of Heating Medium

The heating media used in retort are steam, steam/air, water, direct flame, or fluidized bed.

36.4.2.2.1 Saturated Steam

Latent heat is transferred to food when saturated steam condenses on the outside of the container. If air is trapped inside the retort, it forms an insulating boundary film around the cans, which prevents the steam from condensing and causes underprocessing of the food. It also produces a lower temperature than that obtained with saturated steam. It is therefore important that all air is removed from the retort by the incoming steam using a procedure known as venting [8]. After sterilization, the containers are cooled with water. Steam is rapidly condensed in the retort, but the food cools more slowly and the pressure in the containers remains high. An overpressure of air is therefore used to prevent strain on the container seams (pressure cooling). When the food has cooled to below 100°C, the overpressure of air is removed and cooling continues to approximately 40°C. At this temperature, moisture on the container dries to prevent surface corrosion, and label adhesives set more rapidly. Rigid polymer trays heat more rapidly than conventional container owing to their thinner cross-section. Trays are processed in conventional equipment using saturated steam at 121°C.

36.4.2.2.2 Hot Water

Foods are processed in glass containers or flexible pouches under hot water with an overpressure of air. Glass containers are thicker than metal cans to provide adequate strength, and this, together with the lower thermal conductivity of glass, results in slower heat penetration and longer processing times than for cans, and there is a higher risk of thermal shock to the container. Foods in flexible pouches heat more rapidly owing to the thin cross-section of the container. This enables savings in energy and causes minimal overheating near the container wall. Liquid or semi-liquid foods are often processed horizontally to ensure that the thickness of food is constant across the pouch. Vertical packs promote better circulation of hot water in the retort, but special frames are necessary to prevent the pouches from bulging at the bottom, which would alter the rate of heat penetration and hence the degree of sterilization achieved [8].

36.4.2.2.3 Flames

High rates of heat transfer are possible at flame temperatures of 1770°C. The consequent short processing times produce foods of high quality and reduce energy consumption by 20% compared with conventional canning. Each can is scanned by an infrared controller after processing, instead of the usual procedures. High internal pressures (275 kPa at 130°C) limit the application of this method to small cans [8].

36.4.3 Description of Processing Equipment

A variety of retorts which use "pure" steam as the processing medium, i.e., steam free of air, are available. Steam retorts with batch container handling are vertical and horizontal still retorts, crateless retorts, and agitating retorts. Steam retorts with continuous container handling include continuous rotary sterilizers and hydrostatic retorts. Retorts operating procedures must ensure that a uniform processing temperature is achieved and maintained throughout the location of containers during the process.

36.4.3.1 Batch/Still Retorts (Horizontal and Vertical)

Batch steam retorts are usually arranged either vertically (Figure 36.1) or horizontally (Figure 36.2) and are used for canned products which are placed into baskets immediately after seaming, and are then placed inside the retort shell. The retort is made out of a metal shell pressure vessel which is fitted with inlets for steam (A), water (B), and air (E) and has

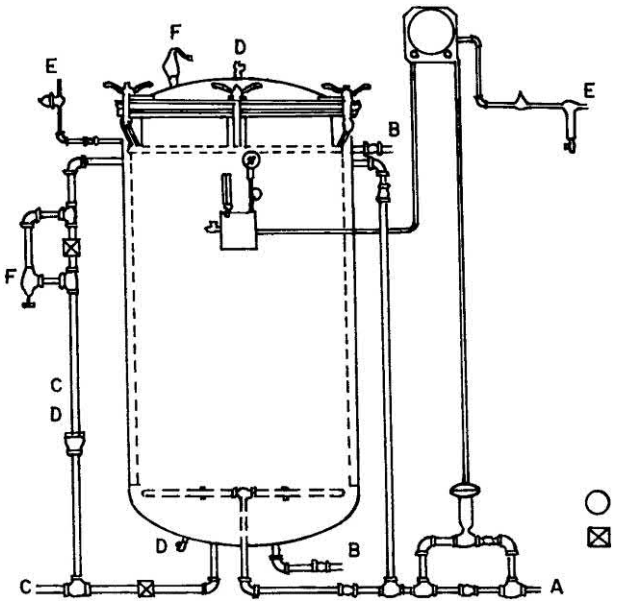

FIGURE 36.1 Vertical batch retort. (From Paine and Paine [102].)

outlet ports for venting (D) air during retort come up, and for draining (C) the retort at the end of the cycle. A pocket for a thermometer or temperature-recording probe/sensor and pressure gauge is located on the side of the vessel. To ensure adequate steam movement around the temperature sensors, the pocket is fitted with a constant steam bleed (D). On vertical retorts, the lid is hinged at the top and secured to the shell during processing by several bolts. In horizontal steam retorts, the door is usually on the end of these machines, which can swing open. A safety valve and pressure relief valve (F) are also provided for safety of the equipment [9].

The operating cycle for this type of retort involves loading the sealed containers into the retort, bringing the retort up to a temperature of around 100°C, and then allowing steam to pass through the vessel to the atmosphere for sufficient time so that all air in the retort and between the cans is removed (venting) before the retort is finally brought up to the operating pressure and processing temperature. At the end of the processing time, the steam is turned off and a mixture of cooling water and air introduced into the retort to cool the cans. The purpose of the air is to maintain the pressure in the retort following the condensation of the residual steam after the initial introduction of cooling water. If this pressure is not maintained the containers may deform due to pressure imbalances between the internal pressure in the cans and the retort. As the temperature drops, the pressure in the retort may be controlled and gradually reduced until atmospheric pressure is reached and water can be allowed to flow through the retort, cooling the cans to a temperature of about 40°C before they are removed from the retort. Cans are removed from the retort at this temperature since this allows the surface of the cans to dry rapidly by evaporation, so reducing the risk of leaker spoilage [10]. The water is preferably sprayed, or alternatively the retort may simply be filled and allowed to stand for sufficient time for the cans to cool to 40°C before unloading the containers.

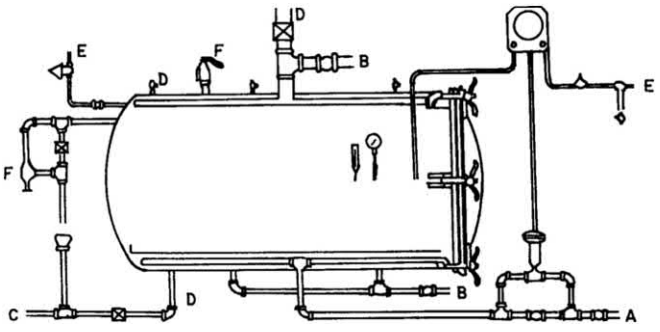

FIGURE 36.2 Horizontal batch retort. (From Paine and Paine [102].)

Both systems are static in operation. For other types of product, it is possible to assist the rate of heat penetration by agitating the cans in the steam environment by rotation either about the horizontal axis in a horizontal retort or by rotation in the vertical plane in a vertical retort.

36.4.3.1.1 Steam/Air Retort Systems

The use of glass and plastic containers has increased the use of alternative retorting systems. With these types of containers, it is usually not sufficient to rely on the strength of the containers alone to counteract the build-up of internal pressure during heating, but a constant overpressure of air is required to ensure the integrity of the package during heating. Thus the heating medium used in this type of retort is often a mixture of steam and air in proportions designed to provide the necessary steam temperature and air overpressure to maintain the package integrity. In order to ensure adequate mixing of the steam and air these retorts are fitted with a fan system to disperse the steam and air, to eliminate the development of cold spots in the processing chamber [9].

Control of this type of retort system can be difficult, particularly in ensuring an adequately uniform temperature distribution in the retort environment when the steam is being mixed with cold compressed air. Here, unlike in the case of saturated steam retorts, the presence of air must not permit a reduction in the partial pressure of the steam and hence retort temperature, but only provide the overpressure needed to ensure package integrity. However, the steam and air must be intimately mixed so that pockets of cold steam/air mix do not form in the retort and lead to inadequate processing of the cans.

Three major classifications of steam/air retorts may be identified on the basis of methods used to mix and circulate the gaseous media: air makeup, positive flow, and forced convention. In steam/air processing, heat is supplied primarily from the latent heat of condensing steam, in contrast to sensible heat transfer in superheated water systems. As a result, it is essential to have a homogeneous steam/air mixture reach all product locations. Since air is present during the process, it is unnecessary to purge all of the air from the retort by venting prior to the holding period. However, a venting procedure is advantageous for initial heating of the retort shell, retort cars, and product support racks, as well as for providing faster heating to low viscosity, convention-heating products.

36.4.3.1.2 Air Makeup Systems

These are designed such that after the desired temperature and pressure are reached, small valves along the top of the retort are left open to provide continuous venting of the retort during the heating period. The venting results in the pressure dropping to less than the set point; this causes an air makeup valve to open to reestablish the retort pressure. As air enters the retort, the temperature tends to decrease; this signals for the addition of steam, which causes a further increase in pressure. Because of the repeated deviation from the temperature and pressure set point conditions, it may be difficult to maintain stable operating conditions using this methodology. Additionally, the addition of steam and air independently may produce a nonhomogeneous heating medium. In one system activation of the air makeup valve also activated the steam valve such that steam and air, mixed outside the retort in the pipe connected to the spreader, flowed into the retort in response to a pressure drop, but this also could result in a pressure overshoot.

36.4.3.1.3 Positive Flow Systems

These are designed to improve retort control and stability by controlling pressure and temperature independently. A temperature controller operates a proportional valve on the steam line, adding steam to the retort and to maintain the set temperature, while a pressure controller for the air inlet and vent lines maintains the retort pressure. A drop in the pressure to below the set point causes the air supply valve vent to open and the vent valve to close. When the pressure exceeds the set point, the opposite occurs and the retort is vented. During processing, a constant flow of air is added to the retort, thereby causing the pressure to exceed the set point and the proportional flow vent valve to remain partially open during the process. Since steam and air are constantly vented under these conditions, temperature control would require the steam valve to remain partially open. Consequently, a continuous flow of steam and air would pass through the vessel to create a homogeneous mixture throughout the retort.

36.4.3.1.4 Forced Convection Systems

In contrast, these utilize a powerful fan to circulate the heating medium through the retort and maintain a uniform mixture of steam and air throughout the vessel. During this process, steam is added to replace that which has condensed in heating the load, and, theoretically, after the process is established there should be no need to add air to the vessel until the cooling cycle begins [11].

36.4.3.2 Water-Processing Retorts

This system is mainly used for the processing of glass jars. Raining water techniques (Figure 36.3) require the use of either an external steam injection system or heat exchanger system outside the direct environment of the retort. In the latter case, the cold water feeding the system is combined with the recycled heating medium and raised to the temperature required in the retort before being admitted to the sterilization chamber through a spray arrangement. The containers are arranged to allow good contact between the hot water heating medium and the product either using spacer bars or distribution plates. It is imperative that a good distribution of the water occurs as otherwise stratification may occur and certain containers will receive inadequate heating. Control of the temperature in this system is difficult, but the safest practice is to base the thermal process received by the product on the outlet temperature of the retort, i.e., the temperature measured in the return line to the heat exchanger [9]. The velocity of water in these retorts when passing over the packages is of vital importance as this will influence the rate of heat transfer to the product due to its effect on the heat transfer coefficient. This is unlike saturated steam retort processes where the heat transfer coefficient can be considered infinite [11].

36.4.3.3 Crateless Retort Systems

The vertical retort has grown in size, given up its crates, and become automated. These retorts are large and without crates and have been recognized as a universal symbol of low-acid food processing. They are usually 2.5 m high and 2 m in diameter with four to five times greater capacity than the conventional three-basket vertical retort. The crateless retort is filled with water, which acts as a cushion for cans filled from an automatic conveyor; after loading with cans a hydraulic lid is closed. Steam is admitted through the top opening, and this forces the water out of the retort through the bottom opening. The hot water can be recycled in another retort or in the next cycle. After processing, cooling water is let in through the bottom and is discharged through overflow. After the cooling

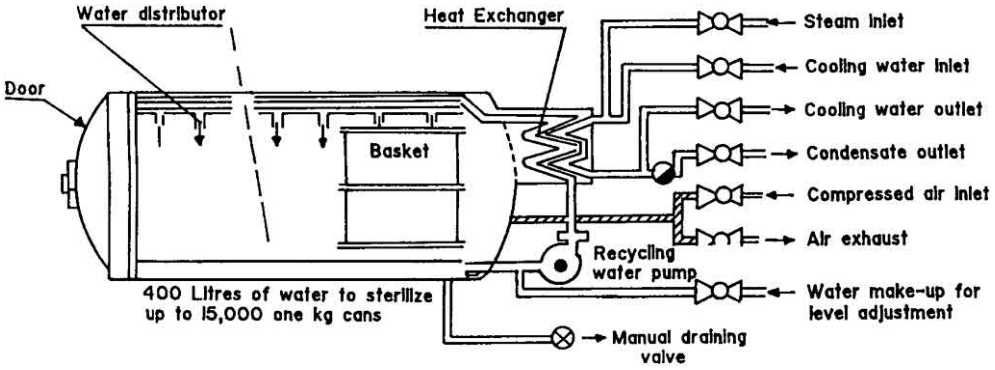

FIGURE 36.3 Water-processing retorts. (From Richardson and Selman [9].)

cycle, the retort is drained off and the bottom door is partially opened and the cans fall onto a shaker screen and are conveyed by belt to the unscrambler [12, 13]. It is critical that the steam condensate be removed from the bottom of the crateless retorts with top steam entry.

36.4.3.4 Agitating Retorts

There have been a number of different batch-agitating retorts designed to provide product agitation by rotating the containers end over end or side over side. The one most used is the Orbital Rotary Pressure Stabilizer (FMC Corp., Madera, Calif.), also known as the Orbitort. The unique design of the orbital sterilizers allows for the simultaneous loading and unloading of containers by a reel and spiral assembly. This assembly consists of an inner reel with steps attached to a drum to hold the containers, and an outer reel, which holds a spiral. While the containers are being loaded, the outer reel (spiral) is locked to the shell, and the inner reel is rotated. This allows the containers to be indexed along the steps of the inner reel following the path of the spiral. After loading, the two reels are locked together, holding the containers in place. During the processing cycle, the locked reel assembly and containers are rotated at 15–35 revolutions per minute. Since the inner reel is constructed from a drum, the time required for venting of the orbital sterilizer is greatly reduced because of the reduced volume of air to be removed. Steam enters the shell through a slotted trough at the bottom of the shell, and air is exhausted through five 50-mm diameter vent pipes located along the top. The retort drain valve is also open during the first portion of the venting cycle for condensate removal. Generally the venting schedule is completed in 2–3 minutes [14].

36.4.3.5 Continuous Rotary Sterilizers

These systems are composed of at least one heating shell and one cooling shell and are designed for continuous handling of containers at up to 600 cans/min. Containers from the sealing machine enter the first shell through a self-sealing rotary valve which maintains the pressure within the shell. Each shell is designed with a "Spiral T" permanently attached to the wall, and a reel assembly with steps to hold the containers. As the reel turns, the containers follow the path of the spiral through the shell. After a container travels the length of the shell, it either is transferred to another shell by a rotary transfer valve or exits through a discharge valve. The venting and come-up procedures are performed without containers present in the vessel. This allows more flexibility in the design of the operating procedures, compared to batch systems. Continuous rotary sterilizers are fitted with two or three 50-mm diameter vent lines. The typical venting schedule calls for venting the units for 7 min and to at least 105°C with the vent valves wide open and the drain valve at least partially open. Alternatively, the air may be removed through only the bleeders, drain, and purge lines rather than through the main vent lines. While air removal in this manner does take more time than traditional venting methods, it requires less operator involvement [11].

36.4.3.6 Cascading Water Retorts

The Steriflow cascading water retorts are designed and manufactured by Barriquand, Paris, France. The company manufacturers both stationary and end-over-end rotational systems that have been installed internationally for processing foods and pharmaceuticals. Cascading water retorts utilize high-velocity superheated water to sterilize containers of food. Heating and sterilization are achieved by superheated water steaming at a high flow rate over the containers. An overriding air pressure is available for glass jars and flexible and semi-rigid containers, to protect the physical integrity of the container and seal.

A schematic of the retort is shown in Figure 36.4. Water is heated by a welded plate heat exchanger located at the back or at the side of the retort in the middle. On the single door units, the heat exchanger is located at the end opposite the door; on the retorts with the door on both ends, the heat exchanger is located on the side of the shell and water enters at the top center of the retort. The super-heated water is fed into the retort through a distribution manifold. This water is continually recycled through the heat exchanger. In the heat exchanger, steam transfers its latent heat to the internal water, which is then showered from the distribution manifold over the product. The water cascades over the containers, not touching the sides of the shell and only touching a portion of the shell bottom. Therefore, it is not necessary to heat the entire shell during the come-up time, which can save energy. The same water is successively used for sterilizing and cooling the product. Therefore, the cooling is achieved with sterilized water, which means that chlorine doesn't need to be added in cooling water.

After passing over the containers, water passes through filters that keep debris, such as pieces of glass or product, from recirculating through the system. Both the water manifold and the filters are designed to be easily cleaned. The water manifold is a hinged gate at the end or ends next to the door, which can be opened and cleaned regularly. Since the opening for cleaning is opposite the water entrance, all debris is pushed to that portion of the manifold. This design is important to prevent the distribution holes from becoming clogged and perhaps reducing the water flow through a portion of the manifold. The bottom filters are also easy to remove and clean.

The first step is usually a preheat step, or a tempering step in the case of glass jars. Usually a certain minimum time is specified to get a more uniform come-up time for each cook. The second step is an overshoot of both time temperatures. This step is inserted to make sure that the mercury thermometer registers the scheduled temperature at the beginning of the sterilization phase. This step is critical because the controlling probe and the mercury thermometer are not located in the same place; the mercury thermometer lags behind the controlling probe. The third step is the sterilization phase. For this step it is recommended that the operating temperature be 1°C above the schedule retort temperature. The reason, common to most restarting systems, is to make sure that the mercury thermometer is at or above the schedule retort temperature during the entire sterilization phase. Time, temperature, and

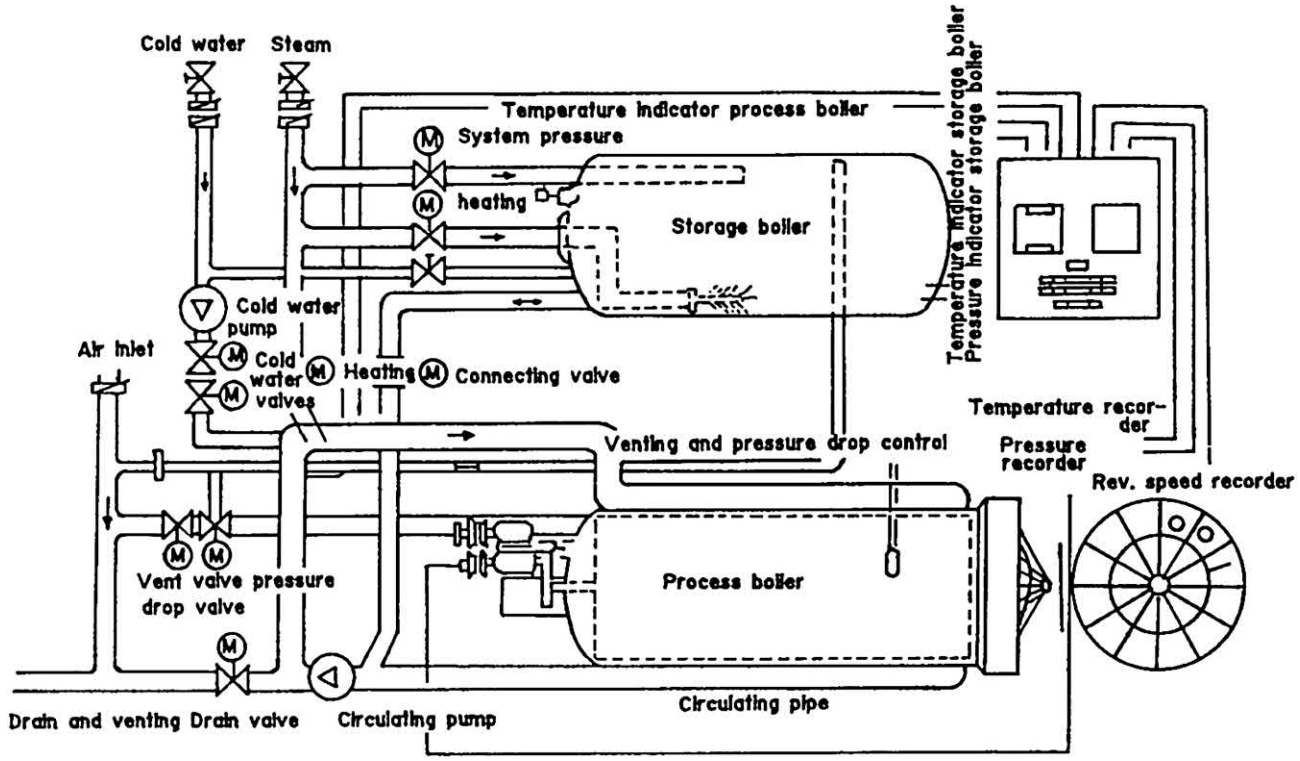

FIGURE 36.4 Horizontal circulating water retort (from Perkins [12]).

pressure are controlled. If the control in temperature drops below the set point, the timer stops until the correct temperature is achieved again. The fourth step is a pressure cooling step to protect plastic or semi-rigid containers from bucking or glass containers from losing their lids during the first few minutes of cooling. The final step is an atmospheric cooling. The actual times, temperatures, and pressure for each program depend on factors such as product formulation, container material and shape, entrapped air, product quality considerations, and steam, water, and air supplies [15].

36.4.3.7 Rotary, Full, Immersion, Hot-Water Sterilizers

The typical rotary hot-water sterilizer consists of two hot-water drums—the upper (storage) drum the lower (working) drum. Sterilization of the food takes place in the storage drum after it receives preheated hot water from the storage drum. During rotation cages turn in the same vertical plane within a rotating framework, called the "rotor insert." Containers in the cages travel in end-over-end fashion in the hot water if loaded in a vertical orientation. Overpressure is usually supplied with steam in the storage drum, although steam or compressed air may be used with a slight installation modification.

As thermal energy in the lower drum is given up to the product, cages, and shell during the process, more energy is introduced into the working drum through an external steam mixing or distribution chamber. Steam is injected directly into the system's circulating hot water from the working drum through a diffuser located within the chamber. There is no direct steam injection into the shell in these units. Water is pulled from bottom or side ports spaced equally along the shell of the working drum, where it is pumped through the mixing chamber for heating. Water travels through top or side water inlet ports into the working drums in a "top-to-bottom" or "side-to-side" circulation pattern. Rotating the cages during come-up, heating, and cooling cycles helps to distribute thermal energy in the system, and reduces the come-up and cool-down cycle times.

Temperature and pressure are independently controlled in these systems. Temperature and pressure sensor connections for the recorder system are located in the thermometer pocket at the horizontal center plane of the working drum. A resistance temperature device (RTD), sometimes referred to as a "PT-100," is located near the right side of the front end of the storage drum and controls the storage drum water temperature. A second RTD controls the temperature in the working drum and is positioned either before or after the mixing chamber in the circulation line or in the mercury-in-glass (MIG) thermometer well. After the heating phase is completed, a portion of the process water is pumped back into the storage drum, where it is heated to the required temperature set point for the next cycle. The circulation pumps are rated at approximately 400 gals/min with a 250-gal/min typical flow rate. The pumps use on/off, proportional valves and valve actuators on the units [16].

36.4.3.8 "Hydrolock" Continuous Cooker/Cooler

Hydrolock is a continuous, agitating cooker/cooler for high-speed-short-time sterilization of a wide variety of sizes and shapes of containers. The system is applicable to the processing of cans, glass jars, semi-rigid plastic and metal containers,

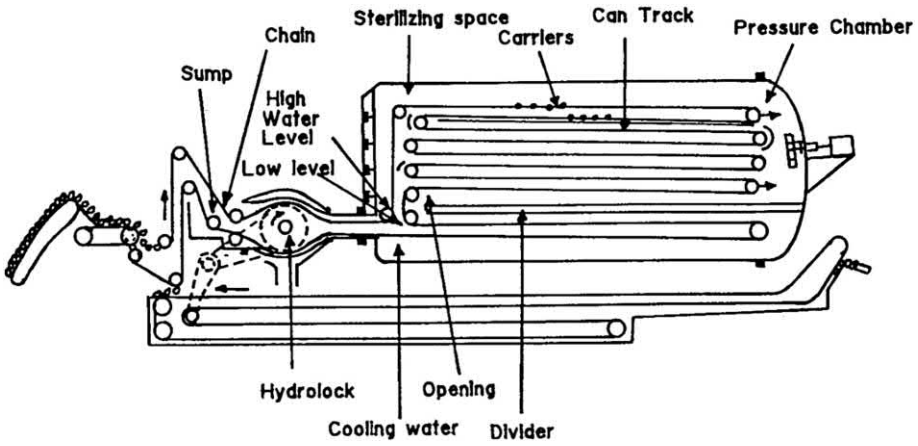

FIGURE 36.5 Hydrolock continuous cooker. (From Brody [20].)

and retortable pouches. It is also capable of processing plastic and metal containers with heat-sealed closures [12, 17–20]. The basic parts of the system are (Figure 36.5) the water lock, cooker/cooler, chain carrier system, cooling system, and water-circulating system. Containers enter and travel through the process between two parallel conveyor chains. These chains enter and leave through water into a rotating pressure lock, sealed partly by water and partly by mechanical means. This facilitates preheating of incoming and precooling of outgoing containers. After loading through the lock, the containers are continuously conveyed through the steam chamber and finally into precooling water in which the conveyor passes. Containers exit through the same rotating pressure lock through which they entered and pass along a cooler conveyor. The hydrolock is equipped to provide overhead pressure during the cooling cycle to the container integrity. Final product cooling is completed in two passes of atmospheric cooling below the pressure vessel. Cans roll in shallow water in a stainless-steel "pan" being pushed by stainless-steel rods attached at their ends to roller chains. Any heating medium can be used with the system: saturated steam, water, or a steam–air mixture. When an over-riding air pressure is required, as with glass containers, aluminum cans, plastic containers, or flexible pouches, air is mixed with the steam by means of one or more turbo fans which produce a homogenous mixture of the two gases.

36.4.3.9 Hydrostatic Pressure Sterilizer

This sterilization method is more commonly known as "hydrostatic sterilization" because the steam pressure in these units is maintained by water pressure. Hydrostatic cookers are continuous pressure cookers in which the operating pressure is maintained by water pressure. The schematic of the cooker is shown in Figure 36.6. Hydrostatic cookers have two components: water chambers and steam chambers. The temperature of steam in the steam chamber is controlled by pressure produced by the water legs and can be regulated by moving the level of water in the leg [13, 19, 21]. Containers are conveyed into the cooker through a water leg at 80°C. This is the down-traveling water leg, and the container temperature begins to increase. As the containers move down this leg, they encounter progressively hotter water. In the lower part of this leg the water temperature reaches about 100°C, and then, near the water seal area next to the steam chamber, the water temperature is about 107°C. In the steam chamber the can is exposed to a temperature of 115 to 130°C, the steam temperature being set to suit the product undergoing sterilization. Upon leaving the steam chamber, the can again goes through a water seal

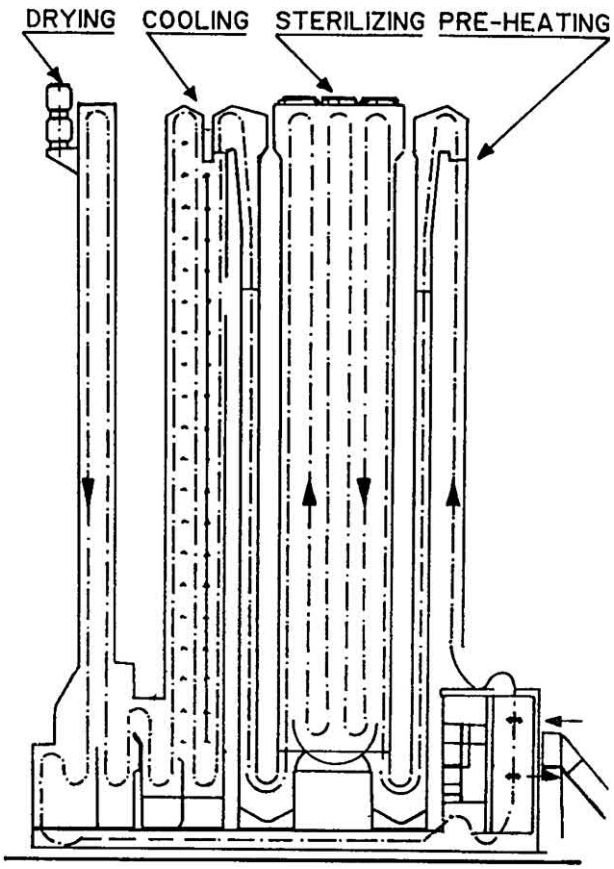

FIGURE 36.6 Hydrostatic pressure sterilizer (internal details). (From Perkins [12].)

into water at a temperature of about 107°C where the cooling cycle commences, under pressure.

36.4.3.10 Hydrostatic Helix

The major advantage of the hydrostatic cooker is its compact size. The hydrostatic cooker has no mechanical valves or locks and thus can be a truly continuous-motion retort. The helical pump or hydrostatic helix consists of a rotating coiled tube in which each turn of the coil is charged at the intake partly with liquid and partly with air. The coil rotates about a horizontal axis. With no pressure at the discharge, the rotating coil may meter liquid at a rate proportional to its rotational speed. With a discharge backpressure, the liquid in each coil turn forms a series of additive hydrostatic legs. The hydrostatic head developed is a function of the number of turns of the helix and the diameter. When the coil is rotated, liquid can enter the coil by gravity flow for one-half turn only, when the first turn (acting as a manometer) is in the upright position. As the coil continues to turn through the next half turn, only air can enter because the "manometer" is inverted. Thus, equal volumes of liquid and gas are alternately introduced into the helix in a repetitive cycle. The helical pump thus operates with many short columns of gas [22].

36.4.3.11 Continuous Pallet Sterilizer

Hydrostatic sterilizers, because of their size and the complexity of their water recirculation systems, are very expensive to construct and erect [12]. The continuous pallet sterilizer is basically a continuous vertical retort through which cans are transported on pallets. The feed and discharge of the pallets are effected, without pressure loss, through venting locks. Each filled, unprocessed pallet load is conveyed by a rack and pinion arrangement into the lock. After the outside pressure door of the infeed lock is closed, steam is introduced, first at atmospheric pressure to purge air from the pallet and chamber and thereafter under pressure to equilibrate the lock with the retort. After the venting-equilibration cycle, the pallet is moved forward until it is at the base of the retort. Pallets slowly ride upward on their four railroad-like wheels. The processed pallets leave the top of the retort through a "let-down" lock. The flexibility of a retort, in terms of container type, is shared by the continuous pallet retort by virtue of the capacity of a round vessel to withstand much higher pressures than a rectangular hydrostatic sterilizer tower. Hot water sprays, overpressured with air and steam with superimposed air pressure may be used as the sterilizing media. This equipment can be used for continuous processing of pouches, semirigid aluminum containers, institutional half steam table trays, and glass jars.

36.4.3.12 Flame Sterilizers

Infrared radiation as an indirect heat source was developed into flame sterilizers/cookers. Flame cookers attempt to increase the temperature differential between the heating source and the food product in order to increase the rate of heat penetration. By increasing the rate of agitation, the probability of burn-on is markedly reduced [13, 20, 22]. Gas burners at 1100°C provide the heat source to impart the high-temperature-short-time effect. The cans are placed in very close proximity (just a few millimeters away) to the burners and are kept in constant rotation, with a temperature differential between the can and contents not exceeding 1°C. Thus, even fully lithographed cans may be heated without damage. There is no possibility of imparting counterpressure, so cans must be fairly rigid to withstand internal steam pressure. With low-viscosity products, extremely high rates of temperature increase (e.g. 0.25°C/s) of contents are possible. The unit depends on continuous axial rotation (about 120 rpm) to move the cans along the burners and to obtain the internal turbulence. Some units have a steam preheat section. A schematic of the unit is shown in Figure 36.7 [23]. The steriflame units consist of three sections. The first one is a steam preheater, where the cans are heated to a temperature of approximately 100°C. In the second section, the cans roll through a series of open flames at 1100°C produced by specially constructed gas burners. The rolling motion of the cans increases the rate of heat transfer into the whole mass of the food. Next the cans pass through an intermittently heated burner holding section for about 4 to 5 minutes. Spray cooling follows the heating cycle. The total elapsed time in the cooker is generally less than that required for batch retorting.

36.4.3.13 Fluidized-Bed Sterilization

The fluidized-bed retort is a cooker in which sand or ceramic pellets are used as the heat transfer medium. The medium is

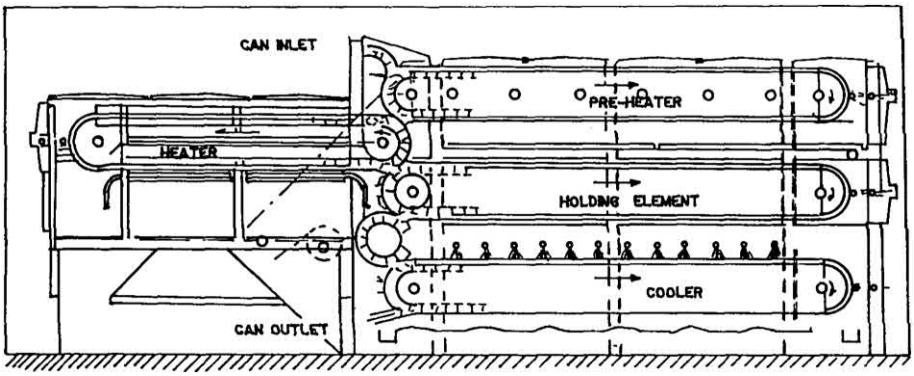

FIGURE 36.7 Flame sterilizer (longitudinal section). (From Beauvois et al. [23].)

kept hot and fluid by a flame underneath and an air stream. The particles behave much like boiling liquid. Cans move through the bed, meeting the same resistance as they would if the medium were a thick liquid receiving some abrasive effect from the particles [20]. The main advantage of the system is the close temperature control (e.g., 1°C at 1000°C) and that it does not require a pressure chamber. The process is continuous, and several sizes may be sterilized simultaneously. The main disadvantages are the possibility of burning and discoloration of the can surface, and damage of the can seals.

36.4.3.14 Hot Sterilization

Hot air with very high velocity (approximately 600 m/min) is employed to decrease the thickness of the non-turbulent air layer adjacent to the can surface. High-velocity air in excess of 150°C also creates a large temperature differential between the surface and the contents. Cans are axially rolled through to create forced convection within the can contents, thus reducing the possibility of burning or overcooking [13].

36.4.4 Temperature Distribution in the Retort Systems

There are numerous critical tests that must be performed to properly establish commercial sterility processes for any retorting application. The establishment of the "scheduled" (i.e., commercial sterility) process by a process authority depends not only on the ability of the food processor to properly control critical factors which relate to the pre-retort preparation of the product and the package in which the food is to be sterilized but also on those factors which specifically relate to the delivery of the thermal process to the packaged food. The manner in which the sterilizer is designed, installed, and operated is of critical importance. Failure to address these concerns will have a direct and significant impact upon the lethality (sterilization value) designed into (and actually obtained in) the process. The FDA not only requires that temperature distribution tests be performed but also expects that certain data be collected and procedures followed. In addition, FDA [21CFR113.4 (b) (10) (i)] and USDA [9 CFR 318(381). 305(C) (2)(x)] regulations require that these data be evaluated by a "recognized competent process authority."

The traditional means by which acceptable process delivery conditions are verified is to use thermocouples, RTDs, or thermostats to generate time/temperature histories at pre-assigned strategic locations inside the sterilizer. These data are collected from "zero time" (when the heating medium first contacts the containers in the working drum) until a "to-be-determined time" at which all temperature-measuring devices attached to the sterilizers indicate same in the recording devices. Most important, the time at which the lowest temperature lead meets the true "set point" temperature of the control program is critical. This exact time/temperature condition is the traditional process calculation reference point from which process hold times are determined. The "official reference instrument" against which all other sterilizer temperature control devices are adjusted is the MIG thermometer. All thermocouple lead readings must be able to compare to the MIG thermometer readings. Temperature distribution is, then, the uniformity of sterilizer temperatures and the stability of sterilizer temperatures at any given time during the entire process cycle, including the come up, holding, and cooling phases.

Temperature distribution in batch, rotary, or hot-water sterilizers is affected by numerous critical plant conditions and system future: (i) *Product initial temperature*: Lower initial temperatures usually lengthen retort come-up time and worsen temperature uniformity and stability. (ii) *Storage drum temperature*: The storage drum temperature is usually programmed to be 15–20°C above the targeted control set point in the working drum. If the hot water drop temperature is too high, some semi-rigid and flexible containers may be damaged and the temperature gradients between outside and inside the container cage position can be excessive. If the hot-water drop temperature is too low, too much heating in the working drum must then occur, also creating wide temperature gradients. (iii) *Working retort venting*: Venting the working retort for too long in sterilization removes excessive energy from the system, extends come-up time, and forces more mixing chamber steam injection during the come-up phase. Too short a venting time does not allow the storage drum/working drum fill step to occur properly and causes pressure control problems in the working retort. Ideally, a venting time of approximately ½ min/cage is appropriate (i.e., 2 min for a four-cage 1,100-mm unit). (iv) *Working retort RTD location*: The control RTD may be located before or after the mixing chamber in the water circulation line. When the RTD is located after the mixing chamber, the control device measures the hottest water in the circulation system; this results in a less aggressive steam valve response and a slower but smoother ramp to temperature in the come-up phase. If the RTD is located before the mixing chamber, the control device measures the coldest water in the system, and the steam valve to the mixing chamber experiences a "response lag" by fully opening for too long. This causes temperature overshoot at the end of the come-up period. (v) *Container type and geometry*: Low-profile containers (cans, pouches, plastic trays, or bowls) must be filled into racking systems, which may create a considerable number of cage layers. Increased layers create increased resistance to the heating medium flow. Generally, full loads of large cylindrical containers exhibit a shorter come up time and improved temperature uniformity in all process phases. (vi) *Container handling system*: The cages, dividers, and racks for handling the containers must be designed to provide maximum cross-sectional open area (CSA) created by slots or perforations in the sides and bottoms of the cages. Spacer mats or divider sheets between layers of containers must be designed for maximum open area to enhance water flow past container surfaces. (vii) *Rotational speed*: Generally, as rotational speed increases come-up time decreases and temperature uniformity and stability improve. (viii) *Number of cages*: The larger the unit and the greater the number of cages, the slower the come-up time, and the greater temperature differences throughout the drum must be overcome. (ix) *Retort design and operating environment*: Regardless of the retort

manufacturer, it is advisable to perform temperature distribution studies in each batch, full-immersion, rotary hot-water retort. Design modifications, valve settings, blocked ports, and the number of retorts operating simultaneously in conjunction with other steam demands in the plant will affect test results and should be monitored closely. Rotary retards to be added to an existing line must also be tested for temperature distribution [16].

36.4.5 Exhausting

The exhausting of containers for the removal of air should be controlled so as to meet the conditions for which the process was designed. Vacuum in canned foods may be obtained by pre-heating foods prior to closing. In producing a vacuum by this means, the product may be heated prior to filing, or it may be heated both before and after filling. Heat in this case is employed to expand the product, to expand and drive out the occluded and dissolved gases in the product, and to reduce the air in the headspace before closure. The length of heating and the final temperature attained before closure have a very important relationship to the ultimate vacuum in the can. Heating may be accomplished by passing the filled can through a steam or hot water exhaust box. It is common to refer to exhaust box treatment as "thermal exhaust" and to preheating before filling as "hot fill." Exhaust boxes are generally best adapted for canned foods that can readily be heated, such as brine- and syrup-packed fruits and vegetables. The major disadvantages of exhaust boxes are in their bulkiness and their large steam requirements. In mechanical vacuum closure by high-speed vacuum closing machines the filled cans while cold or at a rather low temperature are passed into a clincher which loosely clinches the covers without forming an air-tight seal. The cans are then transferred through a suitable valve into a vacuum chamber, subjected to vacuum for an instant while in the vacuum chamber, sealed, and then ejected through another valve. Vacuums drawn on the machine while the cans are in the vacuum chamber may be varied over a wide range, depending mainly on the desired final vacuum in the can and also on the temperature of the liquid contents. This method of exhausting air from canned foods subjects the contents to a vacuum for a rather short interval of time before closure. Therefore, the air is withdrawn mainly from the headspace and only partially from the product itself and proper adjustment of the headspace is necessary for proper performance.

36.4.6 Quality of Canned Foods

36.4.6.1 Plant-Origin Foods

The purpose of heat sterilization is to extend the shelf life of foods while minimizing the changes in nutritive value and eating quality. Differences between the heating characteristics of microorganisms, enzymes, and sensory or nutritional components of foods are exploited to optimize processes for the retention of nutritional and sensory qualities. This is achieved in practice by a reduction in size or cross-sectional area of containers, by agitation during processing, or by aseptic processing. The extent of thermal processing which a food receives is dependent upon the composition and physical characteristics of the product and is the result of a combination of time and temperature. Physicochemical changes occurring during processing and storage are the factors which determine the product quality in terms of both its sensory properties and its provision of nutrients to the consumer. Reactions take place during both the process itself and in subsequent storage. Generally the changes which occur during storage are slow, particularly when compared with those occurring in an equivalent unprocessed material, and it is on this basis that heat preservation is effective in providing materials outside their normal seasons and in a convenient, prepared, often formulated, form ready for consumption or reheating and then consumption. The physical and chemical reactions which occur during processing can be desirable or undesirable, are often more significant and certainly occur much more rapidly than those during storage. The degree of heat processing varies according to the product. In turn the changes occurring in processing are influenced by the time and temperature of the process and the composition and properties of the food material [24] and its environment [25].

36.4.6.1.1 Sensory Quality

The heat process itself has a major effect on the quality of a food product and is responsible for a range of changes taking place. Starch gelatinization and structural protein denaturations have a direct influence on the texture of a food product. Heat-induced reactions such as the Maillard reaction affect the color and flavor as well as the nutritional status of the food [26, 27]. In general, changes that occur before the heat process are less important than those during or after processing since it is the manipulative and thermal procedures of food production which have the greatest effect on tissue damage and the resultant mixing of cell contents from different materials.

36.4.6.1.2 Texture

The tissue damage which occurs during the heat processing of plant material is of two types. These are destruction or damage to the semi-permeable cell membranes, and disruption of the intercellular structures with resultant cell separation [28]. The effects of these types of tissue damage are a loss in cell turgor and cellular adhesion which give rise to loss of crispness and softening of the heat-processed product. Other major influences on the texture of heated foods arise from the denaturation of proteins. Even with relatively mild heating conformational change affecting the tertiary structure of protein can be observed [29]. Denaturation of the proteins may follow. The hydrogen bonds, maintaining the secondary and higher structure of protein, rupture, and predominantly random coil configuration occurs [30]. This leads to considerable changes in the chemical and physical properties of proteins due to losses in solubility, elasticity, and flexibility [29, 31]. This mechanism also causes enzyme inactivation and

breakdown of proteinaceous toxins and antinutrients. They cause turbidity leading to either a precipitate or gel, which will greatly alter their water-holding capacity and also lead to increased thermal stability [32]. In fruits and vegetables, softening is caused by hydrolysis of pectic materials, gelatinization of starches, and partial solubilization of hemicelluloses, combined with a loss of cell turgor. Calcium salts may be added to blanching water or to brine or syrup, to form insoluble calcium pectate and thus to increase the firmness of the canned product. Different salts are needed for different types of fruit (for example calcium hydroxide for cherries, calcium chloride for tomatoes, and calcium lactate for apples) owing to differences in the proportion of demethylated pectin in each product.

36.4.6.1.3 Color

The color of a food product is determined by the state and stability of any natural or added pigments and the development of any coloration during processing and storage. Natural pigments are generally unstable compounds that are broken down on heating but whose stability is dependent upon many factors. In fruits and vegetables, chlorophyll is converted to pheophytin, carotenoids are isomerized from 5,6-epoxides to less intensely colored 5,8-epoxides, and anthocyanins are degraded to brown pigments. Anthocyanins are fairly heat-stable compounds but take part in a wide range of reactions, e.g., with ascorbic acid, sugar breakdown products, such as hydroxymethyl furfural, and other reactive phenolics which bring about their breakdown [33]. Factors that accelerate degradation include high levels of oxygen in the product and storage temperature. Conversely, anthocyanins can be undesirable in a product and can be produced on thermal treatment of leucoanthocyanidin [34, 35]. They give rise to defects, such as very dark broad beans and red gooseberries. Other problems can occur with anthocyanin pigments due to the formation of metal complexes, for example, the bluing of red fruits and the pinking of pears when exposed to tin [36, 37]. The flavonoid rutin, present in asparagus, can also form a complex with iron causing dark discoloration in lacquered cans where iron dissolution can occur [38] and in which the colorless tin complex is not formed.

Carotenoids are mostly fat-soluble and are responsible for yellow, orange, and red coloration. They are unsaturated compounds and are therefore susceptible to oxidation, giving rise to off-flavor and bleaching. In addition, two types of isomerization can occur, namely, *cis–trans* isomerization and epoxide isomerization, which can give rise to lightening of the color. The temperature of storage is considered to have a greater effect on the isomerization than the heat process itself. The two major groups of porphyrin-based pigments are chlorophyll and the heme compounds, both of which are very sensitive to heat. On processing, chlorophyll is converted to pheophytin with an associated loss of green color [38]. Several approaches have been taken to try to reduce the color loss such as adjusting the pH [39, 40] and the use of HTST treatments. In the latter case although improvements were observed after processing these were lost during storage [41].

Betalins are water-soluble pigments, which are susceptible to oxidation and loss of red color. Browning of heat-preserved beetroot products is an example where residual oxygen in the product or headspace causes the appearance of a chocolate-brown color. Heat processing itself in the presence of oxygen has a major effect on the end-product quality, and this is demonstrated by the comparison of products packed in plain tin-plate cans with the identical material processed in lacquered cans or glass jars. In the plain tin-plate container dissolution of the tin during processing removes a major proportion of oxygen from the pack, and little is available to react with the food. Some products such as pale fruits, tomatoes and tomato formulations, mushrooms, and milk products are particularly susceptible to such heat-induced oxidative changes. It has been demonstrated that a brownish color develops in beans dipped in tomato sauce packed in different container types [42]. Ascorbic acid is often used as an antioxidant and can be effective in improving color in certain products, e.g., mushrooms. It can be degraded to produce reactive compounds, which further react to form brown pigments.

36.4.6.1.4 Flavor

Generally, heat preservation does not significantly alter the basic flavors of sweetness, bitterness, acid, or salt. In fruits and vegetables, changes are due to complex reactions which involve the degradation, recombination, and volatilization of aldehydes, ketones, sugars, lactones, amino acids, and organic acids. Major changes can occur in the volatile flavor components. One of the most important sources of volatiles is lipid oxidation or oxidative rancidity. The three stages are (i) initiations, (ii) propagation (i.e., formation of highly reactive hydroperoxides), and (iii) termination. The initiation uptake of oxygen, in the presence of catalysts, such as metal ions or metalloproteins can initiate oxidation, but it can also be enhanced by heat or light. The reaction does, however, have low activation energy (4–5 kcal $mole^{-1}$). The hydroperoxides formed take part in secondary reactions to give rise to a range of volatiles including aldehydes, ketones, and alcohols, and they produce typical rancid or stale off-flavors.

Volatile flavor compounds are also produced via the Maillard reaction. Since the first scheme for the reaction was put forward [43] a great deal of research has been undertaken. The reaction occurs during heating and extended storage, is influenced by water activity, with an optimum for flavor generation at intermediate values of around 30% water [44], and is accelerated by high pH and buffers such as phosphates and citrates [45]. The first stage of the reaction is fairly well-defined and involves the condensation between carbonyl groups of the reducing carbohydrates and the free amino acids or protein and rearrangement to produce amatory compounds. This leads to loss of protein nutritional quality but does not affect the sensory properties significantly [46]. The second stage is very complex and gives rise to numerous products, many volatiles, and is responsible for many characteristic flavors and off-flavors in food materials. The loss of volatile constituents can also present problems in heat-preserved foods. The breakdown of essential oils in citrus products can result

from oxidation. Packaging can also have a direct influence on volatile scalping.

36.4.6.1.5 Nutrients

Both physical and chemical reactions occur in heat-preserved foods, which influence nutritive value (Table 36.1). Physical factors such as the loss of soluble nutrients, or leaching, can be significant for products in which there is a carrying liquid discarded before consumption. Chemical reactions include heat damage to labile nutrients such as vitamins. One of the most fundamental changes which can occur in a heat-preserved product is the movement of water and solids within the food material during processing, storage, and reheating. In a formulated product or a product in which the entire pack contents are consumed, such changes can be largely disregarded, from the nutritional point of view, in that they do not alter the total amount of the nutrients consumed. Products which are packed in a liquor which is discarded before consumption often exhibit dilution, dehydration, or loss of total solid materials from the edible portion. Sterilized soya-meat products may show an increase in nutritional value owing to an unidentified factor that decreases the stability of the trypsin inhibitor in soybeans.

36.4.6.1.5.1 Proteins Heat preservation can lead to both desirable and undesirable changes in the nutritive quality of proteins. They are susceptible not only to heat but also to oxidation, alkaline environment, and to reaction with other food constituents such as reducing sugars and lipid-oxidative products. The total amount of crude protein generally appears relatively unchanged due to heat processing [47, 48] but can suffer from leaching into the liquid component of some products [49]. The crude protein levels, however, appear to be stable during subsequent storage of canned vegetables [47, 48]. The changes that occur are associated with tertiary structure, functionality, chemical changes related to digestibility, and amino acid availability. Canning of potatoes also leads to losses of amino acids though this has been shown to vary depending on the specific gravity of the potato [50]. Lysine is again particularly vulnerable with a reduction in its availability of about 40%. Some of the losses found in canned potatoes may be due to the leaching of the protein into the brine [49] although the major cause of loss of amino acids on heat preservation is the Maillard reaction. Soybeans and many other legumes also undergo improved protein digestibility and bioavailability, especially of the sulfur-containing amino acids on heating due to inactivation of trypsin inhibitors and unfolding of the major seed globulins.

TABLE 36.1
Effect of Heat Processing on Major Nutritional Components

Nutrient	Effect
Dry matter	Loss of total solids into canning liquor
	Dilution
	Dehydration
Protein	Enzymic inactivation
	Loss of certain essential amino acids
	Loss of digestibility
	Improved digestibility
Carbohydrate	Starch gelatinization and increased digestibility
	No apparent change in content of carbohydrate
Dietary fiber	Generally no loss of physiological value
lipids	Conversion of *cis* fatty acids to *trans* by oxidation
	Loss of essential fatty acid activity
Water-soluble vitamins	Large losses of vitamins C and B, due to leaching and heat degradation
	Increased bioavailability of biotin and niacin due to enzyme inactivation
Fat-soluble vitamins	Mainly heat stable
	Losses due to oxidation of lipids
	Losses due to leaching
Minerals	Possible increase in sodium and calcium levels by uptake from canning liquor

36.4.6.1.5.2 Vitamins The effect of heat preservation on vitamins is generally detrimental although mild heating conditions can have beneficial effects on the bioavailability of certain vitamins, particularly biotin and niacin. This is due to enzyme inactivation and the inactivation of binding agents [51]. The stability of vitamins varies under different conditions with vitamin C and thiamin being most susceptible to degradation through heating. The fat-soluble vitamins are the more stable of the two sets, although these can be degraded by oxidation especially when heated. Losses of water-soluble vitamins during processing can be considerably higher. Vitamin C is the most labile of the vitamins and can be lost during storage of the fresh material, food preparation, washing, and blanching as well as by degradation on heating and leaching into a carrying liquid during the process. Studies on garden peas and carrots have shown that as much vitamin C can be lost in the storage of the fresh produce for 7 days prior to cooking as that lost in canning. Much of the vitamin C lost during canning is leached into the canning liquor. Thiamin is the most heat sensitive of the B vitamins especially under alkaline conditions, and it is also susceptible to leaching during any washing or blanching stages. Thiamin, however, is less labile than vitamin C and retention of 60 to 90% is usual in canning [52]. Folic acid and pyridoxine are also susceptible to degradation by heating and, in the case of folic acid, also by oxidation. Canning of potatoes can lead to losses of vitamins up to 30% [53]. Riboflavin and niacin are both relatively stable on heat preservation although riboflavin is very sensitive to light and will undergo degradation in the presence of both heat and light together [54]. Heat-preserved foods often require less cooking than fresh foods, and the differences in the vitamin content between the fresh and the processed food at the point of consumption can often be negligible. In canned fruits and vegetables, significant losses may occur in all water-soluble vitamins, particularly ascorbic acid/vitamin C.

36.4.6.1.5.3 Minerals Minerals are generally stable in most of the conditions encountered in heat preservations i.e.,

heat, air, oxygen, acid, or alkaline. Losses of minerals, however, can occur during processing, especially of vegetables, due to leaching into canning liquor. Conversely, certain minerals, for instance sodium and calcium, can be taken up by the food from the cooking or canning liquids. Comparisons between fresh and canned vegetables have shown higher ash content in canned products in all cases. This is due to the uptake of sodium, and to a lesser extent of calcium from the brine. Between 15 and 50% of potassium can be lost primarily by leaching in the canning of vegetables. Slight leaching of zinc and negligible changes in iron content occur during processing. Heating has been seen to increase the bioavailability of iron in spinach, and the presence of fructose also leads to increased iron bioavailability [55]

36.4.6.1.5.4 Carbohydrates Carbohydrates are less susceptible than most other food compounds to chemical changes during heat preservation. The levels of total and available carbohydrates in vegetables have been found to be very stable on canning and subsequent storage of the canned vegetables. However, there are some effects of heat on various carbohydrates. The effect of sugar on protein and iron bioavailability and the relationship between starch, texture, and palatability are more important. Gelatinization of the starch also aids digestibility of foods. A good example of this [53, 56] is the potato which in its raw state is largely indigestible. The exact effect of heat preservation on various types and constituents of dietary fiber has not been fully investigated. Cellulose, the main constituent of dietary fiber, hemicelluloses, and pectins are together responsible for the structure and texture in plant foods [57, 58] and can be disrupted by heating which leads to a softening of the food and increased palatability as discussed earlier, generally, without any loss in the physiological value of the dietary fiber. Over-heating can lead to breakdown in the cells enabling water-soluble nutrients, for instance certain minerals, vitamins, and pectins, to be leached out. Although dietary fiber is considered to be largely unaffected by heat processing, the exact relationship between time/temperature conditions, dietary fiber breakdown, and the extent of nutrient loss due to fiber breakdown requires further study.

36.4.6.1.5.5 Lipids Lipids, especially unsaturated lipids, are prone to oxidation when heated in the presence of air or oxygen, resulting in losses in nutritional value of the food product. Although the major effect of lipid oxidation is in the flavors of foods, oxidation can lead to a conversion of the natural *cis* fatty acids to *trans* fatty acids [55]. The digestion and absorption of *trans* fatty acids are comparable to that of the *cis* fatty acids, and their nutritional value as an energy source is not affected. However, *trans* fatty acids do not generally possess essential fatty acid activity, i.e., as precursors of prostuglandins, thromboxanes. This activity is dependent on a *cis* 9, *cis* 12 methylene interrupted double bond system, but provided that sufficient linoleic acid is consumed the *trans* fatty acids do not appear to inhibit essential fatty acid metabolism [59, 60]. The oxidation of lipids has also been implicated, as previously noted, in the loss of protein quality and can inhibit the activity of the fat-soluble vitamins A, D, and E as well as vitamin C and foliate. The oxidation of fats in processed foods, however, can be controlled by the exclusion or minimization of oxygen and the use of antioxidants. The effects of heat preservation on the nutritional value of fats can therefore generally be considered as negligible.

36.4.6.2 Animal-Origin Foods

36.4.6.2.1 Color

The time–temperature combinations used in canning have a substantial effect on most naturally occurring pigments in meat foods. The red oxymyoglobin pigment is converted to brown metmyoglobin, and purplish myoglobin is converted to red-brown myohaemichromogen. Maillard browning and caramelization also contribute to the color of sterilized meats. However, this is an acceptable change in cooked meats. Sodium nitrite and sodium nitrate are added to some meat products to reduce the risk of growth of *Clostridium botulinum*. The resulting red-pink coloration is due to nitric oxide myoglobin and metmyoglobin nitrite. Loss of color is often corrected using permitted synthetic colors.

36.4.6.2.2 Flavor and Aroma

In canned meats, there are complex changes (for example pyrolysis, deamination, and decarboxylation of amino acids, degradation, Maillard reactions and caramelization of carbohydrates to furfural and hydroxymethylfurfural, and oxidation and decarboxylation of lipids). Interactions between these components produce more than 600 flavor compounds in ten chemical classes [61, 62]. Other volatiles have been identified as having a significant effect on the flavor of foods and perhaps one of the most dramatic is the development of "catty taint." This is an extremely unpleasant and potent odor produced by the reaction of unsaturated ketones, notably mesityl oxide, with natural sulfur-containing components of the food [61, 62]. Heating is essential in the formation of the taint, and incidents have been widespread due to the diverse availability of the unsaturated ketones. Examples include processed meat products using meat from cold store, painted with a material containing mesityl oxide as a solvent contaminant [63], canned ox tongues which had been hung on hooks coated with a protective oil [64], and pork packed in cans with a side seam lacquer which had been dissolved in impure solvent [64, 65].

36.4.6.2.3 Texture

In canned meats, changes in texture are caused by coagulation and a loss of water-holding capacity of proteins, which produce shrinkage and stiffening of muscle tissues. Softening is caused by hydrolysis of collagen, solubilization of the resulting gelatin, and melting and dispersion of fats through the product. Polyphosphates are added to some products to bind water. This increases the tenderness of the product and reduces shrinkage. Small changes in the viscosity of milk are caused by modification of K-casein, leading to an increased sensitivity to calcium precipitation and coagulation.

36.4.6.2.4 Nutrients

Canning causes the hydrolysis of carbohydrates and lipids, but these nutrients remain available, and the nutritive value of the food is not affected. Proteins are coagulated, and, in canned meats, losses of amino acids are 10–20%. Reductions in lysine content are proportional to the severity of heating but rarely exceed 25%. The loss of tryptophan and, to a lesser extent, methionine reduces the biological value of the proteins by 6–9%. Vitamin losses are mostly confined to thiamin (50–75%) and pantothenic acid (20–35%). However, there are large variations owing to differences in the types of food, the presence of residual oxygen in the container, and methods of preparation (peeling and slicing) or blanching. In some foods, vitamins are transferred into the brine or syrup, which is also consumed. There is thus a smaller nutritional loss. Heat sterilization of meat leads to a reduction in digestibility of the meat proteins and damages amino acids especially the essential sulfur-containing amino acids and lysine, with 10–15% losses in beef [66]. Heat preservation has two important effects on the quality of foods: (i) Many of the changes (sensory or nutritional) which occur during the thermal process are not restricted to heat-preserved foods. In many instances the process replaces the conventional cooking which the food receives prior to consumption. Reheating the heat-preserved food is a relatively mild treatment that does not significantly affect the quality. (ii) Heat-preserved foods make available to the consumer a wider choice of sensory experiences and nutritional benefits without the constraint of seasonality and the burden of preparation.

36.4.7 Packaging of Canned Foods

Under the regulations, "hermetically sealed container" means a container that is designed and intended to be secure against the entry of microorganisms and to maintain the commercial sterility of its contents after processing. The container is an essential factor in the preservation of foods by canning. After canned foods are sterilized, it is the container that protects the canned food from spoilage by recontamination with microorganisms. It is then most important for the success of the canning operation to use good-quality, reliable containers and properly adjusted closing machines. Thus, the seams and closures produced will be according to the guidelines necessary to prevent access of microorganisms into the container during the cooling operation and during the shelf life of the product.

36.4.7.1 Tin-Plate Cans

Today the choice is from among (i) tin-plate body and ends, (ii) tin-plate body and one end, aluminum convenience end, (iii) three-piece aluminum can (rare, but available and used, with adhesive side seam, for alcoholic cocktails), (iv) tin-free steel with tin end, tin-free steel end, aluminum end, or a combination, (v) tin-free steel body, (vi) adhesive joined side seam, (vii) welded side seam, (viii) draw and iron two-piece aluminum can, (ix) conventional top chime, (x) neck-in top flange so that chime is flush with body, and (xi) draw and iron two-piece steel cans not commercially available except in small sizes for aerosol cans [20].

36.4.7.1.1 Two-Piece Cans

All of the major and secondary can-making and can-handling equipment manufacturing firms produce two-piece draw and iron cans. One of the significant commercial cans is a very small 28 to 57 g (1 to 2 oz.) unit. It is evident that a two-piece steel can would eliminate the long seam and one double seam, and thus preclude two sources of potential leakage. The amount of metal used would be reduced below that used for a three-piece. Two-piece steel cans offer the advantages of a two-piece aluminum can at a lower price [20].

36.4.7.1.2 Three-Piece Cans

Three-piece "sanitary cans," consisting of a can body and two end pieces, are used to seal heat-sterilized foods hermetically and also for other food products like powders, syrups, and cooking oils. Presently, the three-piece cans are widely used, but other cans like two-piece cans, aluminum cans, and other flexible containers are slowly replacing them [20].

36.4.7.1.3 Aluminum Cans

The main applications are where inherent advantage can be realized over the tin-plate such as lower shipping expense, freedom from food and can black sulfide discoloration or rust, easier puncture opening, and where special easy-opening features are desirable [20]. Steel cans are so well-established in the canning industry that exceptionally good reasons are required before a change of material is contemplated. The future use of aluminum for cans, for processed food use, to a great extent depends on the price at which it may be sold to the users, relative to that of an equivalent steel can. Aluminum cans offer advantages of product quality, and economy for the canning of certain food products. The use of easy-open lids is also a significant point which has a strong appeal. Aluminum cans do not rust, and their appearance, always bright, can be an important sales argument. An important advantage of aluminum cans is that they are lead-free. But aluminum cans dent easily, abrade, and are not interchangeable with steel cans.

36.4.7.1.4 Collapsible Tubes

Aluminum may also be used in the form of collapsible tubes for packaging processed food products. Sterilized foods packaged in collapsible tubes for the feeding of astronauts and high-altitude aviators have been developed. The aluminum tube fitted with a hollow handled plastic spoon, which can be attached to the neck of the tube, should make a desirable and convenient package for feeding infants or bedridden patients [20].

36.4.7.1.5 Composite Cans

Another development is the foil/fiber can, more commonly called the composite can. Used earlier for refrigerated biscuit dough, this material is now being used for frozen concentrated orange juice. The composite spiral wound can of fiber/polyethylene/aluminum foil has the major share of the juice and

juice drink frozen concentrate canning. Composite cans have been successfully employed for shortening and with polyvinylidene chloride coating, for vacuum packing of roasted and ground coffee. There has been considerable publicity on the use of composites, for beer, hot fills, pasteurized, and even retorted foods [20].

36.4.7.2 Glass Containers and Metal Closures

36.4.7.2.1 Containers

The chemical and physical properties of glass make it an ideal container material for canned foods. It is a chemically stable material. However, in long-term storage of aqueous solutions, and most particularly of acid foods, a very small amount of alkali may extract from the glass, and in some instances, lesser amounts of SiO_2 or silica. These materials are commonly found in all food products; therefore, the glass container is considered quite inert and is nonadditive in the packaging of most, if not all, food products. It does not support or facilitate microbial growth on its surface, and like metal it is impermeable to gases, liquids, bacteria, and odors. One very apparent characteristic of the glass container is its transparency. While the visibility of the product contained is attractive to the consumer, it does impose restrictions on the canner as to the appearance of the product [67]. Commercial glass jars are formulated and designed to withstand the thermal shocks normally encountered in the canning process. The maximum temperature shock as measured by the temperature differential is generally 45°C. However, they can withstand wider temperature differentials, but only under certain conditions. They are also designed to resist the mechanical shocks normally encountered in a well-designed and maintained filling and packaging line. Their resistance to vertical pressure allows the application of various capping methods and stacking [67].

36.4.7.2.2 Metal Closures (Caps)

The various metal closures that are used in food canning are (i) Twist-off or Eurotwist, (ii) Eurocap and EurocapX, (iii) Pry-off, (iv) Press-twist (PT), and (v) Deep-Press (DP) [67]. The metal closure along with the sealant is designed specifically for each type of glass finish to permit the attachment of a proper seal and efficient closure. For shipping and storage, the nonstackable caps are packed in bulk in cartons, with or without plastic liners, and the stackable caps in overwrapped rolls. The cartons are palletized and either shrouded or strapped. Each carton should be labeled to identify the contents and manufacturing lot. Staples should not be used to close the cartons because they may contaminate the closures [67].

36.4.7.3 Retortable Pouches

Thermally processed laminate structures are made out as retortable pouches. Shelf life, toughness, resistance to puncture, and ability to withstand high temperatures are some of the important characteristics for selecting materials for flexible containers. The retort pouch was designed to be a package that would offer the shelf-stability of canned foods with the quality of frozen foods. The materials configuration of this package has been enhanced over the past several years to bring the pouch even closer to this goal. Typically, the retort pouch consists of a 0.5-mm polyester film laminated to 0.000035- or 0.0007-in-gauge aluminum foil. This is in turn laminated to a 3-mm modified polypropylene film. Each of these three substrates plays an important role in the finished package [68]. On the outside, the polyester provides toughness, abuse-resistance, and printability. The package can be printed with color ranging from simple one- and two-color instructions to full-color vignettes of the food product. The actual printing is applied to the "reverse" side of the polyester film, trapping the inks between laminates to protect against scuffing. In the middle, the aluminum foil is the key to the retort pouch's being a completely shelf-stable food package, with no expensive freezing or refrigeration required. Aluminum is the lowest cost barrier to light, moisture, oxygen, and microorganisms. On the inside, the polypropylene film performs two important functions; first, it is inert and does not react to food, so that virtually the entire range of processed foods can be packaged in this one basic material. Second, it provides exceptionally strong heat-seals that can withstand the pressure and temperature demands of retorting and contribute to a shelf life at least equal to that of cans [68].

36.4.7.3.1 Advantages of the Pouch

The retort pouch is an integral component of the food distribution system with food product quality and package convenience. The thin profile and increased surface area of the retort pouch permit rapid heat penetration and much more efficient processing than with cans. Typical time savings in the cook cycle of a retort process are up to 40%. This reduction in heat exposure results in improved food product quality—better taste, color, and texture than similar products processed in cans. There is also a potential for nutritional advantage as well, particularly where heat-sensitive nutrients are concerned. Packing a food in a retort pouch results in a better-tasting product [68].

36.4.7.3.2 Advantages for the Consumer

From the consumer's viewpoint, the retort pouch is certainly the most convenient food package. Completely shelf-stable, retort-pouched foods may be stored in the cupboard along with other dry goods. Foods packed in retort pouches are sterilized and are ready to eat. Foods may be heated to serving temperatures before consumption. This can easily be accomplished by heating in boiling water for about 5 minutes. In this manner a variety of foods may be conveniently prepared at the same time, with no messy pots and pans to scrub. With the advent of the microwave oven, the true convenience of food preparation in boiling water is now less utilized. All that boiling water does to a retort-pouched food product is heat it; since the temperature of the boiling water is reasonably constant, the pouch can remain in the pot for 6 to 8 minutes and still deliver a satisfactory result, while the consumer is occupied elsewhere. In addition, retort pouched foods are easily prepared in microwave ovens. The contents are poured onto the serving plate and heated for about 1–2 minutes. The added

stiffness of the aluminum foil makes the retort pouch easy to tear open, using the notches provided. Disposal of empty pouches after use is extremely convenient, as they are easily flattened and contain no dangerous sharp edges. This is particularly important in foodservice operations, where more pouches are disposed of and take more space [68].

36.4.7.3.3 Advantages to the Processor

Retort pouches offer important advantages to the processor by cost savings. The packaging materials cost for retort pouches is lower than for steel cans (comparing total package cost for a pouch and outer carton vs. a three-piece steel can, lid, and label). A roll of retort pouch stock takes up 85% less space than the equivalent number of empty cans, providing warehouse space savings on the front end of a packaging operation. The retort pouch offers savings in freight because it is lighter in weight than other packages. For example, 1000 225 g (8 oz) steel cans weigh approximately 50 kg (109 lb), compared to just over 6 kg (12 lb) for equivalent pouches. With lighter package weight, more food product can be shipped per truckload in unrefrigerated trucks. One of the principal advantages of the retort pouch is that the package is sized to the food product, not vice versa as with cans. Thus, where liquid, or brine, is not essential to the food product, much of it may be eliminated, offering even further cost and freight savings [68].

36.4.7.3.4 Advantages to the Retailer

Retort pouches can be merchandised anywhere in the store—near the checkout counter or in end aisle displays. Initially, retort pouched foods are marketed in paperboard cartons, for puncture resistance and product display; down the road, pouches may be marketed without cartons, printed with full-color illustrations, and merchandised on pegboards or special shelf units. [68].

36.4.7.3.5 Other Advantages

An environmental impact study has shown that the retort pouch, from package manufacture to consumer use, requires less energy than canned food (in cans or glass) or frozen food. The pouch also made a more passive contribution to the waste-disposal systems than other packages [68].

36.4.7.3.6 Retort Pouch Technology

A summary of the state of the retort pouch technology and its various aspects can be explained under the following headings [69]: (i) films—for a temperature range of 116 to 124°C, 9- to 25-micron polyester/9- to 25-micron foil/75-micron polyolefin (modified polyethylene or ethylene-propylene copolymers and blends) can be used. For temperatures up to 138°C, 12-micron polyester/9-micron foil/15-micron oriented nylon-6/50-micron polypropylene shall be used. (ii) Products—over 100, ranging from commodity vegetables to "ready meals." (ii) Package design—flat four seal, ranging from 10 to 100 mm × 5 mm to 175 mm × 20 mm for 150 to 300 g (5 to 10 oz) contents to 300 mm × 450 mm × 25 to 12 mm for institutional packs, for 2.5–3.5 kg (5–7 lb) contents, with folding carton or polymer bag over wrap. (iv) Pouch packaging equipment—from roll stock, intermittent motion packager for 25 to 60 pouches per minute with steam flush and closure sealing, or could incorporate in-line vacuum sealing without transfer to separate machine. From roll stock, continuous motion packager for 250 pouches per minute. From preformed pouches, filler-sealers for 25–60 per minute, can with squeezing action or steam flush for air removal. (v) Retorts—horizontal batch, water or steam-air cook, modified to assure uniform distribution of heating media; use of retort racks, with separate heating media accumulation tank; suitable for high-temperature (135°C) cooks. Continuous horizontal or vertical retorts for water or steam-air can also be used. (vi) Cartoning—standard folding carton equipment.

36.4.8 Energy Aspects of Canning

Energy analysis of the operation of the food sterilization unit is useful in two respects: first, it provides quantitative information on energy requirements of use in designing the energy generating and delivery system, and second, it evaluates the modes of energy loss. Information obtained from the energy analysis can be used for quantifying energy conservation practices [70]. Energy required for manufacturing, transporting, and processing were estimated for two alternative systems (canning line, and retort pouch line), each capable of producing about 45 metric tons of processed spinach per 8-hour shift.

The following conclusions can be drawn: (i) Container manufacturing required more than 80% of the energy required in each system. (ii) A pouch processing line will have much higher electrical requirements than a comparable canning line. However, costs associated with electrical use are small compared to total costs. (iii) The total energy requirement for a retort pouch packaging system is significantly less than that for a can packaging system. (iv) Container and energy costs for a retort pouch packaging system are significantly lower than those for a comparable can packaging system. (v) A comprehensive economic analysis must be conducted before a decision to adopt retort pouch processing technology can be made.

A dominant factor influencing total energy use in the canning industry is the heat requirements of food sterilization. The continuous cookers used in canneries are typically more energy-efficient than batch processing in retorts [71]. Energy consumption rates in operating various sterilizing equipment have been compared. The energy requirements of a rotary pressure retort, a rotary atmospheric retort, and a flame sterilizer were estimated, and the overall heating efficiency was 47.7%, 31.2%, and 27.5%, respectively [72]. The comparative costs of the heat required for sterilization of canned products by different equipment (Table 36.2) have been reported. The thermal energy balance of a stationary retort was studied [73]. Only 16.7% of the steam supplied was used in heating the cans and contents, and the remainder was lost during venting (36.4%), heating of the retort and crates (16.4%), along with the condensate in the bottom of the retort (11.2%) and through radiation (19.3%). The study indicates significant loss of steam

TABLE 36.2
Energy Costs Required for Thermal Processing of Canned Foods by Different Equipment

Processing Equipment	Comparative Costs of Heat		
Static retort	100[a]	100[b]	100[c]
Continuous rotary atmospheric retort	------	-------	64
Continuous rotary pressure retort	------	-------	46
Hydrostatic retort	20	56	------
Fluidized-bed retort	------	38	------
Microwave retort	1230	-------	------
Flame sterilization	56	-------	88

a = values in this column from ref. 103
b = values in this column from ref. 74
c = values in this column from ref. 72

during venting. Data from different canneries showed steam consumption to be quite consistent for the retorting operations, averaging 3 kg/min of steam per 24 No.2 cans. During venting, the peak of steam consumption may vary between 1135 and 2720 kg/h for a standard 3–4 crate retort, depending upon the size of the steam inlet line. The peak demand drops off to an operating demand of 45 to 68 kg/h after the vent valve is closed and the retort reaches operating temperature. A novel fluidized-bed retort [74, 75] involves heating and cooling of cans in a fluidized bed of sand or other granular material of high density. Fuel savings can be significant with a fluidized-bed retort. This is because the heating medium (usually air) does not go through a phase change and recycling of the heating medium improves the energy efficiency of the equipment.

36.5 ASEPTIC PROCESSING

36.5.1 Introduction

The development of the HTST processing methods for sterilizing in a continuous flow has brought about the need for aseptic packaging of the product. It is only through the use of aseptic packaging that the benefits of HTST treatment can be fully realized. Aseptic packaging will exhibit the greatest quality improvement over conventional canning when viscous low-acid products are processed. Many products can be commercially sterilized prior to packaging by continuous processes so that their organoleptic and nutritional quality is not significantly affected. Products such as puddings, sauces, dips, and pastes are currently aseptically processed. In the techniques applied to aseptic packaging, continuous heat exchangers can be designed so that any temperature profile may be applied. Aseptic packaging of foods is a process which enables products, sterilized in bulk or on-steam, to be filled and sealed into sterile containers under aseptic conditions. There are two reasons for its use: (i) to enable containers to be used that are unsuitable for in-package sterilization, and (ii) to take advantage of high-temperature-short-time (HTST) sterilization processes, which are thermally efficient and generally give rise to products superior in quality to those processed at lower temperatures for longer times [76].

Application of the aseptic process involves (i) sterilization of the product, (ii) sterilization of the packaging material, and (iii) maintenance of the sterility during the filling and sealing operations. The advantages of aseptic packaging of food products are that it provides a higher quality product; a wide variety of packaging materials of different sizes and shapes can be used; and there is minimum handling of the containers during the sterilization process. Also, it provides a high surface area for efficient heat transfer [77]. Aseptic processing and packaging, however, has limitations, and it does not offer advantages with all products. Some of the disadvantages that are generally cited are large capital investment, applicability to limited range of products, and requirement of relative homogeneity of the fluid and need for sophisticated instrumentation [77].

36.5.2 Sterilization Systems

The production of a sterile product by continuous flow sterilization involves (i) heating the product by passing it through a suitable heat exchanger to raise it to operating temperature, (ii) passing the product through a holding section for a predetermined time to effect sterilization, and (iii) cooling it to a temperature of 35°C or less prior to aseptic filling. The heat exchange process is limited to liquids containing small particles with a cross-section of less than about 8 millimeters. For sterilization of large pieces, special equipment is required [78, 79]. The ideal system would raise the temperature in the heat exchanger to the required value, thus eliminating the holder tube requirement. It is not possible to use a sufficiently high temperature and short residence time for this purpose with many products since (i) viscous products are difficult to heat uniformly and evenly to the operating temperature, (ii) the presence of small particles makes it desirable to impose an unheated section in order to equilibrate temperatures, (iii) the products may contain heat-resistant enzymes, which are more likely to survive processes at the top end of the temperature range, and (iv) the criticality of the process makes control difficult. The key components of the aseptic systems are the timing or metering pump, product heater, holding tube, cooler, and back-pressure valve which are characteristic of practically all aseptic processing systems. The type of aseptic processing equipment selected is basically dependent on the pH, the viscosity or consistency of the product, and on whether it contains particulate and their size.

36.5.3 Processing Equipment

36.5.3.1 Infusion Sterilization

36.5.3.1.1 Steam Injection Sterilization

This is the most rapid method of heating the product, facilitating the attainment of sterilization temperature within seconds. Combined with the rapid method of cooling by injection of the hot product into a vacuum chamber and evaporation of

an equivalent amount of water, a very high-quality product is obtained. The method is combined usually with heating and cooling in heat exchangers to the low temperature range (80°C) [80].

36.5.3.1.2 Liquid Infusion into Steam

This system involves infusion of a thin film of liquid into a steam atmosphere, facilitating rapid heating. Cooling is also achieved by infusion of the liquid into a vacuum chamber. The system is a versatile processing method designed primarily to heat and cool fluid foods within seconds. It produces the fastest heating methods, and this minimizes the flavor changes and product damage normally associated with high processing temperatures. It is especially important for low-acid products that require sterilizing up to 150°C. The system may be pre-piped and packaged or field-assembled to meet specific plant space requirements. Acquisition costs for infusion heating systems are low when high flow rates are being processed. There are few moving parts, and service costs are low. However, the method is suitable for particle-free liquids only. The heat recovery efficiency is only about 50%.

36.5.3.2 Tubular Aseptic Sterilizer

Tubular aseptic sterilizing is an indirect heating/cooling method that uses stainless-steel coiled or straight tubular heat exchangers. The tubing diameter is relatively small compared to product flow. As a result, extremely high flow velocities within the tubing maximize turbulence. High turbulence induces rapid heat transfer [20, 80]. The tubing diameter is suited to the product flow and viscosity. Tubes are fabricated into coils or bundles and placed, along with special media baffles, into stainless-steel jackets. Hot water, steam, or cold water passes through these jackets to heat or cool the product flowing within the tubes. A series of horizontal tubular heat exchangers and a vertical holder tube heat and hold the product at the required sterilizing temperature and time. For low-acid products, 150°C with a holding time of 2–4 seconds is used. High-acid product would normally be heated to around 95°C and held for approximately 30 seconds. From the holding tube the product flows to another series of vertical tubular heat exchangers for cooling. This system provides high heat-transfer rates and a scrubbing action that reduces "burn off" or fouling in the tubes, resulting in a very short processing time. This helps to preserve the natural flavor of the product. The system has considerable flexibility in the range of products it can handle and the temperature range at which a specific product is processed. They are completely self-contained requiring only product and utility hook-ups to be made during installation. There are no gaskets to replace on the high temperature side. Most systems are available with regeneration as an option. Regeneration may be as high as 85% depending on flow rates, product characteristics, and regeneration option used.

36.5.3.3 Swept Surface Sterilizer

This type of heat exchanger is similar to a tube heat exchanger but is provided with a central rotating shaft carrying a scraping device for the heated surfaces. This prevents burning and fouling of foods at the surface and also provides a mixing action. The system is used when a viscous material or one containing small, discrete particles is to be processed. Swept surface sterilizing is an indirect heating/cooling method. With the continual removal of product from the cylinder wall the product film is reduced to an absolute minimum, permitting long processing runs without product build-up on the heat exchanger wall [80]. Heat-sensitive products can be processed, and the system is versatile for aseptic processing of different products. Products can be processed over a broad temperature range and viscosity with or without particulate. The various horizontal and vertical configurations allow this form of heat exchanger to be adapted to specific systems or plant requirements. It may be used in series with other types of heat exchangers for products such as starches that might increase in viscosity due to processing.

36.5.3.4 Plate Sterilizer

A plate heat exchanger (described in the pasteurization section) can also be used for aseptic processing.

36.5.4 Packaging Systems

Aseptic packaging refers to the filling of a cold commercially sterile product under sterile conditions into a pre-sterilized container and closure under sterile conditions to form a seal that effectively excludes microorganisms. Aseptic literally means the exclusion of microorganisms from the environment. Aseptic processing is really a method of packaging because foods are not sterilized or cooked or otherwise altered by aseptic methods. Rather, they are handled or moved by aseptic methods to assure they retain the microbiological quality with which they started. In general, aseptic packaging is coupled with HTST or UHT methods of food sterilization, and the two processes are joined in a complete system to produce what are referred to in the trade as aseptically processed foods. However, the total aseptic equipment is not an actual integrated system, and the processor must purchase the sterilizer and the aseptic packager as separate units and then tie them together.

36.5.4.1 Sterilization of Packaging Materials

Package sterilization has been accomplished by using a number of methods and their combinations [81]. The most common methods are based on the use of (i) a super-heated system; (ii) hot, dry air; (iii) hydrogen peroxide; (iv) a combination of hydrogen peroxide and ultraviolet light; (v) a combination of hydrogen peroxide and heat; (vi) heat of the co-extrusion process; and (vii) irradiation by gamma rays. These methods are given in Table 36.3 [82].

36.5.4.1.1 Super-Heated Steam Systems

In this system, sterilization of the container and its closure is accomplished by the application of heat using superheated steam. The advantage of this system is that it can achieve high temperatures at atmospheric pressure; however

TABLE 36.3
Methods for Sterilizing Aseptic Packages

Method	Application	Advantages/Disadvantages
Superheated steam	Metal containers	High temperature at atmospheric pressure; microorganisms are more resistant than in saturated steam
Dry hot air	Metal or composite juice and beverages containers	High temperature at atmospheric pressure; microorganisms are more resistant than in saturated steam
Hot hydrogen peroxide	Plastic containers, laminated foil	Fast and efficient method
Hydrogen peroxide/UV	Plastic containers (preformed cartons)	UV increases effectiveness of hydrogen peroxide
Ethylene oxide	Glass and plastic containers	Cannot be used where chlorides are present or where residue would remain
Heat from co-extrusion process	Plastic containers	No chemicals used
Radiation	Heat-sensitive plastic containers	Can be used to sterilize heat-sensitive packaging materials; expensive; problems with location of radiation source

microorganisms are more resistant to super-heated steam than saturated steam.

36.5.4.1.2 Dry Hot Air Systems

Hot air sterilization has similar advantages and disadvantages as super-heated steam. There are currently no units of this type utilized in the production of low-acid foods, but the equipment has been used for the production of juice and beverages.

36.5.4.1.3 Hydrogen Peroxide Systems

A number of systems utilize hydrogen peroxide in combination with heat and/or other adjuncts. In this system, the packaging material is not metal and it comes in rolls rather than in preformed containers. The system also utilizes a different sterilizing medium. The rolls are continuously fed into a vertical machine which sterilizes, forms, fills, and seals the package. Sterilization is accomplished with a combination of hydrogen peroxide and heat. The heat necessary for sterilization may be obtained by a heated stainless-steel drum. Contact with the drum heats the peroxide and effects sterilization. Another system uses packaging material from rolls that are continuously fed into the machine which forms, fills, and seals the package. The packaging material travels through a bath of hot hydrogen peroxide which softens the material for forming. Cups are then formed, filled, and sealed with lids which also traveled through a hydrogen peroxide bath. Another system utilizes preformed cups to which a lid foil is heat-sealed after filling. The cups are fed into the machine where they are sterilized by the peroxide spray followed by heating. The lid material is sterilized by being passed through a peroxide bath. All filling and sealing are done in a chamber that is kept sterile by maintaining a positive pressure with filtered sterilized air. Another system that utilizes preformed cartons sprays the inside of the carton with low-concentration hydrogen peroxide. This sprayed carton then passes under a UV light source which acts synergistically with hydrogen peroxide in destroying microorganisms. Results of tests, using suspension of microorganisms, have shown this combination to be very effective.

36.5.4.1.4 System Utilizing Heat of Extrusion Process for Sterilization

This is a form-fill seal packaging system and relies on the temperature reached by thermoplastic resin, during the co-extrusion process used to produce multi-layer packaging material, to produce a sterile product surface. During production, the multilayer package material is fed into the machine where it is delaminated under sterile conditions. This removes a layer of material and exposes the sterile product-contact surface. The container material is then thermoformed into cups. The lid material which is also delaminated is then sealed onto the cup after filling. The sterility of the forming, filling, and sealing areas is maintained by sterile air under positive pressure.

36.5.4.2 Aseptic Filling and Packaging Machines

Aseptic filling and packaging systems can be classified into categories based on the type of packaging material and the method of forming the container (Table 36.4) [83].

36.5.4.2.1 Form/Fill/Seal Machine for Pouches

Figure 36.8 shows the principle of operation of an aseptic vertical form/fill/seal machine for three-sided sealed pouches [84]. The packaging material from reel, usually a complex multilayer material, is sterilized by hydrogen peroxide in a heated bath, which is the siphon lock to a sterile chamber with a slight overpressure of sterile air. In this chamber the film is dried, folded over a shoulder to form a tube, and sealed at the long seam. Then the tube, which is closed at the bottom by the cross seal, may be drawn to the non-sterile exterior of the chamber through a tightly fitting flexible lock. Sterile filling inside the chamber is performed using sine filler. In the tube, the contents are protected by a neutral atmosphere of sterile nitrogen, which maintains a very low oxygen concentration in the headspace of the packs. Grippers spread the sealing zones and vertically reciprocating sealing bars with cutting knives outside the sterile cabinet transport down, seal, and cut off the pouches. The pack output is 15–35 pouches/min, depending on size. Products that are, at present, filled by these machines include various tomato products, and sauces such as cheese sauce and pizza sauce with particulate. Meal constituents and curries could also be filled [85]. The filling system has CIP and SIP characteristics. Pre-sterilization of the filling system with pressurized steam and of the sterile chamber of the machine by condensed hydrogen peroxide vapors, and also heated air, is performed automatically.

TABLE 36.4
Classification of Aseptic Filling and Packaging Systems

Category	Examples of Systems
I. Metal and rigid containers sterilized by heat	
A. Steam/metal containers	Dole canning systems
	Drum fillers, e.g., scholle, FranRica
B. Hot air/composite can	Dole hot air system
II. Webfed paperboard sterilized by hydrogen peroxide	Tetra Pak (BrikPak)
	International paper
III. Preformed paperboard containers	Combibloc
	Liquipak
IV. Preformed, rigid/plastic containers	Metalbox Freshfill
	Gasti
	Crosscheck
V. Thermoform–fill–seal	Benco Asepack
	Bosch Servac
	Connoffast
	Thermoforming USA
VI. Flexible plastic containers	
A. Bag-in-box type	Scholle
	Liquibox
B. Pouches	Asepack
	Prepac
	Prodopak
	Inpaco
	Bottlepack
C. Blow molded	Serac
	ALP

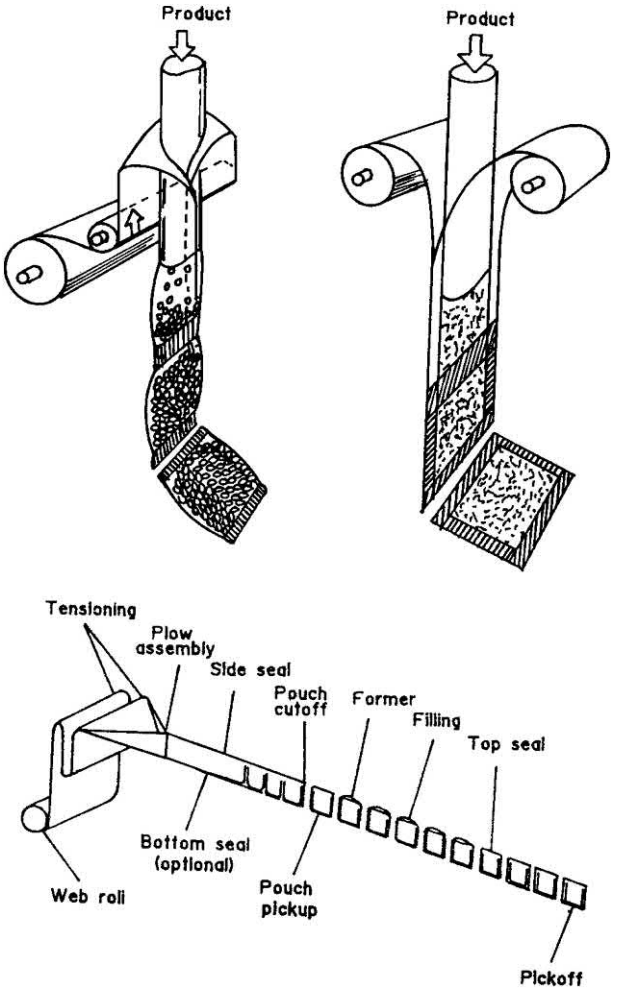

FIGURE 36.8 Form/fill/seal machines. (From Potter and Hotchkirs [84].)

36.5.4.2.2 Thermoform/Fill/Seal Machine for Cups and Trays

Film for both the cups and trays and the lid are drawn from rolls and transported into the totally closed sterile cabinet through a heated hydrogen peroxide bath. The lower film is heated locally, thermoformed with plug assistance by pressurized sterile air, and the formed packs are then filled. Filling is performed by special piston filler with reciprocating valves having cutting edges. This filler is able to deposit mixtures with particulate of a few millimeters in size. The shafts of the sliding valves and pistons penetrate the vessel for the product that has to be filled. At the mechanical drive external non-sterile air is separated from the sterile air above the product by rolling diaphragms. After filling, the lid is applied to the filled web and sealed at the rims. Headspace gas flushing may be performed. Now the webs may be transported to the non-sterile outside through a contour lock without risk of infection, where the final sealing of the packs, notching, and cutting are carried out [85].

36.5.4.2.3 Filling and Closing Line for Bottles and Jars

The containers, which are pre-cleaned and heated by a special rinser, enter the sterilizing machine in one lane, and they are sterilized in several lanes upside down, by treating inside and outside with hydrogen peroxide vapors and then drying with sterile air. The containers are inverted and transported intermittently to the piston filler. In the next stage the containers are closed with metal caps, which were sterilized with pressurized steam upon entering the machine. For liquid products, magnetic-inductive metering devices are used for filling. For plastic bottles heat-seal closures from foil are applied [85].

36.5.4.2.4 The Tetra Pak System

The principle of this system is to take the packaging material directly from the reel and to form it continuously into a tube. The tube is sealed below before filling and above after filling. The main advantage of this pack is that there is no headspace in the finished pack. The pre-creased web of packaging material unwinds over rollers, which soften the transverse crease. The web is immersed in hydrogen peroxide bath for sterilization. The packaging material is a lamination made of pare, foil, and polyethylene. This combination gives a light and gas barrier, strength, and heat-sealing properties [20, 76]

36.5.4.2.5 Conoffast System—Continental Can Co.

The system employs prefabricated and sealed pouches that may be internally sterilized by any one of four methods.

Empty pouches are fed through an ultraviolet chamber to minimize external pouch contamination and then filled using hypodermic needles in a superheated steam atmosphere. The needle is withdrawn, and the puncture area is heat sealed. Ionizing radiation has been suggested to sterilize the pouch material surfaces. Steam pressure sterilization restricts the packaging materials to those which can resist the temperatures. To sterilize the filling and sealing area and to sterilize the needle, superheated steam at 145°C can be used [20, 76]. The Conoffast system also utilizes the basic package forming–filling–sealing system. Sterilization of the inside of the package in this system is based on the high temperatures generated within the thermoplastic resins during the extrusion process used to produce the multi-laminated packaging material. During the aseptic packaging operation, the top plastic sheet is delaminated, exposing a sterile surface of the packaging material to the food in a sterile environment within the Conoffast unit. Before filling, the packaging material is thermoformed into cup-shaped containers. Sterile food product is filled into the package under sterile conditions. Then the packages are sealed with packaging material from which one layer has been delaminated, again exposing a sterile surface to contact with the food. Sterility during the forming, filling, and sealing operations is maintained by performing these operations in a sterile environment under positive pressure.

36.5.4.2.6 The Combibloc System

In this system premade carton blanks are used, which are die-cut, creased, side-seamed, and printed at the factory origin. This facilitates a more perfect flame-welded seam, thus ensuring good integrity of the seal, and the packaging machinery can handle different sizes with a simple height adjustment. A carton blank is drawn from the magazine by suction pads and placed on a mandrel. The sealing surface at the bottom of the carton is softened by hot air. The bottom is folded, pressed, and sealed against the end face of the mandrel. The top is pre-folded and then passed on to the aseptic zone where it is sterilized by hydrogen peroxide spray. After filling, the package top is folded and sealed by ultrasonic welding [76].

36.5.4.2.7 The International Paper System

In this system the packaging material is taken from a reel. From the reel the web passes through a series of scoring rollers into a hydrogen peroxide bath for sterilization. The horizontal seals are made by alternating jaws and an induction heater. Individual packages move to the final folding and sealing station for sealing of top and bottom flaps [76].

36.5.4.2.8 The Gasti System

This system operates with preformed cups made of plastic or aluminum. This facilitates greater flexibility in the operation and allows container quality to be approved in advance. In operation, preformed cups are dispensed from a magazine and are sterilized using hydrogen peroxide vapor. The cups are then filled in the sterile section and are sealed with presterilized lids [76].

36.5.4.2.9 The Liqui-Pak System

This system uses a combination of two sterilizing methods to obtain aseptic packages viz. hydrogen peroxide and ultraviolet light. This approach has a synergistic effect which results in a more effective bactericidal action than high concentrations of hydrogen peroxide and ultraviolet light used individually. The cartons travel through the sterile area against a flow of filtered air. The filler is unique with a plastic bellows mechanism for sterile dispensing of the product. After filling, the gable-carton is heat-sealed in a conventional manner [76].

36.5.4.2.10 The Metal Box "FreshFill" System

This system uses preformed cups sterilized by hydrogen peroxide. The product is filled by a multi-head filler, with the filling chamber isolated from other machines areas by sterile air overpressure generated by an ultrafilter. The filled cups are sealed using a pre-sterilized foil material and stamped out in the conventional manner. Before start-up, the filling chamber, fillers, and supply line are sterilized with steam at 130°C for 20 minutes [76].

36.5.4.2.11 Avoset System

This system packs fluid products in glass and cans and then in aerosol containers. The system sterilizes containers and product separately and brings them together in a sterile environment. The entire piece of equipment is placed in a controlled environment, and all critical elements are sterilized. An operator is present to monitor the equipment. Although sterility is assured, distribution under refrigeration to retard biochemical changes is generally recommended [20, 76, 86].

36.5.4.2.12 Manton-Gaulin (Pet Inc.)

The system is basically a glove box. Polyethylene bags are sterilized in the glove box with an ethylene oxide mixture and are heated to 49°C for 6 hours. After sterilization, the gas is replaced by sterile air. Sterile mix is aseptically pumped to the filing nozzle within the glove box. Using glove box techniques, the operator fills one bag at a time through the rigid spout. The spout is heat sealed with a laminated foil material. The filled bag leaves the glove box through a chlorinated water trap and is dried outside of the aseptic filling area [20, 76]. A Scholle container with a semi-automatic aseptic system for filling 6-gallon polyethylene bags has been used. Sterile conditions are maintained by pressurized sterilized air and a continuous spray-mist of chlorine solution over a hinged-cap fitment on the bag during filling.

36.5.5 Quality of Aseptically Processed Foods

The basic consideration for sterilizing at high temperatures for a short time is that for each 10°C (18°F) increment in temperature, the sterilization required for destruction of bacteria is reduced by a factor of ten, while the rate of destruction of nutrients and of other chemical reactions affecting product color and flavor increases by a factor of approximately three. This is called the "z" value. /The higher the sterilization temperature, the larger the difference between rates of

destruction of reactions. This is the concept upon which the most important advantages of aseptic processing and packaging systems are based. Because of this the organoleptic and nutritive characteristics of the products processed by aseptic processing systems are retained as compared to those processed by other systems, such as conventional canning [87]. Chemical and flavor changes during high-temperature heating are particularly severe in low-acid foods, which require more severe heat treatment to be sterile. At higher processing temperatures, bacterial spore destruction is much faster than the destruction of food constituents. Foods processed by aseptic processing are better in color and higher in thiamin than those made by conventional canning processes. Aseptic processing is used commercially in the dairy industry and to fill fruit juices and purees, pea soups, sauces, tomato paste, etc.

The effect of HTST sterilization on the nutritive value of meat products has been a subject of great interest. Protein quality may be degraded by the destruction of one or more of the essential amino acids, formation of inter- and intramolecular bonds resistant to digestive enzymes, and alteration in the rate at which the various amino acids are released from protein. This results in a mixture of amino acids that may be less efficient for metabolism and assimilation. The essential amino acids tryptophan, methionine, and lysine are also destroyed by HTST sterilization. Destruction of methionine and accumulation of sulfur dioxide are the main chemical indices of the effect of cooking meat proteins at 120–150°C. Protein denaturation is not the only change that occurs during heat processing. Hydrolysis of proteins and polypeptides also takes place. Collagen, elastin, and reticulin compose the connective tissue of meat and are insoluble in water and salt solutions. Collagen is transformed by heating into soluble gelatin. In this conversion, some of the crosslinks are broken, resulting in shortening and disorganization of the protein chains. The conversion also accounts for higher protein solubility in the processed meat products. Aseptic strained meat has been shown to be more nutritious and higher in thiamin retention. Aseptically processed meat and vegetable products lose thiamin and pyridoxine, but other vitamins are largely unaffected. There are negligible vitamin losses in aseptically processed milk, and lipids, carbohydrates, and minerals are virtually unaffected. Riboflavin, thiamin, pantothenic acid, biotin, nicotinic acid, and vitamins B_6 and B_{12} are unaffected. Nutrient losses also occur during periods of prolonged storage, and these should also be considered when assessing the importance of sterilized foods in the diet.

36.5.6 Nutritional Aspects of Aseptically Processed Foods

The use of HTST processes is particularly adaptable to aseptic processing. The destruction of nutrients during the thermal processing is dependent on (i) time–temperature treatment used as the basis of the process and (ii) the rate of heat transfer into the product. In an aseptic processing system, as the processing temperature is about 150°C for a very short period, the nutrient retention is greatly enhanced. The effects of heat treatments of equal microbial lethality on selected food constituents including nutrients, color, proteins, and flavor compounds have been reported [88]. The retention of vitamin C in tomato juice improves during HTST processing. For natural products containing enzymes the limitation of the benefits of HTST processing occurs when the basis of the process shifts from microbes to enzymes at a temperature of 130 to 145°C for shorter periods.

In an evaluation of HTST aseptic processing [89] it was found that thiamin retention was significantly greater in HTST products than conventionally canned and retorted products. For pyridoxine, the benefit of HTST was not as evident, as destruction of pyridoxine is not as temperature-dependent as that of thiamin. HTST aseptic processing also results in significant improvements in organoleptic qualities [90]. Most of the reports on the effect of thermal processing on nutrients only contain information on the content of a specific nutrient after the thermal process and give the percentage retention or loss of the nutrient. As there are numerous processing methods and time–temperature possibilities for accomplishing commercial sterilization, it is improper to assume that the nutrient losses reported in the literature represent the average or norm for the industry. Hence, the data on such nutrient losses are of limited value but can be used as a guideline for selecting an optimum process schedule [90]. Nutrient losses range from 0 to 90%, depending on the nutrient and the product. These losses represent the sum of the losses during the entire processing including blanching. In some of the studies [91–93], the temperature for sterilization of foods has been optimized to maximize retention of nutrients or minimize the production of an undesirable product.

36.5.7 Packaging of Aseptically Processed Foods

36.5.7.1 Introduction

Packaging of aseptically processed food is the most critical key for a successful operation. The product has to be packaged in the form desired, which will yield the benefits anticipated after the product has been sterilized. This includes process design, process equipment, formulation, and raw material quality. Besides the machinery used, the materials used for the container and the closure and the sterilants that can be used with these materials are important. The aseptic packaging system must be capable of filling the product produced by the UHT or HTST system in an aseptic manner and sealing the container hermetically so that sterility is maintained throughout the handling and distribution process. Thus, the system must be capable of (i) being connected to the processing system in a manner that enables aseptic transfer of product to take place, (ii) being effectively sterilized before use, (iii) carrying out the filling, sealing, and critical transfer operations in a "sterile" environment, and (iv) being cleaned properly after use. The packages in use vary from traditional tinplate cans and glass bottles to the non-rigid and semi-rigid containers based on thermoplastics or combinations of thermoplastics with paperboard and metal. The type of container used will be influenced by the nature of the contents, cost,

and its acceptability to the consumer. The relatively low cost and wide acceptance by the consumer are the main reasons for the recent proliferation in the use of the carton-type packs for fruit juice, juice-based beverages, and dairy products. In addition to systems producing packages intended for sale directly to the public, bulk packaging installations are used for conserving raw materials or intermediates intended for reprocessing or for use in catering establishments.

Many systems have been proposed for the aseptic packaging of food, but some authorities consider that not all those proposed meet the criteria for full asepsis. Thus, they should be more accurately described as ultra-clean fill machines and used as a means of extending the shelf life of products distributed through the chill chain. Some systems, by their nature, restrict the packaging material to simple monolayer plastics, and many foods packaged in these materials have a limited shelf life due to their poor oxygen barrier characteristics. Others are able to employ multilayered barrier plastics or to include aluminum foil as a component, and in such cases, shelf life is much improved. Containers made from glass or metal of adequate thickness may be considered impermeable [76]. The method of sterilizing the package, or material from which it is formed, is important in retaining the characteristics of the packaging material. Sterilizing processes may alter the characteristics of the package, or material, and render it undesirable for packaging the food product. Obviously, the material must perform and produce the results desired. Some of the factors that should be considered include (i) performance with the food (gas transmission, water transmission, absorbance—packaged product flavors, odors, colors, and vitamins being absorbed by the container material, adsorbance—a few molecules being extracted from the package material and being held by the product, combinations of absorbency and adsorbancy, chemical inertness to the food, or desirable reactions with the food, sterilization, wet ability, temperature limitations, and inertness to the sterilizing agents, can could be laminated or special surfaces applied, material handling characteristics (empty)), (ii) cost, (iii) form and mechanical characteristics (can it be molded, size limitations, shape limitations, easy-to-open closures available, temper-proof closures or temper-evident systems available, configuration after storage, material handling characteristics and suitability for use with conveyors, labelers, casers, and over cappers), (iv) shipping and handling (toughness or strength, type of over wrap or cases required, fillers between packages in the cases required), and (v) compliance with regulations (Food safety FDA, FSIS, 3A, PMO etc.,) [94].

The materials that are used for aseptic packages are practically infinite. This is because the use of laminated materials, using plastics as well as metals, and the development of new plastic materials and alloys, occurs regularly. There are also variations within a defined product so it may vary from different manufactures, even though generally it is the same. For example, paper from a supplier may vary from paper that comes from another vendor. The same is true for metals such as steels and aluminum, plastics, and laminates, etc.; these variances can cause the product to change over a short or long period of time. Some of the common materials used for aseptic packages include the following: (i) stainless steel (bins, tanks, and rail cars), (ii) carbon steel (cans and closures), (iii) aluminum (cans and closures), and (iv) plastics (cups and square/rectangular packages) (acetal, nylons (66 or others), polypropylene, polyester, polycarbonate, acrylic, acrylonitrile-butadiene-styrene (ABS), polyvinyl chloride (PVC), polystyrene, high-density polyethylene, low-density polypropylene, ethyl vinyl acetate (EVAL), ethyl vinyl alcohol (EVOH), polyvinylidene chloride (PVDC), paper, paper-based laminates, plastic-based laminates) [94].

It should be taken into consideration that new materials are constantly being proposed for approval by the FDA for aseptic packages with specified types of sterilants. Also, certain laminates that exist today are made in a single polymer form; hence, a resin may contain three or four different polymers that have combined properties. The reason for manufacturing laminates out of various materials is to build in to the packaging material(s) those properties that are most critical for the food product over a period of time (which may be short, medium, or long), and it will be either inert to the product or react with it in a favorable way, such as tin cans reacting with citrus juices. The problem of the food product compatibility with container materials over a period of time should be briefly addressed. This is an area that has not received the attention it should have from packaging manufacturers or food processors.

Materials can absorb desirable components from the food, thereby causing the food to have less flavor, color, odor, and nutrients. Another condition that exists is that the packaging materials can actually have certain molecules stripped from it, thereby changing food product's color, flavor, odor, and vitamin content. Also, there are combinations of the two where the material used for packaging reacts with the food to change its properties, and in turn the food reacts with the packaging material and loses some of its desirable characteristics. This situation is never ending and may actually accelerate as color changes occur [94].

36.5.7.2 Aseptic Packaging

In general, aseptic packaging is coupled with HTST/UHT methods of food sterilization, and the two processes are joined in a complete integrated system to produce aseptically processed foods.

36.5.7.2.1 Drums

The drum is placed under the filling chamber and then raised up to seal against a gasket. Saturated steam is introduced into the drum, and the interior of the drum is pressurized with steam. After a total 2.5-minute cycle, a filling tube lowers into the drum and dispenses sterile product to fill the drum. The filling tube retracts, and a sealing head with magnetically attached lid swings over the drum. Steam pressure is employed to apply pressure to crimping jaws to fix the gasketed lid into place. Alternatively, an empty drum and cover are placed in a filling retort, and both are steam sterilized under pressure. Sterile product is then filled into the drum,

and the lid is placed. The drum is removed, and another cycle is initiated. The capacity of the system with two filling retorts is 24 drums per hour [20, 95]. The advantages claimed of the drum system are lowered shipping weight because one large reusable container is used rather than 75 No.10 cans plus 12 to 13 corrugated cases, product recovery is higher because there is far less surface area to drain, And further, the labor cost of emptying one 200 L container is significantly lower than the cost of opening 75 cans.

36.5.7.2.2 Tanks

Instead of pulping, finishing, and concentrating into paste for bulk handling, tomatoes are simply chopped, sterilized, and filled aseptically into 380 L (100-gallon) tanks. Tomatoes are washed, chopped into chunks, heated in tubular heaters, cooled, deaerated, and subsequently filled into tanks under a nitrogen blanket. Storage tanks are galvanized steel, lined with a baked-on epoxy coating. Tanks are chemically sterilized before filling [20]. The basic objective is to provide tomato processors with a large source of raw material that can be converted into many different products over a long period. Among the products that can be made from chopped tomatoes are paste, puree, sauce, catsup, pizza sauce, juice, and chili sauce.

36.5.7.2.3 Glass Containers

Aseptic packaging in glass containers has not been broadly successful on a commercial basis. Juice is heated to 93°C and held for 9 seconds and cooled to 20°C in a heat exchanger. Bottles of 1 and 2 L are cleaned by rinsing with water. After washing, bottles are discharged into a closed area blanketed with 99.9% sterile, dehumidified air. The filler is sterilized with boiling water prior to operation. Closures are steam sterilized and taken into the cleanroom. Sterile juice is filled into the "sterilized jars" and capped in the clean area. The product, known as aseptic cold-pack juice, is reported to have a long shelf life under 10°C [20]. At room temperature storage, hot-filled (conventional) juice has an acceptable shelf life of one month as compared to three months for cold-filled juice. The basic problem with glass is that the maximum temperature differential glass containers can withstand is approximately 15°C. Thermal shock between inner and outer surfaces leads to unequal thermal expansion sufficient to crack the glass.

36.5.7.2.4 Plastic Containers

The concept of aseptic packaging holds that pre-sterilized product is filled under aseptic conditions into a pre-sterilized container. As long as the container can exclude microorganisms and prevent the passage of gas, the container material need not be rigid. Metal in heavy gages and glass are both fabricated into rigid containers. There are no rigid plastics that are employed commercially for sterile packaging. All plastic materials are partially permeable to moisture and gas. Because of implied low strength characteristics, food products that have been sterilized are packaged in semi-rigid materials. Paperboard with appropriate coatings is also utilized to form semi-rigid packages [20]. Two basic types of semi-rigid systems are in commercial use: (i) thermoform, fill, and seal, and (ii) preformed cups, fill, seal [20].

36.5.7.2.5 Flexible Packages

The Tetra Pak AB system is often considered as a flexible packaging system. Technically, it is not a flexible packaging system because it is made of paperboard rather than a true flexible material. The polyethylene pouching material is sterilized using a hydrogen peroxide bath. The vertical form, fill, and seal milk pouching equipment is converted for aseptic packaging [96].

36.5.7.2.6 Reclosable Aseptic Packaging System

Reclosing is useful for products such as milk, fruit juice, and wine. Shaking is important for products such as pulpy fruit juices. The system consists of a closure with two parts. The visible part is a rectangular polypropene chassis with a cap that snaps open and shut on a hinge. The device is glued to the top corner surface of the pack with hot-melt adhesive [97]. Underneath the cap is the second part of the system—an aluminum pull tab that covers the pouring hole and provides good tamper evidence. The pull tab, which is welded to the inner liner of the package, is easy to peel off. It reveals a long, pear-shaped hole that has excellent pouring characteristics. The reclosing system is extremely sanitary, unlike "punch" style cap devices that require users to poke a finger into the product in order to open the package. High-quality long-life product is achieved by the aseptic filling process. This package provides easy stackability, space saving in terms of transportation (both filled and unfilled cartons), low weight, cost savings in carton material production, and a high level of environmental friendliness. The reclosable system increases the intrinsic value of the carton and provides the consumer with easy opening, spill-free pouring, and reliable reclosure as well as hygienic handling. After reclosure, the product is protected and can be shaken as necessary. The product quality remains unimpaired, protected from foreign flavors. The carton with the system fitted is ideal for refrigerator storage. The new carton image is completed by the slim, elegant shape suggestive of high quality.

36.5.8 Energy Aspects of Aseptic Processing

Energy aspects of aseptic processing have been widely carried out on milk, and most of the data available are on milk products. The energy requirements of aseptic processing units containing steam injection without regeneration, and tube heat exchangers as applied to the processing of milk have been evaluated. For steam infusion the system consumed about 1000 kJ/kg of milk [98]. For tube heat exchanger the system consumed about 400 kJ/kg milk [99]. The total energy requirement in the HTST system for milk processing was about 225 kJ/kg of milk. The break-down of the energy was 98 kJ/kg milk thermal, 30 kJ/kg electrical, and 97 kJ/kg refrigeration. The steam-infusion system requires about 360 kJ/kg of milk as it is a direct contact heating system and is requires more compared to indirect heating as in a tube

heat exchanger [100]. Cooling below 30°C is not required for aseptic processed milk. This saves more energy and requires about 100 kJ/kg of milk. In addition, the aseptic processing of products does not require post-processing refrigeration resulting in further savings of 900 kJ/kg of product [100]. The most widely used heat exchangers in aseptic processing of foods are plate and tubular types. If direct heating and cooling of product to sterilizing temperatures are used, the energy consumed is considerable. Therefore, the use of regeneration of heat is important [101]. The plate heat exchanger holds a distinct edge in this regard; regeneration efficiencies of 90% (direct) or 85% (indirect) have been used. Tubular units can achieve regeneration by indirect methods, whereby a secondary water flow exchanges heat from the preheater tubes to the cooler tubes. Indirect regeneration requires four times the surface as does direct, for the same heat recovery; as a result, regeneration efficiencies over 70% are rare. Steam injection/infusion systems are not efficient: for example, with milk duties regeneration accounts for only slightly more than 50% of the total heat input. Regeneration with swept surface units, while not impossible, is not used due to capital cost consideration.

37 Cooking and Frying of Foods

M. N. Ramesh and Mohammed Al-Khusaibi

CONTENTS

37.1 COOKING

Some foods are consumed raw, and others are cooked. There are several reasons for this. Cooking improves the flavor of the food, for instance, the flavor of uncooked flour or sour apples is not very pleasant, but when the flour has been converted into bread and the apples stewed with sugar, their flavor is much improved. On the other hand, fresh strawberries are not cooked as this would spoil the delicious flavor of the raw fruit [1]. Cooking may also improve the attractiveness of food. Eating a raw chop is not much relished, but after cooking, it has an appetizing appearance and a good smell. Even more important, cooking may make food more digestible. It would be difficult to eat the flesh of a raw chop (or uncooked flour) even if you wanted to, but after cooking, it is much more tender and so easier to chew and digest. Finally, cooking may improve the keeping quality of food and make it safe. For example, milk may be boiled to delay the souring process and kill bacteria. The preservation of food by heat treatment is quite distinct from cooking.

Cooking is only one part of food preparation. Apart from the actual cooking process, ingredients may have to be blended together, and they may need special preparation by soaking, sieving, or chopping. Seasoning, spices, herbs, and sauces may be used to improve the flavor and color, and garnishes may be added to improve attractiveness, and texture may be improved by grinding, mashing, or mixing.

37.2 COOKING METHODS

Cooked food is food that has been changed in various ways by heat treatment. The heat may be applied in a number of ways; it may be dry or moist, it may be applied by means of fat or by infrared radiation [1] (Table 37.1).

TABLE 37.1
Summary of Cooking Methods

Method of Heating	Method of Cooking	Description
Dry heat	Baking	Cooking carried out in an oven
	Roasting	Baking with the addition of fat
	Grilling	Using direct radiant heat
Moist heat	Boiling	Using boiling water
	Stewing and poaching	Using hot water below its boiling point
	Steaming	Using steam from boiling water
	Pressure cooking	Using water boiling above its normal boiling point
Fat	Frying	Using hot fat
Infrared	Similar to rapid grilling	Using infrared radiation
Microwave	Similar to rapid grilling	Using microwaves

37.2.1 Dry-Heat Methods

37.2.1.1 Baking

When food is cooked in an oven, it is said to be baked. Baking is a rather slow method of cooking, but it has the advantage that large quantities of food can be cooked evenly. Baking is similar to roasting as both use dry heat. It is common to say that baking denotes the dry-heat cooking of a flour mix (starch-based formula) while roasting is the dry-heat cooking of protein-based food products. Baking depends on a list of defined ingredients and a set of instructions about combining these, which are called the formula [2]. Every ingredient in the formula has a specific role (e.g., structure builder, tenderizer, flavor enhancers), and the accuracy of these ingredients is crucial to achieving the desired quality. Some baked products are leavened by either yeast fermentation (yeast) or chemical gas production (baking soda or baking powder). In addition, the proper oven temperature is significant so every ingredient functions properly at the desired timing during the baking process. Baking temperature highly depends on the product being baked which depends on the ingredients and their proportions in the formula.

37.2.1.2 Broiling and Grilling

Broiling and grilling are other methods of applying dry heat. In broiling, the food is placed beneath a red-hot source of heat, usually a glowing metal grid. Radiant heat is directed onto the surface of the food which is rapidly heated. Broiling heat is applied to the top surface of the food, and the food should be turned from time to time. Infrared grilling makes use of heat rays which have longer wavelengths than visible light. Some of the radiation used in normal grilling is of this kind, but in infrared cookery, the proportion of infrared radiation is much increased, and this reduces cooking time to such an extent that a steak, for example, may be cooked in a minute. Grilling is similar to broiling but the heat source comes from beneath the food. The heat sources can be coal/flame or radiant heat.

37.2.2 Moist-Heat Methods

Although cooking with water involves using low temperatures, it is a relatively quick method of cooking because water has a great capacity for holding heat and for transferring this heat rapidly to food by means of convection. In moist-heat cooking, food is heated by either water or steam. Boiling uses boiling water; simmering uses water near, but below the boiling point and is similar to both stewing (for meat and juice) and poaching (for fish). Boil-in-the-bag cooking uses boiling water indirectly, but because the food is sealed in the bag this method prevents loss of flavor and soluble nutrients into the cooking water. In steaming, steam is used directly to heat the food or indirectly to heat the container. Although steaming is slower than boiling, cooking may be sped up by the use of a pressure cooker, in which steam is produced at higher than normal pressure. The increase in pressure raises the temperature at which water boils, so the cooking temperature is increased and the cooking time is reduced.

In essence, a pressure cooker is a pot with a well-fitting lid arranged so that steam can be safely generated under pressure. The pot and lid lock together by means of a groove to make the cooker pressure-tight. The food to be cooked and the required amount of water are put into the pot, which is then closed. When the closed pot is heated, air is driven out through the air vent until the cooker is full of steam. In pressure cookers with a pressure indicator, the vent then closes and pressure builds up to the value required. Slow heating only is then needed to maintain this pressure, which is shown by the pressure indicator. Should the pressure rise too much, steam automatically escapes through the air vent. The fusible plug is a second safety device; this will melt if the cooker overheats or boils dry.

37.2.3 Frying

Frying involves the immersion of food pieces in hot oil. Oil has a lower heat capacity and hence heats up faster compared to water. Different oils can be used for the different types of frying; the choice depends on the smoke point of the oils. Oils with high smoke points such as sunflower, corn, soybean, palm oil, and palm olein are preferred for deep frying. Frying is popular due to the development of unique organoleptic characteristics in food being fried. The process is characterized by mass and heat transfer.

37.2.3.1 Deep Frying

In this method, food is fully immersed in oil, which is heated to frying temperature (160 to 220°C). This results in a pleasant flavor, golden brown color, crispy outer texture, and cooked core. Different oils can be used for deep frying depending on their smoke point. The process is characterized by mass and heat transfer. A substantial amount of oil is transferred from the frying bath to the food, and water is also transferred from the food to the water bath. This results in a food with a new moisture and oil content compared to the raw material.

37.2.3.2 Shallow Frying (Pan Frying)

Food is partially submerged in a shallow pan with enough oil to cover the bottom of the pan. Although such a method is quick, the heating of the food is uneven and it should be turned from time to time. Lard, drippings, and vegetable oils (e.g., olive oil, corn oil, and cottonseed oil, often blended together) are best for shallow frying.

37.2.4 Microwave Cooking

In ordinary cooking, heat is applied to the outside of food and it gradually penetrates into the inside. In microwave cooking, the heat is generated within the food. In a microwave oven, microwaves penetrate the food and are converted into heat within the food. Thus the whole food heats up very quickly. Microwaves can only penetrate food to a depth of 3–5 cm; thus, small pieces of food are cooked very quickly. Larger pieces of food are cooked more slowly, however, because where the microwaves cannot penetrate the food is heated by conduction.

The great advantage of microwave cooking is its speed. For example, a fish fillet is cooked in only 30 seconds, a chop in 1 minute, a portion of chicken in 2 minutes, and a baked potato in 4 minutes. For this reason, microwave ovens can be especially useful in places such as canteens, snack bars, and hospitals, where food often has to be kept hot for long periods before it is eaten. Microwave ovens also have some disadvantages. For instance, cooking times must be carefully controlled. In addition, food does not turn brown or develop crispness in a microwave. Crispy bacon or conventional-looking brown crusty chops need to be finished off under the broiler.

37.2.5 Slow Cooking

The use of microwave ovens and pressure cookers is intended to speed up cooking, but recently cookers designed to slow down the cooking process have been introduced. Slow cookers are electrically heated and made of a material with good insulating properties such as earthenware so that heat transfer to the food is slow and a steady temperature is maintained during cooking. Slow cookers work on low power (1 kW) so that the cooking temperature remains below 100°C. The result is that food is cooked at a low, even temperature over a long period, usually 4–6 hours. Slow cookers are much more economical to operate than conventional ovens. Slow cooking is ideal for cooking casseroles, stews, and cheaper, tougher cuts of meat so that they become tender, facilitating reduction in weight loss by evaporation. It also prevents loss of juices because the slow cooker is sealed and no moisture escapes.

37.3 APPLICATION OF HEAT

The three common systems of heat application are (i) indirect heating by combustion gases conducted through flues, radiators, or past surfaces of the baking chamber such as the underside and backside of the chamber, (ii) semi-direct heating in which part of the combustion gases are forced into baking chamber to create pronounced convection currents, and (iii) direct heating using electricity or gas with ribbon-type burners [3].

A fourth, indirect method that utilizes high-pressure steam tubes is used to a very limited extent. The indirect firing system utilizes isolated combustion chambers from which the hot combustion gases are circulated by either suction or pressure through a bank of radiator tubes and are either returned to the combustion chamber or vented to an exhaust flue. The radiator tubes, which transverse the baking chamber, give up their heat by radiation and convection to the baking chamber. Depending upon the size of the oven, several combustion chambers or unit heaters may be used, each equipped with a burner, circulating fans, ducts, radiator tubes, and temperature controllers. The radiator tubes can be so arranged that radiated heat is applied to both the top and bottom of the pans. Because of the inherent limitation of the radiating heating surface that can be designed into an oven, the heating efficiency of indirect-fired ovens is generally less than that of direct-fired ovens.

The semi-direct firing system resembles the indirect system in using a separate combustion chamber and relying on radiator tubes to carry the hot combustion gases to the baking chamber. Here, however, the radiators are provided with either thin slots or small holes so that the hot gases are forced into the oven chamber, thereby creating extensive convection chambers, which are further augmented by a forced draft. In this system, the baking effect is produced by convectional and radiated heat, and in this way, advantage is taken of the special benefits offered by both methods of heat transfer.

In direct gas-fired ovens, ribbon burners are placed directly in the baking chamber, crosswise to the travel of the oven trays or conveyors. Originally, an air–gas mixture was supplied to the burners by an aspirator in which the combustion air was drawn into the mixing unit by the vacuum created when the gas was forced through the gas orifice under pressure. Each burner has its own gas control valve which must be manipulated individually for heat control. The aspirator system has a number of disadvantages, principal among which is its tendency to flame-out under certain operating conditions, thereby creating hazardous oven conditions.

A safer and more efficient firing method has been devised in which gas and air are mixed prior to being fed through a common header to the individual ribbon burners. In this system, filtered air is supplied to an air–gas mixing unit. One such unit is provided for each oven zone consisting of as many as 15 or more ribbon burners. In this way, all burners in one zone can be throttled uniformly by means of a single zone control valve. The unit mixer in which the air and gas are mixed is under pressure for each individual ribbon burner. With this system, the gas and air headers for each top and bottom heat zone are provided, respectively, with a zero gas regulator and an air valve controlled by an automatic temperature controller. The gas regulator and air valve operate together to uniformly supply the correct amounts of gas and air to the unit mixer in the zone. For balancing the heat distribution across the width of the oven, flame distributor-type burners are used, which provide a three-zone control of the burner flame across the oven.

The direct gas-fired system is the simplest and most efficient method of oven heating. By proper design and distribution of ribbon burners, uniform gas consumption can be obtained throughout the oven. The velocity of the combustion gases coming out of the burner ports, together with the natural convection currents created by the generated heat, supply sufficient turbulence to produce fairly uniform temperatures throughout the chamber as long as the size, number, and location of the burners are adequate and the control equipment is correctly engineered and installed. In some direct-fired ovens, forced convection is applied to obtain a more efficient utilization of the heat energy by recirculating the chamber atmosphere past the ribbon burners rather than venting it to outside.

In the steam-tube system, oven heating is performed by a series of high-strength, hermetically sealed tubes that are partially filled with water or a heat-stable liquid possessing a high boiling point. The tubes are installed in the oven so that a short portion of each tube protrudes into the combustion chamber, where direct heat is applied to cause the water to vaporize into high-pressure steam. The balance of the tube extends into the baking chamber. The tubes are slightly inclined toward the fire box so that steam condensate returns to the heated ends to be revaporized. Because saturated steam at atmospheric pressure has a temperature of 100°C, and because baking temperatures are normally within the range of 182–232°C, it is evident that considerable pressure must be developed in the steam tubes to attain baking temperatures.

Heat transfer in this system is principally by radiation and is, hence, governed by the physical law that states that the heat rays radiated from any one source vary inversely to the square of their distance. Therefore, the steam tubes must attain much higher temperatures than the actual baking temperature. The magnitude of the pressure developed within the tubes is indicated by the fact that a temperature of 335°C requires a steam pressure of 13,800 kPa. The use of steam tubes as a method of oven heating has been largely discontinued as it is relatively inefficient and lacks the necessary flexibility of heat control.

37.4 COOKING EQUIPMENT

The objectives of the cooking process are to reduce the moisture content of the product mixture, to melt, to solubilize, to caramelize, if necessary, and to invert. There are many types of cooking equipment, which may be classified in several ways for the convenience of discussion. According to the working mode, they are batch cookers, semi-continuous cookers, and continuous cookers. According to the method of heating, they come as direct-fired cookers or steam-jacketed cookers. According to the working pressure, they are atmospheric cookers, pressure cookers (steam-injection cookers), and vacuum cookers.

37.4.1 Batch Cookers

37.4.1.1 Steam Kettles

Food preparation of liquids and pumpable foods (including particles) is carried out in kettles or in heat exchangers. Kettles are used in batch operations. Heat is supplied to the foods through the kettle wall from condensing steam in the steam jacket covering most of the kettle wall. The jacket is equipped with an air-venting valve and a condensate-removal system with a steam trap. The food is transported to and from the wall into the bulk of the food by a flow created by the density differences between hot and cold products or by mechanical agitation. The free convection flow develops easily when the heat supply is sufficient for a rapid steam pressure build-up in the jacket. In the flow pattern, only a thin layer of the fluid close to the wall will be involved in the heat transfer. The heated fluid will rise to the top of the volume and spread over the top surface. The major part of the volume will slowly fall towards the bottom, where it will contact the heat-transfer surface again.

Models of steam kettles differ in relation to (i) depth, which may be deep or shallow, (ii) steam jacketing, which may be full or two-thirds, (iii) mounting, which may be on legs, a pedestal, or wall-mounted, (iv) type, such as tilting or stationary, and (v) source of steam, which may be direct or self-generated. The materials commonly used are aluminum and stainless steel; the finish may be dull or polished. All steam equipment should have safety valves and pressure gauges. Those having self-generated steam should have an automatic low-water cutout and a thermostatically controlled cutout heat. Tilting kettles should have a secure device for stopping them at any desired degree of tilt.

37.4.1.2 Steam Cookers

Steam cookers vary in (i) number of compartments (single or in stacks of two or three) and size, (ii) source of steam, (iii) type of base, and (iv) design. Steamers should have heavy-duty gaskets. Cooking containers must be suitable for the material to be cooked, should minimize handling, and should permit suitable load size for workers to lift. The use of serving pans may often minimize transfer.

37.4.1.3 Vacuum Cookers

This system is used for the production of hard candy, jelly, gum candies, and low-boiled sweets. The main components of the vacuum cooker consist of a cooking chamber, a kettle under it with a vacuum facility, a stirrer inside the cooking chamber with a variable-speed drive, a vacuum pump with a spray condenser and control system. The finished product is discharged into the kettle, which is hence called the draw-off kettle [4]. The ingredients are fed into the cooking chamber by dosing or manually. The cooking temperature and time are controlled automatically. The product after cooling is discharged into the draw-off kettle through suction created by vacuum pump. During this process, the cooked mass will be evaporated under vacuum pump. The draw-off kettle is lowered after reversing the vacuum to unload the product.

37.4.1.4 Rotary Cereal Cooker

This is a single rotating pressure cooker, controlled either automatically or manually and mounted on a horizontal axis. The cooker consists of a stainless-steel barrier with a slide valve or door for charging and discharging; steam is injected at 200 kPa working pressure through a flexible hose and rotary

union [5]. The pressure cooker consists of an all-welded stainless-steel double-conical barrel with annular rings at each end to which are bolted endplates. The barrel has a centrally positioned opening fitted with a door for charging and discharging. Steam injection is through a 50-mm diameter stainless-steel braided flexible hose and rotary union mounted at the end of each stub shaft. Steam passes through the center of each shaft into a stainless-steel steam chest, which is integral with the shaft and endplate. Steam injection and exhaust are controlled through a system of stainless-steel ball valves. Pressure in the cooker is indicated at each end by a pressure gauge.

37.4.2 Continuous Cookers

37.4.2.1 Pressure Cookers/Blanchers

The Balfour continuous pressure cooker: The Balfour continuous pressure cooker can handle particulate foodstuffs ranging from cereals and diced vegetables to regular whole beetroots and potatoes, including diced meat. It is designed for the continuous feeding of process materials into and removal from the cooking vessel, which utilizes steam under pressure. The retention time of the process material can be strictly controlled and varied according to requirements [5]. The main cooking section consists of a plain helical screw conveyor operating within a circular body—the body being designed to operate at the maximum steam pressure. Pressure lock systems are fitted at both the inlet and outlet ends. The size of the cooker is directly proportional to the required cooking time and inversely proportional to the total process time [6].

The Turboflo blancher/cooker: The Turboflo hydrostatic blancher/cooker uses a unique steam injection and energy-circulation system for blanching and cooking potatoes, vegetables, fruits, meats, and poultry. It combines the benefits of energy efficiency and improved product quality and saves processing time and also requires less floor space. The cooker achieves process time savings of up to 30%. The fully enclosed and insulated chamber prevents steam from escaping and saves energy. Products blanched in this cooker retain more nutrients and have both better color and better taste and thus customer appeal. The energy-circulation method features a fan-driven steam path, which penetrates the product mass evenly to assure thorough blanching/cooking of the product. The modular section design provides maximum flexibility for food processors [7].

37.4.2.2 Steam Cookers

A continuous steam cooker has been developed at CFTRI. The equipment is a continuous conveyor with a facility for open steaming into the chamber. A water inlet is provided through a flow meter to add a measured quantity of water during processing. The chamber is steam-jacketed for additional heating. A variable-speed drive is provided to vary the residence time of cooking. A rotary valve is fixed at the inlet end to control the material feed rate. The conveyor speed and the rotary valve speed are matched with sprocket and chain drive [8]. A stationary water-draining device with a stainless-steel trough and stainless-steel and nylon sieving screens is installed at the discharge of the machine, which greatly helps in the quick separation of water from the cooked product.

The product to be cooked is carefully washed, and water is fed into the cooker at a measured rate (flow rate depending upon the output and variety). Steam is let into the system by opening the steam valves at controlled pressures. Steam supply is maintained at a constant rate for both the spreader and the jacket. The product is continuously fed from the hopper through the rotary valve at the required rate. At the end of the set residence time, a uniformly cooked product is discharged through the outlet chute. The product is collected from the mesh and is ready for consumption.

37.4.2.3 Microfilm Cookers

Microfilm cookers are available as atmospheric or vacuum cookers. They are suitable for all types of high boiling and can also be used for low boiling. They are very efficient cookers using the scraped-film principle, which results in extremely rapid cooking. This reduces process inversion to a minimum. The scraped film also means that confectionery containing milk products can be handled on this machine without the risk of burning or the need for frequent cleaning [5]. The principal uses of this machine are for feeding possible depositing food products. In the case where a depositor is to be fed, a vacuum cooker should be chosen. The plant starts with a free-standing stainless-steel reservoir for dissolved syrup. This is fitted with inlet filters. The syrup is pumped from the holding tank into the cooker by an infinitely variable syrup feed pump, which has a manually adjusted control. The preheater, rotor, syrup feed pump, discharge pump, vacuum pump, metering pumps, electrical control panel, and steam controls are all mounted on a column framework.

The rotor is a scraped film evaporator made up of a bronze steam-jacketed tube with a high-speed rotor fitted inside the center. The rotor has hinged blades, which wipe the inner surface of the tube. The sugar is spread in a very thin film and is moved through the cooking tube by a combination of gravity and the design of the hinged blades. The cooked sugar is discharged from the microfilm cooker in one of two ways, either by gravity from the base of the rotor or by a discharge pump and delivery pipe. Gravity discharge can only be used in the case of atmospheric cooking. Where vacuum cooking is used, a discharge pump is necessary to withdraw the sugar from the vacuum. A discharge pump can also be used with an atmospheric cooker.

37.5 EFFECTS OF COOKING ON NUTRIENTS

During cooking great changes take place in the nature of food. Different foods behave in different ways when cooked. These effects apply to all foods [9].

37.5.1 Fats

When fats are heated, they melt, and if they contain water, it is driven off as water vapor. At 100°C, fats containing water appear to boil; this is caused by the water being given off as

steam. Fats are stable to heat and can be heated almost to their boiling point before they start to break down. It is because of this fact—and also because they have high boiling points—that fats are used for cooking. When fats are heated too much, they break down, producing an unpleasant-smelling smoke. Fat on the outside of meat and in bacon darkens in color on strong heating, and if the temperature is too high some breakdown and charring may occur. Unsaturated fatty acids are more susceptible to oxidation than their saturated analogs, and polyunsaturated content in aquatic species was demonstrated to decrease during storage and cooking [10–13]. It was found that polyunsaturated fatty acids content remained unchanged in some kinds of products under certain methods of treatment [10, 14]. Gladyshev et al. [15] studied the fatty acids in fillets of humpback salmon unfrozen, boiled, fried, roasted, and boiled in a small amount of water. Heat treatment in general did not decrease content of polyunsaturated fatty acids of the ω-3 family (eicosapentaenoic, EPA; and docosahexaenoic, DHA), except a modest reduction during frying. Cooked humpback appeared to be a valuable source of essential ω-3. It was hypothesized that the absence of a significant reduction of polyunsaturated fatty acids in the red flesh of fishes of the salmon family during heat treatment may be due to a high level of natural antioxidants which formed in the course of evolution as adaptation to their ecological niche [15].

37.5.2 Carbohydrates

When exposed to dry heat, carbohydrates are broken down and darken in color. For example, sucrose browns on caramelization and finally chars and becomes black, while starch is broken down into more easily digested dextrin and also darkens and eventually chars. Many foods that contain both sugars and protein turn golden brown and change flavor on heating. These changes occur in the toasting of bread and the baking of bread, cakes, and biscuits, and contribute to the pleasant flavor and attractive color of these products.

When a mixture of starch and water is heated, the starch granules absorb water and swell and gelatinize, forming a thick white paste. This is why starchy material (e.g., flour) is used to thicken sauces. On cooling, the paste sets and forms a gel. Uncooked starchy foods are difficult to digest because the digestive juices cannot penetrate into the starch grains. Cooking causes the starch granules to swell and gelatinize.

The polysaccharides starch, cellulose, and pectin are important constituents of fruit and vegetables. On cooking, insoluble cellulose changes little, except to soften, whereas starch softens as it gelatinizes and pectin becomes more soluble and dissolves somewhat, allowing cells to separate and making the fruit or vegetable easier to eat. Fruit with a high pectin content, such as apples, becomes soft and pulpy on cooking.

37.5.3 Proteins

Proteins undergo great changes when they are heated. Many proteins coagulate when heated; for example, egg white coagulates when it is heated above 60°C. As proteins coagulate they become solid. For example, when milk is heated a skin forms because some of the proteins have coagulated. Cheese is another important protein food, and when it is heated it softens and on further heating, some of the proteins coagulate and the cheese becomes stringy and tough. Not all proteins coagulate on heating, which is important when considering how to cook protein foods. Collagen and elastin, for example, are two important insoluble proteins in meat, and because they are not soluble, they are not easily digested. Their presence in meat makes it tough, and as the cheaper cuts of meat usually contain more collagen and elastin than more expensive ones, they are usually tougher. Tough meat must be cooked in a way that will make it tender. If such meat is cooked at high temperatures for long periods it remains tough or may even become tougher. Tough meat needs to be cooked slowly using low temperatures; both dry-heat and moist-heat methods may be used.

Tough meat is often cooked slowly using moist heat (e.g., stewing). This converts the tough collagen into gelatin. Gelatin is a soluble protein and so is easily digested. Slow cooking using dry heat is also effective in converting collagen into gelatin. Elastin softens on cooking, but not to the same extent as collagen. Bertram et al. [9] studied the thermal denaturation of meat protein by NMR and DSC. The denaturation of myosin rods and light chains occurred at 53–58°C, and heat-induced changes in myofibrillar water as well as between actin denaturation at 80–82°C and expulsion of water from meat.

37.5.4 Mineral Elements

Heat does not affect mineral salts found in food because they are stable substances that do not break down at the temperatures used in cooking. Moist-heat methods of cooking, such as stewing and boiling, cause loss of salts, which are soluble in water. Boiled fish, for example, is rather tasteless because of the considerable loss of mineral salts that occurs during cooking. However, the salts are present in the water in which the fish has been boiled, and this liquid or stock can be used for making a tasty sauce to eat with the fish.

37.5.5 Vitamins

Dry-heat cooking methods destroy those vitamins which are unstable to heat. Vitamin C is destroyed at quite low temperatures, and so all methods of cooking cause some loss of this vitamin. To make the loss as small as possible, foods containing vitamin C should be cooked for as short a time as possible and should be eaten as soon as they are cooked. Two of the B vitamins, thiamine and riboflavin, are unstable at high temperatures. Riboflavin is the more stable of the two, and little is lost except at high cooking temperatures, such as those used in rapid grilling. Thiamine is largely destroyed at high temperatures, such as are used in grilling and roasting. Cooking with moist heat causes loss of water-soluble vitamins, as well as those that are destroyed at low temperatures. Vitamin C is

both soluble in water and unstable with heat, and therefore some loss during cooking cannot be avoided. Vitamin C is also destroyed by oxygen present in air and dissolved in cooking water. Leaching is also the main reason for high losses of ascorbic acid during cooking. The rate of destruction is hastened by enzymes present in the plant or fruit. These enzymes are set free by crushing or chopping. Different studies found a decrease of ascorbic acid by boiling up to 75% [16–18].

The B vitamins are soluble in water in varying degrees, thiamine being the most soluble. A considerable proportion of the thiamine in foods may be lost during cooking, especially if they are boiled in alkaline solutions. For this reason, alkaline substances, such as sodium bicarbonate, are not added to green vegetables to prevent loss of green color during cooking. The amounts of the other B vitamins lost during cooking are small and not important. Vitamins A and D are insoluble in water and stable except at high temperatures. There is therefore little, if any, loss of these vitamins during cooking.

In green vegetables, β-carotene is incorporated in the carotenoid-protein complexes in the chloroplasts. These carotenoproteins have an inhibitory effect on carotenoid digestion and absorption [19]. In orange or red fruits β-carotene is dissolved in oil droplets in the chromoplasts and can be readily extracted during digestion [20–22]. Food preparation, e.g., mincing and cooking, can increase the extractability and therewith the bioavailability of β-carotene from the food matrix by softening or disruption of plant cell walls and the destruction of carotenoid-protein complexes [23–26]. Cooking can also lead to an isomerization of the natural substances, mainly the all-*trans*-form of β-carotene to its *cis*-isomers. *Cis*-isomers are less bioavailable, and the provitamin A-activity is lower [27, 28]. Bernhardt and Schlich [19] studied the influence of different domestic cooking methods (boiling, stewing, steaming, pressure steaming, microwave) on the all-*trans*- and *cis*-β-carotene as well as the α-tocopherol content in fresh and frozen broccoli and red sweet pepper. In fresh broccoli all cooking methods lead to a significant release of all-*trans*-β-carotene. In frozen broccoli no change of α-tocopherol occurred. In the fresh and frozen peppers no change or a significant loss of α-tocopherol and all-*trans*- and *cis*-β-carotene was observed. A slight increase in the *cis*-isomers of β-carotene can only be found by cooking fresh broccoli. Oxidation promoted by the presence of light, heat, and oxygen is the main reason for destruction of carotenoids [29, 30].

37.6 HEALTH ASPECT OF COOKING METHODS

Polycyclic aromatic hydrocarbons (PAHs) are pollutants that are found in food products due to soil or water contamination. These are believed to have carcinogenic, cytotoxic, and mutagenic effects. PAHs are also found in charcoal-grilled or roasted food products due to the combustion of charcoal and are also found in smoked food products [31]. It has been also anticipated that PAHs are formed during frying. The smoke of oil during deep-fat frying emit PAHs, mainly three- and four-ringed PAHs [32]. Different concentrations are found in the smoke emitted from different edible oils, and that might be related to the degree of saturation of oils [33]. In 2006, a working group formed the International Agency for Research on Cancer (IARC) concluded that the emissions from the high frying temperatures are "probably carcinogenic" [34]. PAHs might be volatilized during frying [35], and this might explain the low levels of the compounds in the frying oils and samples being fried [35, 36].

The discovery of acrylamide in food in 2002 prompted concerns about the formation of this compound during cooking at high temperatures. Acrylamide is formed as a result of Maillard reactions which take place at high temperatures such as during frying, roasting, and baking. It has been considered a carcinogenic compound. The content in some commercial food products is in the range of 196–303 μg/kg [37]. Asparagine has been identified as the main amino acid involved with the reducing sugars in the formation of acrylamide [38, 39]. N-glycoside is a Maillard reaction intermediate product and is also responsible for the formation of acrylamide. Several factors have been reported to affect the concentration of acrylamide formed during frying: The frying temperature (the higher the temperature, the higher the concentration), frying time (the longer the time, the higher the concentration) [40, 41], potato variety (sugar content, mainly glucose and fructose) [5], presence of phenolic compounds in the oil [41], and pre-treatments such as blanching or soaking in acidic solutions [42]. Biedermann-Brem et al. [43] studied the effect of reducing sugar on the quality and acrylamide content of roasted potato. It was concluded that insufficient color and flavor development is obtained when the reducing sugar content is less than 0.2 g/kg (wet basis). On the other hand, a high concentration of acrylamide is formed when the reducing sugar level is greater than 1 g/kg. Acrylamide was also detected in roasted coffee beans. The temperature and roasting time affect the content of acrylamide formed [44]. It has been reported that acrylamide concentration decreases with increased roasting temperature [45–47]. Acrylamide is also formed during baking [48].

Furosine and 5-hydroxymethylfurfural (HMF) are products of Maillard reactions. They are produced during cooking methods such as boiling, grilling, roasting, and frying while frying has been shown to produce the highest concentrations of furosine and HMF. Steaming did not show any significant increase compared to the raw material [49, 50]. Different cooking methods resulted in different concentrations due to the differences in thermal damage they cause. HMF has been reported to have potential genotoxic and mutagenic activities [12, 51].

38 Extrusion Processing of Foods

Kasiviswanathan Muthukumarappan and Gabriela John Swamy

CONTENTS

38.1 INTRODUCTION

Industrial applications of extrusion technology have led to the launch of a rich extrusion processing culture. This has developed gradually from endless communication amongst practitioners and scientists. Polymer extrusion has had the benefit of widespread technical exploration and modeling, making it promising to forecast process performances. However, food extrusion processing, along with the reported designs, is fairly new, and it suffers from a deficiency of printed material. In addition, food extrusion inclines to be more segmented and application-oriented. Therefore, a multidisciplinary approach is necessary, for which a comprehensive estimate of the process performance is not yet available. The purpose of this chapter is to provide extensive information on extrusion processing. This chapter has been inspired both by existing applications of extrusion technology and by emerging techniques. The objective of this effort is to bridge the space between long-term experience in extrusion and the science of extrusion in order to create a link between the world of extrusion practitioners and that of imaging engineers in the field of food engineering. For this purpose, the generic extrusion process idea has been applied in order to represent and converse the

extrusion processing culture and to shape the structure of the chapter content.

Extrusion is a process that combines several unit operations including mixing, cooking, kneading, shearing, shaping, and forming. Food ingredients are fed through a hopper, and the feed moves along various sections with the help of a screw and exits through a die. During the journey inside the extruder, the ingredients are formed into a dough with partial cooking. Extrusion is operated in both batch and continuous methods. This technique is extensively operated as a continuous process in the cooking of food materials, texturization, and shaping of food, impregnation of fibrous materials, and fractionation of solid–liquid media [1]. The industrial application has generated numerous foods of the modern world such as 3D snacks, snack and feed pellets, three-dimensional breakfast cereals, pellet-to-flakes cereals, partially filled cereals, crispy flatbread, puffed foods, textured vegetable protein (TVP), and encapsulated flavors [2, 3].

The food industry employs both single-screw and intermeshing corotating twin-screw extruders. In particular, the cereal and oilseed processing industry extensively uses extruders to generate products of various shapes, sizes, and textures. Extrusion technology transforms cereal flours to prepare ready-to-eat (RTE) food products and functional ingredients by a series of steps, such as kneading, cooking, forming, and texturizing functions [4]. Due to efficient technology transfer, the cereal processing industry has benefited enormously in applying extrusion technology to create value-added products. On the other hand, the oilseed processing performs initial transformation of oilseed by fractionating its main components. The resulting products include the seed hulls, vegetable oil, and proteins. Specific designs of single-screw extruders for solid–liquid separations have been designed to suit the process.

Extrusion processing is the controlled incorporation of materials and energy into a food through restructuring or reassembling operations. This thermomechanical process is very useful in producing low-fat snacks and has the advantage of increasing protein and starch digestibility, solubilizing fiber, inactivating toxins, antinutritional factors, and undesirable enzymes, such as lipoxygenases and peroxidases [5]. Starch gelatinization can occur at levels from 12 to 22% moisture content; however, it has been indicated that at low moisture contents, gelatinization is accentuated because of the high shear stress, the heat generation, and the mechanical disruption of the granules. A partial gelatinization is necessary for a further degradation that will reduce the size of sugar chains and thus the product stability after expansion will be lost. However, a lesser degradation is not enough for opening the starch granules and reducing the ability to adsorb water, which serves later as a means for expansion. For these reasons, it is important to know the microstructure changes after the extrusion process and microwave expansion of the pellets. The conversion of feed ingredients to a usable product by the application of novel and versatile techniques of extrusion can be very useful from an economic point of view. However, the microstructure and textural changes in the product after processing and during storage are still not known. The effect of extrusion temperature, moisture content, screw speed, and storage conditions on the product microstructure, texture, and functional attributes needs to be evaluated for further applications of extrusion processing.

Extrusion is rapid, flexible, and relatively inexpensive when compared to most other food processing operations. It exposes the raw material to high temperature, pressure, and shear force to mix and cause physical and chemical changes, which constitutes cooking, and gives extruded snacks a variety of shapes and flavors. Extruded snacks are frequently low in nutritional density and high in fat and starch. Twin-screw extruders, on the other hand, provide versatility and are successfully used to process complicated material systems. Snacks have long been a part of the American diet and are rapidly increasing in popularity. Extruders are the dominating technology of most snack food production. In developed countries where protein energy is deficient, snacks are widely consumed. Extrusion cooking, a dominant technology in pet food manufacturing, is a widely used technique in snacks and the confectionery industry as well.

Technological developments in the expansion of breakfast cereals and snack items, in particular, were hindered by the difficulty of achieving and then maintaining steady conditions for extrusion with single-screw extruders. A prime target of consumer advocates and nutritionists is to effectively improve the quality and nutrition of snack foods. Extruders have taken their position in the food industry, which seems to be irreplaceable. The variety of extruded products ranges from pasta, ready-to-eat breakfast cereal, and snack food, to confectionery, pet foods, and aquaculture feeds. Its most important commercial application is high-shear extrusion cooking, a process used to produce dry expanded foods in a wide range of forms. Of the many operations of an extruder, mixing, heating, and shearing are among the most important to bring about desired texture in the final product exiting from the diet. Preconditioning, extrusion, cutting, and drying are primary unit operations in most industrial extrusion processing. Extrusion of heterogeneous ingredients makes as good a use of art as it does science. Controlled expansion is a desirable feature in extrusion processing.

38.2 TYPES OF EXTRUDERS

The design of extrusion equipment, with prime focus on the hardware components, is covered in this chapter. The hardware part has been discussed extensively, as they have a direct impact on the performance of the extrusion process. Single-screw and intermeshing corotating twin-screw extruders have been elaborated, as they equally support the generic extrusion processes. Extruders can be classified as in Figure 38.1.

38.2.1 Single-Screw Extruder

Single-screw extruders are readily available in a number of shapes and sizes, and the barrel, screw configuration, and screw can be varied to suit a particular variety of product characteristics. The main advantages of single-screw over

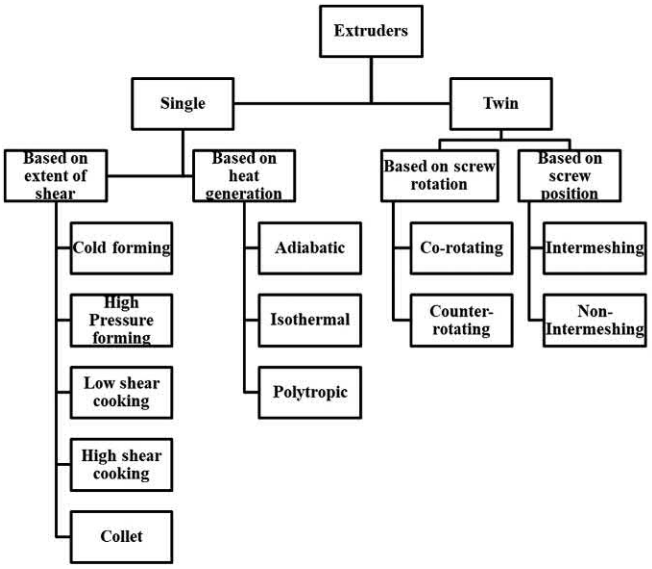

FIGURE 38.1 Extruder classification based on design and function. (From Muthukumarappan and Swamy [1].)

twin-screw extruders are that they are mechanically very simple and the cost is half the price of similar-sized twin-screw extruders. Because of this, single-screw extruders are used wherever possible in the industry and in academic research. The material is conveyed along the length of the screw by a drag flow mechanism, where drag is directly proportional to screw speed. In general, single-screw extruders possess poor mixing ability, which necessitates the premixing of ingredients prior to extrusion.

38.2.2 Twin-Screw Extruder

A twin-screw extruder comprises two screws rotating either in the same direction (corotating) or in the opposite direction (counterrotating). Based on screw configuration and degree of intermeshing, twin-screw extruders can be classified into fully intermeshing, partially intermeshing, and non-intermeshing. Corotating twin-screw extruders are the most common in the food and snack industry for their pumping efficiency, good control over residence time distribution, self-cleaning mechanism, and uniformity of processing. Counterrotating intermeshing twin-screw extruders were developed for the processing of polyvinyl chloride, which comprises resin beads that are slippery and difficult to process in a single-screw extruder. Twin-screw extruders are more flexible in operation than single-screw extruders, but they are more expensive. Some of the advantages of twin-screw extruders include the ability to handle a variety of materials (viscous, oily, sticky, and wet) and a wide range of particle sizes, a nonpulsating feed, positive pumping action, self-cleaning, and scaling up.

38.2.3 Extruder Design

The basic design of an extruder is that of a single-screw extruder. Modification in the number of screws, the direction of rotation of the screws, and the intended application are the factors that add up in the twin-screw extruder [6]. Figure 38.2 shows the design of a single-screw extruder. The functional components of extruders are classified as follows:

- Motor and the gearbox: These are responsible for the kinematics of the extruder. The mechanical power is generated by these components.
- Screw-barrel assembly: These may contain three to four sections to convert the feed to a dough-like material. A heating and cooling device may be attached depending on the product.
- Die assembly: The processed material is shaped, formed, or textured. This section is crucial, as this constriction also determines the quality of the product.

- Visual and operating cabinet: The computer system helps to monitor equipment operation. The screw speed and temperature at various sections of the barrel can be set here. In addition, the resulting torque can be observed here.

38.2.3.1 Screw

The screw is the central part of an extruder. Screw diameter (D) is the distance between two flights across the screw shaft. Channel depth (h) is the distance from the top of the flight to the root. Pitch (t) is the distance between consecutive flights. All these parameters vary depending on design and the manufacturer. The helix angle (Φ) is the angle between the flight and a line perpendicular to the screw shaft, and it varies between 12° and 15°. Clearance between the flight tips and barrel (δ) is usually 0.5 mm, and it ensures efficient pumping of the material. The axial flight width (e) of a screw is usually 10% of the screw diameter. The relative motion of the screw and barrel causes drag flow, which can be calculated by applying downstream velocity over the screw channel cross-section. Drag flow is a simple function of screw speed (N) and geometry, and is independent of viscosity for any screw design:

$$Q_d = \propto N \tag{38.1}$$

where Q_d is volumetric drag flow and α is the drag flow geometry parameter. In general, geometry parameter increases with screw diameter, channel depth, and pitch. The geometry factor for rectangular channels and shallow flights can be calculated as

$$\propto = \frac{1}{2}\pi^2 D^2 h\left(1-\frac{ne}{t}\right)\sin\theta\cos\theta \tag{38.2}$$

where n is the number of flights. All extrusion processes experience heat generation from the shearing of the viscous product. The drive motor power reflects the amount of heat generated during extrusion. The total energy transfer can be approximately described using the following equation and is a product of screw speed, shear stress (viscosity, screw speed), and surface area (extruder diameter and length):

$$Z = \pi^3 D^2 N^2 \mu\left(\frac{\pi D}{2h}+\frac{ne}{\delta}\right)l \tag{38.3}$$

where μ is the viscosity of the product and l is the wetted screw length. Some manufacturers make a screw in one piece (Figure 38.3C), whereas others make them in segments (Figure 38.3A and 38.3B). These segments are interchangeable in any order depending on the requirement on the continuous spline or key of the shaft. The most frequently employed screw configurations in the food industry are variable pitch, constant depth, increasing root diameter, increasing number of flights, and decreasing diameter. In single-screw extruders, screw geometry not only influences different functions such as mixing, kneading, heat, and pressure development but also the capacity of the extruder.

The movement and transformation of material within a single-screw extruder can be categorized into three sections: feeding, transition, and metering. The feed throat of the screw accepts the low-density preconditioned or dry blend, with deep flights and long pitch facilitating movement. The function of the feed section is to ensure the transportation of material down the screw and to fill it completely. The feed section is typically 10–25% of the total length of the screw. The transition section is also called the compression or kneading section because of its function. The food material loses its powder/granular form and changes into an amorphous or plasticized dough, thereby increasing the density. A decrease in screw pitch and flight depth and angle are the most common ways to achieve transition/compression/kneading. The transition section is the longest section of the screw, being approximately half the total screw length. This section of the screw can have forward, neutral, or reverse pitched elements depending on the application. The metering section is the part of the screw with shallow flights, which increases shear rate to maximum within the screw. A twin-screw extruder has more options because the entire screw section can consist of combinations of conveying elements, kneading elements, reverse screw elements, and additional elements. A combination of thermal and mechanical energy inputs plasticizes the food material above its melt transition temperature thus increasing the density. The compression ratio (channel depth at feed to channel depth at discharge) has a direct impact on shear development and temperature profile within the extruder barrel. A gradual decrease in flight depth in the direction of discharge and a decrease in pitch in the compression section are the most common ways to achieve compression. The compression ratio typically ranges from 1:1 to 5:1. However, for excluding air from the cereal product and improving heat transfer efficiency, a modest compression of less than 3:1 is often used.

A good mixing action is one of the most important functions of an extruder. As mentioned earlier, single-screw extruders have poor mixing ability, but this can be solved by introducing a mixing section in the screw configuration. A

FIGURE 38.3 Screw design. (A) A screw element; (B) typical screw elements; (C) screw is formed by attaching several elements together in various configurations. (From Moscicki [22].)

venting screw is used whenever necessary to vent moisture or other volatile gases trapped or contained within the extruder. A hole made in the barrel at a proper position and a larger fill in the screw releases the pressure of the material.

38.2.3.2 Barrel

The barrel is the cylindrical housing that accommodates the rotating screw and should be mechanically strong enough to withstand the pressure developed in the barrel and resist wear. A common practice is to relate the barrel length to diameter (L/D) ratio with the throughput of a single-screw extruder. Barrels are composed of honed and nitrided stainless steel (416) in various L/D ratios. Nitriding may not be effective when abrasive materials are fed into the extruder. Hardening of stainless steel lowers corrosion resistance but has a negative effect on heat transfer. A thicker biometallic coating not only addresses abrasion and corrosion but also improves wear resistance. The L/D ratio can be varied to accommodate the geometrical design of the individual components. It has been observed that food extruders typically have L/D ratios ranging from 1:1 to 20:1. For macaroni extrusion, screws are designed with L/D ratios between 6:1 and 9:1 with a screw diameter of 120–200 mm. However, an L/D ratio of 30 is required for accomplishing both cooking and forming of cereals in a single extruder. Typically, twin-screw extruders have a shorter barrel length than that of single-screw extruders. It is observed that the L/D ratio has no real meaning with twin-screw extruders in the usual sense, probably because the feeding is controlled by other devices as described later. Most of the food materials are sticky in nature during cooking and thus smooth-bore extruder barrels are not desirable. In order to accomplish positive transport, a material must slip on the rotating screw and this is enhanced if the barrel wall is grooved (longitudinal or spiral). In general, the extruder barrel is segmented and these segments are jacketed to allow temperature control of individual zones. Heating is typically accomplished with overheated steam, hot oil, or band heaters, whereas cooling is achieved with tap water. Heaters are usually located along the barrel, with a thermocouple in each zone to control the heaters and barrel temperature. The most common type of thermocouple used on extruders is the K thermocouple. Cooling facilitates the handling of products after extrusion by increasing the viscosity, which results in better retention of shape, and by reducing stickiness. Low shear stress (forming) extruders are used to densify materials with high moisture content and have a long L/D ratio, which imparts a low level of mechanical energy per unit of throughput. Expanded products are produced in high shear stress extruders, which have the shortest L/D ratios.

38.2.3.3 Die

Dies are openings at the end of the die section through which the product is extruded (Figure 38.4). They play an important role in determining the physical properties of the product such as density, expansion, surface texture, and final shape based on die design, extrusion configuration, processing conditions, and blend. Highly restrictive dies increase barrel

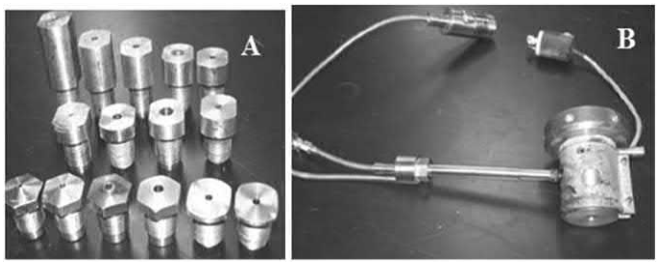

FIGURE 38.4 (A) Die nozzle designs. (B) Die design. (From Moscicki [22].)

fill, residence time, and energy input. The simplest form of die is a hole, annular openings and slits being common. In general, small-scale extruders have only one opening in the die assembly, whereas large-scale extruders have multiple openings, which alter die shear rates. Cereal processing normally requires multiple die openings. High shear rate dies are responsible for imparting energy to starch-bearing products, thereby promoting starch damage that results in an increase in water solubility in addition to other final product characteristics. Die insert, die plate, and breaker plates are other options of die used in the food industry.

38.2.3.4 Feed System

In order to achieve consistent and uniform operation of an extruder, ingredient feeding should also be uniform and consistent. Feed throat and hopper geometry should allow material to flow freely into the extruder with minimum restriction. The feed hopper should have sufficient capacity for continuous operation and it is an integral part of the feeding system. The feed rate of modern extruders is typically controlled by a variable speed auger and vibratory feeder weigh belts. Live bottoms are hoppers equipped with devices at their discharge outlets that ensure a continuous flow of ingredients; the volume of material must be sufficient to allow an orderly shutdown of the system if necessary. When the fat content of a formulation exceeds 12%, that portion of fat above the 12% level should be introduced into a single-screw extruder in a separate ingredient stream. Preconditioning is an essential step, blending steam and water with dry ingredients to achieve temperature and moisture equilibrium. This operation not only hydrates the dry ingredient but also begins the cooking under slower shear conditions than those that exist in the extruder and this process allows the extruder to focus on final heating and forming. Preconditioning increases residence time and capacity and reduces mechanical energy consumption. Preconditioning enhances flavor development and aids the final product texture. Modern preconditioners have a double-shaft design with different dimensions and speeds, and can be operated at both atmospheric pressure and elevated pressures, resulting in better mixing with retention times between 2 and 4 minutes.

38.2.3.5 Drive System

The main function of the drive system is to provide power to rotate the extruder screw(s). The drive usually consists of an

electric motor, a reduction gear, a torque transfer system, and a bearing support mechanism. The size of the motor depends on the application and capacity of the extruder and may be as large as 400 hp. For instance, a low shear stress (slow speed) extruder may require a motor of 13 hp, whereas a high shear stress extruder used for the production of light density expanded snacks may require a motor of 160 hp per ton of throughput. In general, the synchronous speed of an electric motor is 1800 rpm; however, the actual maximum speed of the motor is 1725–1750 rpm because of slip. The screw speed of food extruders is normally less than 500 rpm. Required speed reduction is usually accomplished through a V belt or gear. Gearbox construction for a single-screw extruder is simple because the gearbox has only one output shaft to drive the screw. Gearbox construction for a twin-screw extruder is complicated because there are two output shafts to rotate two screws and because there is limited radial space to accommodate bearings to support both the radial and thrust load from the extruder. In general, a three-bearing arrangement (two to support the radial load and a third to absorb thrust load) is used if a single-screw extruder has a motor size of more than 100 hp.

38.3 EXTRUDER VARIABLES

Screw speed, barrel temperature, screw and barrel configuration, die opening, and feed rate are some of the parameters that affect extruder performance. Extruder operation depends on pressure buildup in the barrel (prior to exiting the die), slip at the barrel wall (transportation), and the degree of filling.

38.3.1 Screw Speed

In general, screw speed is responsible for the rate of shear development and the mean residence time of the feed. The heat dissipation from the mechanical energy input to dough depends on screw speed, which in turn influences dough viscosity. In some cases, the completion of texture formation and chemical reactions within the barrel requires a long residence time, which corresponds to slow screw speed.

38.3.2 Barrel Temperature

In order to avoid plugging and backflow of material, the feed zone temperature is low and barrel temperature ramps up as the material travels down the screw. Barrel temperature usually has a positive effect on the degree of starch gelatinization and extrudate expansion, whereas it has a negative effect on product color, especially at elevated temperatures. Several studies have indicated that elevated temperature leads to more moisture evaporation when exiting the die, and thus results in more expanded products.

38.3.3 Feed Rate

Extruder feed rate depends on the type of screw element, screw speed, type of feeding element, and feed moisture. Feed rate has an influence on residence time, torque requirement, barrel pressure, and dough temperature.

38.4 FEED INGREDIENT VARIABLES

Feed composition, moisture content, and particle size have the greatest effects on extrusion. These factors are discussed in the following sections.

38.4.1 Feed Composition

The typical composition of any blend consists of starch, protein, lipid/fat, and fiber, which all contribute to product quality. Starch degradation usually reduces product expansion. It is essential that infant and weaning foods have high starch digestibility, which is largely dependent on full gelatinization [7]. Lipid levels over 5–6% act as a lubricant, reducing slip within the barrel and resulting in poor product expansion. If the production of porous and expanded product is not the target, then a fat level of 15–18% can be used in single-screw extruders and a fat level of 20–22% in twin-screw extruders. The lipid content of the extruded product is low. Rancidity is an issue for extruded products during storage because of lipid oxidation, which causes rapid deterioration of sensory and nutritional qualities [8]. Sugar and salt (functional ingredients) have more effects on wear than other ingredients. In cereal processing, sugar concentration has a negative effect on viscosity, and high sugar concentration inhibits gelatinization, requiring higher temperatures to achieve the same degree of product expansion. Salt will assist in obtaining uniform moisture migration after drying of third-generation pellets during moisture equilibration. In general, salt reduces water activity, which leads to poor product expansion. Generally, fiber is a noninteracting component that contributes to low expansion, cohesiveness, durability, and water stability. High fiber content usually results in high screw wear [9].

38.4.2 Feed Moisture

Moisture is a critical variable that has multiple functions in starch gelatinization, protein denaturation, barrel lubrication, and final product quality. Processing is uneconomical at in-barrel moistures below 20% and results in undesirable nutritional quality. However, a dry extruder can process materials with 8–22% moisture with no additional drying of extrudates. In general, a medium shear stress extruder can handle food with 16–30% in barrel moisture, whereas a low shear stress extruder can handle food with more than 30% in-barrel moisture (pasta dough has 31%). An increase in moisture content will have a pronounced effect on the rheological properties of the melt in the barrel. High-moisture feeds decrease the mechanical energy requirement and reduce the wear and thereby operating cost. However, most extruded snacks have a moisture content between 8% and 12%, and require additional drying to impart the desired texture and mouthfeel. High moisture reduces vitamin loss during extrusion due to limited thermal degradation.

38.4.3 Feed Particle Size

As a general rule of thumb, the extruder feed should not have particles larger than one-third the diameter of die holes. Particle size also plays an important role not only in moisture distribution, heat transfer, and viscosity but also in final product quality. Coarse ingredient particles have more effect on wear than fine particles. A product composed of fine particles will have good water stability, water absorption index, expansion, and floatability.

38.5 INTERRELATIONSHIPS OF EXTRUDER AND INGREDIENT VARIABLES

A better understanding of the interactions between the extruder and ingredients within the barrel facilitates the development of not only screw and barrel configurations for converting mechanical energy to heat through friction but also new products. Extrusion experiments typically examine two to three variables, but many factors are important. The outer square shows the primary extruder and ingredient variables and the inner square shows the secondary variables. Viscosity is a reflection of the molecular weight of functional polymers and its measurement correlates with the energy input to an extruder. Although viscosity and residence time are placed in the inner square, they are affected by other variables in the same square. In general, an extruder converts ingredients into dough. Gelatinization of starch causes a substantial uptake of moisture, resulting in an increase in dough viscosity. An increase in feed rate and screw speed and a reduced L/D ratio has a negative effect on product residence time, which in turn affects dough viscosity. As screw speed increases, dough viscosity decreases because dough exhibits non-Newtonian behavior. High temperature and low moisture are responsible for the formation of Maillard compounds and heterocyclic chemicals, resulting in a typical cooked grain flavor. High barrel temperature, screw speed, specific mechanical energy (SME), low feed moisture, die diameter, and throughput are the variables that increase vitamin loss during extrusion. A die with long land results in a dense product and thereby increased bulk density. The amount of starch, protein, and fat present in the blend affects product expansion and firmness. The torque indicates the amount of energy absorbed by the material due to shear exerted by the screw(s). Motor torque is a very sensitive indicator of stable operation during extrusion. Fluctuation in motor torque usually indicates non-steady state extrusion conditions; it occurs when there is erratic feeding and surging, and may cause plugging of the die. Therefore, one must ensure uniform and consistent feeding. SME indicates the extent of molecular breakdown or degradation that the material undergoes during the extrusion process. An increase in moisture content decreases the viscosity of dough in the extruder, shortens the mean residence time, and reduces the conversion ratio of extruder mechanical energy into heat energy, and consequently SME becomes lower.

In general, the power supplied to a screw is used to transport, compress, and shear the melt/mass. Considering shear stress on the melt at the inner wall and the contact area of a single-screw extruder, the power requirement can be calculated using the following equation:

$$P = \tau\pi^2 D^2 NL \tag{38.4}$$

where P is power (W), τ shear stress (N·mm^{-2}), D screw diameter (mm), N screw speed (rpm), and L length of filled section (mm). This equation defines the thermomechanical process for a given screw geometry. SME is defined as the mechanical energy input required to obtain the unit weight of extrudate and can be calculated by the following equation:

$$SME = \frac{\omega}{m_f} \tag{38.5}$$

where SME is specific mechanical energy (W·h·kg^{-1}), Γ torque (N·m), ω angular velocity (s^{-1}), and m_f mass flow rate of feed (kg·h^{-1}). These equations show that the torque developed in an extruder is apparently the product of shear stress and filled length since the screw speed is expressed as angular velocity. Screw speed directly influences extrusion because the peripheral velocity of the screw (πDN) is proportional to screw speed. The filled length and shear stress during extrusion depend on total throughput and in-barrel moisture content.

Typically, SME is an indication of the viscous dissipation of mechanical energy, which is provided by the screw drive shaft, into the dough due to frictional resistance. The SME for direct expansion of cereals is as high as 80 W·h·kg^{-1}, with high shear provided by high screw speeds and/or shallow screws. As screw speed increases, SME also increases because the changes in energy input to the screw are of a greater order of magnitude than the decrease in torque associated with the decrease in apparent viscosity due to the shear thinning behavior of non-Newtonian material. An increase in barrel temperature generally leads to a decrease in dough apparent viscosity, which not only results in low SME to the drive screw shaft at a given speed but also produces a more expanded product on die exit.

Any variable affecting the viscosity of the material in the extruder would correspondingly affect torque [10]. Feed composition plays a role in affecting secondary extrusion variables including torque. At low screw speeds, the residence time of the viscous melt is increased, allowing greater plugging of the die section and subsequent increases in torque. The torque required to turn the extruder screw is also related to degree of fill in the extruder barrel. Increasing barrel temperature contributes to a decrease in viscosity, which results in flowable material and thus a lower required driving force. At constant temperature, viscosity decreases with increasing moisture content because water acts as a lubricant.

Residence time influences the degree to which the raw material experiences shearing, heating, shaping, mixing, and reaction. The effect of moisture content on the mean residence time is the result of two opposing effects of moisture content on rheology of feed material in the barrel and die of the extruder. On the one hand, increasing the moisture

content of feed material results in a decrease in viscosity of feed dough in the barrel of the extruder, and lower force is required to pump the melt through the die. On the other hand, temperature in the die due to viscous dissipation is lower, and the lower temperature of the feed increases the viscosity at the die, which tends to increase the restriction of flow through the die.

38.6 FUNCTIONS OF AN EXTRUDER

Numerous functions can be carried out in an extruder for food, feed, and other industrial applications.

38.6.1 Agglomeration

Ingredients can be compacted and agglomerated into discrete pieces with an extruder. The main purpose of agglomeration is to improve certain physical properties of food powders such as bulk density, flowability, dispersability, and stability. Agglomerated products are easy to use by consumers and hence are preferred over the traditional nonagglomerated products that are usually nonflowable in nature. One of the problems identified in the pasta-making process is the formation of large wet agglomerates. Researchers have characterized the wet agglomeration properties of semolina and a whole hard white winter wheat flour enriched with flaxseed flour [11, 12]. The flour compositions were semolina 100% (S), whole wheat 100% (WW), semolina–whole wheat (49:51) (SWW), semolina–flaxseed (SCF/SFF) (90:10), whole wheat–flaxseed (WWCF/WWFF) (90:10), and semolina–whole wheat–flaxseed (SWWCF/SWWFF) (39:51:10). Samples were hydrated to 30%, 31%, 32%, 33%, and 34% moisture content and extruded. SFF hydrated above 30% moisture had the largest agglomerates. Recommendations were 30%, 32%, 33%, 34% moisture for SFF, SCF, WWFF and SWWCF.

38.6.2 Dehydration

During normal extrusion processing, a moisture loss of 4–5% can occur. The rate of moisture loss depends on the feed. In the case of high starch products, moisture loss can be greater than 80%. In certain cases, the situation depends on the feed and process parameters. A barley–oat breakfast cereal supplemented with 10% green or yellow pea was extruded at barrel temperature 81.9–103.6°C, die temperature 57.3–77.3°C, and screw speed 200 rpm [13]. The physicochemical properties of extruded cereal were determined, and it was found that the moisture content increased with increase in oat content. In other cases, the moisture flashes out as vapor and the resultant product is crispier.

38.6.3 Expansion

Product density can be optimized by extruder operating conditions and configuration. The extruded product usually puffs and changes texture due to the reduction of forces and release of moisture and heat. The extent to which it does so is known as the expansion ratio. Corn starch with carrot pomace (5, 10, and 15 g/100 g) was extruded at with initial feed moisture levels of 15, 22.5, and 30 g/100 g [14]. Corn starch without any added pomace was extruded as a control treatment. Maximum expansion was observed in extrudates with 5 g/100 g carrot pomace and at 15 g/100 g feed moisture.

38.6.4 Gelantinization

Extrusion cooking improves starch gelatinization. During extrusion, the physicochemical transformation of starch takes place without any additional chemicals. Barothermal treatment causes gelatinization of starch. This process is accompanied by rupture of intermolecular bonds, resulting in rupture of starch grains and a significant increase in water absorption. The amylose fraction of starch has greater binding properties than the amylopectin fraction. The degree of changes in starch depends on properly selected process parameters and the residence time of raw material in the extruder [15].

A twin-screw extruder was employed to blend yam, rice, and cornflour [16]. Yam flour (10–40%), feed moisture content (12–24%), and extruder barrel temperature (100–140°C) were the factors selected to characterize the gelatinization. The water absorption index, an index of starch gelatinization, varied between 5.23 and 6.34 g/g dry solid. At higher moisture content, viscosity was reduced and allowed the starch molecules to circulate. This phenomenon increased heat penetration and resulted in greater gelatinization.

38.6.5 Mixing

Various screws are accessible, which enable different mixing actions in the extruder barrel. Starch is a hydrophilic biopolymer. An intense mixing process is vital to combine the hydrophobic molecules and to attain the anticipated dispersed phase morphology. Shear stress distributions indicate that increasing screw speed decreases the maximum shear stress undergone by the particles. However, at higher screw speeds, particles are exposed to higher capillary ratios and these show that mixing efficiency is increased. In short, a decrease in the shear stresses does not essentially lower mixing efficiency because a simultaneous decrease in blend viscosity leads to a higher capillary ratio. Research indicates that increasing the screw speed not only helps fine dispersion but also retains lipophilic bioactives susceptible to mechanical stresses [17].

38.6.6 Protein Denaturation

Animal and plant protein can be denatured by extrusion cooking. The modification of proteins during extrusion cooking is mainly attributed to thermal effects and shear. Protein denaturation is the primary thermal effect. Under the influence of high temperature and moisture, native proteins lose their structure (globular, micellar), unfold, adsorb water and "melt." Just as starch gelatinization, in extrusion cooking, protein denaturation occurs at lower moisture content, resulting in a

high viscosity melt [18]. In the case of soy protein, it has been shown that the protein in the extrudate is completely denatured, provided that extrusion temperature was above 130°C. Pea and kidney bean seeds were extruded at 148°C and 156°C, respectively [19]. Protein solubility at various pH values and in various solvents was carried out. Analysis of protein fractions was performed by SDS-PAGE. Results indicated that protein solubility from both raw and extruded legumes was significantly higher in saline solutions. The protein solubility of extruded pea and kidney bean flours decreased sharply with respect to native flours when extraction was done in a buffer (pH 7.0) alone. The experiment suggests that extrusion caused insolubilization of protein by noncovalent interactions and disulfide bond formation. Denaturation and aggregation led to a decrease in the superficial hydrophobicity resulting in the establishment of a three-dimensional network with higher water-holding capacity, smaller oil absorption capacity, and lower protein solubility. Furthermore, aggregation decreased the protein solubility.

38.6.7 Texture Alteration

Textures can be changed by varying operational parameters and feed/additives in the extrusion system. The extruded product usually puffs and changes texture because of the reduction of forces and release of moisture and heat. Research was conducted to formulate a functional dairy ingredient by extruding milk protein concentrate with 80% protein [20]. The ingredient was incorporated in high-protein nutrition (HPN) bars. This resulted in favorable texture attributes, such as reduced firmness and improved cohesiveness. Protein ingredient, storage temperature, and storage time had a pronounced effect on the max force, shear force, adhesiveness, cohesiveness, and crumbliness during instrumental texture measurement. The control sample became less cohesive around week 18 at 22°C and week 10 at 32°C. During the two-bite test, after one compression the HPN bars deformed. The crumbliness of the HPN bars with extruded MPC80 increased gradually at 22°C, whereas the increase was more distinct at 32°C. Extruded MPC80 HPN bars were softer, stable, and cohesive as compared to spray-dried control MPC80 even after extended storage.

38.6.8 Thermal Cooking

Instead of just combining feed, a desired cooking effect can be achieved in the extruder. The cooking process takes place within the extruder where the product produces its own friction and heat due to the pressure generated (10–20 bar). The process can induce both protein denaturation and starch gelatinization under some conditions. A ready-to-eat snack was developed from finger millet through extrusion cooking. Seven composite mixes were formulated with different compositions of brown finger millet flour, maize flour, rice flour, full-fat soy flour, Bengal gram flour, and skimmed milk powder [21]. Extrusion cooking was carried out using a twin-screw extruder. The operating parameters were temperature 140°C, screw speed 300 r min^{-1}, and die diameter 3 mm. The bulk density ranged from 0.1618 to 0.3946 g cm^{-3}, and expansion ratio values oscillated between 2.42 and 3.50. The sample containing the least amount of finger millet flour of about 10% had the lightest color, while the mix with the highest amount of brown finger millet flour (40%) had the least value for hardness. The average scores of sensory evaluation indicated that all the extruded products were within the acceptable range. The most acceptable extrudates were obtained from brown finger millet flour, maize flour, rice flour, and full-fat soy flour in the ratio of 20:50:20:10, which had an expansion ratio of 3.5, hardness 23.37 N, and organoleptic characteristics 8.87.

38.7 ADVANTAGES OF EXTRUSION

The principal advantages of extrusion technology compared to traditional food processing methods include the following:

- *Adaptability*: A wide variety of extrudate production is feasible by altering the minor ingredients and the operational parameters of the extruder. In addition, it can enhance product differentiation by accommodating consumer demand.
- *Product characteristics*: The shape, texture, color, and appearance can be changed very easily without major changes in the hardware, which is not easily feasible using other production methods.
- *Energy efficiency*: Redrying of extrudates is not required, as the extruders operate with relatively low moisture while cooking food products.
- *Low cost*: The estimated savings using the extrusion process are raw material (19%), labor (14%), and capital investment (44%). Moreover, it needs less space per unit of operation as compared to traditional cooking systems.
- *New product line*: Extrusion has the ability to transform animal and vegetable proteins, starch, and other food materials to create unique and attractive food products.
- *High productivity and automated control*: An extruder delivers continuous high-throughput processing. It is completely automatic.
- *High product quality*: Extrusion is a high-temperature/short-time (HT/ST) heating process. This reduces nutrient loss and improves the digestibility of protein and starch. In addition, high temperatures also destroy antinutritional compounds such as trypsin inhibitors, detrimental enzymes (lipases, lipoxidases), and microorganisms.
- *No effluent*: New environmental regulations are stringent and expensive. Extrusion results in little or no waste streams.
- *Process scale-up*: Pilot plant experimental results can be used to scale up the extrusion system for industrial production.
- *Use as a continuous reactor*: Extruders are being used as continuous reactors in several countries

for deactivation of aflatoxin in peanut meals and destruction of allergens and toxic compounds in castor seed meal and other oilseed crops.

38.8 CRITICAL FACTORS IN EXTRUSION PROCESSING AFFECTING MICROSTRUCTURE

Raw ingredient compositions, processing equipment selection, and processing parameters are independent variables that can be experimented to create new extrudates [22]. Though the parameters are independent, they are correlated since discussions on one variable will usually encompass the others. Selection of raw materials has a remarkable influence on the extrudate texture, uniformity, extrudability, nutritional quality, and economic viability. Generally, extrusion converts cereal/pulse blends into a dough. The starch gelatinizes and increases moisture absorption, thereby increasing dough viscosity. On the other hand, protein influences the elasticity and gas-holding properties, which is a characteristic of hydrated and developed glutinous doughs. Some proteins are responsible for the adhesive and stretchable functional properties.

The rich nutritional property is the basis for raw material selection in extrusion. Economics and raw material availability are vital factors too. During purchase, desirable characteristics are listed and can be verified by proximate analysis. However, the nutritional properties are only vaguely recognized and no test exists to monitor quality. Storage and preprocessing prior to extrusion significantly affect when the materials are subjected to heat, pressure, and shear. Cereals and pulses that have been recently harvested behave much differently than raw materials stored for 6 months during extrusion. A sample library listing acceptable and unacceptable ingredients helps in maintaining a smooth-running extruder.

38.8.1 Selection of Hardware Components

Choosing the proper extruder configuration is critical to successful extrusion. The manufacturer of the extrusion equipment should be able to assist in tailoring configurations for processing a specific product. There are many types of extruders, and each has a specific range of applications. An improper extruder selection for the specific application very rarely results in a smooth-running process. Once the proper extruder is selected, it must be assembled correctly and then adequately maintained. Training is important, and the supplier of extrusion equipment must be able and willing to provide this service. Knowledge of what parts will wear and what their useful life will be will avoid costly and inconvenient shutdowns. Records are imperative in this endeavor and greatly reduce the necessity of costly parts inventories. Processing equipment selection is highly important. The highest operating efficiency and versatility at low cost are the key factors considered during hardware selection.

The rate/capacity of the plant is crucial, as it may help in futuristic activities such as plant expansion. The extrusion system, whether a single-screw or co-rotating twin-screw configuration, must accomplish a number of phenomenon in a very short time under controlled, continuous, steady-state conditions. These phenomena include tempering, feeding, mixing, cooking, cooling, and shaping. The pressure, temperature, moisture, microstructure, texture, and resulting viscosity of the extrudate are affected by the system configuration and processing conditions. Selection of the proper system configuration includes choosing from the following hardware components: (i) feed delivery system, (ii) tempering or preconditioning phase, (iii) extruder barrel components, and (iv) die and knife configurations.

Familiarity with the extrusion properties of ingredients and the interaction of such equipment parameters as screw speed and hardware design can allow a general classification of all extruders into three categories (Figure 38.5). These three categories rank extruders by relative shear stress and product categories. Once the hardware is selected, a list of independent variables that the extruder operator can directly manipulate include

- Incoming recipe (the actual recipe, particle size, and moisture and temperature resulting from preconditioning)
- Rate (the rate at which the recipe is introduced into the extruder)
- Percent steam addition (steam at 6–9 bar can be injected directly into the material in the extruder barrel)
- Percent water addition (water at various temperatures and 3 bar can be injected directly into the material in the extruder barrel)
- Percent liquid addition (other liquids and/or gasses can also be introduced into the extruder barrel)
- Extruder and die configuration
- Temperature and flow rate of thermal fluid to barrel jackets
- Extruder speed (requires a variable speed drive)

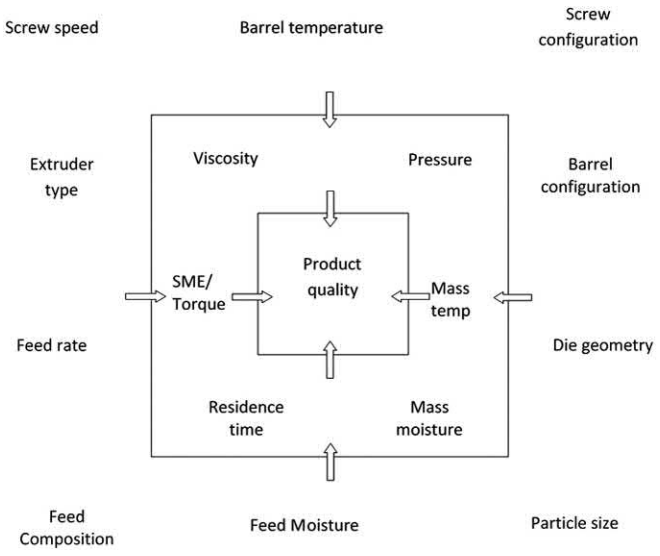

FIGURE 38.5 Interactions between extruder and ingredient variables.

When changes from this list are made, they will in turn affect other operating variables (referred to as dependent variables): (i) material retention time in the extruder barrel, (ii) product temperature in the extruder barrel, (iii) product moisture in the extruder barrel, and (iv) pressure in the extruder barrel.

38.9 SUPERCRITICAL FLUID EXTRUSION

The formation of carbon dioxide (CO_2) during extrusion normally enhances extrudate expansion [23]. During cereal extrusion, sodium bicarbonate reacts with acidulants or acids produced by the oxidation of starch during extrusion to form CO_2 [24]. Instead of relying on CO_2 formed during extrusion, CO_2 can be injected into the extruder; thus the degree of expansion and structural homogeneity of starch or cereal flour extrudates can be controlled using blowing agents. CO_2 is the solvent of choice for use in supercritical fluid extrusion (SCFX) because it is generally recognized as safe (GRAS), nonflammable, noncorrosive, and inexpensive; its critical point is at 31.06°C and 7.386 MPa. High temperatures (130–170°C) and shear used in traditional extrusion prevents the use of thermally labile/heat-sensitive ingredients such as some flavors, colors, and whey proteins. SCFX uses supercritical CO_2 (SC-CO_2) as a blowing agent to facilitate the formation of cellular structure in extrudates in place of the expansion of water upon exit of the extruder barrel in conventional extrusion. A four-step process has been developed: (i) development of a dough with gas-holding properties by mixing alone; (ii) injection of SC-CO_2; (iii) creation of controlled thermodynamic instability by manipulation of pressure and/or temperature in the extruder; and (iv) control of the degree of cell growth during setting of the product through appropriate die selection and postextrusion drying and cooling processes.

Product expansion by CO_2 offers several advantages over steam expansion: a closed-cell structure; CO_2 does not condense, resulting in cell collapse; and the product's interior is very nearly oxygen-free. Moreover, the melt pH is low because dissolved SC-CO_2 inhibits the Maillard reaction, which otherwise would cause further loss of essential amino acids. The physical properties of starch-based SCFX extrudates are governed by both extrusion and postextrusion parameters, including die geometry, pressure drop rate, residence time, ingredient composition, and drying temperature. Expansion and cellular characterization of the starch-based extrudates produced with SC-CO_2 injection may be governed by viscosity-dependent parameters, including gas retention capability, CO_2 diffusivity, and the pressure drop rate. An increase in the degree of gelatinization of starch–water mixtures using 0.45 wt% SC-CO_2 injection increased expansion and average cell density, and decreased average cell size. SCFX technology is a patented process that has already resulted in new developments in cereals, confectioneries, pastas, flavorings, pharmaceuticals, snacks, and other products. SC-CO_2 injection rate and product temperature at the die are the critical factors controlling the expansion and texture of the final product.

38.10 COST ECONOMICS OF EXTRUSION

Cost economics is essential in preparing the capital and operating cost estimates and profitability analysis of any food processing plant [25]. Based on the process flowchart, one can calculate the material and energy balances and the utility requirements of the processing plant [26]. The capital cost includes the cost of equipment, installation, commissioning, site development, buildings, and land. The cost of the extruder depends on the type of extruder (single/twin), construction material, capacity, accessories (preconditioner, dryer), and the manufacturer. Extruders are available for research and development at laboratory scales (4.5–36 $kg{\cdot}h^{-1}$) and for large-scale industrial production. A pilot-scale single-screw extruder (76.2 mm diameter and 305 mm length) with a capacity of 90 $kg{\cdot}h^{-1}$ would cost about $70,000, with an extra $20,000 if a live bottom hopper is included [22]. Capacity varies from 25 to 25000 $kg{\cdot}h^{-1}$, with motor power varying correspondingly from 22 to 450 kW. Similarly, cost of the extruder also varies from $75,000 to $750,000. The cost of a single-screw extruder is about half the price of a twin-screw extruder, and maintenance costs are lower. Although wet extruders (steam/water can be injected into the barrel) have higher capital costs than dry extruders (no external heating through addition of steam/water or jacket heating), they usually have lower operating costs. In general, wet extruders have higher capacities than dry extruders because of the large drive motor requirements per unit throughput on dry extruders.

Direct production costs can be divided into raw materials (basic ingredients, sugar, salt, color, additives, etc.), labor (operator, supervisor, plant engineer, etc.), utilities (gas, steam, water, and electricity), packaging, spares, and maintenance [27]. Fixed charges comprise depreciation of equipment and facilities, interest on borrowed capital, local tax, insurance, rent, etc. Raw material constitutes 35–60% of the cost, labor 5–10%, packaging 25–50%, utilities 5–10%, and all others including maintenance 5% [28]. The wide variation in raw material and packaging costs depends on the type of product and packaging. Packaging costs have increased considerably and depend on the type of product and size of the pack. Profitability depends on the volume of product; for instance, a high-volume product may have a profit of about 25%.

38.11 CONCLUSION

Extrusion technology has substantially modified the technological environment of processing industries in recent decades. Since its first introduction in the 1930s in the polymer industry, extrusion processing has never stopped expanding its technical contribution, owing to the establishment of extrusion cooking. Hence, extrusion processing technology is able to provide relevant and cost-effective processing solutions in the food and feed industry. The productivity, versatility, and reliability of extrusion cooking have made it one of the favorites, and currently, it is widely used in the cereal processing industry, both in food and feed areas, particularly when viscous biopolymeric materials, mixing of solids or liquid ingredients, or

special texturization are involved. Major commercial applications have been introduced over the years, which have required significant engineering development to design extrusion processing lines adapted to the specificities of extrusion-cooking technology. The complexity of food extrusion processing has clearly emerged from the different topics presented in this chapter. The complexity results mainly from the nature of the raw materials used in extrusion cooking, the specificities of the conversion process, and the physical characteristics of the final products produced by the process. Food extrusion deals with natural food materials such as starch and protein-based materials with characteristics that vary extensively depending on many factors such as botanical origin, climate, harvesting, and storage conditions. All these factors significantly affect the physicochemical ability of food materials to sustain the extrusion process. The future of extrusion processing technology will be more driven by the development of process intensification, owing to principles of sustainable development and the subsequent need for sustainable processing technologies. The need for sustainability will promote and boost the development of extrusion processing technology.

39 Food Preservation by Freezing

Mohammad Shafiur Rahman and Jorge Fernando Velez-Ruiz

CONTENTS

39.1 MODE OF PRESERVING ACTION

Freezing provides a significant extended shelf life, and it is successfully employed for the long-term preservation of many foods. The freezing method is still one of the most widely used methods of food preservation even though several new technologies, such as high pressure, infrared irradiation, pulsed electric field, and ultrasound freezing, continue to emerge. Freezing changes the physical state of a substance by changing water into ice when energy is removed in the form of cooling below freezing temperature. Usually the temperature is further reduced to storage level (e.g. –18°C). The

freezing process can be clearly shown by using freezing or cooling curves and phase diagrams.

The freezing of foods slows down, but does not stop, the physicochemical and biochemical reactions that govern the deterioration of foods [1]. There is a slow progressive change in organoleptic quality during storage, which does not become objectionable for some time [2]. The loss of quality of frozen foods depends primarily on storage temperature, the length of storage time, and the thawing procedure. Microbial growth is usually stopped below –7°C, and both enzymatic and non-enzymatic changes continue at much slower rates during frozen storage [3].

The freezing process reduces the random motion and rearrangement of molecules in the matrix [3–5]. Freezing involves the use of low temperatures, and reactions take place at slower rates as the temperature is reduced. The presence of ice and an increase in solute concentration can have significant effects on the reactions and state of the matrix [6]. The final influence of temperature on chemical reactions due to freezing could be grouped as (i) normal stability (a temperature decrease results in a slower reaction rate, thus better stability when foods are stored), (ii) neutral stability (the temperature has no influence on the reaction rate), or (iii) reversed stability (a temperature decrease results in an increased reaction rate) [7]. Regardless of the type of aqueous system, concentration during freezing causes the unfrozen portion to undergo marked changes in such physicochemical properties as ionic strength, pH, viscosity, water activity, surface and interfacial tension, and oxidation-reduction potential. It is important to note that oxygen is almost totally expelled from ice crystals as they are formed [8]. Three types of cell damage occur due to freezing: osmotic damage, solute-induced damage, and structural damage [6].

In slow cooling, ice forms slowly in the external cells. If there is sufficient time, water from the cells migrates out by osmotic pressure. This results in cell shrinkage and some membrane damage. This water does not return to the cells on thawing due to the damage of cell wall, and the consequence is drip loss [6]. The concentration of the solute increases as freezing progresses. Thus, high solute concentrations in the unfrozen matrix, in particular high salt, can cause damage to many polymeric cell components and may kill the cell [9]. This concentration effect is present whether freezing is fast or slow. Cryoprotectants, such as sugars, are usually added to the aqueous phase to reduce salt-induced damage [6]. In addition to the concentration effect, the formation of ice within the cell may cause damage to the delicate organelle and membrane structure of the cell. As a consequence, enzyme systems may be released, leading to a variety of effects, including off-flavor production. This can be prevented by blanching, a pre-freezing heat treatment that denatures enzymes [6].

It is possible to design and control a convenient freezing process through an awareness of the mechanisms of damage for each particular food item [6]. In general, freezing preservation is far from perfect, and awareness of this fact is needed if techniques are to be developed to overcome known shortcomings and to assure that this method remains competitive with the other major methods of food preservation [10]. A strategic quality approach (quality enhancement) may provide a higher success rate for new frozen food products [11]. Product quality improvement and reduced energy or increased process efficiency are major issues related to the freezing process.

39.2 FREEZING RATE AND QUALITY

Controlling the freezing process, including careful pre-freezing preparation and post-freezing storage of the product, is an important aspect of achieving a high-quality product [12]. An important factor in the quality of frozen foods is the freezing rate [13]. Generally, fast freezing produces better-quality frozen food than slow freezing, although the reason for this is not as well-understood as is sometimes stated. The rate of freezing of plant tissue is important because it determines the size of the ice crystals, cell dehydration, and damage to the cell walls. Ice crystal structure is crucial for the preservation of the quality of frozen products [14].

In the case of animal tissue, the concentration of salt within the cells is higher than that in the extracellular region. Consequently, freezing starts outside the cells due to the freezing point depression induced by the solute concentration in the cells. As soon as ice appears, the solute concentration rises. This is a characteristic phenomenon of freeze concentration. At some point, osmotic pressure difference causes water to flow through the semipermeable cells to the extracellular region in order to balance the chemical potentials. This dehydration of the cell is accompanied by shrinkage of the cell, which is not normally lethal. The freezing rate affects this process because rapid freezing results in less cell dehydration (since water has less time to diffuse out of the cell), less breakage of cell walls, and less textural damage. The more rapid the crystallization, the smaller the ice crystals and the less damage is caused by the process of freeze concentration. Consequently, a reverse situation holds for thawing. Slow heating allows equilibrium to be reached as the melted water diffuses back through the cell wall.

In the case of plant tissue, there is evidence that large ice crystals can cause mechanical damage to cell walls in addition to cell dehydration. In agarose gels, large ice crystals (100–300 μm) with increasing interstitial spaces grow under slow freezing conditions at –25°C, while small ice crystals (1–2 μm) form during rapid freezing in liquid nitrogen [15]. Bevilacqua et al. [16] measured the diameter of the intracellular dendrites and extracellular ice crystals for meat frozen under simulated conditions similar to industrial freezing. They correlate the ice crystal diameter with the characteristic freezing time. De Kock et al. [17] studied the effect of freezing rate (cryogenic, fast; mechanical, slow) on the quality of cellular and non-cellular precooked starchy foods. Quality was determined immediately after freezing, as well as after frozen storage, by chemical, physical, microscopic, and sensory methods. The rapid freezing of cellular starchy food resulted in a better-quality product than slow freezing immediately after freezing. Rapid freezing of non-cellular starchy food, however, produced a product that was only slightly better in quality than the slowly frozen product. After storage, the

rapidly frozen cellular product was better in quality than the slowly frozen product, although the difference was smaller. The slight advantage gained by rapid freezing of the non-cellular product was lost in the progress of storage [17].

Symons [18] expressed that undue emphasis on the importance of freezing speed is sometimes misleading. Unless freezing is excessively slow, days or weeks rather than hours, most products are comparatively insensitive to the speed of freezing. In any case, an increase in volume of around 10% is associated with freezing of most foods. Broadly speaking, faster freezing is marginally better than slower in most products. This is particularly true for fruit and vegetable products, but less so for animal tissue [18]. Moreover, the initial advantage obtained by fast freezing is lost during storage due to re-crystallization [17]. Although fast freezing has advantages, some products may crack or even shatter if exposed directly to extremely low temperatures for a long period. Hung and Kim [19] reviewed the fundamental aspects of freeze cracking and strategies for its prevention. The mechanisms to explain freeze cracking vary, and the proposed mechanisms are:

Volume expansion: The volume expansion due to the formation of ice, and amount of empty space in a microstructure are the primary factors affecting the degree of mechanical damage to cells during freezing. In addition, differences in moisture content, composition, or amount of un-freezable water may cause different degrees of cracks [20].

Contraction and expansion: Cracking may also act to relieve the product of internal stress from non-uniform contraction during rapid cooling [21, 22]. On the other hand, both contraction and expansion may cause freeze cracking [23].

Internal stress: Fast freezing will cause crust formation at the surface, which serves as a shell and prevents further volume expansion when internal portion of the unfrozen material undergoes freezing. This process then contributes to the internal stress buildup later in the freezing process. Freeze cracking occurs if the internal stress exceeds the strength of the exterior frozen material during processing [24]. The distribution of the stress is the controlling factor, and it is governed by absorbing (dissipating) the stress into the structure or reflecting the stress to cause a buildup of internal stress [25].

Miles and Morley [26] studied the internal pressures and tensions in meat during freezing, frozen storage, and thawing. A maximum stress of almost 6000 kPa is possible. They found that during freezing internal compression developed at a rate that increased as freezing progressed, and most of the pressure was developed after the center had started to freeze. Generally, the circumferential tension in the outer surface of the muscle reached a breaking point, and a shallow crack formed along the length of the muscle or the surface yielded, causing a bulge [26]. Kim and Hung [25] found that size, moisture content, density, modulus of elasticity, Poisson's ratio, and porosity all had significant influence on freeze cracking. However, no single property completely explained the development of freeze cracking [25]. Excessive freezing speeds can ruin a food product. The build-up of internal pressure during very rapid freezing shatters the already frozen external layers and produces very small crystals, leading to scattering of incident light [18]. The current practice of quick freezing is generally chosen in order to save processing time (cost) and factory space. Moreover, rapidly chilled muscles become tough on freezing and thawing, a phenomenon known as cold shortening (not a problem in poultry) [18].

In foods containing microbial cultures, it is important to maintain their activity. Rapid freezing causes detrimental effects on the yeast activity of frozen dough. This may be due to the formation of intracellular ice crystals invariably lethal to yeast cell membranes [27]. Yeast activity decreased significantly when the rate of cooling was increased from 0.98 to 1.57°C per minute [28].

39.3 MICROBIAL ASPECTS

The detrimental effects of freezing on microorganisms may be desirable or undesirable, depending on the types of food products. In frozen foods, without any added beneficial cultures, microbial growth or spoilage is not desirable, whereas care must be taken to reduce the damage in cells during freezing of foods containing microbial culture. The maximum recommended storage temperature at which microbiological spoilage ceases lies between –9 and –12°C. Although microbiological spoilage can be avoided at these temperatures, the enzymes present in the product still play a part in spoilage. Hence, hygienic conditions or heat processing (blanched or cooked) can lead to a longer shelf life [18]. Freezing causes the apparent death of 10–60% of the viable microbe population, and this proportion gradually increases during frozen storage [29].

39.3.1 Pathogens and Spoilage Microorganisms

Microorganisms differ considerably in their sensitivity to freezing; thus the main concern is organisms that are likely to survive the freezing treatment and grow when the product is thawed. There is considerable variation in the ability of bacteria to resist damage by freezing [30]. In general, Gram-negative bacteria are less resistant to freezing death than are Gram-positive bacteria. Nonsporulating rods and spherical bacteria are the most resistant, while bacterial spores, such as *Clostridium* and *Bacillus*, remain unaffected by freezing. Bacteria in the stationary phase are more resistant than those in log phase [2, 29–31]. Genera commonly encountered in frozen food include *Pseudomonas*, *Achromobacter*, *Flavobacter*, *Micrococcus*, *Lactobacillus*, *Corynebacterium*-like catalase-positive rods, *Enterococcus*, *Streptococcus*, *S. lactis*-like streptococci, *Aerococcus*, and *Pediococcus* [29, 32]. Gianfranceschi and Aureli [1] studied the survival of *Listeria monocytogenes* during freezing (–50°C) and frozen storage (–18°C) when inoculated into chicken breast, ground beef, spinach, mozzarella cheese, and codfish. They observed only a slight decrease in the viable population ranging from 0.1 to 1.6 log after 57 min at –50°C. *Listeria monocytogenes* cells were more resistant to death and injury when they were inoculated in ground beef and chicken breast, whereas they were less resistant in fish. A further reduction in viability of

survival cells (up to 1.0 log) was detected after 240–300 days of storage at –18°C [1].

The effects of freezing on several foodborne pathogens were reviewed by El-Kest and Marth [33]. The modes of damage to the bacteria cells were reviewed by Archer et al. [30]; the principal site of damage to bacterial cells during freezing has been shown to be the membrane. Very rapid cooling of cells from room temperature to –150°C resulted in more lipid crystallization before any rearrangement of intramembrane particles could occur. This leads to damage being mainly limited to the area around the cytoplasmic membrane. In slowly frozen samples, phase separation of the outer and cytoplasmic membranes was induced, causing the outer membrane to be split off by extracellular ice crystal formation. This damage could be reduced by the addition of a cryoprotectant, which modifies ice crystal formation. Damage to membranes leads to the leakage of internal cell materials, such as potassium ions, β-galactosidase, low molecular solutes, amino acids, RNA, and single- and double-strand DNA. The release of these substances has been correlated negatively with cell viability [30]. Another type of damage is osmotic dehydration of the cell caused by extracellular ice formation and the resulting increase in extracellular solute concentration. This process causes the intracellular macromolecules to move close to the membranes. The development of repulsive forces gives rise to large anisotropic stresses in the membranes, resulting in deformation, phase separation, and formation of a non-lamellar phase. Moreover, salt addition and lowered pH also play a role in the complex nature of freeze injury and cell survival [30, 34].

39.3.2 Beneficial Microorganisms

In fermented foods, such as yogurt, frozen storage should increase the viability of beneficial cultures incorporated for their potential health benefits and control of other spoiling microorganisms. The potential beneficial roles of bifidobacteria in the human intestine reported include antagonistic effects on enteropathogenic bacteria, breakdown of carcinogenic N-nitrosamines, and suppression of liver tumorigenesis [35]. Thus, bifidobacteria is incorporated in dairy products. Kebary [35] studied the visibility of *Bifidobacterium bifidum* in the fermented dairy product zabady. The numbers of bifidobacteria surviving after 5 weeks of frozen storage (–25°C) of zabady was higher ($>10^7$) than the minimum level necessary to achieve the beneficial effect of bifidobacteria (10^5–10^6/mL). The total bacterial count decreased as the amount of added bifidobacteria increased. This could be due to the effect of antimicrobial substances produced by bifidobacteria [35]. In eight strains of *Lactobacillus acidophilus*, higher rates and greater activity were always obtained by storing cultures at –80°C, but most strains stored at –30°C also survived well. The viability of frozen cultures was affected more by storage temperature than by cooling rate [36]. The plate counts decreased less than 1 log cycle and fermentation activity was 40–70% when cultures of *Lactobacillus delbruchii* ssp. *bulgaricus* were stored at –80°C for 1 year. However, fermentation activity was less than 10% when cultures were stored for 1 year at –30°C [37]. The fermentation activity of *Streptococcus salavarius* ssp. *thermophilus* was similarly reduced to 10–60% after 1 year of storage at –30°C. Protective solutes can be used to improve survival.

Yeast cells in bakery products do not withstand freezing well. This can be partially compensated for by increasing the amount of yeast used in the formulation or adding improved yeast strains having a better survival rate in freezing [18]. The freeze–thaw tolerant yeast should have high trehalose content in addition to reduced activity [38]. Trehalose has been reported to perform a cryoprotectant function in the yeast cell [39]. Although the amount of yeast in the formulation could be increased, much higher levels of yeast, 6–8%, have a detrimental effect on the aroma and flavor of the baked product [40]. When dough pieces were made up and frozen immediately after mixing, yeast activity remained stable after prolonged storage periods. When fermentation was allowed to proceed after mixing and before freezing, the yeast became less tolerant of freezing temperature and its activity declined. This may be due to a change in yeast cells' membrane sensitivity [41].

39.4 PHYSICAL CHANGES AND QUALITY

39.4.1 Free and Bound Water

Different types of water are present in frozen foods. These can be broadly categorized as free and un-freezable water, which does not freeze even at very low temperatures. A major cause of product degradation is the amount of unfrozen water present in the frozen matrix. Unfrozen water is known to be reactive, particularly during frozen storage, rendering the product susceptible to deteriorative and enzymatic reactions and limiting its frozen shelf life. Thus, the concept of the glassy state is being applied to frozen foods stability, since molecular mobility reduces the reaction rates of the unfrozen water matrix and other components [12]. Generally, un-freezable water molecules in aqueous solution are immobilized translationally or rotationally by solutes [42]. The amount of un-freezable water can be measured experimentally and mathematically computed for different types of foods.

39.4.2 Weight Loss

Dehydration or weight loss should be regarded as an important quality parameter for frozen unpacked foods, mainly in animal tissue. Foods lose moisture during the freezing process because their surface is exposed to heat and a moisture gradient exists with the environment [43]. Weight loss of meat during freezing and frozen storage was found to be 0.28–2.98% during the freezing process, meanwhile the loss during freezing and storage ranged between 1.67 and 6.15% [43].

39.4.3 Recrystallization

Ice recrystallization during frozen storage influences product quality in different ways. Recrystallization of solutes and

ice in frozen foods is also important to quality and shelf life. A polymer is least prone to crystallization at temperatures below glass. In general, the rate of recrystallization is highest at the midpoint between the melting and glass transition temperatures. Fluctuations in product temperature of 2–3°C, as are likely to be found in bulk cold stores kept at –18°C or colder, are unlikely to cause perceptible damage even over long periods [18]. On the other hand, frequent large fluctuations during retail display and during the carry-home period cause ice crystals to ripen or grow, coalesce, and move to the product surface. This leads ultimately to a dried product if packaging is permeable to moisture, allowing the sublimed or evaporated water vapor to escape. The loss of moisture results in toughening of animal tissue and greater exposure to any oxygen present.

39.4.4 Retrogradation

Quality loss by staling and starch retrogradation occurs most rapidly at chill temperatures in baked goods. After baking, starch from the loaf progressively crystallizes and moisture is lost. Until a critical point of moisture loss is reached, freshness can be restored by heating and reabsorbing starch crystals. A tight wrap helps to keep the moisture content high for a certain amount of time. The complete crystallization of starch produces the crumbly texture of stale bread. Slow freezing is to be avoided in order to reduce the time spent at chill temperatures. Amylase is a useful antidote to bread staling. In general, moisture migration during frozen storage is the principal cause of staling [18, 44]. It has been reported that repeated freezing and thawing treatments favored starchy paste retrogradation, which is related to a mild hydrolysis of starch chains [45].

39.4.5 Protein Denaturation

Some protein denaturation and solubility changes are known to occur as a result of freezing, but the practical significance of these changes is not clear [2]. Fish muscle has a unique arrangement of muscle fibers. It is divided into a number of segments called myotomes, which are separated from one another by a thin sheath of connective tissue called the myocomma or myoseptum [46]. Fish deterioration during frozen storage is associated with a decrease of protein solubility and extractability, diminishing the nutritional value [47]. Quality loss during cold storage of meat is characterized by an increasing loss of water-holding capacity, a decrease in protein extractability, a decrease in sulfhydryl groups, and a slight loss in ATPase activity [2, 48]. In frozen meat, water losses are related to the denaturation of myofibrillar protein [49]. The water-holding capacity of the meat and biochemical properties of actomyosin, such as enzymic activity, viscosity, and surface hydrophobicity, are affected by freezing. The expressible moisture in adductor muscles increased during freezing and frozen storage. These changes were accompanied by actomyosin denaturation. The myosin and paramyosin of the actomyosin complex were most affected [50]. An amino group from some essential amino acids, such as lysine, can react with the carbonyl group of reducing sugars during processing or storage [51]. Peptides and amino acids are also increased in the drip fluid, as are nucleic acids, indicating protein changes and structural cellular damage [2]. During freezing water molecules freeze out and migrate to form ice crystals, resulting in the disruption of the organized H-bonding system that stabilizes the protein structure, and the hydrophobic as well as the hydrophilic regions of protein molecules become exposed to a new environment. This may allow the formation of intermolecular cross-linkages either within a protein molecule or between two adjacent molecules [46].

39.4.6 Freezer Burn

Moisture loss by evaporation from the localized surface of a product leads to freezer burn, an unsightly, white color, which can be mistaken for mold but is resolved on rehydration during cooking unless it is severe [18]. It is usually in the form of patches of light-colored tissues, produced by evaporation of water, which leaves air pockets between meat fibers [52]. Dehydration of product or freezer burn may occur when freezing an unpackaged food item in blast freezers unless the velocity of air is kept to about 2.5 m/s and the period of exposure to air is controlled. This dehydration can be controlled by humidification, lowering of storage temperatures, or better packaging [44]. A single package of spinach and cauliflower experienced a 1.5-fold increase in loss of moisture per 2.8°C rise in temperature between –17.8 to –6.7°C [53]. The loss of moisture occurs faster when product is held in a temperature cycle as compared to a constant temperature during frozen storage [54].

39.4.7 Glass Formation

The glass transition has a dramatic effect on frozen food quality. The product is most stable below maximal-freeze-concentration temperature (i.e. T_m', T_g''', or T_g'), and moisture has little influence on these temperatures. The presence of low molecular weight solutes lowers the T_g', and high molecular weight solutes exert little effect. This means that with increasing maturity many vegetables display a decrease in sugars and an increase in starch, thus increasing the maximal-freeze-concentration temperature and the stability of frozen foods.

39.4.8 Functional Properties

The functional properties of any food product are normally affected by differences in freezing and thawing methods. Properties such as rheological, both flow and dynamic, texture, mechanical, consistency, appearance and sensory attributes, and water-holding capacity, among others, have been related to freezing and thawing processes. The changes in specific functional properties become microscopically related to structural modifications or rearrangements of the food items. The rheological properties of fresh and frozen–thawed okra dispersions were significantly different when measured

at 20–80°C. The dispersions were pseudoplastic with both the consistency coefficient and flow behavior index influenced by temperature. The consistency coefficient was higher for unfrozen sample than frozen–thawed sample when measured at 20 and 50°C, but the reverse was observed at 80°C. The flow behavior indices were not different at any temperature between 20 and 80°C [55].

Navarro et al. [56] studied the effect of the freezing rate on the rheological response of gelatinized starch pastes containing lipids. Low freezing rates increased the viscoelasticity, reduced the apparent viscosity, and led to higher structural changes of the pastes; in contrast, high freezing rates maintained the same rheological characteristics of the unfrozen samples. Graiver et al. [57] evaluated the viscoelastic behavior of refrigerated and frozen mozzarella cheese, finding differences in the viscoelastic response. The storage modulus was higher for refrigerated samples in comparison with frozen cheese, in which modifications in cheese microstructure by freezing were observed with SEM methodology. Further, the freezing was related to casein hydrolysis, cheese matrix softening, and proteolysis acceleration.

Texture is important in frozen vegetables [58, 59]. After freezing-thawing, firmness decreased, rupture strain increased, and consequently crispness decreased [58, 60]. The rate of freezing was critical to tissue damage. The optimum freezing rate of carrots was established as –5°C/min using a programmable freezer and based on texture and histological structure [61, 62]. Chinese cabbage leaves crack when frozen rapidly with liquid nitrogen. The optimum freezing rate for Chinese cabbage was 2°C/min considering tissue softening and drip loss. Freezing and thawing accelerated the release of pectin, but the freezing rate did not greatly affect pectin release [58]. Fruits, such as strawberries, apples, peaches, and citrus, contain thin-walled cells with a large proportion of intracellular water, which can freeze, resulting in extensive cell rupture and radical alteration of the mechanical properties of the material [63]. Maestrelli et al. [59] studied the effect of freezing on three quality parameters of transgenic parthenocarpic (parthenocarpy produces seedless fruits) eggplants, in which the firmness of the transgenic eggplants showed a decrease. As the tissue of apple and potato freezes, ice crystals form extra- or intracellularly, pushing the cells apart or rupturing cell walls and producing large voids within the tissue. Changes in mechanical behavior (wedge penetration, tensile, and compression) of the material were directly related to the degree of cell damage by freezing [64].

Mashl et al. [65] studied the unidirectional freezing of a gelatinized corn starch–water mixture and found that at freezing velocities less than or equal to 7.5 μm/s, starch granules were alternately pushed or entrapped by the advancing solid–liquid interface. This produced a segregated structure consisting of alternating high-starch and low-starch bands; thus segregation of the starch within the product occurred, which is detrimental to consistency, texture, and appearance. At a velocity of 10 μm/s, the frozen product was homogeneous.

The development of rancid flavors and progressive toughening accompanied by the development of cold store flavor are the principal sensory changes in seafood [18]. Deterioration in the texture and functionality of fish tissues by frozen storage takes place faster than in other animal muscles [47]. The firming of the soft texture characteristic of young fish with the early onset of protein denaturation is preferred by most taste panelists [66]. Flavor change is probably more critical than texture since this can occur early [67]. The denaturation of myosin increased in a frozen solution. The rate of formation of insoluble, high molecular weight protein aggregates increased as the temperature decreased below the freezing point and reached a maximum near the eutectic point of the solution [68]. Because of the concentration effect, pH can also change during freezing. A decrease in pH to more favorable values for degradation results in faster protein denaturation [7]. Fish gradually loses its juiciness and succulence after freezing and subsequent frozen storage. In gadoids, the chemical breakdown of trimethylamine oxide (TMAO) to dimethylamine (DMA), and formaldehyde (FA) and the subsequent cross-linking of FA to muscle proteins produced textural breakdown and resulted in a cottony or spongy texture. In this case, free water exists loosely like a sponge. When eaten, the fish muscle loses all its moisture during the first bite, and subsequent chewing results in a very dry and cottony texture [46]. In non-gadoid species, such as crab, shrimp, and lobster, muscle fibers also tend to toughen and to become dry during freezing and storage.

Thawing and refreezing could lead to quality deterioration [4]. Dyer et al. [69] reported accelerated deterioration for refrozen cod fillets stored at –23°C. Changes in enzyme activities of α-glucosidase and β-*N*-acetylglucosaminidase in rainbow trout on thawing, refreezing, and frozen storage were observed, but they did not relate to differences in sensory attributes [70]. Cowie and Little [71] reported no correlation between decreasing protein solubility and sensory attributes for cod stored at –29°C. Thawed and refrozen fish muscle displayed a faster decline in myofibril protein solubility than once-frozen fish and had reduced water-holding capacity, but analysis of proton spin-spin relaxation times indicated no changes in water location. The decline in protein solubility was not caused by complete protein unfolding. Long thawing times of 30 h before refreezing and storage resulted in cooked fish having a gray appearance and stale flavor [4]. Whole fish when thawed exhibits less textural change than filleted fish due to the presence of the backbone, which provides structural support for the flesh [46]. Gaping in fish fillet may be observed to worsen if fish are slowly frozen. Love and Haq [72] showed that the rate at which whole cod were frozen had little effect on the gaping of the fillets cut after thawing, although very slow freezing did cause a small increase [72].

The functional properties of cheese, which also changed after freezing and thawing, include meltability, stretchability, elasticity, and free oil formation, cohesiveness, and others with a specific meaning. Meltability is the capacity to flow together and form a uniform continuous melted mass. Stretchability is the tendency upon pulling to form fibrous strands that elongate without breaking. Elasticity is the capacity of the fibrous strands to resist permanent deformation. Free oil formation

is the separation of liquid fat from the melted body into oil pockets. Viscosity is due to particle segregation or coagulation. Luck [73] concluded that frozen storage was suitable for cream cheese, unripened camembert, and brick cheese, but not for Gouda or cheddar cheese. Mozzarella cheese, originated in Italy, is consumed worldwide largely due to the popularity of pizza and similar foods. Mozzarella differs from most cheeses in that it is often consumed in a melted state. Consequently, the functional properties, such as meltability, stretchability, elasticity, and free oil formation, are important to the quality of the product. Cervantes et al. [74] concluded that freezing (one-week storage) and thawing did not affect the mozzarella cheese quality as assessed by compression, beam bending, and sensory evaluation. Dahlstrom [75] showed poor meltdown, acid flavor, fat leakage, free surface moisture, bleached discoloration, and poor cohesiveness immediately after thawing, but normal characteristics reappeared after the thawed cheese was aged for 1 to 3 weeks. Bertola et al. [76] studied the freezing rate and frozen storage (3 months at –20°C) of mozzarella cheese. The functional quality loss (meltability, apparent viscosity, free oil formation) can be avoided as long as the product is aged from 14 to 21 days at 4°C before being consumed. The frozen mozzarella cheeses that had been ripened for about 14 days produced a product similar (hardness, adhesiveness, cohesiveness, springiness, and non-protein nitrogen) to refrigerated cheese at the same stage of aging [40].

39.5 CHEMICAL CHANGES AND QUALITY

39.5.1 Rancidity

Oxygen is the bugbear of almost all frozen foods, leading to oxidative rancidity (if any unsaturated lipids are present), loss of color, and development of off-flavors. Freezing results in a concentration of solutes, which catalyze the initiation of oxidative reactions, and disrupt and dehydrate cell membranes, exposing membrane phospholipids to oxidation. Membrane phospholipids are highly unsaturated and have been demonstrated to be the initiation point of oxidation in muscle tissue [2].

The degradation of lipids in frozen peas during storage at –18°C led to flavor damage due to the formation of hydroperoxides, thiobarbituric acid, and fatty acids, particularly in unblanched samples [77]. The lipid oxidation was mainly due to lipoxygenase and lipohydroperoxidase breakdown products [78]. The hydrolyzed and oxidized products of lipids affect the quality of frozen vegetables [79].

Oxygen availability and tissue composition play important roles in the acceleration of lipid oxidation of frozen fish. Lipid hydrolysis occurs in fish during storage, which may affect lipid oxidation. Free fatty acids are more readily oxidized than the equivalent esters when lipoxygenase is involved [80–82]. Lipid oxidation in mackerel minces occurred continually as long as the samples were exposed to air independent of hydrolytic activity, but was deactivated or retarded by cooking the sample or by lowering the storage temperature (–40°C). Lipid oxidation was observed not only in the free fatty acids but also in the triacylglycerides and the phospholipids extracted from mackerel mince [83]. Mincing destabilizes the fish due to a high level of incorporated oxygen and cellular disruption, making the lipids susceptible to oxidation. Most methods for frozen fish mince stabilization are based upon one or several of the following three strategies: (i) removal of pro-oxidants, oxygen, or components susceptible to oxidation, (ii) alternation of pro-oxidants, antioxidants, or other components influencing the oxidation, or (iii) addition of components that can protect fish mince lipids against oxidation [84].

Washing of fish mince helps the removal of various antioxidative components and the relative increase in both polarity and un-saturation in remaining lipid fraction. Heating also affects the oxidative stability of fish mince by (i) altering pro-oxidative enzymes, such as lipooxygenases [85], lipooxidases [86], and microsomal enzymes [87], (ii) changing the pro-oxidative properties of myoglobin and other hemoproteins [88], and (iii) enhancing the production of aqueous [85] and lipid-soluble [89] antioxidants. Undeland et al. [90] studied the lipid oxidation stability of frozen minced herring at –18°C by pre-heating and pre-washing. Stability increased due to heat inactivation of catalytic enzymes without activation of hemoproteins. Washing reduced the stability by removing pro-oxidative enzymes from cooking and caused a reduction of antioxidants as well as a relative increase in phospholipids and free fatty acids in the fat. In the case of herring fillets, the removal of the skin prior to storage at –18°C was shown to affect the stability of underlying tissue negatively. The abundance of hemoproteins, free metals, and enzymes in the under-skin layer resulted in very severe oxidative changes, especially when the fillets were stored skinned. The unfavorable composition of the under-skin layer includes a lot of dark muscle, the silver surface, and the highest fat content and the lowest level of α-tocopherol. Such local productions of oxidation products can spoil the entire flavor of the fillet; protection or removal of unstable tissues at an early stage during processing can be important factors in the improvement of frozen herring storage stability [90].

Poultry fat becomes rancid during very long storage periods or at extremely high frozen storage temperatures. Rancidity in frozen whole poultry stored for 12 months is not a serious problem if the bird is packaged in essentially impermeable film and held at –18°C or below. The danger of rancidity is greatly increased when poultry is cut up before freezing and storage because of the increased surface exposure to atmospheric oxygen [44]. Antioxidants, like BHA, BHT, or tocopherols, and metal chelators such as pyrophosphates, tripolyphosphates, or hexametaphosphates are effective in reducing oxidation. The distribution of antioxidants in meat is difficult; thus including tocopherols in animal feed results in the deposition of tocopherols in membrane locations. This is much more effective in preventing the initial step with phospholipids [2]. The frozen storage stability of antioxidant-treated beef heart surimi is reported [83, 91]. Among various lipid- and water-soluble antioxidants, propyl gallate was found most protective and effective for inhibiting lipid and protein oxidation during short-term frozen storage [92]. Lipid

and protein oxidation in beef surimi with propyl gallate and cryoprotectants (sucrose, sorbitol) was minimal at –70°C. The freezing-thawing process caused lipid and protein oxidation in the frozen sample at –15 and –29°C. Oxidation increased rapidly after 4 weeks. Propyl gallate inhibited lipid oxidation but was ineffective against protein changes. After 12 weeks cryoprotectants promoted lipid and protein oxidation in the absence of propyl gallate [93].

Malonaldehyde is one of the decomposition products of auto-oxidation of polyunsaturated lipid materials in food. Malonaldehyde is the main component in the 2-thiobarbituric acid (TBA) value that is used to evaluate the degree of oxidation of lipids. Malonaldehyde reacts with myosin from trout. The rate of reaction of malonaldehyde with α-amino groups of myosin was greater at –20°C than at 0°C and almost equal to that of 20°C [8].

The oxidant level should be increased in frozen dough formulations, as oxidants increase dough strength. A higher shortening level is recommended for frozen dough production. Generally, shortening protects the dough structure from damage due to ice crystallization [41].

39.5.2 Color, Flavor, and Vitamin Loss

39.5.2.1 Color Loss

The most important color changes in fruits and vegetables are related to three biochemical or physicochemical mechanisms [94]: (i) changes in the natural pigments of vegetable tissues (chlorophylls, anthocyanins, and carotenoids), (ii) development of enzymatic browning, and (iii) breakdown of cellular chloroplasts and chromoplasts. Pineapple for processing should be of optimum ripeness with a yellow color, good aroma and flavor, and free from blemishes, such as black heart, water blister, yeasty rot, or brown spot. For frozen pineapple slices, semi-translucent, highly colored slices are generally considered the most attractive and have the best flavor. Pineapple color is important because it is often the basis for judging product acceptability. The golden color of pineapple fruit is mainly due to carotenoids, which become more predominant with ripening as chlorophyll content decreases. Heat processing, freezing, and thawing lead to cell disintegration, pigment degradation, and isomerization of carotenoids [95–97].

Color and flavor are important sensory attributes, and vitamin content is a functional attribute of frozen foods. The green color of vegetables is lost by the chlorophyll degradation during freezing and frozen storage resulting from the conversion of chlorophyll to pheophytins and/or to the destruction of both chlorophyll and pheophytins, giving a dull khaki color. During storage, chlorophyll is converted to pheophytin with a loss of green color and vitamin C; these can be used as objective indicators of quality [18, 29, 98].

Chlorophyll was bleached during fat peroxidation, oxidation of glycolic acid and by α-hydroxy acid dehydrogenase, and chlorophyllase, which hydrolyze the phytal ester group of chlorophylls and phephytins [99]. Storage temperature and time, acidity, and blanching time affect the loss of chlorophyll in frozen vegetables. A ten-fold increase in the conversion rate occurred with an approximate 8.3°C increase in temperature. Blanching decreased the loss of chlorophyll during frozen storage [29]. Various inorganic salts, such as sodium chloride, potassium sulfate, sodium sulfate, and sodium or ammonium bicarbonate, have been used to reduce chlorophyll loss [94].

The maximum stability of carotenes in frozen spinach was 2 years at –28.9, 1 year at –6.7, and 7 days at 4.4°C [100]. Carotene retention curves were sigmoidal with three regions: Initiation, acceleration, and retardation. They were typical of autocatalytic reactions. Lipoxygenases were the major enzymes involved in carotene degradation [101]. Moharram and Rofael [29] reviewed carotene degradation in frozen vegetables. Martins and Silva (2004) reported a high sensibility of chlorophylls (color a and b values) at –18°C, and results showed that color a and b values retained only 10.96 and 10.82% for chlorophylls during 60 days of frozen storage.

In poultry, a light surface color for carcasses is considered important and is best achieved with rapid surface freezing, which generates a smooth chalky white surface. This is achieved by supercooling the product and forcing nucleation of a high number of small ice crystals. These crystals stay small because there is little water migration to already formed crystals during such a fast process. Numerous small ice crystals cause the surface to reflect light and appear white in color [2]. An alternative approach is to crust freeze the outer part of the carcass rapidly using liquid brine immersion, spray systems, or cryogenics like liquid nitrogen or carbon dioxide, and then to move the partially frozen bird to air blast or cold storage for the remainder of the process. A freezing front migration rate of 2–5 cm/h is recommended to achieve fast freezing effects and 0.1–0.2 cm/h for slow freezing [2, 52].

Darkening of bones is a condition that occurs in immature chickens and has become more prevalent as broilers are marketed at younger ages. Darkening may arise during chilled storage or during the freezing and defrosting process. It occurs because some of the heme pigment normally contained in the interior of the bones of particularly young chickens leaches out through spongy areas and discolors the adjacent muscle tissues [2, 44]. Leaching only occurs in carcasses from relatively young birds because the bones are not completely calcified and are more porous than in mature birds [2]. The development of dark bones was greatly reduced by a combination of freezing and storage at –35°C and immediate cooking after rapid thawing [102]. Aside from this combination, the freezing rate, time between slaughter and freezing, temperature and length of storage, and temperature fluctuations during storage have no marked influence in preventing this discoloration [44]. While eating qualities do not change, the appearance constitutes a negative factor in consumer acceptance [2].

In crustaceans, a dark discoloration defined as blackspot or melanosis is developed after the trauma of capture, freezing, and thawing process, and it is unattractive to consumers, reducing the market value. This oxidative enzyme reaction, followed by auto-oxidation and polymerization, may be prevented by the application of sulfiting agents in combination with freezing [103]. Rotland et al. [103]) carried out an

experiment in which different concentrations of sodium metasulfite (included in HQ-Bacterol F), temperature and time of immersion, and subsequent freezing storage of rose shrimp were applied. They found that untreated shrimps showed melanosis after 19 hours of ice and with a decreased market value at 27 h, whereas samples treated with 2% HQ-Bacterol F for 5 min maintained their market value. Further, quick freezing appeared to be a good method in addition to the sulfiting agent to prevent the melanosis phenomenon, and following storage for 3 months did not affect the appearance of blackspot.

39.5.2.2 Flavor and Aroma Loss

Freezing affects the flavor and aroma of frozen foods. For example, the freezing of strawberries is usually associated with a reduction in aroma and the development of off-flavor. The decrease in aroma is due to the rapid decomposition and diffusion of esters [104, 105], whereas the concentrations of franeol and mesifurane linked to strawberry flavor are not affected by freezing [105]. The off-flavor of frozen strawberries differs from that of frozen vegetables [106–108]. Off-flavor in frozen vegetables is usually due to insufficient blanching. Deng et al. [109] found that the development of off-flavor in frozen–thawed strawberries was due to the chemical production of H_2S rather than enzymatic activity. The identity of H_2S was verified both chemically and using gas chromatography–mass spectroscopy analyses. The olfactory properties detected by sensory analysis indicated the presence of sulfurous compounds. Usually, H_2S is derived from the sulfur-containing amino acids cysteine or methionine during processing. Deng et al. [109] also showed that amino acid was not the main precursor of the off-flavor compounds, but the off-flavor development in frozen strawberries can be attributed to the breakdown of the cells by freezing, thereby decreasing the pH in the cytosol, which in turn leads to the release of sulfide ion as H_2S. The duration of the production of H_2S was longer in strawberries at –40 and –80°C than at –20°C. This may be due to the low boiling point of H_2S (–59.0°C). Vigorous crushing of fresh strawberries also gave rise to the production of H_2S. Thus, structural damage is one of the important factors.

In fish and seafood, formaldehyde is formed during cold storage by the enzymic decomposition of TMAO. It is a good objective criterion of time–temperature exposure in frozen gadoid species [110]. The formaldehyde reacts with proteins, thereby decreasing their solubility in salt and buffer solutions [18, 92]. Santos-Yap [46] mentioned that changes in the flavor of fish and seafood generally occurred in three distinct phases during frozen storage: (i) gradual loss of flavor due to loss of or decrease in concentration of some flavor compounds, (ii) detection of a neutral, bland, or flat flavor, and (iii) development of off-flavors due to the presence of compounds such as acids and carbonyl compounds that are products of lipid oxidation.

39.5.2.3 Vitamin Loss

The retention of nutritional components in foods is a concern when any type of preservation method is used, but freezing is probably the least destructive [2]. The destruction of vitamin C (ascorbic acid) occurs during freezing and frozen storage. This loss is influenced by blanching conditions, types of freezing, package, and time–temperature conditions [29]. The loss is mainly due to the oxidation and/or to the action of ascorbic acid oxidase [79]. A ten-fold increase in the rate of loss of ascorbic acid per 8.9C rise in storage temperature of frozen vegetables was found [111]. Generally, frozen vegetables stored at –24°C displayed better ascorbic acid retention than those at –12 and –18°C, respectively [29]. Blanching improves ascorbic acid retention in vegetables. A combination of microwave energy and steam or water blanching yielded frozen products with better ascorbic acid retention than conventional procedures [112]. The reduction in vitamin C in frozen mashed potatoes could be overcome by the addition of encapsulated vitamin [113]. Vitamin B losses sometimes occur in frozen meat products. B vitamin losses may be significant in frozen poultry products, but most losses are the result of the subsequent thawing and cooking treatments rather than of the freezing process [2]. Martins and Silva [98] suggested that the shelf-life determination of frozen vegetables should depend on nutritional quality rather than only sensory attributes.

39.5.3 Release of Enzymes

The disruption of plant or animal tissues by freezing leads to the release of enzymes bound to the structures. Beef and pig skeletal muscles contain two isozymes of glutamic-oxalacetic transaminase: One in the mitochondria and the other in the sarcoplasm [114]. Hamm and Kormendy [115] found that freezing and thawing causes a remarkable increase of glutamic-oxalacetic transaminase activity in the muscle press juice. Fish contains malic enzymes in two forms: Free and latent. The latter is solubilized by the disruption of the tissue caused by freezing and thawing [116]. Barbagli and Crescenzi [117] found that the activity of cytochrome oxidase in extracts of tissues after freezing and thawing was increased by 15 times in chicken liver, by 2.5 times in trout, and by four times in beef muscle compared to extracts of unfrozen samples. Thus, a method was developed to distinguish between fresh and frozen meat based on the enzymes released [115, 117–119]. Around 0°C enzymic breakdown of protein becomes the principal cause of quality loss, and below –8°C microbiological spoilage ceases and protein denaturation coupled with oxidative rancidity in fatty species become the chief factors affecting quality [18].

39.5.4 Hydrolysis

Generally, starch in vegetables does not change significantly during frozen storage [120]. Rofael [79] observed no significant changes in starch of beans, peas, okra, or mallow during storage at –18°C for 1 year. The reducing sugars of these frozen vegetables were increased during storage due to the hydrolysis of both oligo- and polysaccharides of these products. Thus, the amount of reducing sugars is a good indicator of storage life [29]. Martins and Silva [98] found significant

starch degradation rates for green bean at –6, –12, and –18°C during the initial days of storage. In melons, total cell wall polysaccharides decreased more during the first 5 months than during the second 5 months of frozen storage. This suggested that pectin and hemicellulose fractions were modified and solubilized by either mechanical or enzyme-catalyzed changes in cell wall polymers [121]. However, freezing preservation of pineapple slices led to minimal changes in soluble solids and sugar content (fructose, glucose, and sucrose), pH, titratable acidity, and nonvolatile organic acids (citric and malic acids) after a year of frozen storage at –18°C [122, 123].

39.5.5 Acetaldehyde Formation

The formation of acetaldehyde in frozen vegetables increases during storage; thus it is an indication of shelf life [79]. Acetaldehyde is a product of aerobic fermentation of pyruvate in plant tissues [124]. The amount of acetaldehyde formation depends on the pretreatment, such as blanching time and storage period [29, 79, 125]. Chow and Watts [125] found that acetaldehyde increased when fresh vegetables were heated beyond the minimum required for enzyme inactivation. Dimethylamine content, formaldehyde content, and shear force measurement correlated very well with the sensory texture score of frozen red hake [126]. The enzymatic breakdown of TMAO to dimethylamine (DMA) and formaldehyde affects textural changes in fish species during frozen storage. Further, formaldehyde's contribution to protein changes in muscle during frozen storage would clarify the toughening mechanism. Frozen storage and fluctuation in temperature affect both dimethylamine and formaldehyde formation in frozen fish [127].

39.6 COMPARISON BETWEEN DIFFERENT FREEZING METHODS

Bartolome et al. [128] evaluated the influence of freezing (cold room –18°C and air-blast freezer –50°C) and frozen storage (–18°C for 0 to 12 months) on the color and sensory quality of pineapple slices (Smooth Cayenne and Red Spanish cultivars). No differences were found in sensory analysis (color and appearance) between the cultivars, frozen at different rates, compared to fresh product, or after 1year of frozen storage. However, both cultivars were suitable for freezing. The freezing methods (liquid nitrogen, –120°C and stored at –40°C; individual quick freezing at –43°C and stored at –40°C; and conventional deep freezing and storage at –20°C) showed total color changes as 15.5, 29.0, and 38.2% respectively in frozen date fruit stored for 9 months [129]. Similarly, instrumental texture profile analysis (TPA) parameters decreased during storage; for example, after storage for 9 months hardness decreased to 21.0 N from the initial 119.5 N in the case of liquid nitrogen followed by 30.0 N for quick freezing and 42.2 N for conventional freezing. Similarly, polyphenol activity increased from 0.034 to 0.147, 0.184, and 0.287, respectively while peroxidase increased from 0.039 to 0.054, 0.063, and 0.163, respectively [129]. However, liquid nitrogen and quick freezing showed no significant difference. Sucrose decreased from 21.8 g/100 g sample to 12.3, 5.1, and 0.0, respectively, while glucose increased from 5.0 g/100 g sample to 7.9, 10.7, and 13.0, respectively, and fructose increased from 4.6 g/100 g sample to 7.2, 7.6, and 7.7 after 9 months of frozen storage [129].

39.7 PRETREATMENTS FOR FREEZING

It is important to realize that successful freezing will only retain the inherent quality present initially in a food item and will not improve quality characteristics; thus the quality level prior to freezing is a major consideration. The use of high-quality initial materials based on standards and grades is essential to high-quality frozen products. The levels of intrinsic product quality measures, such as freshness, suitability of variety or genetics for freezing, soil nutrients for foods of plant origin, and dietary factors for foods of animal origin, are affected. In addition, harvesting or slaughtering methods, and processing such as blanching, cooking, chilling, and the addition of antioxidants also have profound effects. Microbiological quality prior to freezing remains a major determinant to post-thaw quality. Although freezing can reduce some pathogens, there is also usually significant survival. Thus, other methods must be used to ensure the elimination of pathogenic organisms from frozen poultry [2, 130]. The commonly used pretreatments are discussed in the following sections.

39.7.1 Blanching

Most vegetables and some fruits are blanched before freezing. Blanching destroys the semi-permeability of cell membranes, destroys cell turgor, removes intercellular air, filling these spaces with water, and establishes a continuous liquid phase. As a result, ice crystallization can occur through the entire matrix of food without interruption during the freezing process. Blanching also affects texture, color, flavor, and nutritional quality by inactivating enzymes. Cell turgor is an important component of the eating quality of many fruits. It is produced by the internal pressure of cell contents. Reduced turgor is perceived as softness and lack of crispness and juiciness. When turgor is an important product characteristic, blanching and freezing may not be acceptable. If the product is cooked before consumption, the retention of turgor through earlier processing is not necessary since thermal treatment is more severe than blanching or freezing [6, 29]. Blanching also has other advantages, such as the destruction of microorganisms, and wilting of leafy vegetables, assisting packaging [3, 94]. Further, blanching favors reductions of some undesired compounds that are present in some leafy vegetables, such as nitrates, nitrites, and oxalates [131]. The effect of blanching, at 70°C for 15 or 30 s, and frozen storage on the stability of -carotene and capsanthin in red pepper was elucidated by Morais et al. [3]. Both time of blanching and frozen storage were simultaneously included in two multilinear equations describing the concentration of -carotene and capsanthin. There were significant differences in the decomposition rate of pigment related to cultivars and process conditions.

Properly blanched vegetables have a long shelf life at frozen food temperatures enabling them to be exported all over the world and to span the seasons [18]. Blanching of fruits may be detrimental in many cases, resulting in (i) rapid discoloration by enzymatic browning [18], (ii) loss of texture, (iii) formation of cooked taste, (iv) some loss of soluble solids, especially in water blanching, and (v) adverse environmental impact due to energy requirements and disposal of used water [94]. Blanching at 70–105°C associated with the destruction of enzyme activity. Hot water blanching is usually carried out between 75 and 95°C for 1 to 10 minutes, depending on the size of the individual vegetable pieces. High-pressure steam blanching is more energy-efficient than water blanching. It is important that cooling be carried out shortly after blanching, especially for products to be frozen [94].

The enzymes involved in the production off-flavor are catalase, lipoxygenase, and peroxidase, and their heat stability varies with the types of vegetables and fruits. Peroxidase and catalase seem to be the more heat stable, and thus could be used as an index of adequate blanching for vegetables. A 95% loss of enzyme activity following blanching is considered adequate. The quality of blanched frozen vegetables was improved if some peroxidase activity remained at the end of the blanching process. The activities of most enzymes are greatly dependent on the pH of the tissue or the blanching water. Additives, such as citric acid, sodium chloride, and carbonates, can be used in water depending on the purpose [29, 94, 132]. Bottcher [133] reported that the highest-quality products were obtained when the following percentages of peroxidase activity remained: Peas, 2–6.3%; green beans, 0.7–3.2%; cauliflower, 2.9–8.2%; and Brussels sprouts, 7.5–11.5%. It was concluded that the complete absence of peroxidase activity indicated overblanching [94].

39.7.2 Heat Treatments

Texture is an important quality attribute of frozen fruits and vegetables. Loss of tissue firmness, disruption of the cell membrane, and excessive softness are the major consequences to be avoided [134]. Low temperature and long-time pretreatment were useful in improving the texture of frozen vegetables by avoiding excessive softness. Carrots heated for 30 min at 60°C and frozen above –5°C/min (optimum rate) should escape both cell damage and excessive softening [62, 135]. The de-esterification of pectin by pectin-methylesterase during preheating prevented transelimination of pectin [136–139]. Fuchigami et al. [140] found that preheating followed by quick freezing was effective in improving excessive softness and cell damage. The optimum preheating occurred with 30 minutes at 60°C or 5 minutes at 70°C, and the optimum freezing was at –5 to –50°C. Preheated carrots retained a firmer texture than those blanched in boiling water. After preheating, the amount of high-methoxyl pectin decreased and low-methoxyl pectin increased. The quick freezing process resulted in better texture than slow freezing.

Loss of texture was accompanied by the release of pectin. Slow freezing accelerated the release of pectin as compared to quick freezing. Preheated carrots were slower to release pectin. The degree of esterification of pectin substances in raw carrots decreased during preheating, freezing, and thawing. Cell damage in quick-frozen carrots was slight. Product preparation prior to freezing may include cutting, deboning, slicing, and other operations to provide greater convenience. A greater variety of products cooked prior to freezing are becoming popular with consumers. These include breaded and fried portions, cured and smoked products, and items in marinades or broths [2]. The freezing rate of precooked chicken affects the quality of the product. Breaded precooked drumsticks frozen with liquid nitrogen are susceptible to cracking, separation of meat from the bone, and development of small areas of white freezer burns next to the surface [44]. Cooked products are likely to exhibit greater increases in lipid oxidation than raw products during storage. This is due to the oxidative change and higher TBA values making the product more susceptible to further oxidative changes during frozen storage. Antioxidants are very effective in stabilizing cooked chicken during frozen storage [141–143].

39.7.3 Dipping Pretreatments

In many cases, foods are dipped or soaked in different solutions before freezing, and the type of solute used depends on the desired purpose. Apple slices are commonly treated by soaking in 1% salt solution in order to remove intercellular air. Fruits are also dipped in ascorbic acid and sugar solutions to minimize browning or blanched for a short time to inactivate enzymes [6]. Paredi et al. [50] studied the effect of dipping in polyphosphates on the biochemical properties of adductor muscles during freezing and storage at –30°C. Immersion in polyphosphates solution was effective in reducing water loss in stored muscle. In addition, it delayed the decrease in enzymatic activity (Mg^{2+}–ATPase) and provided some protections for the myosin light chains without affecting either the extractability or the viscosity of actomyosin from frozen stored muscles.

In many cases, the frozen product is protected by a suitable glazing compound. A glaze acts as a protective coating against the two main causes of deterioration during storage: dehydration and oxidation. It protects against dehydration by preventing moisture from leaving the product, and against oxidation by mechanically preventing air contact with the product. Oxidation can also be minimized if the glaze carries a suitable antioxidant [44]. For products intended for short-term storage, glazing can be practically utilized as a viable alternative to storage without a protective covering [46]. Moreover, glazing treatment could be a cheaper alternative to expensive packaging systems for fish stored at –20°C [144]. The different glazes available include inorganic salt solutions of sodium acid phosphate, sodium carbonate, and calcium lactate, alginate solution, also known as *Protan* glaze, antioxidants, such as ascorbic and citric acids, glutamic acid, and monosodium glutamate, and other edible coatings, such as corn syrup solids [145].

39.7.4 Bacterial Ice Nucleators or Antifreeze Proteins

The application of bacterial ice nucleators to the freezing of some model food systems and real foods, such as salmon, egg white protein, and cornstarch gels, elevates nucleation temperatures, reduces freezing times, and improves the quality, such as flavor and texture. These can also be used in freeze concentration of fresh foods for the modification of their properties [146]. The use of bacterial ice nucleators is a unique application of biotechnology, as it directly improves freezing processes [147]. When bacterial cells were added to isotropic aqueous dispersions of hydrogels composed of proteins and polysaccharides, the bulk of the water was converted into directional ice crystals at subzero temperatures not lower than –5°C, and resulted in the formation of anisotropically textured products [147]. Details of this topic are reviewed by Wolber [148] and Li and Lee [147]. Antifreeze proteins, found in polar fish and cold-tolerant insects and plants, can affect freezing in several different ways: (i) by lowering the freezing temperature, (ii) by retarding recrystallization on frozen storage, and (iii) by promoting ice nucleation causing supercooled solutions to freeze more rapidly [12, 149]. Mizuno et al. [42] studied the effect of solutes on the antifreeze and immobilizing activities of water. The antifreeze activities of saccharides that consisted of glucose were higher than others, and in salts those that possessed a higher ionic charge had higher antifreeze activities. In water-soluble amino acids, a few amino acids that formed no eutectic mixture above –20°C had especially high antifreeze activities. The high antifreeze activity is caused by high immobilizing activity for water molecules, and the immobilizing mechanism varied with the type of solute [42]. The antifreeze proteins depress the freezing point by attaching to ice crystals and interfering with water molecules joining the ice lattice. Computer modeling suggests that at least for one antifreeze peptide, the molecules are arranged in an antiparallel fashion with cooperative side-to-side-binding [150].

There are two groups of antifreeze proteins: Antifreeze glycoproteins and antifreeze proteins. The primary structure of the antifreeze glycoproteins is a repeating (Ala–Ala–Thr) sequence with a disaccharide attached to the threonine residue. The antifreeze proteins have various structures. Type I proteins have an α-helical structure, whereas type II and III proteins have some unusual secondary structures. Synthetic anti-freeze peptides may have also practical applications in foods [150]. The phenomenon of cold acclimation in carrots was related to biochemical and physiological changes in the fresh plant [149]. The presence of antifreeze protein within the roots was related to cold acclimation and its quality enhancement through freezing.

39.7.5 Osmotic Concentration

Partial removal of water by osmotic treatment to freezing is recognized as convenient for reducing cellular damage of fruits and vegetables, which causes softness after thawing [151]. Osmotic concentration of vegetables prior to freezing is a pretreatment that can improve end-product quality [94, 151]. It is well-established that osmotic dehydration improves the product quality in terms of color, flavor, and texture. The merits of osmotic dehydration for product-quality improvement and process efficiency have been reviewed earlier [152–154]. The effects of sugar on the quality of frozen fruits have been reviewed by Skrede [155]. However, in the literature there is not much fundamental information about the mechanisms of flavor entrapment in the food matrix, color retention, and physics of textural improvement. In the frozen food industry, high energy levels are used for freezing because a large quantity of water is present in fresh foods. A significant proportion of this energy could be saved if plant materials were concentrated prior to freezing [156]. A reduction in the moisture content of food can reduce refrigeration load during freezing. Partially concentrating fruit and vegetables prior to freezing saves packaging and distribution costs [157]. The product quality is comparable with that of conventional products. The process is referred to as dehydro-freezing.

39.7.6 Cryoprotection

Meat and fish muscle is susceptible to freeze denaturation, which decreases gel-forming potential, water-holding capacity, and protein solubility. Cryoprotectants are generally added to protect fish myofibrillar proteins from freeze denaturation during frozen storage [158]. Polydextrose, sucrose, and sorbitol have been reported to protect against freeze denaturation of Alaskan pollack surimi [159]. These are low in cost, safe, and have good solubility and beneficial functional effects [160]. Sucrose is usually combined with sorbitol to reduce sweetness. The cryoprotective effect of sugar is enhanced by adding polyphosphate [161]. Polydextrose proved to be an effective cryoprotectant for both pre- and post-rigor beef. Arakawa and Timasheff [162] found that cryoprotectants increase the surface tension of water as well as the binding energy, preventing withdrawal of water molecules from the protein and thus stabilizing the protein. Phosphates had no cryoprotective effect but did increase pH and enhanced protein extractability, which may enhance gel-forming and water-holding properties [52].

Park et al. [158] found that cooked gel strength was unaffected by the freezing of beef or pork surimi-like materials for 48 h, and the addition of cryoprotectants (3 or 6% sorbitol, 3% glycerol, or 3% sucrose) before freezing had no effect on gel-forming ability. The washed myofibrillar proteins from beef muscle were quite stable during freeze-thaw treatment up to 6% sodium chloride. No difference in gel-forming ability after freezing with or without added salt was found. Wierbicki et al. [163] also reported no detrimental effects on water-holding capacity due to salting of meat prior to freezing. The interaction between salt ions and muscle proteins occurs rapidly, compared to the normal process of shrinking or coagulation of muscle proteins [164]. Dondero et al. [165] studied the cryoprotective effects of 18, 20, 25, and 36 DE maltodextrins at 8% (w/w) in surimi from jack mackerel stored at –18°C for

27 weeks. They found that 20 and 25 DE maltodextrins as well as sucrose or sorbitol mixtures were the most effective in stabilizing surimi proteins during frozen storage [165].

Poultry meat showed little deterioration upon freezing, and isolated myofibrillar systems made by the surimi procedure are less stable [160]. Kijowski and Richardson [166] found that mechanically recovered meat from broilers had reduced functionality when no cryoprotectants were used. Sorbitol or sucrose showed some protection of the gel-forming ability of frozen samples, and sorbitol or sucrose with tripolyphosphate gave stronger gels after freezing or freeze-drying than fresh samples. The combined presence of sorbitol, sucrose, and tripolyphosphate restored most functional properties of frozen or freeze-dried material to the levels of the fresh material. Most of the loss of functionality during freezing or freeze-drying was caused by loss of solubility of myosin and, to a lesser extent, actin. Freeze-drying had a greater effect when no additive or NaCl was present. The blast-frozen and freeze-dried samples with no cryoprotectants had a very coarse structure with no obvious fine network system. In the presence of sorbitol or sucrose there was a finer meshwork for freeze-dried material, which was finer for frozen material. In the presence of sorbitol or sucrose with tripolyphosphate, the network was even finer but with fewer obvious spaces in the matrix for both freeze-dried and frozen material. These were observed by scanning electron microscope.

Whole egg and yolk products are fortified with salt or sugar before freezing to prevent coagulation during thawing. The selection of additive depends upon the finished product specifications. Salt (10%) is added to yolks used in mayonnaise and salad dressings, and sugar (10%) is added to yolks used in baking, ice cream, and confectionery. Egg whites are not fortified as they do not have gelation problems during defrosting [44]. Table 39.1 shows the effects of freezing on the functional properties of liquid egg products [167]. High molecular weight (HMW) polymer cryoprotectants have the following advantages over low molecular weight (LMW) cryoprotectants [168]:

1. HMW polymers do not generally penetrate the cell membrane and remain in the extra-cellular suspensions and/or outer surface of the cell.
2. HMW polymers do not produce a significant freezing point depression within the range of concentrations that can be applied in practice.
3. There is no binary eutectic, i.e. the hydrated polymer does not crystallize from aqueous solution as LMW agents do.
4. HMW polymers have the ability to keep a substantial portion of the solution from freezing.

Although the presence of HMW polymeric cryoprotectants is limited to the extracellular suspension medium, HMW additives affect the intracellular composition by the efflux of intracellular water due to chemical potential change across the membrane when extracellular ice is formed [168].

39.7.7 Irradiation

High-dose irradiation can produce changes in the chemical composition and taste of fish and seafood. A combination of irradiation and freezing can be used in foods. A combination treatment involving freezing in conjunction with irradiation has recently been proposed as a means of retarding spoilage. It has been reported that parts of Europe irradiated frozen seafoods from Asia to eliminate microbial pathogens such as *Salmonella*.

39.8 STORAGE AND DISPLAY

Packaging, storage, and display also affect frozen food quality. Loss of quality in frozen foods is a gradual process,

TABLE 39.1
General Effects of Freezing Rate, Storage Time, Storage Temperature, Thawing Rate, and Additives on Functional Properties of Liquid Egg Products

	Effect on Functional Properties		
Factor	**Egg Albumen[a]**	**Egg Yolk[b]**	**Whole Egg[c]**
Freezing rate	Slower rate causes: reduced viscosity and increased foam stability	Slow rate causes: increased viscosity and gelation	Same as liquid egg yolk but less severe
Storage time	Longer time causes: reduced viscosity and increased foam stability	Longer time causes: increased viscosity and gelation	Same as liquid egg yolk but less severe
Storage temperature	Lower temperature causes: reduced viscosity and less severe	–18°C results in maximum increase in viscosity and increased foam stability	Same as liquid egg yolk but gelation
Thawing rate	Faster rate causes: some protein denaturation less severe	Slower rate causes: increased viscosity and gelation	Same as liquid egg yolk but gelation
Additives	None normally needed	2% NaCl and 8% sucrose	None normally needed inhibits gelation; 10% used commercially

Source: Dawson [167].

[a] Freezing usually has only a slight effect on egg albumen properties.

[b] Freezing often has a drastic effect on egg yolk viscosity.

[c] Freezing has a greater effect on whole egg properties than albumen but less than the effect on egg yolk.

the changes being slow or very slow, cumulative, and irreversible [18]. Optimum quality requires care in every stage of the processing, packaging, storage, and marketing sequence. The storage temperature is important for frozen food. Symons [18] mentioned that the speed of freezing was not as important to product quality as the maintenance of adequately cold temperatures (–18°C or less) during distribution. A package for frozen products should (i) be attractive and appeal to the consumer, (ii) protect the product from external contamination during transport and handling, and from permeable gases and moisture vapor transfer, (iii) allow rapid, efficient freezing and ease of handling, and (iv) be cost-effective. To provide the greatest protection, a package must be well-evacuated of air (oxygen) using a vacuum or gas-flushed system and provide an adequate barrier to both oxygen and moisture [2, 44]. Since cost is involved in vacuum or modified-atmosphere packaging, these should only be used when necessary for quality. For example, vacuum packaging need not be used if lipid oxidation is not the limiting factor affecting the shelf life of a product.

The shelf life of frozen foods kept in open display cabinets at –15°C packed in 23 different types of plastic, cardboard, and laminate was studied. It was found that aluminum foil-laminated and metallized packages gave the best results. This is due to low levels of oxygen permeability, water vapor transmission, and light transparency, and less fluctuating temperatures [169]. Two terms used to describe the shelf life of frozen foods are practical storage life (PSL), and just noticeable difference (JND). Practical storage life is the level of quality expected for the product by the ultimate consumer. Just noticeable difference is usually determined by a trained taste panel and then multiplied by an arbitrary figure, generally between 2 and 5, to arrive at a practical storage life [18]. In some sensitive products, such as peaches, cauliflower, and red-pigmented fish, the PSL may be close to the JND [18]. Most frozen products enjoy a shelf life of many months or even years [18].

Quality losses of frozen food increase log-linearly with the storage temperature when greater than –18°C [170]. The rate of quality loss increases about 2–2.5 times for every 5°C increase over –18°C [5, 51, 171]. In poultry, it has been suggested that shelf life is likely to change by a factor of 3.5 for each 10°C change, up or down [2]. In seafood kept at around 0°C, enzymic breakdown of protein becomes the main cause of quality loss; below –8°C microbiological spoilage ceases, and protein denaturation coupled with oxidative rancidity in fatty species become the chief factors affecting quality [18]. Some types of foods, such as fish, pork, animal organs, fried chicken, and spinach, can be maintained in a high-quality state for only 3–7 months at –20°C, whereas other foods, such as beef, sugared fruits, many bakery products, and many vegetables can be maintained in a high-quality state for more than 12 months at –20°C [10]. Fish stored at –29°C will have a shelf life of more than a year [44]. The practical storage life values are determined by the International Institute of Refrigeration (IIR) by Symons [18].

39.9 THAWING

Thawing as a final and obligatory step of the freezing process is quite important. Thawing properly is essential to maximize quality retention and safety of frozen foods. Microbiologically safe thawing processes are (i) inside a refrigerator at temperatures below 5°C, (ii) microwave oven, or (iii) as part of the cooking treatment [98]. Although thermal processing in microwave and cooking assures better microbial destruction when compared with thawing inside a refrigerator, sensory quality retention is compromised. In a study on green beans quality loss upon thawing, Martins and Silva [98] found that sensory parameters, such as flavor and color, were more sensitive to thawing at refrigeration temperature (3–7°C), than nutritional properties, such as vitamin C and starch contents. In a study of Virtanen et al. [172], the thawing time of a model food system, based in wheat flour, was reduced to seven parts, when they combined microwave energy and cold air in comparison to convective thawing at ambient temperature, but no quality changes were quantified. High pressure, microwave, ohmic, and acoustic thawing are innovative applications that are being explored to improve conventional thawing methods. High-pressure methods preserve food quality and reduce the necessary time for thawing, but some inconvenient characteristics have been mentioned, such as high costs, protein denaturation, and meat discoloration [173]. Similarly, microwave, ohmic, and acoustic thawing may require shorter thawing times, but some limitations have been found. Heterogeneous heating, controlled frequencies, and many more investigations need to be considered with these new thawing methods [173].

39.10 COLD CHAIN TOLERANCE AND QUALITY

39.10.1 Temperature Cycling

The steps in the frozen food cold chain are freezing, transport by refrigerated vehicle or container, distribution store, retail display cabinet, the unrefrigerated period between retail outlet and home, and time in a home freezer before being consumed in the frozen state, thawed, or end cooked. Temperature abuse at any of the above steps causes quality deterioration. Time-temperature indicators have been proposed to monitor the lack of adequately cold temperatures during the cold chain. Fluctuations in storage temperature may contribute to deterioration of frozen foods [29].

39.10.2 Time–Temperature Tolerance Indicators

The concept of time–temperature tolerance (TTT) to describe frozen food stability is important. Physicochemical, chemical, or biological reactions give an irreversible indication (usually visible) of the history of the product. These indicators are placed on the outside of the packages and combine the time and temperature conditions to which they have been exposed [94]. Temperature history indicators do not provide a precise record of temperature as it changes with time, as do time-temperature recorders or digital data acquisition systems, but

are less costly [174]. Indicators that respond continuously for all temperature conditions are said to be full-history indicators, whereas devices that respond only for the period of time during which a temperature threshold has been exceeded are called partial-history indicators [174]. A more detailed review of time–temperature indicators is given by Taoukis et al. [175]. The applicability and effectiveness of time–temperature integrators (TTI) as monitors and controlling tools for frozen chain and distribution of frozen vegetables, green peas, and mushrooms were assessed by Giannakourou and Taoukis [176]. In this analysis, TTI response provided a reliable indication of the relative quality status of the frozen products, in which these TTI tools may be utilized as a base to optimize the management system and consequently to improve consumer acceptance [176].

39.11 EMERGING FREEZING TECHNOLOGY

Freezing process can be used as one of the hurdles in combined methods of food preservation. Piotrowski et al. [177] carried out a study with osmotic dehydration, freezing, and microwave convective drying to preserve strawberries. In the case of apple cubes, an osmotic dehydration treatment followed by freezing provided good quality and acceptance. The optimum conditions were found to be 55°Brix, 35°C for the solution, and 60 min of osmotic dehydration time with fast freezing [178]. Sun and Li [13] and Li and Sun [179] applied ultrasound with freezing to potato tissues, which resulted in an improved freezing rate. Higher freezing rates produced better cellular structure, less intercellular void formation, and less cell disruption when studied by cryo-scanning microscopy analysis. The application of power ultrasound was effective in improving the structure of frozen-then-thawed potatoes. A combination of dehydration in concentrated solutions and freezing was applied to muskmelons [180] and strawberry slices [151] in order to identify improvement in texture and structure. Moisture reduction of muskmelon, prior to the freezing process, improved the quality by reductions in exudate loss and texture after thawing [180]. Also after thawing, the pre-dehydrated strawberry samples exhibited a better tissue organization than the frozen slices without pretreatment, the best texture corresponding to the air-dried and the osmotic concentrated-air dried strawberry samples [151]. Fagan et al. [181] utilized a modified atmosphere packaging, with different N_2/CO_2 ratios, combined with freeze-chilling, to extend the shelf life of raw whiting, mackerel, and salmon, finding that these combined technologies confer logistical benefits, not only during frozen storage, also in product distribution and retailing.

Recently, Zhan et al. [182] reviewed the emerging freezing technologies to improve the quality and safety of frozen foods. These include high-pressure freezing, electrically and magnetically assisted freezing, ultrasound-assisted freezing, and utilization of antifreeze protein. These have been developed to minimize the disadvantages of traditional freezing methods, which cause damage to the cell structure, increased drip loss, and poor sensory value. At high pressure and different temperatures water forms different states of ice, and high pressure can be classified into three types: (i) high-pressure induced freezing, (ii) high-pressure shift freezing, and (iii) high-pressure assisted freezing [183, 184].

An electric field enhances the orientation or rotational movements of polar molecules, and thus it affects water molecules under electric field [185]. It causes the early formation of ice crystals due to the minimization of free energy, and enhances the nucleation process [186, 187]. Therefore, electric field or electric disturbance during freezing showed positive effects on the quality of frozen foods [188, 189]). The magnetism of water molecules forms closer molecules as a higher number of hydrogen bonds are formed. This makes the network more stable with increased thermal conductivity and a raised freezing point of water, thus controlling supercooling with delayed ice formation [190–192]. Similarly, microwave-assisted and radiofrequency-assisted freezing are being tested for their potential use in foods [182]. These can induce the dipole rotation of water molecules and cause disturbance in ice nucleation, formation, and growth. This is due to the rearrangement of the hydrogen bonds with an applied electric field, which makes a stronger water network [193, 194]. The ultrasound-assisted freezing has also been tested for foods. The cavitation and micro-streaming effects generated by ultrasound intensify heat transfer, promoting the formation of ice crystal and fracturing large ice crystals [179, 195]. Zhan et al. [182] mentioned in his review that all these methods have more or less positive effects on meat, especially controlling ice crystals by creating smaller, homogeneous, and regular-size crystals as compared to the conventional ones. They ultimately better preserve microstructure and quality. However, more confirmatory works need to be done to explore both positive and negative dimensions of these new technologies.

39.12 CONCLUSION

Freezing is one of the commonly used methods of food preservation, and it provides relatively better quality as compared to drying and canning. The varied rate of freezing causes the formation of different types of ice crystals, thus affecting the structure of the frozen and thawed foods. The detrimental effects of freezing on the microorganisms depend on the types of pathogens, spoilage, and beneficial microbes. Freezing changes free and bound waters in foods, moisture loss, recrystallization, retrogradation, protein denaturation, freezer burn, glass formation, functional properties, hydrolysis, acetaldehyde formation, oxidation, color, flavor, aroma, and vitamins. Different pretreatments, such as blanching, heat treatment, dipping treatments, and osmotic drying, can improve the quality of frozen foods. In addition, the utilization of bacterial ice nucleators, cryoprotectants, and antifreeze proteins is emerging. The emerging technologies, such as electric and magnetic field, radiofrequency, microwave, ultrasound and high pressure, are being explored for controlled ice formation and for enhancing the quality of frozen foods.

40 Freezing Methods of Foods

Jorge Fernando Velez-Ruiz and Mohammad Shafiur Rahman

CONTENTS

40.1 INTRODUCTION

Food preservation by freezing is a process based on the effect of low temperatures in a range of –2 to –18°C for commercial purposes, although lower temperatures can be used. It was conceived to preserve perishable foods for long periods of storage with good quality. However, there are significant differences in the shelf life of frozen foods when the storage is carried out at –12°C (or higher temperatures) compared to at –18°C. Freezing as natural phenomenon is very old and as a transformation process is one of the conventional food preservation technologies. The invention of a freezing unit by Reece in 1867 used ammonia as the refrigerant. In 1893, a load of 60,000 tons of salmon were transported from Kamchatka to United States. Clarence Birdseye, a food researcher and trader, developed freezing plate equipment, and in 1931 this pioneer founded a company to market frozen foods.

There are two main factors involved in food preservation by freezing; one is the increasing of osmotic pressure or water activity reduction, due to concentration of solutes, and the second is maintaining the low temperature through the storage. The concentration of solutes is achieved through crystallization of water, which contributes to prevent microbial growth and to destroy microbial cells to some extent. In addition, there are fewer deteriorative reactions due to the high viscosity of the concentrated solution. Maintaining the low temperature during storage is very important, because both biochemical and chemical reactions as well as microbial growth are minimized, and it contributes to the high quality of frozen products [1].

It is very interesting to observe that the economic growth of developing countries is quantified on the basis of how many people have a domestic refrigeration unit. On the other side, people from developed countries may freeze almost all foods, because they have at least one freezing unit. Raw food materials change with time, the overall cost for freezing preservation being lower than that for canning and/or drying if the freezer can be kept full [2–4]. Different pretreatments, such as blanching, sulfating, and cooling, are used to reduce the freezing time as well as to produce high-quality frozen foods. The design or selection of freezing equipment implies the knowledge of several aspects and fundamentals, such as the freezing point, heat requirements, processing times, and relation between unfrozen water as a function of temperature. This chapter presents different types of freezing methods with their descriptions, advantages, and limitations.

40.2 FUNDAMENTALS OF THE FREEZING PROCESS

The freezing process may be divided into three stages, based on the temperature evolution; in the first stage, or "cooling" (above the freezing point), the temperature of the food is decreased from its original condition or initial temperature to the freezing point (Figure 40.1). In the second stage, or properly freezing (at constant temperature), as a natural phenomenon the freezable water changes from liquid to solid state. Finally, the third stage or "subfreezing" (below the freezing point): food decreases its temperature from its freezing point to the storage temperature, and the ice formation increases. These three stages can be observed in Figure 40.2, which shows the freezing curve for three different foods (i.e. three levels of water content); the first curve was developed for a vegetable with high water content (97.8%) and consequently exhibited a freezing point (–0.10°C) close to water. The second

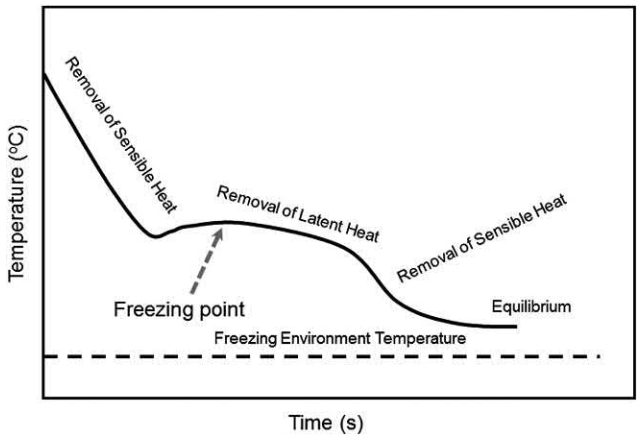

FIGURE 40.1 Typical temperature–time curve for a freezing phenomenon.

curve corresponds to a dispersion (mixture of milk and solids from nut) with medium water content (64.9%); then its freezing point is also close to that of water but lower (–1.24°C). Whereas the third, a mixture of several ingredients in a paste, had a low water content (13.5%) and showed a very low freezing point (–35.2°C) [3]. Therefore, the best type of freezing method for the specific food item needs to take into account its freezing point as well as complete engineering design. It is important to estimate the refrigeration load of a freezing process based on the fundamentals of heat transfer. Figure 40.3 shows the heat transfer and movement of the frozen layer during the freezing process. We can mention three important aspects that affect the calculation (Figure 40.1); the first one is related to the decrease of temperature (sensible heat) and phase change (latent heat) of the food (Q_F), and the other two, maintenance (Q_M) and losses (Q_L), implying sensible, latent, convective, and conductive heat transfer phenomena. The chamber maintenance requires a heat loss estimation during the storage of frozen foods. The freezing rate depends on the convective heat transfer coefficient and thermal conductivity. A typical range of surface heat transfer coefficient is 5–2000 W/m^2 K [4–6] and thermal conductivity ranges from 0.5 to 1.5 W/m K [4, 7]. Even though the focus of this chapter is not engineering, some process parameters (h, the convective heat transfer coefficient and the latent heat of fusion) and physical properties (k, conductivity, and C_p, specific heat) related to the freezing of foods are included in Table 40.1.

40.3 SLOW AND QUICK FREEZING

A specific freezing method is characterized by two physical phenomena: an initial nucleation or ice generation, followed by crystal growth of the ice cores. The quality of the frozen foods mainly depends on the size of the ice crystals generated through the whole process; thus the rate of freezing is recognized as critical to achieving quality in frozen foods. Therefore, the different methods applied in the food industry may be part of a slow-freezing group or a quick-freezing group. A rapid freezing process generates small intracellular

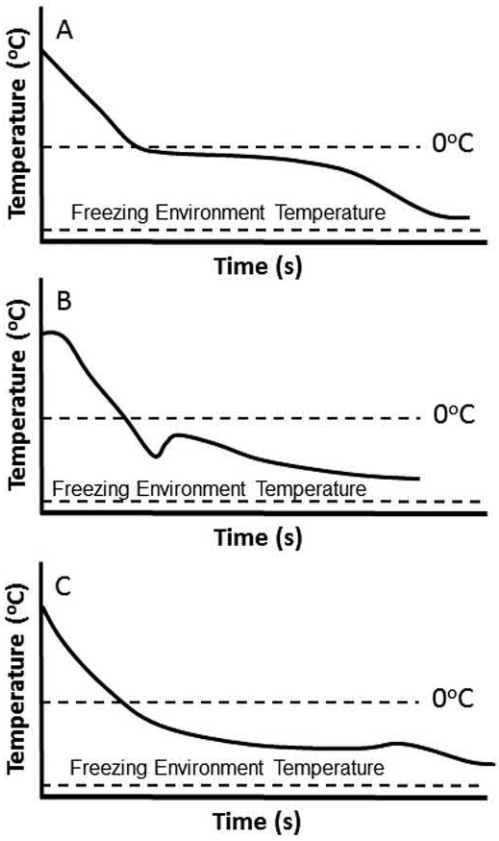

FIGURE 40.2 Temperature–time curve for the freezing of three foods, A: high water content (a vegetable), B: medium water content (a dispersion), C: low water content (a paste).

ice crystals; in contrast slow freezing produces large ice crystals (Figure 40.4). There are several process characteristics that are considered to distinguish both groups; these are emphasized in Table 40.2.

There are different types of freezing systems available for foods. No single freezing system can satisfy all freezing needs because of the wide variety of food products and process characteristics. The selection criteria of a freezing method are the type of product, reliable and economic operation, easy cleaning ability and hygienic design, and desired product quality. Although most of the commercial freezing processes are operated at atmospheric conditions, there are potential applications of high-pressure assisted freezing and thawing of foods, or the use of vacuum conditions [8–11]. The pressure-induced freezing point and melting point depression enables the sample to be super-cooled to low temperatures (e.g. –22°C at 207.5 MPa), resulting in rapid and uniform nucleation and growth of ice crystals on release of pressure. Other results include increased thawing rates, the possibility of non-frozen storage at subzero temperatures, and various high-density polymorphic forms of ice. Details of the applications of this process are reviewed by Kalichevsky et al. [12].

The International Institute of Refrigeration (IIR) used four categories for food freezing based on speed, defined as the "cold front." This is visualized as the line or front that separates the frozen part from the unfrozen part of the food item

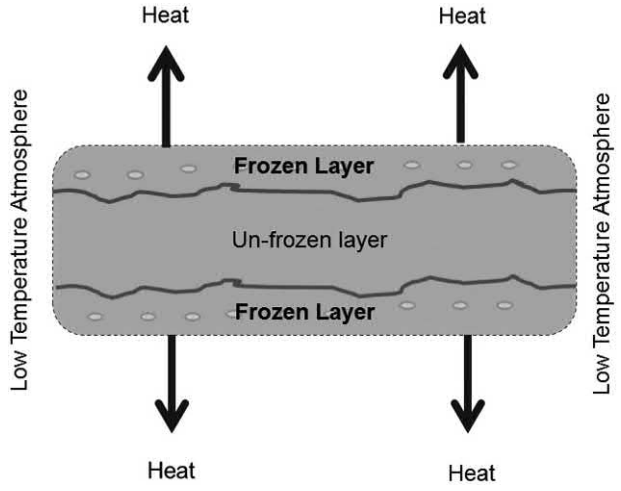

FIGURE 40.3 Heat transfer and frozen layer during the freezing process.

(Figure 40.3). Slow freezing with a front speed of 0.1–0.2 cm/h is used for bulk freezing inside big rooms, quick freezing with a speed of 0.5–3.0 cm/h for blast and plate freezers, rapid freezing with a range of 5–10 cm/h in fluidized units, and ultra-rapid freezing with a front speed of 10–100 cm/h is reached in cryogenic and liquid spray freezers [10, 11].

In the food industry, plate contact, immersion, air blast, fluidized-bed, and cryogenic freezing are common methods, and although these have particular performance characteristics, the number and size of crystals formed during freezing involve several factors, such as the quantity of product, specific properties of the food, characteristics of the particular method, operation conditions of the equipment, heat transfer, and presence of packaging, among others [4, 11].

The quality of the frozen foods depends of the following factors: (i) quality of the fresh food, (ii) application of pretreatments, (iii) selection of the best freezing method, (iv) hygienic process conditions, (v) right freezing speed, (vi) presence of packaging, and (vii) proper thawing. Thawing is very important and transcendent because an incorrect thawing process causes poor quality in frozen foods.

40.4 CONVENTIONAL FREEZING METHODS

Freezing methods may be grouped in four types: (i) freezing by contact with a cooled solid surface (plate freezing), (ii) freezing by contact with a cooled liquid (immersion freezing), (iii) freezing by contact with a cooled gas (e.g. cabinet freezing), and (iv) freezing by cryogenic medium.

TABLE 40.1
Process Parameters and Physical Properties of Some Freezing Systems and Food Products

Freezer Type	Conditions	h (W/m² K)	Example Foods Preserved by the Method	
Cold room	Still air	5–10	Beef carcass, chicken, fruits, vegetables	
Air-blast	Air velocity: 2.5–5 m/s	15–30	Fruits, vegetables, fish fillets	
Tunnel	Counterflow of food item and air	15–60	Grains, soybean, fish fillets	
Fluidized-bed	Suspending airstream	80–120	Carrot cubes, peas, shrimp, strawberries	
Plates	Contact to solid	50–120	Meat steaks, fish fillets, leafy vegetables	
Cryogenic	Gas zone/spray zone	40–60/100–140	Ice cream, shrimp, berries	
Liquid immersion	Circulating brine	60–90	Chicken, turkey, canned foods	
	Specialized refrigerant	500–1200	Fruits, tomato slices, orange segments	
Food item	k (W/m K)	Cp above and	below freezing (kJ/kg K)	Latent heat of fusion (kJ/kg)
Apples	0.513 (before freezing, water 84.9%)	3.65	1.90	281
Bananas	0.481 (before freezing, water 75.7%)	3.35	1.78	251
Chicken		3.32	1.77	247
Ice cream	0.460 (before freezing, at 0°C)	2.95	1.63	210
Milk (whole)	0.473 (before freezing, water 87.0%)	3.79	1.95	294
Oranges	0.580 (before freezing, water 85.9%)	3.75	1.94	291
Shrimp	0.490 (before freezing, water 75.3%, fat 1.2%)	3.62	1.89	277
Strawberries	0.462 (before freezing/1.125 (at –15.5°C)	3.86	1.97	301
Tomato (ripe)	0.571 (before freezing, water 92.3%)	3.99	2.02	314
Turkey	0.343 (before freezing, water 92.8%, fat 12.4%)	2.98	1.65	214
	1.437 (water 92.8%, fat 12.4%, at –9.4°C)			
	1.627 (water 92.8%, fat 12.4%, at –23.3°C)			
Watermelon	0.571 (before freezing, water 92.8%)	3.96	2.01	311
Water	0.594 (before freezing, at 0°C)	4.23 (at 0°C)	2.01	334

40.4.1 Freezing by Contact with Solid Surface (Plate Freezing)

In this method, the product is placed between metal surfaces or plates, cooled either by refrigerants, cold brines, or even other fluids (Figure 40.5). The plate adjustment by hydraulic pressure is usually utilized for good contact with the food surface. The thermal conductivity of metals used for the contact plates is high, being important from the heat transfer viewpoint; however, the manufacture of these plates is importantly governed by sanitary requirements. Plate freezers are only suitable for regular-shaped food materials or blocks, such as fish or meat, as they favor good contact between the surfaces of the plates and the food item.

When the product has been frozen, hot liquid is circulated to break the ice seal and defrost. Spacers should be used between the plates during freezing to prevent crushing or bulging of the package. In the freezing of liquid foods, such as vegetable purees, fruit juices, food concentrates, and ice cream, cylindrical scraped-surface or vertical freezers may be used. When the freezing process is completed, the plates are separated and the frozen food product is removed, for reloading of the next batch into the unit equipment. This equipment may be operated in batch, semi-continuous, or continuous arrangements. The

FIGURE 40.5 Photo of plate freezing equipment (manufacturer: Jackstone).

filled freezer looks like a multilayered sandwich with alternative layers of cold plates and food product.

The number of parallel plates may be separated by up to 9 cm as a function of their position, in a number of 5–20 with a contact area of 1.2–2.5 m^2, for instance plates with dimensions of 0.8×1.5 m^2 or 1.1×2.0 m^2. These freezers may have a capacity of 6000 to 15,000 kg/d or specific capacity of 160 kg/m^2 h. A cabinet with 20 plates has overall dimensions of $2 \times 2 \times 3$ m^3, with weight of 1.8–2.0 tons. One of the important advantages of this type of freezing is its capacity, being two to four times higher than that of the tunnel units [11].

There is a particular type of indirect-contact freezer known as a scraped-surface heat exchanger. It is used mainly for viscous liquid foods, such as ice cream. In this system, a cylindrical tube and a rotor are in the inside part of the equipment, whereas in the external part there exists another tube or a jacket, surrounding the tube surface with refrigerant flowing inside. Around 60–80% of the latent heat is removed from the food, and it leaves the equipment as a frozen slurry [4, 13].

40.4.2 Freezing by Contact with Cooled Liquid (Immersion Freezing)

In this method, food is immersed in a low-temperature brine and nontoxic mixtures of solutes and water (aqueous solutions). Direct contact with liquid could achieve fast temperature reduction through direct heat exchange [9]. The fluids usually used are salt solutions (calcium chloride and sodium chloride), sugar solutions, and alcohol solutions (glycol and glycerol). The solutes used must be safe for the product in terms of health, taste, color, and flavor, and the product must be denser than the fluids. Dilution from the foods may change the solution properties; thus it is necessary to control the concentration.

Due to the direct contact between the cooling medium as a liquid and the food item, the heat transfer is very effective. In order to ensure that the food does not come into contact with some liquid refrigerants, flexible membranes or packaging can be used to enclose the food completely while allowing rapid heat transfer [14]. The water loss and salt gain, respectively, were less than 2 and 1 g/100 g for gelatin gel in immersion

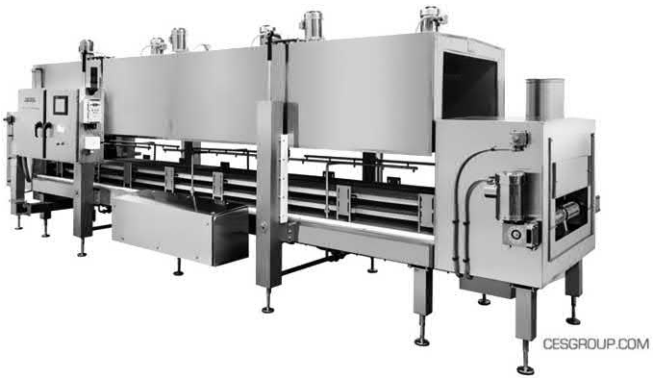

FIGURE 40.6 Air tunnel freezing with a conveyer belt for holding and carrying food (manufacturer: CESGROUP).

freezing with sodium chloride solution, and the salt penetration was hindered by the formation of an ice barrier [15]. A mixture of glycerol and glycol is a liquid–liquid medium that can be used since there is no eutectic point for the solutes. As the temperature is lowered, a point is reached where ice crystals are formed as slush. The temperature at which slush ceases to flow is called the flow point. Methanol or ethanol can also be used. Although the methanol will be removed during cooking, it is poisonous, whereas ethanol is safe. Alcohols also pose a fire hazard in processing plants.

40.4.3 Freezing by Contact with a Cooled Gas (e.g. Cabinet Freezing)

In this method, air in a chamber is utilized. These systems attempt to put the air into contact with as much of the food surface as possible. As the cooling medium by natural convection with a lower surface heat transfer coefficient or blown as forced convection with higher convective, and forced convection air may be used in tunnels (Figure 40.6), a conveyor belt (Figure 40.7), and fluidized-bed equipment. The convection of large quantities of air, due to its low specific heat, may be blown horizontally or vertically to the flow of the food products. For static air in which heat transfer is lower than for forced air, the convective heat transfer coefficient is a function of the air velocity. High velocities are more effective for the freezing of unpackaged food items, particularly when the foods are completely surrounded by the flowing gas.

40.4.3.1 Room or Cabinet Freezing

In this method or system, cold air is circulated inside the room or cabinet, depending of the food quantity, where the food product is placed in trays (e.g. fish fillets) or suspended (e.g. half beef carcasses). Room and cabinet freezers have been used for almost all types of food. Fresh or packaged foods can be frozen in air at temperatures of –18 to –40°C. The natural convection phenomenon of air plays an important role in the freezing speed (i.e. high velocity determines higher heat transfer). In these systems, moisture pick-up from the product surface may deposit on the cooling coils as frost, and acts as an insulation. A cabinet freezer with air velocity of at least 5 m/s generates high heat-transfer rates [9]. When the air is forced or blown through a particular equipment geometry or design, the method is known as blast freezing.

Soyer et al. [16] carried out a study to observe the effect of freezing temperature (–7, –12, and –18°C) and storage time (up to six months at –18°C) on the oxidation of lipids and proteins in chicken meat. They found not significant the effect of the freezing temperature, but found storage time to have an important effect on both oxidation phenomena after three months, and they detected a higher reaction intensity in leg meat than in breast meat.

40.4.3.2 Air-Blast Freezing

In this method, the temperature of food is reduced by cold air flowing at a relatively high velocity. The application of this system is limited to some foods, in which the residence time is low to avoid and control moisture loss through the process. The use of packaging for foods helps to avoid this problem. Air velocities between 2.5 and 5 m/s give the most economical freezing. Lower air velocities result in slow product freezing, although higher velocities increase unit freezing costs considerably [8]. It is useful for foods with a variety of shapes and sizes. This method can use a simple design, and the existing

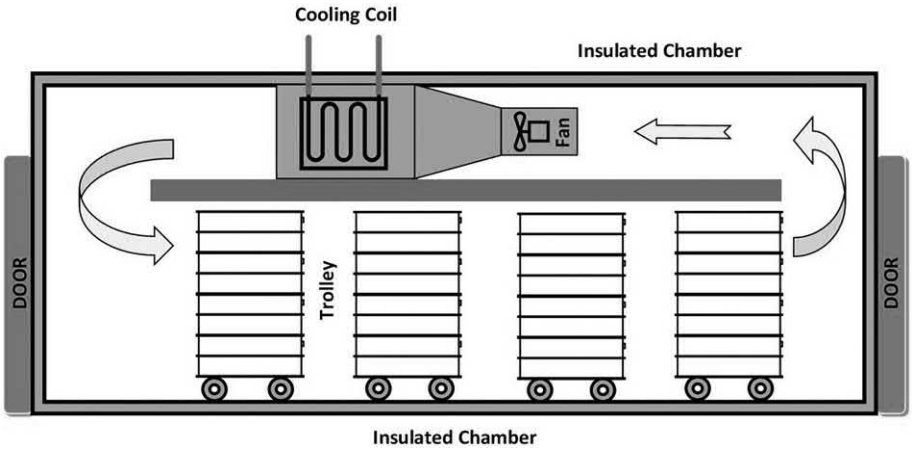

FIGURE 40.7 Air tunnel freezing with trolleys or pellets for holding and carrying food.

designs are divided into tunnel freezing, belt freezing, and fluidized-bed freezing, depending on how air interacts with the product [9, 17].

Silvas-Garcia et al. [18] followed the effect of freezing rate on the solubility, structure, and rheology of gluten proteins and bread quality. The frozen dough at a slow freezing rate exhibited a decrease in the proportion of insoluble polymeric protein and gas retention, as well as resistance to extension, whereas an increase in protein solubility and viscous modulus was measured, in contrast to the dough frozen at rapid rates. In addition, an increase in hardness and a decrease in springiness and specific volume were observed with fast freezing. These changes in properties are very important because the quality of bakery items is related to the viscoelastic properties of the gluten proteins. Santos-Goncalvez et al. [19] also compared the effect of freezing with static and forced air on bioactive compounds and antioxidant activity of strawberry pulp. They found that forced air was better for retaining phenolic compounds and the antioxidant activity of the pulp, where the levels of polyphenol oxidase and peroxidase enzymes were stable. Additionally, as a good advantage for the static air, the freezing method did not affect the anthocyanin levels.

40.4.3.2.1 Tunnel Freezing

In this process, the products are placed in trays or racks in a long tunnel where the cool air is circulated over the product (Figure 40.7). There are single-, double-, and multiple-row tunnels. Due to equipment performance, it may be used for any food item, from fine-cut or minced foods up to whole turkeys and even half beef carcasses. Three basic elements of the tunnel freezer are the push-through device, the trays, and the chain drive system with very good insulation. The tunnel has an entrance door and an exit door for continuous operation, with air temperature of –30 to –40°C and velocity of 3–10 m/s, and it requires powerful fans and large heat exchangers. The freezing time depends on the process conditions in addition to the size and thermal conductivity of the food product; it usually lasts 1.5–6 h, with a capacity of around 85 kg/m^2 h, and obviously, lower times imply higher costs. The advantages of this method are its versatility for food handling, its simplicity and easy cleaning, but it has important disadvantages, such as higher moisture loss (~3%), and the need for larger space and labor in comparison with other freezing methods. Mendez [20] carried out a study to find the effect of freezing and storage on the weight loss of meat. A weight loss of 0.05–1.20% was found depending on the animal part (i.e. sides and quarter of beef and pork), when tunnel freezing with air velocities of 0.8–3 m/s and temperatures of –20 to –30°C is used.

40.4.3.2.2 Belt Freezing

The first mechanized air-blast freezer consisted of a wire mesh belt conveyor in a blast room for continuous product flow (Figure 40.6). It consists of long belts moving through cold airstreams in a parallel or countercurrent arrangement. Uniform product distribution over the entire belt is required for the product, favoring a high surface contact and effective freezing. The systems include a horizontal straight belt, and up-and-down belt, and a curved belt. Controlled vertical airflow forces cold air up through the food product layer, thereby creating good contact with the item and increasing the thermal efficiency. The principal current design is a two-stage belt freezer. Temperatures are usually –10 to –4°C in the precool section and –32 to –40°C in the freezing section [8].

40.4.3.2.3 Spiral Freezing

A spiral belt freezer is a variant of the belt and tunnel systems; it consists of a long belt wrapped cylindrically in two tiers, thus requiring minimal floor space (Figure 40.8). The spiral freezer uses a conveyor belt that can be bent laterally. It is suitable for products with a "long" freezing time (generally 10 min to 3 h), and for products that require gentle handling during freezing. It also requires a spatial air-distribution system [8].

40.4.3.2.4 Fluidized Bed Freezing

A fluidized-bed freezer consists of a bed with a perforated bottom through which refrigerated air is blown vertically upwards in a compacted cabinet. The air velocity must be greater than the fluidization velocity (i.e. value at which the food is suspended/maintained in the air stream). This freezing method is suitable for small pieces or particulate foods of fairly uniform size (2.5–12.5 cm) by forming a bed of peas, diced carrots, potatoes, corns, and berry fruits, and giving sense to individual quick freezing (IQF), where the food units are frozen individually. An air temperature of –34°C is common. The high degree of fluidization improves the heat-transfer rate and results in short freezing times and good use of floor space. Sheen and Whitney [21] found that the surface or convective coefficient was two to three times higher in a fluidized bed than with convective air in a freezer for large food items. This method has several advantages, such as short freezing times, high heat transfer, less food dehydration, and less need for equipment defrosting. It has the limitation that large or non-uniform food units cannot be handled in this type of freezing equipment. Similar characteristics may be assumed for cryogenic units.

FIGURE 40.8 Commercial spiral freezer (Nantong Baoxue Refrigeration Equipment Co.).

40.4.4 Freezing by Immersion and Cryogenic Materials

Food items have direct contact with the freezing medium, similar to air systems, in which the freezing process is completed very quickly, generating frozen food products of superior quality. A liquid refrigerant is utilized, undergoing phase change as the freezing occurs. The food product to be frozen is either immersed in the liquid or sprayed with it, therefore the foods might be protected with an adequate package.

40.4.4.1 Immersion Cryogenic Freezing

In this method, a solution is used (immersion methods) by the application of liquid carbon dioxide (CO_2), nitrogen (N), or Freon fluids (cryogenic methods), with boiling points of –79, –196, and –30°C (Freon 12), respectively. The product is immersed in cryogenic liquid in an immersion freezer.

40.4.4.2 Cryogenic Freezing

In cryogenic freezing, liquefied gases are used in direct contact with the foods, either packaged or unpackaged. Food is exposed to an atmosphere below –60°C through direct contact with liquid nitrogen or liquid carbon dioxide. Other compounds, such as CCl_2F_2 (Freon 12) and N_2O, are also used. Due to their thermodynamic properties and easy handling, nitrogen is mainly used in food processing plants. It is usually used for high-value products due to the high capital cost for gas compression. Very high heat transfer (i.e. highest h) may be achieved with this freezing method, due to the easy and quick evaporation of the cryogenic liquid.

The product can be exposed to a cryogenic medium in two ways: (i) the cryogenic liquid is directly sprayed on the product in a tunnel freezer (Figures 40.9 and 40.10), and (ii) the cryogenic liquid is vaporized and blown over the food in a spiral freezer or batch freezer [1, 4, 11, 22, 23].

Freezing with nitrogen is a very fast method (2.5 times faster than fluidized-bed freezing, for example); thus adequate control is necessary for achieving quality products. It also provides flexibility by being compatible with various types of food products. The rapid formation of small ice crystals greatly reduces the damage caused by cell rupture, preserving color, texture, flavor, and nutritional value. The rapid freezing also reduces dehydration of the products, provides high product throughput, and has low floor space requirements. Thermal diffusivity of the food, however, restricts the heat transfer from the product to the freezing medium [9, 11, 14]. Spraying of the cooling medium is conveniently applied in continuous units, and it is more widely used than direct immersion in the cryogenic fluid.

Cryogenic gases can also be advantageously applied to produce a hard, frozen crust on a soft product to allow for easier handling, packaging, or further processing [24]. The cryo-mechanical technique utilizes a cryogenic gas to create a frozen crust on a fluid product, after which the product may then be conveyed to a conventional mechanical freezer. The combination of these processes offers the advantages of both systems [14]. The advantages of liquid nitrogen are: it is colorless and odorless and is chemically inert and boils at

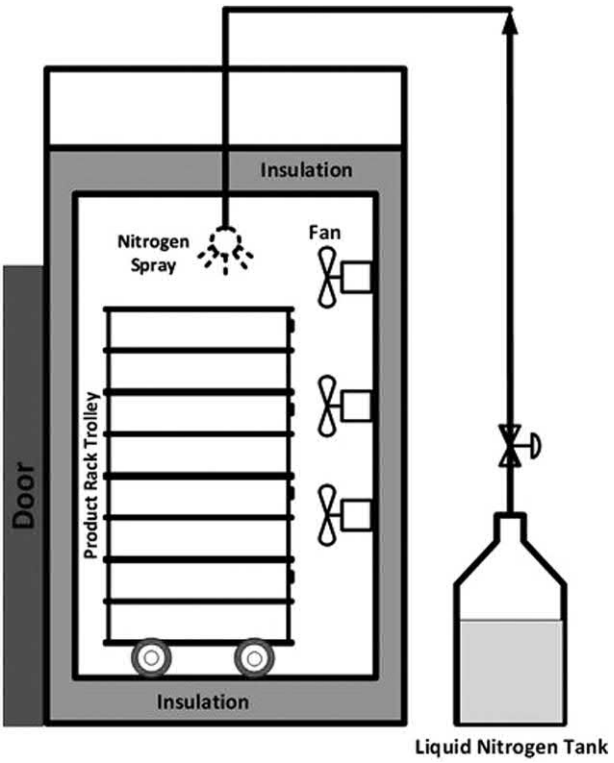

FIGURE 40.9 Cryogenic freezing in a cabinet.

–195.8°C [23]. Among the advantages of the cryogenic freezing method, we have a high freezing rate, low product loss (≤1%), easy handling, low initial and maintenance capital, low need for floor space, and excellent quality products.

Meziani et al. [25] conducted research to study the effect of immersion freezing with nitrogen on physical properties (structure and viscoelasticity) of dough, in which the freezing rate had a significant effect on rheological parameters for sweet doughs, with a higher reduction in elasticity (8.6 and 12%) as the temperature lowered (–30 and –40°C), attributed to the starch degradation and dough dehydration. Nagy et al. [26] completed a study on the effect of different freezing methods on selected properties of a pasta filata cheese using a slow freezer (i.e. static air at –18°C) and two rapid methods (i.e. blast at –30°C and cryogenic at –40°C). They found freezing times of 300, 75, and 50 min, respectively, to reach –12 for the first and –18°C for both rapid processes, resulting in easier-to-thaw cheese for the rapid methods than for the static air. Additionally, they followed other properties such as pH, texture, and sensory evaluation for the thawed food, and observed differences in favor of the quick freezing, which were influenced by the thawing method.

Diamante and Tran [27] compared three freezing methods: standard or static air (i.e. –15°C), blast air (i.e. –36°C), and cryogenic (i.e. –70°C). Although they did not find a significant difference in drip loss of beef meat, the average value decreased with the decrease in freezing temperature.

A cryomechanical freezing, or combined freezing with cryogenic followed by air-blast freezing, was utilized to improve frozen food quality. It is recommended for delicate products with poor mechanical resistance, such as shrimp, raspberries,

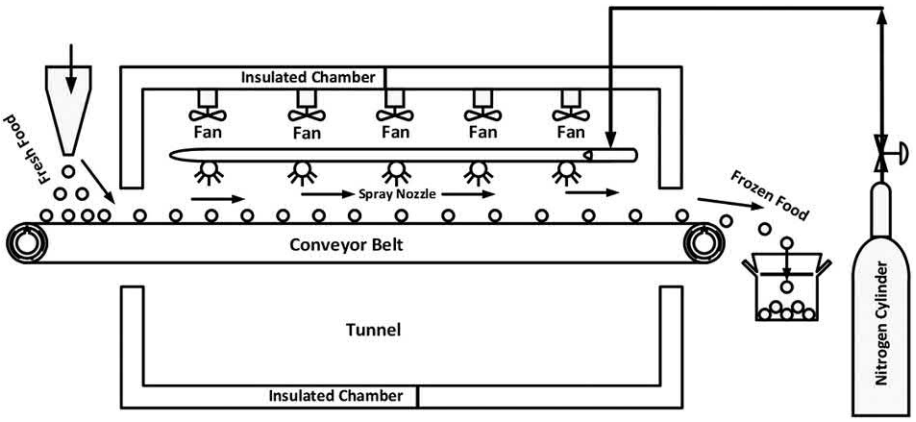

FIGURE 40.10 Cryogenic freezing on a conveyor belt.

and strawberries, or chicken and mushrooms when significant changes occurred in the product [28]. In this combined process, a protective crust formed through the immersion in the liquid nitrogen, characterized to the products.

Due to the importance of the freezing time, food engineers and plant designers need freezing equipment, and simple and accurate predictive mathematical models to calculate the freezing time. Therefore, several works related to modeling have been published in the literature [3, 17, 29–31].

40.5 EMERGING FREEZING TECHNIQUES AND FUTURE RESEARCH

Some new freezing techniques or combinations are being developed for their potential technical and economic advantages, as well as quality enhancements. High pressure and ultrasound, as non-thermal technologies, are being studied and used as pretreatments for foods that are subjected to freezing, in addition to other interesting ideas and variants. In particular, the freezing process and ice–water transitions may be affected by controlling pressure rather than temperature; the freezing point of water and the ice formed are functions of pressure [1].

Several kinds of high-pressure ices with different chemical structures and physical properties have been reported by Fletcher since 1970 and Hobbs in 1974. A pressure-shift or high-pressure freezing process can generate small and uniform ice crystals [32, 33]. Improved structures by pressure-shift freezing were reported for tofu (soybean curd) [34, 35] and carrots [36]. In the case of tofu pressure above 200 MPa, the texture was almost the same as the untreated tofu [34]. Similarly, in the case of carrots above a pressure of 100 MPa, the damage could be reduced significantly [36]. The freezing point of water can be shifted from 0°C at 101.3 kPa to –21°C under 210 MPa [33].

Zhu et al. [33] carried out a comparative study on pork muscle applying pressure-shift, air-blast, and liquid-immersion freezing methods. They found differences in size and distribution of ice crystal and consequent muscle damage, in which the pressure-shift freezing prevented the muscle disruption. Lately, Zhu et al. [37] completed another work, comparing the ice-crystal formation in a gelatin gel by pressure shift and conventional freezing (–20°C). At three pressure levels (100, 150, and 200 MPa), air freezing and immersion freezing were applied to samples, and the researchers observed a larger number of smaller ice crystals for those samples frozen at high pressures, with a better texture in the product.

A dehydro-freezing method is a combined method in which controlled dehydration is applied before the freezing stage; it is mainly promising for the preservation of fruits and vegetables due to their high moisture contents. This technique reduces refrigeration loads, and packaging, storage, and distribution cost, as well as providing a comparable quality to conventional freezing [32, 38]. Agnelli et al. [38] applied and modeled the dehydro-freezing of two fruits, pear disks and apple cubes, using glucose and sucrose solutions, before conventional freezing (air-blast tunnel at –40°C); they obtained good quantitative consistency between the experimental results and model predictions.

Ultrasound is a relatively new technology, and has been applied to some foods as a pretreatment of freezing; it has proven to be very useful for controlling both the nucleation and the crystallization growth processes, by generating nucleation sites. Sun and Li [7] also conducted comparative research on the freezing of fresh potato pieces of $17 \times 17 \times 76$ mm^3, based on microstructural observations of samples subjected or not to power ultrasound and then frozen by immersion in an ethylene glycol–water solution (50:50) at –18°C. They observed much less intercellular space and cell disruption. The freezing rate of potato samples was improved with the application of ultrasound in comparison with samples without this pretreatment. Magnificent cryo-SEM micrographs were obtained for samples exposed to both freezing variants, in which the plant tissue exhibited a better cellular structure and appearance for the potato subjected to power ultrasound. Ultrasound application in carrot juice for 30 min resulted in shorter freezing time for air and immersion freezing at –30°C, although the concentration level also affected the measured parameters. However, freezing by immersion was faster than with air [39].

Concepts based on engineering principles, mathematical knowledge, and modeling, as well as computer simulation,

TABLE 40.3
Engineering Concepts Significantly Related to Freezing Process, Frozen Storage, and Thawing

Engineering Concept	Comment	Tested Food	Reference
Freezing time	Combination of Plank and unsteady heat transfer equations	Beef	Mascheroni and Calvelo [43]
Freezing time	Comparison of existing approaches, analytical and numerical	Strawberries	Heldman and Lund [13]

Heat transfer rates and enthalpy change	Numerical model based on energy equation with the Navier–Stokes equations	Beef, egg	Ho [52]
Quality loss kinetics	Computational evaluation of frozen quality profile	Green beans	Martins and Silva [53]

should be included as part of good process development, equipment design, and optimization of food freezers (Table 40.3). Quality kinetics need to be included in the optimization of the freezing process. The implementation of Hazard Analysis and Critical Control Point (HACCP), with all aspects of Good Manufacturing Practice (GMP), could be properly applied to ensure the quality and safety of frozen foods.

Finally, although the freezing process for foods and the existing options or methods have been revised and exposed, there are two very important aspects that should be emphasized in order to complete the production of an excellent food item, ready to eat. The first is the selection of an appropriate freezing process and the second is the correct storage of frozen food products; well-controlled commercial storage completes the good performance of the freezing process and results in high-quality products. The effects of thawing are often more damaging than the freezing itself. Therefore, not only is the right choice of the freezing method very important, the next two process stages, frozen storage and thawing, are necessary to achieve high-quality products.

41 The Freezing–Melting Process in Liquid Food Concentration

Mohammad Shafiur Rahman, Mushtaque Ahmed, and X. Dong Chen

CONTENTS

41.1 INTRODUCTION

The freezing–melting (FM) process is capable of removing water by freezing it out from solution as ice crystals. Ideally, the ice formed should be free of solutes. First, the solution is partially frozen, and then the ice crystals are physically separated from the residual solution (i.e. concentrated), and finally, the ice is melted to form the product water. Ice crystals formed under the appropriate conditions can be very pure.

The freezing–melting (FM) process or freeze–concentration (FC) has the following advantages: (i) it has very low energy requirements as compared to those of distillation processes [1, 2] since the latent heat of fusion of ice is only one-seventh the latent heat of vaporization of water; (ii) it could lead to a 75 to 90% reduction of the energy required by conventional thermal processes [3]; the costs of concentration by evaporation and FM are listed in Table 41.1; (iii) it operates at low temperatures, which minimizes scaling and corrosion

TABLE 41.1
Comparing Operating Costs of Various Concentration Processes

Application	Cost per 1000 kg Water Removed	
	Evaporation	Freezing–Melting
Fruit juice concentration	$5.40	$1.98
Sugar production	$8.47	$1.32
Desalting seawater	$1.85*	$0.93
Caustic soda concentration	$2.23	$1.06
Black liquor concentration (for paper-pulp processing)	$3.15	$1.52

problems [1, 4, 5], and inexpensive plastics or low-cost materials can be used at low temperatures [2, 4, 6, 7]. In the case of liquid foods, other advantages are (i) less thermal damage of the components, (ii) avoidance of off-flavor development, and (iii) minimal loss of volatile components. A very high surface area and high heat transfer coefficient can be achieved with direct contact between the brine and refrigerant. It has a general absence of pretreatment, chemicals required, and insensitivity of fouling and nature of solution [6, 8], and low ecological impact [7].

The use of FM is more common (instead of evaporation) in concentrating liquid foods due to the reduced loss of volatiles, aromas, color, nutrients, and thermal degradation of food products [9, 10]. The juice and dairy industries have used the technology successfully. It has been utilized commercially for the concentration of citrus fruit juices, for vinegar concentration, and for the concentration of beer and wines. This technology has also been used for concentrating coffee and tea extracts, sugar syrups, maple sugar syrups, dairy products such as milk and whey, and aroma extracts [11]. More common to the food industry are the indirect contact crystallizers, where the refrigeration energy must pass from the aqueous food liquid through the walls of an appropriate heat exchanger. The most common ones are the static layer growth system, layer crystallization on rotating drum, dynamic layer growth system, and suspension crystallization unit. Grenco [12] reported about 50 plants in commercial operation using the FM process in the food industry. Some commercial applications of FM processes in the food industry are listed in Table 41.2. The food industry has tailored the technology to their areas of applications and has taken advantage of the process. Sanchez et al. [13] reviewed the applications of the FM process in fruit juice industries.

The aroma and flavor of fresh pineapple and orange juices produced by FM were better preserved in their sensory qualities than when concentrated by thermal evaporation [9, 14]. There were no significant differences in the browning and turbidity of clarified pear juices (10°Brix) produced by vacuum evaporation (VE), reverse osmosis (RO), and FM and stored at refrigerated storage after 10 days [15]. Juices obtained by RO and FM showed a similar sensory quality, and these were superior to the EV. Similarly, single-strength clear pear juice (10°Brix) produced by VE, RO, and FM showed small differences in color, turbidity, heat stability, and sensory preference after storage for 10 days at 4°C [16].

Traditionally, the disadvantages of the FM process as compared to evaporation and reverse osmosis are its higher capital costs and operating costs during the ice separation [17]. Other disadvantages are (i) in the case of desalination, the retention of undesirable flavors and aromas (initially present in the feed saline water) that may come into the produced fresh water [9]; (ii) FM needs to include the growing, handling, and washing of ice crystals steps in case of desalination, and the need for mechanical vapor compressors; (iii) compressors represent an

expensive method of furnishing the energy requirements of the system [1]; (iv) probably the greatest deterrent to general acceptance of the freezing process is the fact that large plants cannot be designed and optimized with confidence, owing to the complexity of the unit operations in the freezing-unit, melting-unit, and wash-separation column; (v) in the case of desalination, trapping of salt solution in the ice during crystallization requires the crushing and re-crystallization of ice; (vi) a progressive increase in the concentrations of the dissolved substance, and non-condensable gases; (vii) high-quality energy is required for crystallization as compared to low-quality energy used in many evaporation processes; (viii) in the case of desalination, a certain amount of fresh water is required to wash ice so as to reduce salt content in the product water; and (ix) limited variations of the methods for the complete separation of ice from brine are available [18].

41.2 STATE-OF-THE-ART OF THE FREEZING–MELTING PROCESS

41.2.1 General Description

A refrigeration system is required to remove the heat of fusion of the ice from the solution. The quantity of heat which must be removed from the freezing-unit is essentially equal to that which must be added to the melting-unit [1, 6]. The FM process is accomplished in two major stages: ice crystallization (stage I), and separation and melting (stage II) (Figure 41.1). In stage I, nucleation occurs at a suitable supercooling temperature. The nuclei in solution grow to become large ice crystals in a crystallizing unit. In stage II, the crystals are separated from the concentrate by a separator (mechanical), and then the melting process is carried out to produce pure water or to use it to cool the warm solution.

In general, the components of FM process are (i) a *precooler* to cool the feed solution, (ii) a *crystallizing unit*, where sufficient heat is removed from the process fluid to crystallize up to 15% of the mass, and (iii) a *crystal separator and purifier*, where the crystal is separated from the unfrozen concentrate and washed with a few percent of the melted product to remove any adhering concentrate from the surface of the crystal. The separated concentrate is recycled to the freezer to provide any desired recovery, (iv) a *heat pump* that takes heat out of the freezer and transfers it either to cooling water or to the melted crystal (melting-unit) that is removed from the purification section, (v) a *feed heat exchanger*, usually employed to pre-cool the feed by using the cold product and the concentrate, thus reduces the load on the freezer.

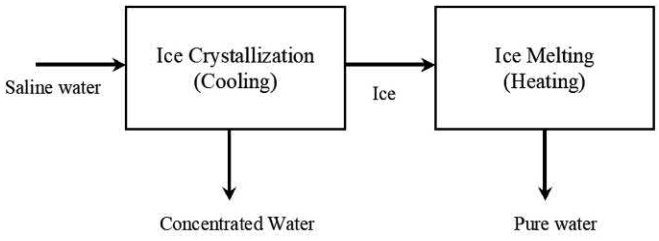

FIGURE 41.1 Freezing–melting process.

41.2.2 Historical Development

The Danish physician Thomas Bartholinus (1616–1680) was apparently the first to report that water obtained by melting of ice formed in seawater was fresh. Almost at the same time Robert Boyle (1627–1691) reported the same observation, foreseeing the phenomenon as a source of fresh water, and the Jesuit Athanasios Kircher (1602–1680) discussed the reason why ice formed in the sea is fresh [19]. The reason for getting fresh water from ice is due to the rejection of solutes at the interface. Freezing in large bodies of water occurs in nature on the surface of oceans, lakes, and bays. The combined heat transfer associated with heat removal by the environment and latent heat release at the water–ice interface result in natural convection flows of water. Freezing seawater releases fluid at the water–ice interface which is denser than the ambient water. The resulting solute buoyancy force therefore acts downward. This solute buoyancy force is in addition to the thermal buoyancy force. Flow visualization revealed that the flow was downward, below the freezing surface. Convection heat transfer rate is found to be strongly affected by solute rejection upon freezing [20]. At the end of the 18th century, the Italian scientist Anton Maria Lorgna (1735–1796) described a method to purify seawater and impure waters by freezing and then melting of the ice. In 1786, Lorgna published his first paper on water desalination by freezing, wondering why nobody had previously applied it in an artificial process initiating what nature does so well and easily in the cold seas: producing blocks of fresh water from ice produced in seawater. He also identified that only one single freezing of seawater produced an ice block with salinity, although much less than seawater salinity, thus a multi-stage freezing–melting process is required [19].

The method of water purification by FM was not of practical interest before the development of refrigeration machines. It was only possible in the coldest regions and seasons. The interest in the process for obtaining fresh water from seawater by freezing was revived in the late 1930s, and an experimental desalting plant has been operated for some years near Rome by the Istituto Superiore di Sanita. The plants operated by the indirect freezing process later revealed themselves to be of limited practical interest in comparison with the direct freezing desalination procedures. The FM process was first used commercially in the 1950s. Research in the 1960s and '70s for desalination, petroleum, and food processing applications provided many technical innovations [21].

41.2.3 Classification of the Freezing–Melting Process

Wide varieties of FM systems are currently on the market [22]. Further details of the different types are available in Heist [3], Deshpande et al. [23], Maguire [7], and Chowdhury [22]. In general, the FM process occurs in a crystallizer, although control of

ice formation and growth has been obtained in numerous ways. A classification of FM processes is given in Table 41.3 based on whether there is direct or indirect contact of refrigerant with the solution. Figure 41.2 shows the main difference between the direct and indirect methods of FM processes. In the case of direct FM, ice is formed within the solution, while in the case of indirect FM ice is formed on the cold metal surface, and refrigerant or coolant is not in contact with the solution.

41.3 DIRECT-CONTACT FREEZING

Direct-contact crystallizers provide for intimate mixing between the refrigerant (such as Freon and butane) and the product to be frozen. The refrigerant in liquid form under pressure is expanded through a nozzle into the product liquid, where it vaporizes at lower pressure. This vaporization provides a refrigeration effect and causes the formation of ice and/or solutes crystals within the product. A typical direct FM system (shown in Figure 41.3) is composed of an ice nucleation, a crystallizer allowing subsequent growth of these nuclei up to a size suitable for separation, an ice crystal separator, a washing-unit, and a melting-unit [5, 24].

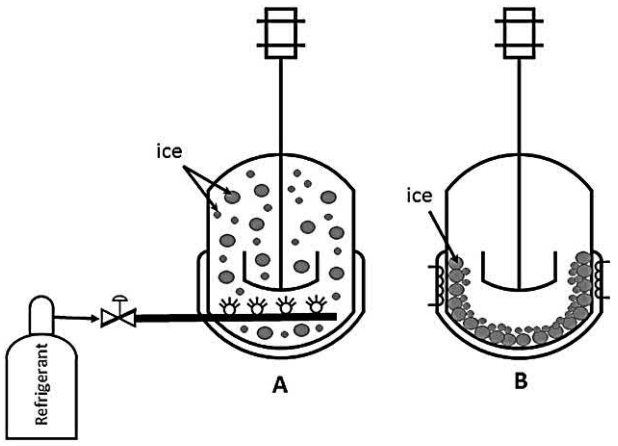

FIGURE 41.2 Two major methods of FM processes. A: Direct FM process, B: Indirect FM process.

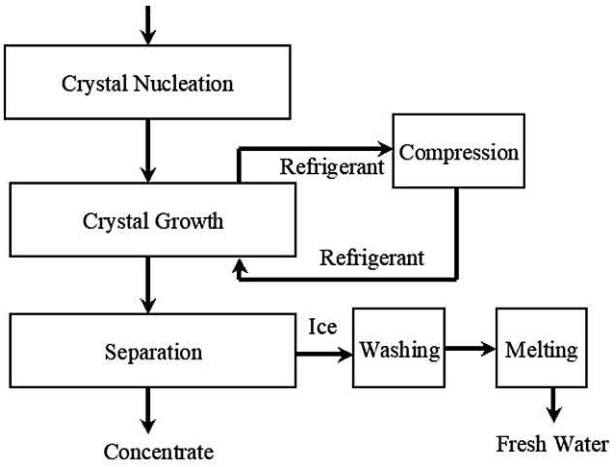

FIGURE 41.3 Schematic of a typical Direct-Contact FM Process. (From Hartel [5].)

41.3.1 Conventional Direct-Contact Ice Forming

A direct-contact freezer uses a spray of refrigerant by jet impact through a nozzle. The main advantages are: a high production rate per unit volume at a low driving force, power consumption is small, the absence of moving parts, and the unit is compact and efficient [25]. The successful design of a direct -contact FM plant significantly depends upon the availability of a suitable refrigerant [26].

There are certain thermodynamic, chemical, physical, and economic requirements, which the refrigerant must meet in order to be suitable for use in the process: (i) the refrigerant should have normal boiling point of –4°C or less and have a vapor pressure below 2.8×10^5 Pa at room temperature, (ii) the refrigerant should be nontoxic, preferably non-flammable, and chemically stable in solution, (iii) the fluid should be virtually immiscible with water and should possess such molecular size factors so as not to form a hydrate under the freezing conditions employed in the process, and (iv) the refrigerant should be cheap and readily available from commercial suppliers [27]. The details of thermodynamic properties of normal butane at refrigeration temperatures are compiled by Kurnik and Barduhn [28]. The refrigerants that could be used are butane, carbon dioxide, nitrous oxide, Freon 114, and Freon 318. Freon 114 and Freon 318 are better choices based on the above factors; however, these materials are relatively expensive when compared to other refrigerants such as butane. Antonelli [29] developed a process

whereby LNG evaporates and generates power, part of the seawater is frozen, and the ice produced is melted at ambient temperature.

It is possible to couple an FM process to an LNG vaporizer [30]. In many cases, gas companies import huge quantities of liquefied natural gas (LNG), which is vaporized from low temperatures to the ambient temperature at the terminals, and then transported through gas pipelines. In this case, seawater could be used as a source of heat for the vaporization of LNG. The cost could be substantially reduced if sea-water could be cooled from the ambient temperature to near freezing. The major operating parameters of LNG cold energy, such as coolant temperature, freezing duration, supercooling, seeding, agitation, crystallizer material, and subsequent washing procedure on ice production and water quality need to be optimized [31]. Theoretical analysis showed that the LNG-FM method consumed 1 kg equivalent LNG cold energy to produce 2 kg of ice-melted water, and the power consumption of this process was negligible [32].

Butane evaporation involves at least three phases, butane liquid, butane vapor, and liquid brine, and its mechanism is correspondingly complex. Simpson et al. [33] studied the evaporation process of refrigerant, describing the dynamics of the bubble motion in a more meaningful way, and recording more readily with the visual evidence of the bubble's motion. The rate of evaporation of butane droplets increased rapidly with diameter ratio and then gradually with one-sixth power, implying that evaporation was controlled by the heat transfer through the transient liquid butane film on the inside surface of the bubble [33].

Orcutt and Hale [34] used mathematical models to study the operational-design economics of a freezing process and to predict the best operating conditions. Optimization computations showed that the economics of process operation depend largely on the temperature maintained in the freezer and the overall difference in refrigerant and equilibrium freezing temperature. An analysis of the linearized freezer dynamic equations showed the freezer to be stable and did not indicate regions that were difficult to control. The cost of the washer-melting unit is influenced by the operation of the freezer, which determines the value of crystal size. The freezer operating costs depend on the brine temperature, which influences both the crystal size and the refrigerant vaporization rate.

The choice of a suitable refrigerant for the process is important. From the viewpoint of cost and stability, the hydrocarbons with four carbon atoms have been recommended. When n-butane is used, the operation is to be carried out carefully because it is at a vapor pressure lower than atmospheric pressure, while i-butane has a considerably higher vapor pressure than atmospheric pressure and can form solid hydrate in contact with the aqueous phase under specific conditions. Formation of hydrates results in the elimination of the ice crystals formed. The mixture with less than 73.8% i-butane cannot form a hydrate at –0.7°C with 1.6% sodium chloride aqueous solution, and this limiting ratio increases with increasing temperature [35].

41.3.1.1 Ice-Crystallization Unit

A direct FM process can be continuous or batch. Energy recovery is one of the important aspects of the process. A butane FM process employs butane as the immiscible refrigerant (Figure 41.4). The refrigerant in liquid form under pressure is expanded through a nozzle into the product liquid, where it boils at lower pressure. The vaporization of butane in the freezer removes heat from the brine, causing a portion of it to freeze as tiny ice crystals (Figure 41.5). Another option is to use a high vacuum to vaporize a portion of the water, which then provides the refrigeration effect for lowering the temperature of the product and causing ice crystallization to occur. This process is able to reduce the residence time in the crystallization unit at least half compared to flash freezing [26]. These types of processes are mainly utilized for the concentration of chemicals and seawater desalination [1, 36]. It is rarely used in the food industry for a number of reasons. The major reason for not using direct-contact freezers in food concentration is that a vapor–liquid interface is created, resulting in a subsequent loss of volatile flavors and aromas. The product then has no superior quality advantages over that produced by evaporation [5].

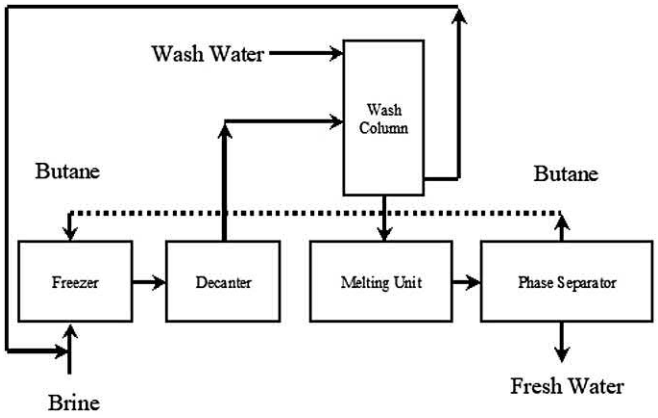

FIGURE 41.4 Simplified flow diagram of a butane FM process.

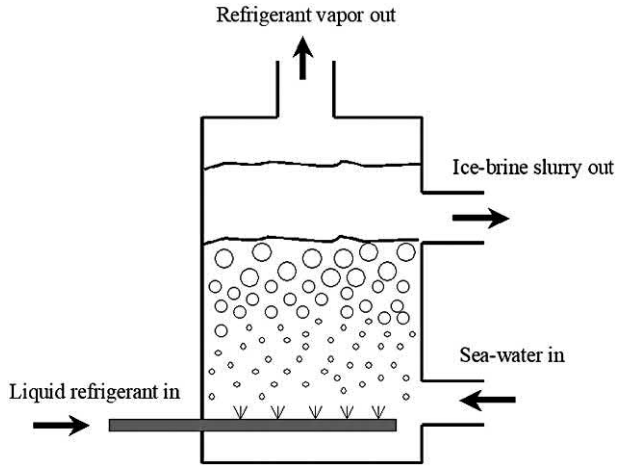

FIGURE 41.5 Schematic diagram of a direct freezing unit. (From Rice and Chau [55].)

The ice nucleation unit produces small ice crystals, which are transferred into the crystallization unit and grown large by ripening (i.e. larger in size) at the expense of smaller ones. In the crystallization unit, the formation and growth of ice crystals should be controlled in such a way that a uniform distribution of large ice crystals suitable for separation is formed. The optimum size distribution for most separators is a monodisperse distribution (narrow range of sizes) with a large mean size. This facilitates the washing step and reduces the amount of product carryover into the separated ice stream. The more efficient the separation process, the less carryover of solute into the separated ice stream, and the more economical the overall process is.

The ice crystals are then collected and transferred to the ice crystal separator and washed with water to remove the brine or solution from the ice crystal surface. The key technology in this system is how to grow ice crystals in the crystallization unit large enough to facilitate the separation between the ice crystals and solutes [37]. From a separation point of view, the formation of a few large ice crystals is desirable. Velocity of nucleation and rate of growth depended on the supercooling and concentration [38, 39]. In highly concentrated sucrose solutions, the nucleation rate did not depend on concentration, and the rate of crystal growth declined due to increase in viscosity [38].

Supercooling and secondary nucleation were identified to be major factors preventing ice crystals from growing large [40–42]. Very high supercooling can create a large number of smaller new crystals. Lower rates of supercooling are, therefore, desirable to prevent excessive nucleation. Lower nucleation rates are required to produce reasonably large ice crystals at an acceptable residence time [23]. The crystal growth at high supercooling occurred dendritic- or needle-shaped, which raised a larger surface area and caused difficulty of separation from concentrated solution.

Thijssen [39, 43] suggested increasing the agitation rates, within certain limits, to lower the nucleation rates, since high mixing rates may promote smaller size due to mechanical damage. Garabedian and Strickland-Constable [44] found that fluid shear does not produce crystal breeding, and collision of a single crystal in pure water produces high rates of nucleation. Polycrystals may well be formed by agglomeration or growing together of fine crystals. The nucleation rate at low stirring rates is determined primarily by the cooling rate, while with intensive stirring it depends primarily on the hydraulic factor [45]. Polymers could suppress the secondary nucleation of ice crystals; thus larger crystal size could be achieved. The suppression depends on the types of polymer and concentration, and is related to the increase of viscosity [42].

The circulation pattern of the ice slurry in the freezing-unit by direct-contact vaporization of an immiscible refrigerant can profoundly affect the quality of the product crystals [46]. Stripping of butane from products has been accomplished in a packed tower with liquid effluents containing less than 0.2 ppm butane which meets some standard for desalinated water [26]. Landau and Martindale [36] reported initial bench-scale studies of novel butane freezers, the most promising of which used a draft tube. The butane introduced at the bottom gave good vertical movement to the slurry, and 25% ice suspensions could be handled. It was found quite unnecessary to use a mechanical agitator, and the unit operates satisfactorily without any additional agitation, and a comparatively small flow of butane vapor, purged in near the bottom of the crystallizer, greatly improves the mixing and ensures reliable operation under all circumstances. This small flow of vapor (containing a negligible amount of incondensable gas and little super heat) is still effective in causing circulation even when the pressure in the bottom half of the crystallizer is above the vapor pressure of the butane [47].

Barduhn [26] concluded that the following points should be considered in designing secondary refrigerant freezers: (i) adequate dispersion of the liquid refrigerant into the solution is of paramount importance, (ii) normal butane is the cheapest and probably best refrigerant and does not hydrate, (iii) short residence time does not necessarily lead to small crystals and poor washability, (iv) the plant should be designed to handle short contact times, and (v) several methods of agitation should be included in design.

Some of the best possible ways of mixing could be (i) the use of fine spray nozzles to introduce the liquid refrigerant under the brine, (ii) pumping vapor from the vapor space through spargers which reintroduces it under the brine, (iii) pumping the entire liquid content of the freezer rapidly around a closed path, and (iv) using conventional mechanical agitators. The latter method is the most difficult to scale up, and furthermore multiple mixers appear to complicate the design and increase costs in large plants. The combination of (i) and (ii) could be a viable option [26].

The ice production rates in a spray freezer can be 10 to 30 times those in stirred tanks. Refrigerants and saltwater are sprayed into a low-pressure space and slurry forms virtually instantaneously, but the particle size averages only 40 microns and the ΔT (temperature gradient between refrigerant and slurry) is very large, 18°C [48]. In the case of RC-318 (C_4F_8) the ice crystal size was a strong function of the salinity, and a marked size maximum occurred at about 0.5% NaCl. A similar phenomenon is also noted in single crystal growth rates from many aqueous solutions [49]. At least two factors, namely diffusion and surface adsorption, could be rate controlling in a continuous crystallizing unit [50]. Depending on the liquid depth and temperature conditions in the freezer, several liquid refrigerant zones may exist [51]. Refrigerant at depths sufficient to suppress vaporization is said to be in the *inactive* zone. Vaporizing refrigerant is in the *active* zone, and if liquid refrigerant accumulates on the surface of the slurry, it is said to form an *excess* zone. Nucleation mainly occurs in the active zone, while crystal growth proceeds throughout the entire brine. The depth of the active zone can be calculated from the relationship between the refrigerant vapor pressure and temperature. It is good to prevent the formation of an excess zone, which generally interferes with good freezer control [34].

The exchange FM process was developed by Johnson et al. [49]. The crystallizing unit is a horizontal vessel, operating

at atmospheric pressure, consisting of three distinct sections: (i) an ice-brine and hydrocarbon disengaging section, (ii) an agitated or contacting section, and (iii) a brine and hydrocarbon disengaging section. The brine entering the agitated section is broken up into small droplets by turbine agitators and counter-currently contacted with a partially solidified stream of normal straight-chain hydrocarbons. The melted hydrocarbon, which contains entrained brine, flows into the disengaging section where separation is effected by gravity and electrostatic coalescence. The electrical coalescer is a horizontal unit consisting of three vertically stacked grids.

Homogeneous nucleation of ice crystals requires a subcooling of several degrees and does not occur in the direct-contact freezing process for which brine temperatures are much closer to the freezing point. All new crystals are formed from existing crystals by secondary nucleation processes such as breaking of crystals by collisions or removal of fragile dendrites by fluid shear [46].

Applying ultrasound to crystallizing systems offers significant potential for modifying and improving the process. The most important mechanism by which ultrasonic can influence crystallization is ultrasonic cavitation, which is particularly effective for inducing nucleation. Using ultrasound to generate nuclei in a relatively reproducible way offers a well-defined starting point for the crystallization process, and allows the focus to be on controlling the crystal growth for the remainder of the residence time in the crystallizing unit. This approach can successfully manipulate crystal size-distribution and hence modify solid/liquid separation behavior, washing, and fresh water purity [52].

The performance of suspension growth systems can be improved by adopting a multi-stage design [12]. The main advantages of the multi-stage plants include lower energy consumption and approximately 50 to 70% lower operating costs than the single-stage process. The loss of soluble solids usually is less than 100 ppm after the washing step in the Grenco systems.

Water from the direct refrigerant FM process would contain excessive amounts of volatile refrigerant, which is undesirable in most cases. This process could retain 80 to 140 ppm of butane, and up to 3% CH_2ClF, CF_2Cl_2, or other halogenated hydrocarbons [53]. These gases must be recovered and recycled down to about 1 to 10 ppm to recover their economic value and/or to prevent explosion hazards, and probably to the 0.1 ppm range to meet public health standards for drinking water [1, 54]. When the dissolved gas is to be recovered after removal, it is important that the process be uncomplicated in order to keep the cost low. Simple flashing of the product streams at reduced pressures is useful, and probably necessary, but not sufficient since the approach to equilibrium in a single-stage flash is not very close because of the very short residence times in spray chambers. In this case, lowering the flashing pressure is the key to maintaining the low ppm of the refrigerants. Bajolle et al. [54] designed a method for stripping butane from water in a packed column down to concentrations as low as 0.6 ppm. The mass transfer of butane from the melted water was experimentally shown to be liquid-diffusion controlled. The results obtained are expected to be valid as long as the thermal effects are not significant, that is, as long as the column is operated at a total pressure not below the vapor pressure of water.

The refrigerant compressor limitations and problems are some of the important limitations for a direct FM process. However, they can be eliminated by the use of a new type of compressor known as the hydraulic refrigerant compressor [55]. The hydraulic refrigerant compressor does not use lubrication (i.e. avoids lubricant contamination), and water and water vapor carried into the compressor inlet have no detrimental effect on the compressor. This compressor is highly efficient; thus it avoids the problem of freeze desalination caused by conventional compressors. At the freezer and melting-unit temperatures, the pressure of the two-phase n-butane refrigerants is very near atmospheric pressure, which is a large advantage in the FM system since the pressure vessels need only to withstand very small pressure differences and can be of minimal strength and cost. The advanced technical skills associated with the design, installation, and maintenance of conventional refrigerant compressors are not needed, and parts are inexpensive. The hydraulic refrigerant compressor is simple, of low cost and low maintenance. It is compatible with the other components of an FM process.

41.3.1.2 Ice Separation

Separation devices can be classified as presses, gravity drainage, centrifuges, filter, and wash columns [39, 56–59]. Filtration has proven less effective for crystal separation, and it cannot be used for washing the crystals. In many cases, screens or filters show a history of freezing up (brine freezing in the openings of the weave) [3]. Arulampalam et al. [60] investigated the effect of various physical parameters on the efficiency of separation and purification. The important factors controlling the separation efficiency of the columns were the axial diffusion of impurity and the mass transfer between the adhering and free liquids around the crystal phase. Modification of the screw conveyor was necessary to facilitate crystal removal. Conventional methods used for the separation of crystals from their mother-liquid prove to be either too slow or too expensive [61].

41.3.1.3 Wash Columns

In the case of an FM process, washing is important to attain certain purity. In the case of a food solution, washing could recover the adhered solution from ice. After the crystals are formed in the crystallizing unit, the crystal/liquid slurry is separated into concentrated liquid and other crystalline components and impurities are washed from the crystal surface, producing pure crystals. To perform the separation, a wash column is used. There are two types of wash column: pressurized and gravity. In the pressurized wash column, the crystals rise to the top and hydraulic pressure forces a wash liquid, derived from the melted pure crystals, to flow down. The applied pressure also squeezes the concentrate through a filter at the bottom of the column. As the wash liquid flows down the column, it removes impurities from the surface of

the crystals. At the interface between washed and unwashed crystals, called the wash front, the wash liquid comes in contact with colder crystals and crystallizes on them. In this way, the wash liquid doesn't mix with the concentrated liquid. Effective washing of ice is one of the most difficult unit operations in the FM process.

The gravity wash column is simpler in design but larger than the pressurized wash column. Its greater height creates the pressure needed to compact the ice bed. It works in much the same way as the pressurized column but at lower pressures. An ice pack is still formed and moved hydraulically up the column. The performance of wash columns depends on the crystal size and shape and on the viscosity of the mother-liquid. Uniformity of crystal size and shape is important to avoid having the wash water seek the path of least resistance and channel through the crystals unevenly.

In order to overcome the difficulties associated with surface tension forces, clean fresh water can serve as a displacing liquid. The displacement process can best be pictured by considering a gravity drainage separation process. The separation by drainage is greatly improved when in addition to draining the brine from the bottom of a batch of ice crystals one adds pure water to the top of the batch and lets water filter through the interstices of the ice bed to displace the remnants of brine. Bosworth et al. [62] suggested a continuously operating separation device based on the displacement principle. In this device, the slurry of brine and ice crystals is introduced into the bottom of a vertical column from which the brine drains through screens at the bottom. The ice crystals move upward by their own buoyancy force forming a porous ice plug at the top of the column where wash water is added from the top. As the ice plug moves upward through the layer of wash water the brine is displaced from the interstices of the porous ice plug and the salt-free ice crystals are harvested at the top of the column and transferred to the melting-unit. The rise of the ice crystals in the column is, however, rather slow, being a limiting velocity for a particle moving through a fluid by buoyancy (or gravity) forces alone. This limiting velocity determines an upper limit to the production rate for such a gravity wash column, a value that is much too low for economic desalinated water conversion. Hahn et al. [63] modified the wash column separator described above to allow the moving brine to provide the driving force for moving the ice particles upward. The discharge screens are located in the vertical walls of the column, about midway between the top and bottom.

Wash columns have been successfully used for both separating the crystals produced in the crystallization section as well as purifying them. These are classified as the flooded column and the drained column. The ice crystal slurry is fed to one end of the column, and the mother-liquor withdrawn from the same side. The compacted ice bed is forced towards the other end of the column, where it is melted by means of a grid of internally heated pipes. The portion of meltwater is used to wash the crystals moving counter-currently in the column [23].

The ice wash column could be a drained or flooded type with either a rectangular or cylindrical shape. Tall screens are desirable, and contouring of the ice surface with the scraper can be very useful. Much higher production rates were possible by cutting out a slot in the center of the column, which fills with wash water, or by cutting a deep V-shaped trough in the ice with the scraper [26]. In a typical hydraulic piston washer-separator column, the ice–brine slurry is fed to the bottom of the column and moves upward. The ice builds up a porous plug until it fills the entire top of the column; the brine flows out of the column through filter screens situated laterally part way up the column walls. As slurry is fed to the column, ice is added to the bottom of the porous plug and the brine flows through the plug. The pressure drop of the brine flowing through the plug causes the ice to move upward, and it is harvested at the top of the column, usually by scraping. The washed ice is melted, and a portion is recycled to the top of the washer separator as wash water. This wash water moves downward by gravity, and some of it leaves the column through the filter screens and the brine from the slurry, but the greater part of the wash water clings to the washed ice [34, 61].

The production of fresh water increases with the increase of ice crystal size, the ice plug length above the screens, concentration of ice crystals in the slurry, and the external mechanical restraining forces on the ice plug. It is also found to increase with a decrease in the ice plug length below the screens, where this length is shown to be an independent parameter for certain slurry feed conditions, such as gravity feed. Shwartz and Probstein [61] provided design criteria for minimizing the capital cost for a given production rate. The theoretical analysis helped to establish the optimal operating conditions for high production rates, sufficiently low salt content in the product, and minimum loss of fresh water. At pressures below about 1.05×10^5 Pa, the driving force in the melting-unit becomes so low that the required melting-unit cross-sectional area increases to large values, which are uneconomical [34].

Centrifuges have also been used to separate the ice crystals from the concentrated liquid. Filtering centrifuges utilize the difference in specific gravity between ice crystal and liquid concentrate to separate ice from liquid with the liquid being forced through the filter basket by centrifugal force. Generally, a water rinsing is required to assure that there is no salt carryover. For food liquids, there is some loss of volatile flavors and aromas due to the airspace created during the separation. It is important to have large ice crystals to ease the ice-crystal separation from the concentrated solution phase [64–66].

Ice particles from liquids during the FM process can be separated by a filter. To increase efficiency, a vacuum is normally applied to pull liquid across the filter. The vacuum filter has been used for separating ice slurry made by direct freezing and vacuum FM systems [67–69]. Solids carryover is one of the problems for the wash column; however, the Grenco system for separation can give up to 100 ppm purity [70]. This wash column operates continuously with counter-current flow of ice and concentrate. The ice crystals are transported to the upper levels of a vertical column by some natural or applied force, where they are then separated by a scraping device.

A small portion of the ice is melted and allowed to pass back down the column, giving the washing effect. Concentrate is removed through a filter at the bottom of the column.

The slurry of the ice crystals in brine is pumped to a wash separation column, where the brine and the ice crystals are separated with the consumption of a small amount of wash water. The washed ice is then sent to the melter-condenser, where it is melted by direct-contact condensation of the compressed butane vapor. The primary compressor must compress the butane vapor in order to attain its condensation temperature in between the brine freezing point and ice melting point. The two liquid phases formed in the melting-condensing unit are separated by a decanter, the liquid butane being returned to the freezer and the liquid water representing the product, except for a small amount which is used as wash water and leaves the wash-separation column with the reject brine stream. The net wash water consumption is about 2% [1].

The forced transport wash column was preferred over the gravity column due to its smaller size and short residence time, which produced relatively pure crystals [71]. In fruit juice production, the most common column used is the piston-type wash column in counter-current washing [72].

41.3.1.4 Melting-Unit

The melting-unit is difficult to characterize although it appears to be a straightforward process. Direct contact melting is easy to achieve; however, scaling up is difficult. In the case of a dumped bed, the characterization of heat transfer data is difficult due to the drainage of water and refrigerant from the bed. An indirect melting-unit requires a heat transfer surface, which reduces the attainable efficiency when compared with the direct-contact melting-unit [6]. A heat pump-operated FM system with a tubular heat exchanger was developed [73]. It selectively produced frozen water from seawater in the evaporator and melted the ice in the subsequent phase when it served as a condenser. The condenser optimally utilized the latent heat of melting of ice to condense partially the refrigerant, and the excess heat is rejected to the ambient environment, and the need for ice scraper/separation mechanisms is avoided. Attia [74] also proposed a similar system by utilizing the heat flow of a heat pump system to increase the whole system efficiency. Ice washing and melting process occurred at the same place of formation by reversing refrigerant flow through the vapor compression cycle so there is no need for ice-handing mechanical systems.

Lloyd [75] applied the concept of integration in order to achieve high utilization of space and to permit adjacent processes to share boundaries. A commercial design using two integral vessels for four main processing steps has been formulated. It showed that capital cost could be reduced by around 20%. Different commercial equipment is available based on this concept.

41.3.1.5 Refrigerant–Brine Interactions

The refrigerant is contaminated by brine spray carryover from the crystallizing unit, which adversely affects compressor performance. Thus, it is necessary to develop separating devices between the crystallizing unit and compressor. These separators must remove ice containing an evaporating refrigerant; thus simple demisters are not permissible because of ice plugging problems attendant to this condition. The dissolved refrigerant is rather easily removed by vacuum stripping of the effluent stream, which can be polished to meet environmental effluent standards by carbon absorption if necessary.

It is important to make certain that during operation of the process, excessive losses of refrigerant do not occur as a result of entrainment and solubility of Freon in the water, and from irreversible processes such as hydrolysis. In addition, if the rate of hydrolysis of the Freon refrigerant is too high, undesirable levels of soluble fluoride could build up in the product water. Stepakoff and Modica [27] developed the solubility data of Freon in order to predict the rate of hydrolysis, which is a function of dissolved Freon in water. They found the economic loss of hydrolysis is less than 0.26c per m^3 water. The solubility of refrigerants decreases with the increase of salinity termed as salting out. The hydrolysis rate was decreased to half for a 3% saline solution relative to pure water at the same temperature and pressure. Completely halogenated hydrocarbons are much less soluble than their partially halogenated counterparts. For example, Freon 142b (CH_3CClF_2) is ten times as soluble as Freon 114 at 1 atm, –4°C. The solubility of Freon 14 (CF_4) is about three orders of magnitude less than that of Freon 23 (CHF_3). The fact that hydrogen-containing Freons are much more soluble than their completely halogenated counterparts can be understood on the basis of hydrogen bonding between the CH group in the halocarbon and the oxygen dipole of the water molecule [76].

The simplest mechanism for describing the hydrolysis of Freon is to assume that the rate-determining step is a slow ionization to a carbonium ion and a halide ion followed by a faster reaction of the carbonium ion with dipolar water molecules [77]. The essential feature of this mechanism is that every carbonium ion which is formed in the primary step is attacked by water at a much faster rate than by halide ions, i.e. the reverse rate of the primary step is very slow. In the case of Freon 31 the mechanism of hydrolysis can be described by the following equations [78]:

$$CH_2ClF \rightarrow CH_2F^+ + Cl^- \qquad \text{(slow)}$$

$$CH_2F^+ + H_2O \rightarrow CH_2FOH + H^+ \qquad \text{(fast)}$$

$$CH_2FOH \rightarrow HCHO + HF \qquad \text{(fast)}$$

The presence of formaldehyde (HCHO) in the hydrolysis of Freon 31 was confirmed by chemical tests, and the rates of formation of chloride and fluoride were found to be identical [78]. Stepakoff and Modica [27] pointed out that a similar effect could occur during the hydrolysis of Freon 114. Stepakoff and Modica [79] determined the hydrolysis rate constants for Freon 21 ($CHCl_2F$), Freon 31 (CH_2ClF), and Freon 114 ($CClF_2CClF_2$) based on the three adjustable parameters, the Arrhenius collision frequency, hydration energy of the carbonium ion, and the ionic distance of closest approach.

The hydrates formation consisted of two phenomena, which were almost always observed when the freezer was being tested at low driving forces. First, the ice becomes oily, somewhat impalpable, and washing becomes poor. Operators called this rotten ice. Second, the level of butane in the storage tanks dropped steadily. This led to the accumulation of butane in the freezer, washer, or melter, and this could be due to hydrate formation. Insufficient agitation at low-temperature gradient can lead to accumulation of the liquid butane in the freezer, and it will then carry over into the washer, reducing the porosity of the ice bed, thus resulting in poor washing. In some cases, when refrigerant is well-dispersed, it shows no hydrate formation even with 80/20 mixtures of iso- and n-butane. Mixed refrigerants for which the vapor–liquid equilibrium is normal (i.e. the temperature–composition diagram is lens-shaped) have a disadvantage since the bubble and dew points differ. In the case of iso- and n-butane this difference between the compositions used is about 1°F. Thus 1°F is added to the total temperature lift of the heat pumping cycle, which adds about 10% to the energy requirement for primary compression beyond what is needed for a pure or an azeotropic refrigerant. Hydrates may also cause channeling in the wash column.

Hydrate formation is one of the problems for the direct FM process. The rate of heat transfer among the four phases present in a butane freezer controls the rate of ice production, and this in turn is determined mainly by the liquid–liquid interfacial area and the intensity of turbulence in the freezer.

The formation of hydrates is one of the problems that occur in the direct freezing process. Iso- and *n*-butane may form hydrates. Having two crystal species present (ice and hydrate) is uneconomical for the process since heat must be removed at the lower of the two formation temperatures and rejected at the higher of the two. In the case of ice and iso-butane hydrate this increases the total temperature lift for the primary compressor by about 1.9°C, which may increase the energy requirement by 30%. Even more serious than this is the fact that the hydrate reduces substantially the permeability of the crystal bed in the wash column. Butane-1 usually shows less hydration compared to normal butane. Operation on butane-1 was similar to that with the butane mixture, and hydrates and rotten ice still appeared under certain conditions. In addition, the smell of the commercial hydrocarbon bothers many people, and it costs about 31c per gallon as compared to 11c for normal and 14c for iso-butane [26]. Fernandez et al. [80] found similar rates of formation in hydrates in the case of propane, F-12 (CCl_2F_2), and methyl bromide (CH_3Br). Roux [81] found that F-31 (CH_2ClF) formed hydrate six to ten times as fast as the above refrigerants. The F-31 hydrate crystals were compact rough spheres with average diameters of 150 to 190 microns. Both propane and methyl bromide hydrates are smaller and much more dendrite-type and probably more compressible in beds. Hydrate properties depend on the type of refrigerants.

41.3.2 Gas Hydrate Method

Gas hydrates are crystalline complexes composed of water and gas molecules. A hydrate-based desalination process was offered in the 1940s [82]. In this process, hydrate is formed first to remove water from the solutions and then dissociated to water and gas. Fakharian et al. [82] developed a three-stage gas hydrate method for desalinated water using natural gas. First, hydrate was formed and concentrated solution was extracted from the reactor. The hydrate was washed with a suitable amount of fresh water to successfully improve desalination efficiency, and hydrate was dissociated to produce fresh water.

41.3.3 Eutectic Freezing

The eutectic FM process was first proposed at Syracuse University. Barduhn [83] devised the process, and Pangborn [84] tested the idea. In the eutectic FM process, salts separate as solids and fresh water from brine as ice. By freezing the water out of these aqueous solutions until they are adequately concentrated to precipitate the salt simultaneously, one ends up with no brine product. The ice and salt crystals nucleate and grow independently and are easily separated since the ice floats and the salt sinks. Using a simple system of sodium chloride and water the essential feature is that at –20°C both ice and $NaCl.2H_2O$ crystals precipitate from solution as heat is removed. Laboratory investigation of the eutectic temperatures of various proportions of the ions commonly found in natural waters (Na, K, Ca, Mg, Cl, SO_4, HCO_3) shows that the process operated well at temperatures no lower than –25°C [85]. This approach could avoid the brine disposal problem as well as the production of byproducts as salts. The main difference between this and the normal freezing process is the presence of the ice–salt separator and the salt filter. Several important variations of this have been proposed.

There is another important difference between normal and eutectic freezing in the crystallizing unit. In normal freezing where the product water is the only goal, the freezer operates near –5°C, and the temperature lift for the primary compressor is thus about 6°C. Two-stage eutectic FM is more economical [8, 85, 86]. The costs are generally much lower than the alternative of reverse osmosis followed by deep-well injection of the reject brine. Actually, deep-well injection could be ecologically unsound. The eutectic FM process may be a meaningful solution to brine disposal [86]. Schroeder et al. [8] pointed out that the eutectic FM processes are likely to become very important processes in the future when they are better developed. A stirred-tank crystallizing unit is required, and a hydro-cyclone separator and floating wash column are used [86]. The hydro-cyclone splits the slurry into a light and heavy cut. The light cut, called the overflow, contains the ice crystals and brine. The heavy cut, called the underflow, contains the salt solids and brine. The salt solids could be separated from the brine, utilizing conventional solid–liquid separators such as filters, and then dried in conventional dryers. The brine filtrate is required in the crystallizer [8].

Hydro-cyclones are compact, simple devices, and have a low pressure drop. Washing is different due to the small ice crystal size, and low slurry temperature. Schroeder et al. [8] identified the possibility of the combination of eutectic freeze

and distillation process, and membrane and eutectic freeze processes. The product stream of eutectic freezing would be a brine of low salinity, which would be returned to the distillation plant or membrane process in actual operation. The cost of the membrane process extremely depends on the brine concentration. The melted ice water from a single freezing without a wash step has three to six times less salt than the feed [87]. Usually a conventional direct-contact FM process operates around –5°C, whereas the eutectic FM process operates at –25°C, thus needing more energy for cooling. The main advantage of the eutectic FM process is that it can separate both ice and salts at the same time and avoids the brine disposal problems. For the precipitate salts, it could also be possible to produce different byproducts.

41.4 INDIRECT-CONTACT FREEZERS

In the indirect-contact FM process, the energy for refrigeration must be passed through the walls of some form of heat exchanger, and heat transfer occurs through a solid barrier [59, 88]. It was found that the growth rate of dendrite-type ice in supercooled water cannot completely be understood on the basis of the heat-flow controlled-growth mechanism but has to be explained on the basis of the combined mechanisms of heat dissipation and molecular-growth kinetics [89, 90]. Indirect-contact systems can be classified into those that are internally cooled and those that are externally cooled.

41.4.1 Internally Cooled

Internally cooled crystallizers can be further subdivided into static layer growth system, layer crystallization unit on rotating drum, progressive crystallization unit, dynamic layer growth system, and suspension crystallization processes.

41.4.1.1 Static Layer Growth System

In layer growth systems, the liquid from which the crystal mass is grown is stagnant, and it is termed static layer crystallization. The static operation of solution crystallization in this process is very reliable and requires very simple equipment without moving parts and without the need for a solid–liquid separation device. The residence time in this process is large because the mass transfer is only promoted by free convection. Large equipment volumes are required due to the batch-wise operation and the slow crystallization rate [91, 92]. The crystal–solution interface per unit equipment volume can be increased by using a plate-type contact surface, but static growth cannot be avoided [93]. High purification efficiency can only be obtained when relative low rates of growth ($<10^{-7}$ m/s) are established since no stirring is applied. The capital cost of the equipment is high, and more economic use can be obtained by carrying out more than one relatively rapid crystallization in series.

Muller and Sekoulov [94] pointed out that the layer freezing process is easier to manage, but the crystal growth upon a cooled surface induces fast crystallization rates, and under these conditions, a rather impure crystal film may be produced. In spite of this moderate crystal purity, the disadvantages are compensated for by the ease of operation, because there are no moving parts and no slurry handling is required. Two mechanisms of crystal growth were found in a batch crystallizer with an external cooler, that contained a large quantity of ice crystals. With the first mechanism, the ice crystals grew larger by the usual kind of growth, governed by heat or mass transfer resistance, and with the second, the ice crystals agglomerated and the agglomerate fused into a very large ice crystal (~1–3 mm in diameter). The second mechanisms occurred not because of the high concentration of ice crystals in the crystallizer but because of long residence time. Large ice crystal agglomerates were not produced when extremely small ice crystals were formed in the crystallizer at the start [66].

41.4.1.2 Layer Crystallization Unit on Rotating Drum

In the layer crystallization with rotating drum FM process, ice forms in thin layers on the heat exchange surface and, after a suitable period of time for the ice layer to build up, is removed from the surface and separated by press from the concentrated liquid remaining. One form of layer crystallizer utilizes a rotating drum immersed in the fluid to be concentrated. Refrigerant is circulated within the drum and causes ice to form on the surface of the drum, which is then scraped free as the drum rotates past a knife [5].

41.4.1.3 Progressive Crystallization Unit

A progressive crystallization FM process is a method of separating solvent from solution based on a concept completely different from the conventional method of layer crystallization described above [95]. A progressive FM process utilizes the concentration phenomena of a solute at the ice–solution interface moving from one end of a vessel to the other end [96]. It is characterized by having only a single ice crystal in the system so that the separation of the ice crystal from the concentrated solution is very easy compared with the conventional method of freezing–melting (Figure 41.6).

The concentration efficiency in progressive FM was related to the ice structure of the freezing front. High FM efficiency was obtained under the conditions at which a smooth solid–liquid interface is formed. The distribution coefficient depends on the ice structure at the freezing front, and operating conditions represented by the moving speed of the freezing front and the speed of stirring in the solution phase [95, 97]. Liu et al. [37] studied the operating conditions of this process on the freeze–concentration ratio and apparent partition coefficient of a solute between the ice and the solution phases (glucose and/or blue dextran). They found that the efficiency of the process is strongly dependent on the moving speed of the freezing front and the agitation or stirring speed at the ice–solution interface. A lower speed of the freezing front and a higher stirring speed produced a better freeze–concentration ratio. A concentration polarization model was useful to describe the effects of the operating conditions on the effective partitioning coefficient [97].

Matsuda and Kawasaki [98] investigated the effects of supersonic radiation and the dissolved air concentration

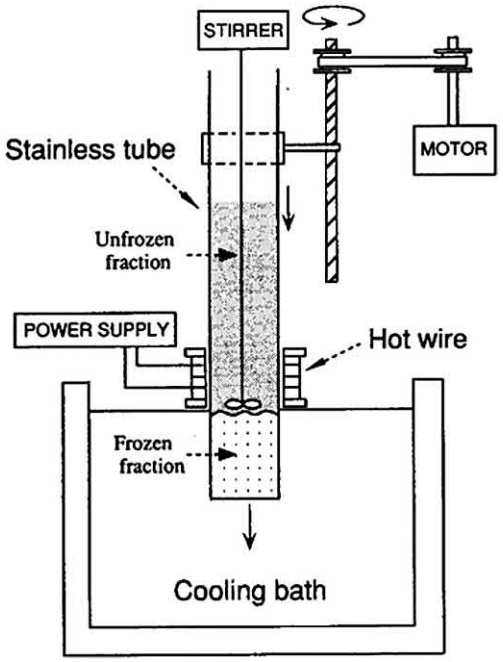

FIGURE 41.6 Apparatus for the progressive Freezing–Melting Process. (From Liu et al. [37])

in the liquid on the efficiency of separation and concentration of glucose and sodium chloride under various freezing rates. They found that efficiency was greatly improved by supersonic radiation and increasing dissolved air concentration. In the progressive freeze-concentration, the major part of the impurity in the ice phase occurred when supercooling occurred before the initial crystallization at the bottom of the sample vessel. Different mechanisms of solute rejection at the interface were observed [99]. Ice-nucleating protein (types of anti-freeze proteins) could be used to suppress initial supercooling [37, 100]. Curran [88] studied the effects of container geometry on the recovery of product water from indirectly frozen saltwater. Saltwater was frozen in containers with a circular or rectangular cross-section, then allowed to melt and drain until the residual ice was potable. Thin rectangular cross-sections were found to be more effective than circular cross-sections. The product water recovery was found to increase with increasing ice height up to 60 cm, beyond which the effect of height was negligible.

The growth rates of ice depend on the ionic salts, surfactants, and water-soluble polymers. Michaels et al. [101] identified that both growth-rate enhancements (up to a factor of about five) and retardations (up to a factor of about three) could be possible in the presence of additives. The type of effect and its magnitude were dependent on the nature of the additive, its concentration, and upon the degree of super-cooling. The effect of solutes may have a consequence of dislocations introduced in the crystal during growth. Miyawaki et al. [102] showed that a tubular ice system with a large cooling surface area was effective as a method for scale-up of progressive FM with an increased productivity and high yield. In this method, the slower growth rate of ice and the higher circulation rate gave the lower effective partition constant as was expected theoretically by the concentration polarization model. The effective partitioning constant was also dependent on the initial solute concentration; the higher concentration gave a higher partitioning constant of solute. By the tubular ice system, coffee extract, tomato juice, and sucrose solution were very effectively concentrated to high concentrations with good yields, showing the high potential of progressive FM for practical applications. The progressive FM process can be easily run at atmospheric pressure and with less complexity. It gives only one block of ice; thus, the separation and melting process is easy.

The main disadvantage is that it requires greater processing times and large temperature differentials [88]. In this case, the partial melting of ice was effective. In this method, the ice crystal formed after progressive FM was melted gradually with time to collect the melted fractions with intervals. Then the initial fractions were found to contain a higher amount of solute. Therefore, the yield could be improved to a necessary level (>90%) by recovering these fractions with the higher solute concentration. The recovered melted ice fraction may be mixed with the feed in the succeeding batch of PFC operation to avoid dilution of the concentrate. The partial ice melting could extend the practical applicability of PFC substantially.

In progressive FH, yield decreases with an increase in solute concentration because of solute inclusion in the ice. Progressive FM was applied for the concentration of sucrose solutions with various concentrations (0.3–40%), a model pear flavor solution, tomato juice (5.3°Brix), and apple juice (12–15°Brix) [103]. In the case of the model solution with pear flavor, the apparent partition coefficient between the ice and the concentrated liquid phase was low to give a high yield, while samples with high solute concentrations showed an increase with an increase in solute concentration to reduce the yield [103]. A partial ice-melting technique overcame the major drawback of progressive FM [103, 104]. Ice cubes from 10% (w/w) sucrose were partially melted, and it was observed that at the lower temperature with relatively faster stirring speed, the initially melted fractions effectively contained a higher concentration of solute than the later-melted fractions. Apple juice with 13.7°Brix was concentrated up to 25.5°Brix by progressive FM using a tubular ice system. Part of the ice was broken down into pieces and used for partial melting by the partial ice-melting vessel. This improved the yield from 63.8 to 85% by recovering the initial 30% melted fraction. In the case of pear juice, after 2.36 times concentration of flavor component (butyl acetate), the yield was improved from 86.7 to 95% by recovering the initial 35% melted fraction. The recovered fraction was recommended to mix with the original solution [103, 104]. A partial ice-melting method was also used for solutions (i.e. fructose, glucose, sucrose, and a simulated juice, 5–20°Brix) to increase overall system efficiency [105]. The ice produced in the four steps of the process retains solutes at levels of 1.0–8.8°Brix (i.e. solute mass fraction in the ice). The recovery of these solutes during thawing can increase overall system efficiency by recovering most of the solutes in the ice. Ten fractions of melted ice at 20°C were

produced. The first thawed fractions showed solute concentrations 1.9–3.3 times higher than the mean solute mass fraction in the ice, while the last fractions were shown to be less than 0.2 times.

The inclusion of solutes is dependent on the initial temperature, on the growth rate, and on the solution concentration. A sweating step after progressive ice crystallization was able to purify ice by operating in-depth draining out of the trapped solution pockets [106–108]. The solution was placed into a tank and the crystallization took place on the external surface of a cooled tube, and the solution is agitated by air bubbling [106, 107]. A fast crystallization step (i.e. 5–14 h) gave quite impure layers, and the use of severe sweating conditions (0°C, 3 h) can lead to salinities lower than 0.5 g/kg, satisfying the drinking water standards. Sweating efficiency depended on temperature gradient, and the main kinetic parameters influencing sweating of ice were initial concentration of ice, sweating temperature, and sweating time [106]. The system of Rich et al. [107] with a seating step included four steps: (i) crystallization of the ice layer by controlling the cooling rate in the tube, (ii) draining off the concentrated brine (iii) purification of the layer by sweating, and (iv) melting of the ice to recover the fresh water. The purity of the crystalline layer was mainly affected by the initial salinity of the brine, and cooling rate. Sweating was able to purify the interior of the ice layer and to reach the drinking water standards.

41.4.1.4 Falling-Film Type

In this type, the solution flows down over the wall of the heat exchanger (well-mixed). Crystals are formed on the wall surface under the falling film. Shear caused by solution flow at the crystal–solution interface increases the mass transfer coefficient and promotes the transport of impurities from the interface to bulk. This process is easy to scale up because of the modular design. Currently, most layer growth processes are used in the chemical industry, and they are seldom used in the food industry.

Local equilibrium at the interface exists, and solute trapping occurs based on the rate of crystal growth [109]. Solutes are distributed between brine and ice crystals. Adsorption on the ice crystal surface and entrapment within the ice may be the major reasons for the presence of the solutes in ice. The distribution or coefficient of salt (ratio of salt in brine and ice) is used to determine the solids in the ice and slurry [110]. Ice growth rates and impurities in ice during layer crystallization of laminar falling film ($50 < Re < 600$) showed that one step layer crystallization had lower separation as compared to the suspension crystallizers with wash columns [111]. In the case of fructose and orange juice, the ice layer on the stainless-steel surface was more pure at low concentrations of soluble solids, low growth rates of ice, high velocity of solution on the plate, and high molecular weight of solutes (i.e. higher molecular weight is less likely to be trapped) [112, 113]. Similarly, low initial concentrations of sucrose, glucose, and fructose produced more purity, and a higher degree of concentration was attained in sucrose solutions in a shorter time as compared to glucose and fructose [114, 115]. In addition, the crystals' orientation is another important factor to eliminate impurities in ice [11, 116].

Falling film FM was used to concentrate oligosaccharides, proteins, and isoflavones from waste-water of tofu processing for developing functional ingredients [117]. The concentration could be increased by a factor of 8 (i.e. 1.9°Brix to a final concentration of 15.5°Brix). A pilot four-stage FM was used to increase the soluble solids content of the whey to 21.8°Brix, and the purity of the ice formed was determined [118]. Falling film FM was used for the concentration of grape juice from 16.4 to 29.5°Brix (Hernandez et al. 2010). It showed an average rate of 1.38°Brix/h with flow rates of 0.8 L/s, and ice production ranged from 1.32 to 1.05 g/m^2 s. In the case of orange juice it showed a linear increase of concentration at a rate of 0.75°Brix/h until a final concentration of 28.8°Brix, and soluts concentration in the ice showed an exponential increase [13].

The drawbacks of a dynamic growth system are that it needs a large solution circulation rate, it needs a large crystallizer volume, a multistage operation is required to attain high purity (sometimes eight to nine stages may be needed), it needs optimization of some variables such as number of stages, reflux ratio, and maximum thickness of crystal layer, the cost and energy efficiency are adversely affected by the need for repeated operation of a batch procedure. A continuous commercial dynamic layer growth process was developed using a counter-current layer crystallization technique called the Bremband belt crystallizer [119]. The main problem of this process is that it is uneconomical.

41.4.1.5 Circular-Tube Type

In this process, ice is formed from a solution flowing through a tube cooled from outside [120–123]. Super-cooling can be obtained in a liquid before it solidifies when forced to flow inside circular tubes. The maximum super-cooling depends on the local tube wall temperature, tube inside diameter, Reynolds number, and a dimensional constant depending on the process [124]. The salt entrainment in the ice layer is one of the major problems in an indirect FM process. Janzow and Chao [125] studied the salt entrainment in ice crystallized from brine on a flat pellet. The ice layer thickness first increases rapidly, reaches a maximum, then decreases. The phenomenon corresponds to the growth and subsequent melting of dendrites. It was believed that brine adhering to the thin plates of ice and perhaps being retained in the interstices by capillary forces is responsible for the relatively high salt concentration found in the melted ice. A rinsing operation could be applied to reduce brine content in the ice layer.

41.4.1.6 Suspension Crystallization Unit

In a suspension crystallization unit, the product to be concentrated is agitated in a vessel cooled by heat transfer through the walls of the jacketed vessel. This vessel may be either a scraped-surface heat exchanger or simply a jacketed kettle vessel. The result of this process is a pumpable suspension of ice crystals in the concentrated product, which must then go to a separation device. Independent control of ice nucleation and crystal growth is very difficult in this type of crystallizer

[5]. Many variations have been investigated to develop a process that allows independent control of ice nucleation and crystal growth [59]. Heterogeneous dendrite ice grows on the wall toward bulk solution due to the large temperature gradient [126]. The induction time of ice fouling was correlated with the degree of supercooling on the cooling wall, and this can be used to estimate the critical time interval between two scraping actions [127]. Ultrasonic radiation was also used for ice nucleation due to the requirement of low supercooling (0.4–0.5°C) [128, 129]. The advantages are (i) an inexpensive plain heat exchanger can be used, (ii) the higher coolant temperature saves capital and operating costs of refrigeration, and (iii) better quality of crystals [130].

A modification of the process above involves the recycling of all or part of the mass in the main vessel. One process recycles the entire crystal slurry through an external heat exchanger, similar to a forced-circulation evaporator, to provide cooling. Nucleation occurs mainly in the heat exchanger, usually scraped surface, while most of the growth occurs in the main vessel. In a slight variation of this system, only the liquid product from the main vessel is recycled by withdrawing the liquid through a filter. This ice-free liquid is then pumped through a scraped-surface heat exchanger operating at a temperature so that liquid remained at high degree supercooled to promote the nucleation of small crystals (50 μm). These fines are then pumped back into the main vessel, where a ripening process occurs. The difference in equilibrium conditions between the fine nuclei and the existing seeds provides the driving force for ripening, which results in the dissolution of the fines and the growth of the seeds as the equilibration process occurs. Large mono-disperse crystals may be formed in this way [5]. In the ripening tank, the unstable sub-critical ice crystals melt and the latent heat they absorb in melting causes freezing on the surface of the large ice crystals in the ripening tank [131]. As small crystals have a lower melting temperature in solution than larger crystals, the small crystals melt and recrystallize on the surface of the larger ones.

The main features of the suspension growth option combined with wash column technology are large single-stage efficiency and large net production per volume of equipment and time period. The suspension option also offers a continuous operation, which may result in lower energy consumption.

A comparison of layer and suspension crystallization growth is given in Table 41.4. Both layer and suspension processes are governed by the same crystallization laws. This means that the results obtained with both process types will, in principle, be the same when the operating conditions are identical. In practice, the main advantages of layer growth in comparison with suspension growth come from simple technology with simple design and scale-up. A high growth rate can be achieved in layer growth processes because heat is transferred through the solid layer. However, a large growth rate usually results in a limited effective distribution coefficient in a single stage. By adding a sweating step and by repeating the operation, high purity can be attained but at higher costs.

Fluidized bed heat exchangers are also used due to their low cost as compared to scrapped-surface heat exchangers [132]. FM of apple juice in a fluidized-bed heat exchanger

TABLE 41.4
Comparison between Layer and Suspension Crystallization Growth

Feature	Layer Growth	Suspension Growth
Purity attainable	Limited per stage (repetition needed)	High in one single stage
Crystal–solution interface	Small (10~100 m^2/m^3)	Large (10,000 m^2/m^3)
Growth rate	Large (10^{-5} ~10^{-7} m/s)	Small (10^{-7} ~10^{-8} m/s)
Purification	Solid–liquid separation, sweating and reprocessing in same unit	Solid–liquid separation, sweating and reprocessing in separate devices
Production rate/volume of equipment	Small	Large
Type of operation	Batch, possibly continuous	Usually continuous
Technical feasibility	Proven technology	Force transport columns: demonstration phase
Heat transfer coefficient	Small (50~400 W/m^2K)	Large (1000~4000 W/m^2K)
Design	Simple	More complicated
Scaling up	Simple	More complicated
Crystal size (distribution)	Not important	Important
Solid–liquid separation	Simple by draining followed by melting	Extra device needed
Pieces of equipment	One single	Several
Moving parts	Only pumps	More moving parts needed
Transport problems	No suspension handling	Pumping of suspension
Incrustation	No, layer is product	Yes, may be hampering
Flexibility	Multipurpose	More tailor-made
Reliability	Restart without loss of product	Loss of product in case of interruption which has to be recycled

Source: Chen [162].

showed that operation remained stable as long as the erosion rate caused by fluidized particles is equal to or greater than the ice growth rate [133].

41.4.2 Externally Cooled

Externally cooled crystallizers employ a heat transfer device external to the main crystallization vessel or channel. One type of externally cooled crystallizing unit employs a heat exchanger to super-cool the liquid feed so that the cold feed provides the cooling effect in the main vessel.

41.4.2.1 Vessel Type (Atmospheric)

Nucleation and subsequent crystal growth both occur in the main vessel. Conditions in the heat exchanger must be closely controlled to prevent nucleation from occurring where it is not wanted [5]. A modification of the external cooling process involves recycling all or part of the mass in the crystallizer. One process recycles the entire crystal slurry through an external heat exchanger to provide cooling. Nucleation occurs mainly in the heat exchanger, usually a scraped surface heat exchanger, while most of the growth occurs in the crystallizer. Ideally, ice-free liquid is cooled to promote nucleation and generate small crystals by being pumped through a scraped surface heat exchanger (SSHE) operating at high supercooling. These fine crystals are then transported with the product into the crystallizer, where a ripening process occurs.

A solution is super-cooled in a heat exchanger without ice formation. Ice crystals are formed instantly in a nucleation device before transport to a separate vessel for growth. The primary aim is to avoid heterogeneous crystallization within the crystallizing unit. The inside wall of the heat exchanger has to be highly polished or coated with a hydrophobic plastic to minimize changes of minimum nucleation and crystallization within the heat exchanger. The concentrated solution was filtered to effect ice separation. Low energy consumption is claimed [134]. Janzow and Chao [135] identified that within a relatively narrow range of super-cooled brine temperatures, large plate-like free ice crystals of up to several inches in length were formed in the bulk of slowly traversing brine simultaneously with the growth of dendrite ice on a cold surface.

It has been reported that ice crystals with 1 mm diameter could be produced by applying the process of ripening vessel [24, 136] with long residence time of ice crystals. Smith and Schwartzberg [137] examined ice crystal size change during ripening. The method of producing large ice crystals, which uses the Ostwald ripening effect, was developed and is now widely used in industry. Shirai et al. [66] and Kobayashi et al. [138] proposed another strategy to make large ice crystals by agglomerating the small ice crystals produced. Theoretical analysis of certain FM systems was also carried out by Bayindirli et al. [110], and Ratkje and Flesland [139]. The agglomeration of ice crystals mainly depended on the seed crystals, initial crystal size distribution, and solute concentration [138]. An extensive agglomeration of ice crystals was observed in low-concentration glucose solution (i.e. 10%, w/w), but not at high concentrations (i.e. 20 and 30%, w/w). However, the Ostwald ripening mechanism in ice suspensions was the most important for crystal size [140]. In order to achieve the optimal function of equipment, the maximum amount of ice in the re-crystallizer must not exceed 40% and the average speed of ice growth was lower in strawberry juice as compared to sugar solutions [141].

41.4.2.2 Vessel Type (Pressure Shift)

Pressure-shift nucleation showed potential advantages over the conventional atmospheric crystallization step at the scraped-surface heat exchanger [142]. Orange juice of several concentrations was crystallized at different pressures and temperatures [142]. It was observed that the higher the final concentration in the juice the smaller the ice crystals formed. The advantages of pressure-shift nucleation over conventional crystallization were (i) quasi-instantaneous formation of ice after expansion, (ii) ice was homogeneously distributed throughout the juice, and (iii) ice formed was round in shape without pockets.

41.4.2.3 Spiral-Finned Type

The spiral-finned crystallizer for progressive freeze concentration is a potentially effective system to concentrate a solution and to produce pure ice crystals. It was designed focusing on increasing the surface area, which affected the rate of heat transfer. A layer of ice crystal was generated on the cooling surface of the crystallizer and adhered to the surface as it grew while coolant was circulated in the cooling jacket to remove heat. This system can offer an attractive alternative for the food industry since it involves no heating and has the ability to produce highly concentrated solution [143]. The efficiency of the system was significantly improved by the lower effective partition constant (i.e. 0.35) and higher solute recovery (i.e. solute recovery of approximately 0.96 g of glucose obtained per 1 g of initial glucose). A maximal ice production of 1.71 g/m^2 s was attained [143].

41.5 VACUUM FREEZING

Vacuum-freezing and vapor-compression systems have been used for seawater desalination. Water can itself serve as the refrigerant in vacuum freezing [144]. In this option, a high vacuum is used to vaporize a portion of water, which then provides the refrigeration effect for lowering the temperature of the product and causing ice crystallization to occur. The washed ice is melted by direct-contact condensation of the water vapor in the melting-condensing unit. All vacuum freezing processes contain a crystallizing unit which is a vessel in which ice crystals and vapor are formed simultaneously by maintaining the vessel close to the triple point (when material could not be considered either solid, liquid, or gaseous) (0.61 kPa). Based on the method by which the vapors are removed, these may be further classified as (i) vacuum-freeze and vapor-compression systems, (ii) absorption-freeze and vapor-compression systems, and (iii) vacuum-freeze and ejector-absorption systems.

In the *vacuum-freeze and vapor-compression method*, a mechanical compressor is used to remove the vapor phase. The vapor is compressed so as to permit it to condense either directly as pure crystals or on a heat-transfer surface. In the case of *absorption-freeze and vapor-compression*, water vapor is absorbed in a material that has a vapor pressure below the triple point and the absorbent has to be regenerated. A conventional refrigeration cycle can be used to provide the heat necessary to drive off the absorbed vapor. The *vacuum-freeze and ejector-absorption* method uses mechanisms to remove the vapor by an absorption cycle or low-pressure steam ejector. The steam that drives the ejector is also used to regenerate the absorbent. The ejector acts as a thermal compressor to raise the quality of the removed vapor so that the vapor can be condensed [23].

In vacuum freezing the compressor must handle a very large volume of low-density water vapor due to the very low vapor pressure of water. Whereas when a relatively volatile refrigerant, such as butane, is used, the freezer pressure is raised to approximately atmospheric pressure, and the volume of vapor to be compressed is greatly reduced. Furthermore, compressor technology for butane from 0.85×10^5 to 1.05×10^5 Pa is much better developed than that for water vapor compression from around 400 Pa. On the other hand, in vacuum freezing, no butane is added to the system, and therefore the complexity and expense of butane recovery, butane make-up, and fire and explosion protection measures are avoided. Hence the relative simplicity of vacuum flash-freezing recommends its use, especially for plants of small size [1]. In the case of vacuum freezing, the residence time is not an important variable, and the process is more heat-transfer controlled, requiring agitation. Moreover, it needs a more efficient design of the melting-unit for the removal of non-condensable gas in the system [26]. Augusto et al. [145] reported the development and application of a mathematical model for the prediction of the low-pressure-vaporization (LPV) process of free water. They focused on defining clearly the two stages of the LPV process (before and after the so-called flash point). The physical domain was divided into two control volumes: (i) the first one contained the mass of free water (i.e. ideally assumed at a uniform temperature); and (ii) the second one included the volume of the vaporization chamber above the water-free surface of the condenser and the vacuum pump. Vacuum crystallization requires semi-continuous operation, limited cost reduction potential, and potential loss of aromas and volatiles from liquid foods [130].

41.5.1 Vapor Compression System

In the vacuum freezing vapor compression process, a large multi-blade compressor is used to compress the vapor from the freezer to the melting-unit. For a plant having a capacity of 227 m^3/day, the compressor is more than 3 m in diameter and needs a fairly high moment of inertia to start. For larger desalting plants of perhaps 4000 m^3/day and above, it is difficult to find a practical compressor [146]. There are two components of a VF system: the vapor removal unit to keep the slurry at or below its triple point and a freezing/evaporation unit to keep ice particles suspended with a fluid slurry–vapor interface. An economical system will have freezer and vapor removal units of nearly the same capacity; both are expensive. In principle, a balance between the size of the evaporation and condensation units could be calculated from existing correlations when standard thermodynamics are known, which is difficult. The primary compressor must compress the water vapor from a pressure somewhat below the vapor pressure of water in equilibrium with the brine at its freezing point up to a pressure somewhat above the vapor pressure of pure water at 0°C. An auxiliary refrigeration cycle is needed to remove the excess energy from the system, for example, standard ammonia cycle removing the heat of condensation of the excess water vapor and rejecting heat to ambient cooling water. Pachter and Barak [147] identified the following modules for increasing the compressor's efficiency: multi-compressor modules, direct-contact and evaporative feed pre-coolers, and multi-stage heat removal compressors of flexible blade type. Burton and Lloyd [148] examined the design considerations of the primary and secondary compressors. Additionally, two other aspects, safety and environment, affecting component specifications were discussed.

41.5.2 Vapor Absorption

In order to realize the low energy consumption advantage of FM, it is necessary to seek a different solution, for example, vacuum freezing ejector absorption process (VFEA) [62, 149, 150]. In an absorptive vacuum freezing process, water evaporates from the freezing solution and condenses on a cold salt solution. Condensing on a flowing cold sodium chloride solution was found to be an inexpensive water vapor removal method. In this process, water vapor is compressed by a combination of steam ejector and absorber loop with the primary energy source being thermal rather than mechanical. The process incorporates an absorption loop, which raises the pressure and temperature of a portion of the vapor evolved in the freezer to a level sufficient to drive the steam ejector. The primary and secondary steam discharged from the ejector is at the stoichiometric temperature required to melt the ice. The absorption loop, in raising the freezer vapor from a level slightly more than 400 Pa to that of the primary steam, acts as a compressor. The ejector has the advantage of no moving parts and is capable of being designed for larger plants. The real novelty was in the fact that the water vapor generated in the freezer is recycled through the system to act as the primary steam for the ejector. The addition of heat was completely separated from the process cycle. For a medium to absorb water vapor, a solution of sodium hydroxide is usually chosen as being most appropriate to the pressures and temperatures in the VFEA process. It is also an inexpensive chemical in comparison to alternate choices and is readily available in large quantities. The average vapor pressure in the absorber is maintained below the crystallizing unit pressure to provide the driving force for vapor absorption. The dilute sodium hydroxide solution from the absorber is heated by the

concentrated solution in the absorber heat exchanger before it enters the concentrator. The main feature of the VFEA process is that it can use low-grade thermal energy, which may be generated by flat plate solar collectors. This combination would seem to be attractive in remote coastal or inland communities [146].

The low operating pressures, below 611 Pa, make the effectiveness of this method dependent on keeping the fraction of non-condensable gas in the vapor phase. Air introduced with the feed and from equipment leaks will accumulate near the condensing interface unless removed by a mechanical pump downstream from the condenser. Non-condensable gas entering the vapor space between the freezing slurry and absorbent will be pushed to the absorbent surface by the water vapor flow impeding water vapor condensation [3, 144]. In many cases, feed saline water intake is first pumped to a vacuum de-aerator in order to remove air and other gases before being pumped into the crystallizing unit [146].

The advantage, which offsets the cost of the low pressure compared to the more usual indirect FM, is that the freezing slurry is chilled uniformly, without a stationary interface between the coolant and the freezing slurry. Stationary interfaces require constant, costly removal of ice or special interface treatment to keep the ice from reducing heat transfer to the coolant. Cost-effective absorber design often is sufficiently complicated that published models and theories are of limited use in predicting performance [151].

41.5.3 High-Pressure Freezing–Melting

The high-pressure freezing during the nucleation stage is effective for very fine control of ice structure size [152]. The advantages are (i) a large amount of the water in the product is frozen instantaneously (i.e. immediately after expansion) and uniformly throughout the volume as compared to the nucleation only on the cold surface or in contact with refrigerant in the traditional systems [153–155], (ii) additional inactivation effects on microbial and/or enzyme due to expansion of solution [130].

The vacuum-freezing and high-pressure ice-melting process was introduced by Cheng and Cheng [156], and improvements were proposed by Cheng et al. [157]. In this process, high-pressure ice-melting (washed ice) and de-sublimation of the low-pressure water vapor are conducted simultaneously and respectively inside and outside of heat-conductive conduits. Thus, fresh water is formed inside of the conduits and a de-sublimated (ice) deposit is formed on the outside of the conduits, which is then melted. In some cases, an in-situ de-sublimate dissolution operation is used. In this case, an aqueous solution is brought into contact with the de-sublimated mass and the conduits are depressurized. The de-sublimate dissolves in the aqueous solution, and an equivalent amount of ice is formed inside of the conduits. It is noted that the result of the in-situ de-sublimate dissolution operation, de-sublimate, is not recovered as product water. The advantages are: it does not require a compressor or absorption solution for the low-pressure vapor, it does not require a regeneration loop or a heat pump (a refrigeration loop) to reuse the heat released in the condensation or de-sublimation of low-pressure water vapor in supplying the latent heat of melting ice, and the process uses commercially available components and can be operated reliably [158]. An extended surface freezer, such as the rotating tray freezer used in this process, is found to have several advantages over the conventional spray freezer or agitated jet evaporator. These advantages are: lost driving force due to back-mixing of brine is lower, the need for a demister is eliminated, power input in the refrigeration is saved although a portion of power is used by the stirrer, and larger crystals can be made so that the crystal washing operation can be facilitated [158].

41.5.4 Vacuum Freezing Multiple Phase Transformation FM Process

In the case of low pressure below the triple point (less than 610 Pa) sublimation occurs and it is called sub-triple point vapor. When a sub-triple point vapor is cooled at constant pressure, it condenses as solid solvent, as ice, and this operation is called de-sublimation. When a super-triple point vapor is cooled at constant pressure, it condenses as liquid. Cheng et al. [159] proposed a vacuum freezing multiple phase transformation (VFMPT) consisting of vacuum evaporation freezing, sub-triple point vapor de-sublimation, de-sublimate melting, super-triple point vapor generation, crystal-washing, and crystal melting. A preliminary economic analysis shows that VFMPT process can be more competitive than reverse osmosis and distillation/evaporation in the range of solute concentrations represented by sea-water desalination both in terms of equipment and operating cost, and in many applications when the concentration is higher VFMPT can be more suitable for a reverse osmosis process, which requires very high pressure. Advantages identified for the VFMPT process are: high heat transfer rates, low energy input, insensitivity to fouling and corrosion, and the ability to handle highly concentrated as well as acidic and alkaline solutions.

41.6 HYBRID SYSTEM

A combination of reverse osmosis and FM could provide an economical alternative for concentrating liquids. The rejected concentration brine disposal from reverse osmosis plants may cause serious environmental impacts. The high concentration of the RO rejected brine limits the choice of the second-stage desalination unit. The energy efficiency of FM makes it a promising choice since the process is independent of fouling, and corrosion is low due to the operation at low temperatures. The economical and energy comparisons between the combined system and separate RO and direct FM units of 200 m^3/h was reported [160]. The combined system can reduce the energy consumption by about 13% and 17% compared to separate RO and direct FM plants, respectively. The combined system can reduce the rejected brine by over 90% of that of a separate RO plant at the same water production. However, the energy savings could be increased to 25% and improvement in water quality could be increased to 71% as compared to the

conventional RO desalination if a heat pump is used in the FM [161]. The use of an electric field and ultrasound-aided process could be used in the freezing-unit in order to enhance the performance. However, all these additions will make the process more complicated.

41.7 CONCLUSION

The FM process has potential for the food industry for concentrating liquid foods. In this process, first ice is formed from part of the water in solution by either direct contact of the coolant or indirect contact as separated by a metal wall. Finally, ice is separated from solution to form concentrated solution and relatively pure water. The main advantages of this process are its low energy requirement and low-temperature operation, thus giving an economic advantage as well as being mild to the solution. There are huge numbers of different types of FM being progressed although the main issue is still its complexity. The recent development of hybrid FM could have economic and quality advantages in liquid food concentration in the food industry.

ACKNOWLEDGMENT

This chapter was written based on the project report funded by the Middle East Desalination Research Center, Muscat, Sultanate of Oman (Project No. 98-BS-032A).

42 Microwave Pasteurization and Sterilization of Foods

Jasim Ahmed and Hosahalli S. Ramaswamy

CONTENTS

42.1 INTRODUCTION

Thermal processing remains the preferred processing technology in the food processing industry ever since the discovery of the process by Nicholas Appert and its subsequent commercialization. The objective of thermal processing is to extend the shelf life of food products without compromising food safety. Thermal treatments, including pasteurization and sterilization, can be employed according to the severity of the heat treatment and the intended purpose [1]. Apart from inactivation of pathogens, thermal treatment can also impart some other desirable changes, such as protein coagulation, texture softening, and formation of aromatic components. However, the process has also got some limitations due to the partial destruction of quality attributes of food products, especially heat-labile nutrients and sensory attributes. The technological revolution, nutritional awareness, and continuous demand for the new generation have necessitated the search for new or improved food-processing technologies. Recently, various emerging food processing technologies, including microwave and radiofrequency heating, pulse-electric field treatment, high-pressure processing, ultrasonic applications, irradiation, oscillating magnetic fields, etc., are being investigated to improve, replace, or complement the conventional processing technology.

Microwave heating (MW) of foods is attractive due to its volumetric origin, the rapid increase in temperature, controllable heat deposition, and the easy cleanup opportunities. It is currently being used for a variety of domestic and industrial food preparation and processing applications. It has been used successfully to finish drying of potato chips, precooking of chicken and bacon, proofing and frying doughnuts, tempering of frozen foods, and drying pasta products. MW processing for fresh filled pasta has become common in Italy since the 1990s, and the technology has been applied to ready-to-eat meals, pasta-based products, and a variety of other foods throughout Europe, Japan, and North America [2]. Recently, MW has been used to heat foods in commercial pasteurization and sterilization applications to enhance microbial destruction and promote better product quality. Several European and Japanese food-processing companies have utilized the technology for commercial pasteurization and sterilization of in-packaged foods while North American companies have still not adopted the technology for commercial applications [3].

Microwave heating is preferred for pasteurization and sterilization over conventional heating for the basic reason that the process is rapid and requires the shortest come-up time to the desired process temperature. To process liquid foods, high-temperature-short-time (HTST) processes have been accepted by the food-processing industry to reduce the adverse thermal degradation in food quality while ensuring food safety [4]. However, the HTST process is not suitable for solid foods processed by conventional methods due to slow heat conduction which often causes overheating at the solid surface during the time needed for the heat to be transferred to the slowest heating point of the food [4, 5]. MW heating has the advantage of overcoming the limitation imposed by the slow thermal diffusion process of conventional heating [5]. The volumetric heat generated by MWs can significantly reduce the total heating time and severity at the elevated temperatures needed for commercial sterilization [6] whereby bacterial destruction is enhanced, but thermal degradation of the desired components is reduced.

Study of the destruction kinetics of microorganisms by MW heating has attracted considerable interest since the 1940s when the first work by Fleming [7] was reported, and the argument between non-thermal and thermal effects was born. Several theories have been proposed to explain how electromagnetic fields might kill microorganisms without heat as summarized in a review by Knorr [8]. On the other hand, some researchers [9] refute any molecular effects of electric fields compared with thermal energy using classical axioms of physics and chemistry. Palaniappan and Sastry [10] advocated that the effects of MW and dielectric heating are the fields where there is a knowledge gap, and further studies are required.

42.2 PRINCIPLES OF MICROWAVE HEATING

Microwaves are electromagnetic radio waves that are within a frequency band from 300 MHz to 300 GHz. Microwave heating refers to dielectric heating due to polarization effects at a selected frequency band in a non-conductor. It differs from capacitive heating by the placement of the sample. In capacitive heating, the sample is placed between the electrodes, while the food material is commonly housed inside a closed cavity in the MW heating. Microwave heating applications have been limited to a few narrow frequency bands (Table 42.1) for industrial, scientific, and medical use to avoid interference with the radio frequencies used for telecommunication purposes. The typical bands are 915 ± 25 MHz and 2450 ± 50 MHz with penetration depths ranging from 8 to 22 cm at 915 MHz and 3–8 cm at 2450 MHz depending on moisture content [6]. The latter, in particular, is used more often in domestic MW ovens while both frequencies are used for industrial purposes. It is worthwhile to note that outside of

TABLE 42.1
Frequencies Assigned by the Federal Communications Commission for Industrial, Scientific, and Medical Use

Frequency
13.56 ± 6.68 kHz
27.12 ± 160 kHz
40.68 ± 20kHz
915 ± 25 MHz
2450 ± 50 MHz
5800 ± 75 MHz
24,125 ± 125 MHz

the United States, frequencies of 433.92, 896, and 2375 MHz are also used.

MW heating in foods occurs due to the coupling of electrical energy from an electromagnetic field in a microwave cavity with the food and its subsequent dissipation within the food product. This results in a sharp increase in temperature within the product. MW energy is delivered at a molecular level, through the molecular interaction with the electromagnetic field, in particular, through molecular friction resulting from dipole rotation of polar solvents and the conductive migration of dissolved ions [11]. The principal mechanisms involved in MW heating are, therefore: dipole rotation and ionic polarization. Water in the food is the primary dipolar component responsible for dielectric heating. In an alternating current electric field, the polarity of the field is varied at the rate of MW frequency and molecules attempt to align themselves with the changing field. Heat is generated rapidly as a result of internal molecular friction. The second major mechanism of heating with MWs is through the polarization of ions as a result of the back-and-forth movement of the ionic molecules trying to align themselves with the oscillating electric field. MW heating is also affected by the state of the constituents, whether they are bound or free, e.g., bound ions have much lower microwave absorptivities [12, 13].

The volumetric heating rate (Q) of the microwave at a particular location is related to the electric field strength by

$$Q = 2\pi f \varepsilon_o \varepsilon'' E^2 \tag{42.1}$$

where f is the frequency of microwaves, E is the strength of the electric field of the wave at that location, ε_0 the permittivity of free space (a physical constant), and ε'' is the dielectric loss factor (a material property called dielectric property) representing the material's ability to absorb the wave.

42.2.1 Microwave Generation

The magnetron is the heart of the MW oven. MWs are generated by a magnetron, which is attached to the applicator controlled by a waveguide. The magnetron consists of the two elements of an electron tube—a cathode and an anode each of which is circular with anode resonant cavities (anywhere from 4 to 80). A magnet (permanent or temporary) is placed around the anode to provide a magnetic field. When the cathode is heated using an electrical filament, it gives off negatively charged electrons, which are attracted by the positively charged anode. The magnetic field around the anode causes the electrons to move in an orbital fashion rather than a straight line as they jump from the cathode to the anode under an electrical pressure of 4000 to 6000 volts. As the electrons approach the anode, they pass by the resonator cavities of the anode, and this causes the electrons to oscillate at a very high frequency (2450 MHz or 915 MHz). The high-frequency oscillations of the electrons in the magnetron are picked up by a small antenna on the top of the magnetron tube. These oscillations are transmitted through a waveguide to a feed box from where they are distributed into the oven cavity.

42.3 ADVANTAGES OF MW HEATING

MW has been successfully used to heat, dry, and sterilize many food products. Compared with the conventional method, MW processing offers the following advantages: (i) MW penetrates inside the food materials, and, therefore, cooking takes place throughout the whole volume of food internally, uniformly, and rapidly. It reduces significantly the processing time and energy, (ii) since the heat transfer is fast, nutrients and vitamins contents, as well as flavor, sensory characteristics, and color of food are well-preserved, (iii) ultra-fast pasteurization or sterilization of pumpable fluids minimizes nutrient, color, and flavor losses, (iv) minimum fouling depositions because of the elimination of the hot heat transfer surfaces since the piping used is MW transparent and remains relatively cooler than the product, (v) high heating efficiency (80% or higher efficiency can be achieved), (vi) perfect geometry for clean-in-place (CIP) system, (vii) suitable for heat-sensitive high-viscous and multiphase fluids, (viii) low cost in system maintenance, (ix) heating is silent and does not generate exhaust gas, (x) flat radial temperature profile for most products, (xi) can be combined with other technologies, such as regenerative heat exchangers and infrared heating, for better process performance

42.4 FACTORS AFFECTING MW HEATING

Some physical, thermal, and electrical properties determine the absorption of MW energy and simultaneous heating behavior of food materials in microwave processing. These properties/factors are briefly discussed in the following sections.

42.4.1 Frequency

For food application, only two frequencies are allocated for MW heating (915 MHz and 2450 MHz), and, therefore, these frequencies are of special interest. The corresponding wavelengths of these frequencies are 0.328 and 0.122 m, respectively. The wavelength has special significance as most interactions of the energy and materials take place in that region and generate instantaneous heat due to molecular friction. Food constituents except moisture, lipids, and ash are relatively inert at prescribed MW frequencies. Also, the frequency (or wavelength) dictates equipment components such as magnetron, wave-guide, and to some extent heating volume.

42.4.2 Dielectric Properties

The electrical properties of materials in the context of MW and radiofrequency heating are known as dielectric properties, which provide a measure of how food materials interact with electromagnetic energy. Biological materials may be viewed as non-ideal capacitors in that they can store and dissipate electrical energy from an electromagnetic field and the properties can be expressed with a complex notation. The complex notation is characterized by dielectric permittivity with a real component, dielectric constant, and an imaginary

component, dielectric loss [13]. The dielectric properties of materials are governed by the following equations:

$$\varepsilon = \varepsilon' - j\varepsilon'' \tag{42.2}$$

$$\tan\delta = \frac{\varepsilon''}{\varepsilon'} \tag{42.3}$$

Where ε' is the dielectric constant, ε'' is the dielectric loss factor of the material, and j is the complex constant. The dielectric constant is a measure of a material's ability to store electric energy, and the loss factor is a measure of its ability to dissipate the electrical energy in the form of heat. Complex permittivity is a measure of a material's ability to couple electrical energy from an MW power generator (magnetron). The dielectric properties of materials mostly govern the heating behavior of food materials during MW heating. The power dissipated per unit volume in the dielectric field is directly related to loss factor (Equation 42.1); however, it may be also dependent on the dielectric constant subject to geometry and field configuration [14]. The ratio of the dielectric loss to the dielectric constant, defined as the loss tangent (Equation 42.3), is related to the material's susceptibility to being penetrated by an electrical field and to dissipate (attenuate) electrical energy as heat. Materials are classified by loss tangent. Those materials that are highly lossy absorb MW energy efficiently, whereas highly transparent materials have low loss factors, such as Teflon, glass, and kerosene, and absorb less MW energy.

42.4.3 Moisture Content

The moisture content significantly affects the dielectric properties of the food product and consequently, the penetration depth of the MW. The uneven heating rate is observed in high-moisture foods because of low MW penetration depth. Low-moisture foods will have a more uniform heating rate because of the deeper MW penetration [15]. The initial moisture content of the product and the rate of moisture evaporation play important roles during MW heating. The heating behavior of water is also phase dependent (liquid water versus solid ice phase) and also depends on the available free water content. At constant temperature, the dielectric behavior of free water remains constant in the lower frequency range (static region) and water dipoles have enough time to reorient themselves with not much absorption of energy, while a significant decrease in dielectric behavior can be observed at the higher frequency (optical region) with no field reversal by the water diploes. The dielectric constant decreases exponentially with frequency (critical frequency) in between the static and optical regions. Phase change results in a significant change in the dielectric properties, and, therefore, these properties for water and ice largely differ in their magnitude.

42.4.4 Mass

A direct relationship exists between the mass and the amount of absorbed MW power, which should be applied to achieve the desired heating. For a smaller mass, the batch oven is suitable, while a larger throughput would often be better in large-capacity conveyorized equipment. Such equipment has the added advantage of providing greater heating uniformity by moving the product through the MW field. Each MW oven has a critical (minimum) sample mass for its efficient operation. It is usually a load of around 250 mL of water in a 1 kW oven. Below this level, a significant amount of MW power is not absorbed into the product, and at very low loads, they may damage the magnetron.

42.4.5 Temperature

MW heating is significantly affected by the level of sample temperature. Dielectric properties may vary with temperature, depending upon the material. Both temperature and moisture content can change during heating, and, therefore, those may have a combined effect on the dielectric constant, dielectric loss factor, and loss tangent, and subsequently on the heating behavior. Freezing has a major effect on a material's heating ability because of the vastly different dielectric properties of ice and water. Water has significantly higher magnitudes of dielectric constant and loss as compared to ice, and these properties are also dependent on the MW frequency [16].

The initial temperature of the food product being heated by MWs should either be controlled or known, so the MW power can be adjusted to obtain uniform final temperatures. If the MW oven is pre-set to increase the product temperature from 20 to 80°C, it will practically reach a target temperature of 95°C with an initial product temperature of 35°C. To compensate for the effect of higher initial temperature, the power of the MW oven should be reduced, or a higher sample mass should be used, or the product should be heated for a shorter duration.

42.4.6 Geometry and Location of Foods

The shape of the food product does play an important role in the distribution of heat within the product heated in an MW oven. It affects the depth of MW penetration and affects the heating rate and uniformity. Irregular-shaped products are subjected to non-uniform heating due to the difference in product thickness [15]. The closer the size (thickness) is to the wavelength, the higher will be the center temperature. Smaller particulates require less heat than larger ones. Also, the more regular the shape is, the more uniform will be the heat distribution within the product. A food of a spherical or cylindrical shape heats more evenly than a square. A higher surface-to-volume ratio enhances the heating rate. Therefore, the heating rate for a sphere will be different from that for a cylinder with the same volume. The relationship between load geometry, load orientation, and oven cavity parameters such as cavity size and geometry, however, are not fully established. For most foods, size and geometry in combination with the energy of a relatively small wavelength such as 2450 MHz would result in non-homogeneous but predictable heating profiles. Recently, it has been advocated that MW

heating uniformity of multi-component foods is dependent on food component placement and the geometry of products and packages [17]. Placement has the most significant effect. The temperature distribution could be balanced partly by taking advantage of edge and corner heating intensification.

42.4.7 Thermal Properties

The heating characteristics of foods are dependent to a greater or lesser extent on some thermal properties such as thermal conductivity, density, and heat capacity. The thermal conductivity of food plays a significant role in MW heating. Materials with higher thermal conductivity dissipate heat faster than the ones with lower conductivity during MW heating. Food with high thermal conductivity will take less time to attain uniform temperature during the holding period. The thermal conductivity of frozen food is higher due to the high thermal conductivity of ice, while freeze-dried foods have lower thermal conductivity. The heat capacity of food measures the temperature response of food as a result of heat input or removal. Heat capacity can be raised by increasing solid content by adding components like salt and protein. Heat capacity along with thermal conductivity and thermal diffusivity constitute the thermal properties of the material. The combination of heat capacity with thermal conductivity and density is represented by thermal diffusivity, defined as the ratio of thermal conductivity to the product's volumetric heat capacity:

$$\alpha = k / \rho c_p \tag{42.4}$$

42.4.8 Secondary Flow in Curved Pipe

Thermal processing requires the coldest point to experience a target minimum temperature for a specified residence time. The coldest point in a continuous-flow process is the region where fluids exhibit the maximum velocity, which is the central axial position in a straight tube. The maximum velocity can vary in a helical coil; therefore, the flow characteristics should be determined. The use of helical coils creates a secondary flow due to the momentum transfer in the radial direction, which ensures better mixing and stabilizes the laminar flow [18]. Dean number (*De*) quantifies this phenomenon and therefore is the dimensionless parameter to characterize flow in helical coils [18].

$$De = \mathrm{Re}\sqrt{D_{tube} / D}_{coil} \tag{42.5}$$

$$\mathrm{Re} = \frac{VD_{tube}\rho}{\mu} \tag{42.6}$$

where Re is the Reynolds number; ρ is the density of the fluid (kg m^{-3}), μ is the viscosity of the fluid (Pa s), D_{tube} is the inside diameter of tube (m), and D_{coil} is coil diameter (m). The secondary flow enhances heat and mass transfer rates in addition to the rate of momentum transfer, the latter one resulting in an increased pressure drop [18]. The heat transfer rates are found to increase by a few percent to several-fold in a helical coil; however, they are a function of types of flow regime (laminar or turbulent), fluid properties, and helix configuration. Recently, the concept of Dean number has been used in MW heating of fluid foods and a Dean number exceeding 100, normally exhibiting plug flow behavior, has been found to be suitable for heating liquids in an MW oven where fluid particles with maximum velocity span across most of the tube [19].

42.5 INDUSTRIAL APPLICATIONS OF MW HEATING

The major industrial applications of MW heating are tempering of frozen meat and poultry products, precooking of bacon for foodservice, sausage cooking, drying of various foods, baking of bread, biscuits, and confectionery, thawing of frozen products, blanching of vegetables, heating and sterilizing of fast food, cooked meals, and cereals, and pasteurization and sterilization of various foods. Brief accounts of individual applications are given below followed by a detailed account of pasteurization and sterilization applications.

42.5.1 Tempering of Fish, Meat, and Poultry

The largest use of industrial MW processing of food has been the tempering of meat for further processing [3]. MW tempering is the process where the temperature of the product is raised from storage temperature (generally below –18°C) to a temperature just below freezing point. In the meat-processing industry, the meat used is usually obtained in thick frozen blocks below –18°C. The first operation on the frozen meats usually is to dice, slice, or separate individual sections into smaller pieces. The mechanical operation requires that the blocks be tempered from their solid frozen state to a point where cutting or separation can be carried out easily without damage to the product. Conventional tempering techniques either with water or air subject the outer surfaces of the product bulk to warmer temperatures for long enough for the heat to penetrate to the center. This results in large temperature gradients. In addition, the conventional tempering process takes a long time (several days) with considerable drip loss especially resulting in loss of protein which represents an economic loss. MWs can easily penetrate the whole frozen product, thus effectively reaching the inner regions within a short time. The MW tempering can be performed in a few minutes for a large number of frozen products (5–10 min for 20–40 kg). The temperature to which a product must be tempered depends upon the type of cutting, slicing, chopping, etc., and also upon product compositions such as the combinations of water, salts, proteins, and fats.

As MWs are absorbed by the material, their intensity is attenuated by the penetration depth. Surface layers retain more energy and heat up faster compared to the inner regions of the product. The loss factor increases with the temperature, the product surface heats up faster and faster, and the penetration depth simultaneously decreases. The lower frequency (915 MHz band) has an advantage for the tempering of thick products because of its deeper penetration and longer

wavelength compared to the higher frequency (2450 MHz) MW. Presently, most food industries use MW at 915 MHz for tempering purposes except where the law does not permit the use of this frequency. Tempering of frozen foods is carried out either in a batch or continuous type MW system (25–120 kW). Presently, manufacturers design the system as per customers' choice, type of food products, and applications. The process has been successfully used by the meat, fish, and poultry industries for further processing while the dairy industry has exploited the technology to reduce the chances of rancidity during bulk freezing of butter.

42.5.2 Precooking of Bacon

Precooking of bacon is the second-largest application of MW heating in the food industry [3]. MW heating is found to be an ideal system for cooking bacon compared to conventional grilling. It is reported that about half of total bacon usage is in foodservice, and virtually all foodservice bacon is precooked in MW ovens. In addition, about 10% of the bacon sold in the supermarket is MW precooked.

As a two-component food, bacon loses the fat component, and the desirable characteristics/quality, rapidly during grilling. MW heating of bacon produces a better structure with less shrinkage. Bacon cookers have changed with time and demand. Earlier, a combination of MW energy and hot air was used in an MW environment [6]. Hot air was used to trap the moisture evaporated during the cooking of bacon. A combination of steam, hot air, and MW energy is also used to cook the bacon. A sufficient amount of fat along with trapped moisture is removed during the heating of bacon at temperatures in the range of 70–80°C using steam. The trapped moisture does not convert to steam and, therefore, is removed along with fat. A complete MW system has also been used for bacon cooking where series of magnetrons (equal input) are used to heat and cook the bacon. The placement of the magnetrons varies among manufacturers.

42.5.3 Cooking Sausage

The third-largest application of MW processing is sausage cooking [3]. The sausage patty quality could be improved along with better yield by using the MW process. In sausage cooking, MW processing is used to reduce drip loss (i.e., loss of water), fat, nutrients, and flavor. Various laboratory-scale systems have been developed for MW processing of sausage but not with much commercial success.

42.5.4 Baking

The first commercial success of MW/radiofrequency energy was in the baking industry [6]. Baking ovens use radiant energy and operate in an unspecified frequency to dry the surface and make porous crust of bread. The first bread baking (proofing) was reported by Fetty [20] at 2450 MHz. A combination of MW and thermal energy was further used to produce a brown and crusted loaf in a short time. Schiffmann et al. [21] patented a bread baking technique in which a conventional heat source along with the MW energy was used in combination, and it was claimed to reduce the baking time by 50%. The unit operations associated with baking, in particular, proofing and baking, lend themselves to MW processing, which significantly improves the heat transfer during processing. Numerous reports are available on the baking of cakes, doughnut processing, and frying.

42.5.5 Drying

MW heating offers distinct benefits in dehydration because of its penetration depth, and the uniform heating results in water vaporizing from throughout the product. This induces an inner pressure that maintains the puffed character of the dried product and preserves color, flavor, and nutritional value. MW drying is rapid and more energy-efficient compared with conventional hot air drying [6]. In MW drying, the removal of moisture is accelerated, and, furthermore, heat transfer to the solid is slowed down significantly owing to the absence of convection. The usual practice of applying MWs to the drying of food materials is at the falling rate period where the migration of water from the center of the products is significantly reduced and drying rate is comparatively slow in the conventional drying process. A two-stage drying process involving initial forced-air convective drying, followed by MW finish-drying, has been reported to give better product quality with considerable savings in energy and time. The bakery industry conventionally uses MWs to finish drying of biscuits and cookies. Moreover, moist bakery products exhibit a higher loss factor (ε''), resulting in more heat generation compared to drying at a later stage with minimum water content.

Potato chips are a very popular fast food around the world. The first large-scale application of MW energy in the food processing industry was the finish drying of potato chips. Conventional drying technology cannot rapidly achieve the desired low moisture levels of potato chips and, also, browning creates another quality problem for the product due to the presence of sugars. Drying of potato chips up to 6–8% followed by finish drying by MW overcomes the difficulty of the process industry.

The application of MW energy in vacuum results in an increase in product temperature; however, the temperature rise is limited to the boiling point of the water at the lowered pressure. At a pressure of 3 kPa, free water boils at 22°C. This maintains a product temperature at a level below the temperature used under atmospheric conditions. MW vacuum dehydration was first used for the concentration of citrus juice in France [6]. MW vacuum drying of agricultural commodities includes various cereal grains, and further, this technology has been adapted to grapes for the production of Grape Puffs™ using zoned MW vacuum dehydration [22]. Applications of MWs for the drying of fruits and vegetables are numerous in the literature. The drying of pasta products and noodles at 915 MHz is a commercial success in many countries.

42.5.6 Blanching of Vegetables

Blanching, a unit operation mostly used in canning, freezing, and dehydration of vegetables, involves short time exposure of the product to boiling water, steam, or MW for the primary purpose of inactivating the oxidative enzymes which otherwise would cause an undesirable change in color, flavor, and texture of the finished product during storage. In canning, the blanching process serves to reduce the microbial load, eliminate dissolved oxygen from the product, and to facilitate better packing of the product into cans. Additionally, it can improve the color, flavor, and sensory characteristics of the product. Water and steam are the media commonly used for blanching. Still, convectional steam blanching remains the most commonly employed method in the food industry. Although it is relatively energy-intensive, however, it retains minerals and water-soluble vitamins better than the conventional water blanching. First MW blanching was reported by Proctor and Goldblith [23] using 3000 MHz for some green vegetables, and the technique was useful for enzyme inactivation. The process can retain vitamin C at the highest level. Most of the results indicated that MW blanching was more effective in retaining water-soluble vitamins in vegetables compared to conventional blanching methods. The inactivation of polyphenol oxidase (PPO) and peroxidase (POX) in red beet was compared using traditional and MW (MW) blanching, and it was found that POX was the more heat-resistant enzyme [24]. At a reference temperature of 90°C, it was observed that, in general, D_r values for POX were smaller than for PPO for both MW and traditional blanching.

42.5.7 MW Effects on Enzyme

Enzymes are probably the simplest system to consider for studying bioelectromagnetic effects in living systems. The effect of MWs (0.3–300 GHz) on living matter has been widely studied, and most of the observed effects have generally been explained by purely bulk heating, i.e., temperature increase induced by the electromagnetic field, according to the classical theory of lossy dielectrics [13]. On the other hand, evidence of MW effects not only related to temperature, as measurable by ordinary means, has accumulated over recent years, but the mechanisms involved are still largely unknown due to experimental and modeling difficulties. The inactivation of many enzymes like wheat germ lipase, soybean lipoxygenase, and pectin methylesterase (PME) was studied at various temperatures using conventional and MW batch heating and found to have higher enzyme destruction rates under MW heating conditions [25–27]. This difference is believed to be associated with some contributory enhanced thermal effects of MWs for enzyme inactivation.

42.5.8 Puffing and Foaming

Ultra-rapid internal heating by MWs causes puffing or foaming when the rate of heat transfer is made greater than the rate of vapor transferred from the product interior to outside. MWs are ideal for producing puffed snack foods.

42.5.9 Concentration

MW heating has also been used to concentrate heat-sensitive solutions and slurries at relatively low temperatures. The process is also applicable to highly corrosive or viscous solutions.

42.6 RECENT DEVELOPMENT IN MW FOOD AND PACKAGING

Recently, food processors have developed many new-generation microwaveable foods with suitable packaging materials to meet these demands. The foods are microwavable and for use at home as well as away from home, via convenience-store or office MW. In many cases, the products' success hinges on a combination of product reformulation and package redesign. High-density polypropylene (HDPP) is a low-cost solution for the MW process over other materials that can withstand the target temperature. For sterilization, PET, HDPP, and various polyester-based materials are available as high-quality trays, pouches, and bags. Glass also is a possibility. The metal cap in glass jar proved to be an advantage.

Some of the products available on the market include Eggology's On-the-go 100% egg whites and Marks and Spencer's Steam Cuisine [28]. The microwaveable product expands during cooking, and the lid automatically pops up. A Steam Cuisine fresh prepared meal requires 6 minutes to cook from the raw stage. Another claim has been made regarding the development of "intelligent double pressure cooking technology" where the first cooking occurs by MWs passing through the specially developed packaging and heating the frozen food materials. The frozen water becomes steam and cooks the food from inside out. In the next phase, as the steams comes out of the food tissue, it is held and retained inside the packaging. As the steam pressure builds, the food cooks from the outside in.

Packaging has played a significant role in the MW processing of foods. Big names like Kraft have developed many new packaging materials that can be used in MW heating of pizza [28]. Another development in MW foods has been reported by introducing aroma in the packaging material. The aroma releases during MW heating of the packaged material. In the future, we may expect more revolution in MW package design to satisfy the never-ending demands of consumers.

Uniform heating of food materials by microwaves is influenced by the package design and some other factors including the composition of food, geometry, and oven design. MW heating of packaged foods (e.g., ready meals) happens when the pressure builds up within the package. In-pack pasteurization can be achieved by specially designed packaging including trays, films, and valves. The shape of the trays is mostly optimized for uniform heating, and they are sealed with plastic films including a valve. Sometimes, various active packaging is employed for microwave heating, in particular, for pizzas, and pies. To obtain uniform heating of pizza, susceptor packages have been used to achieve enough crispiness after microwave heating. A US patent (6414290 B1) describes how susceptor can be employed for uniform heating and browning

of pizza or ready meals with circular shapes. A microwave susceptor consists of a layer of metalized plastic film laminated to a dimensionally stable substrate, such as paperboard. The thickness of the metal is designed in such a way that the metal can absorb MW energy and converts it into heat. Such susceptors are commonly used commercially to brown and crispen food in contact with the susceptor. The improvement in heating is due to the escape of vapor through the apertures, which allows the pizza to remain in contact with the susceptor. However, providing apertures in the susceptor requires a separate step in the manufacture of the susceptor and produces chad that must be disposed of. It also destroys the integrity of the susceptor, which forms part of the package for the pizza.

42.7 MW PASTEURIZATION AND STERILIZATION

Pasteurization is the process that uses a relatively mild heat treatment on foods to kill key pathogens, and inactivate vegetative bacteria and enzymes to make food safe for consumption. Most frequently, milk and fresh fruit juices are pasteurized where the minimum process is necessary to eliminate associated health hazards. However, the thermal treatment given does not kill bacterial spores, and hence the product is not stable at room temperature. Under refrigerated storage conditions, one can expect 2–6 weeks of shelf life. Recently, the process has been upgraded to remove the potential health hazards due to *Salmonella*, *Escherichia coli*, and *Listeria monocytogenes*. Pasteurization of milk is achieved by 30 minutes heating at 63°C or 15 seconds at 72°C. Much higher temperatures have also been used for a shorter period in HTST and ultra-high-temperature (UHT) processes. The temperatures and times are determined by what is necessary to destroy pathogenic heat-resistant disease-causing microorganisms that may be found in the food. After pasteurization the product is then quickly cooled to 4°C. Pasteurization temperatures and times vary, depending on the product nature and the target organism.

Sterilization is a more severe thermal treatment of foods. Traditionally, the process is designed to achieve commercial sterility of the products giving them longer-term shelf stability. The magnitude of thermal treatment is a function of pH, and it accounts for the effects of pH on the thermal resistance of the microbial spores. Foods with high pH (>4.5) support the growth of *Clostridium botulinum* which produces an exotoxin. It is recognized that a thermal process sufficient to eliminate toxin-producing *C. botulinum* from the food should make the food commercially sterile if adequately packaged under vacuum, preventing recontamination, and appropriately stored at room temperature (at <30°C to prevent the growth of thermophilic bacterial spores). Commonly, saturated steam at elevated pressures (135–140°C) and steam-heated hot water are used as heating media for food sterilization. MW sterilization has been studied for potential commercial applications. However, the commercialization has faced several problems with some limited success [29].

Both pasteurization and sterilization are based on time–temperature combination processes applied to food products to achieve intended target lethality. In most cases, target microorganisms are chosen for specific types of food. The death kinetics of the microorganisms play a major role in selecting the target lethality, and therefore, the quantification and accommodation of microbial destruction kinetics is an important step in establishing the thermal process.

42.8 KINETICS OF MICROBIAL DESTRUCTION

The destruction of microorganisms and inactivation of enzymes is generally expressed by nth order chemical reaction as:

$$\frac{dC}{dt} = -kC^n \tag{42.7}$$

where dC/dt is the change in concentration C or microbial population (change C to N) with time t, k is the reaction rate constant, n is the order of reaction. Generally, the destruction of microorganisms is described by first-order reaction kinetics. The thermal resistance of microorganisms is also conventionally characterized in food processing by means of a decimal reduction time (D value, heating time at a given temperature that achieves 90% destruction of the existing microbial population) and the thermal resistance constant (z value, the temperature range between which the D values change by order of 10) [30].

$$D_{T_{ref}} = 2.303 / k \tag{42.8}$$

$$z = \frac{T_2 - T_1}{\log D_1 / D_2} \tag{42.9}$$

The equivalent time necessary for thermal treatment with the known thermal resistance of a microorganism is calculated by integration of the time–temperature history using Equation 42.10:

$$F = \int_0^t 10^{\frac{T(t)-T_R}{z}} dt \tag{42.10}$$

This approach has been commonly used in the thermal processes calculations. A similar concept can be applied for determining kinetics parameters during MW heating; however, non-isothermal heating conditions are involved in this case. Resulting D values can be computed using Equation 42.11:

$$D = t_{eff} / \log(C_o / C) \tag{42.11}$$

where t_{eff} is effective time (similar to F as in Equation 42.10) with T_R as exit temperature of the product, obtained using either model-predicted or experimentally determined time–temperature profiles; C_o and C are initial and final

concentrations of microbial cells. The use of this approach is rather limited in studies on MW effects. Only a few studies reported in the literature describing kinetics during MW heating make use of the transient temperature profiles [27]. But as in thermal destruction, MW destruction kinetics of food constituents such as quality characteristics, enzymes, and microorganisms are required for establishing MW processing.

42.8.1 Come-up Time and Come-down Profiles Corrections

Continuous-flow MW heating has advantages over batch processing where the presence of non-uniform temperature in the product has seriously limited its use. Continuous-flow liquid systems allow the maintenance of the time and temperature achieved in steady-state, the recording of average temperatures during heating, the minimization of the temperature gradient by mixing of the liquid, and the cooling of the liquid immediately at the exit. MW heating involves a non-isothermal come-up time (CUT) inside the oven or cavity. The holding and come-down phases take place generally outside the MW oven. Evaluating kinetic parameters during non-isothermal continuous-flow heating are described in detail elsewhere [26]. From a regression of residual log numbers of survivors versus residence time (uncorrected heating time), the first estimate of D values at the exit temperatures can be obtained, and using them at different temperatures one can get an estimate of the z value. Using this estimated z value and the time–temperature profile, a more effective heating can be computed from Equation 42.10. These effective times can then be used to recalculate D and z. These two steps are repeated several times for the convergence of z value. The come-down period contribution occurs outside the MW oven, and this should be subtracted from destruction to estimate the destruction due to MW heating. To do this, the effective cooling time (t_c) can be computed using the same Equation 42.10 with the z value obtained from conventional thermal destruction studies. The extent of logarithmic thermal destruction (*LTD*) during cooling can be estimated following the relationship:

$$LTD = t_c / D \tag{42.12}$$

Where *D* is the *D* value at the exit temperature obtained from thermal destruction studies. This calculated value is then subtracted from the combined destruction of the microbial population due to MW heating and cooling. Microbial destruction data of test samples can thus be corrected for both come-up and come-down period contribution to lethality. This approach has been used in some studies for comparative evaluation of microbial lethality under conventional and MW heating.

42.8.2 MW Heating Systems

42.8.2.1 Batch Heating

In the batch process, the magnetron-based MW ovens are commonly used for heating purposes. The food sample is placed in the oven for a predetermined time to achieve a target temperature. The power level is normally adjusted to achieve a certain desired temperature difference in a given time frame. The volumetric heat absorbed by the food material during MW heating can be calculated by using the following relationship assuming there is no surrounding heat loss:

$$Q = mC_p(T_f - T_i) \tag{42.13}$$

where m = mass of food (kg); C_p = specific heat (kJ/kg°C); T_f = final temperature (°C); and T_i = initial temperature (°C). The absorbed MW power (P) can be calculated by volumetric heat divided by heating time. P is compared with the nominal MW output to compute the efficiency, and generally over 90% of the nominal power can be used by a large sample.

42.8.2.2 Continuous-Flow Heating

Recently, particular interest has arisen in MW heating in continuous systems, because of its potential benefits to the food-processing industry. In MW heating, the radiant energy heats the product directly, without heating the tube walls, and therefore, MW can penetrate the food to achieve more effective bulk heating. Continuous systems have advantages over the batch ones with increased productivity, a quick rise in temperature, controllable heat distribution, easier cleanup, and automation. Several laboratory-based continuous-flow MW heating systems have been used for fluid foods with different configurations [19, 26, 31–33]. The schematic diagram of a basic continuous flow MW heating is shown in Figure 42.1. The raw fluid is pumped (peristaltic pump) through Teflon or glass helical coils placed inside one or several MW ovens connected in series for heating (alternately several magnetrons can be arranged in one oven). Outside the MW oven, the fluid then passes through a holding section to allow a predefined holding time followed by chilling in some form of a tubular heat exchanger. Thermocouples are used for gathering samples temperatures at the entry and exit sections (external to the oven) while fiber-optic probes are used to monitor the temperature inside the cavity/oven.

To establish steady-state flow-conditions for MW heating, the fluid food is pre-circulated in the system after which the MW ovens are turned on. The volumetric flow rates are determined by various pump settings. For the pasteurization process, the flow rate is set, so that the required exit temperature of the fluid in the MW oven is maintained in the holding section. The temperature of the fluid in the holding section is maintained by an external means [26], or in some cases, the exit temperature is elevated to a slightly higher level than required to allow for the heat loss through the insulated holding tubes [19]. However, time–temperature profiles of most of the cases are generated by transit time–temperature measurement at selected regions.

42.8.2.3 MW-Assisted Pasteurization System (MAPS)

The MW-assisted pasteurization system (MAPS) is a potential thermal processing technology, which is used for the pasteurization of food. MAPS uses MW power as a heating source to inactivate microbes to produce safe prepackaged

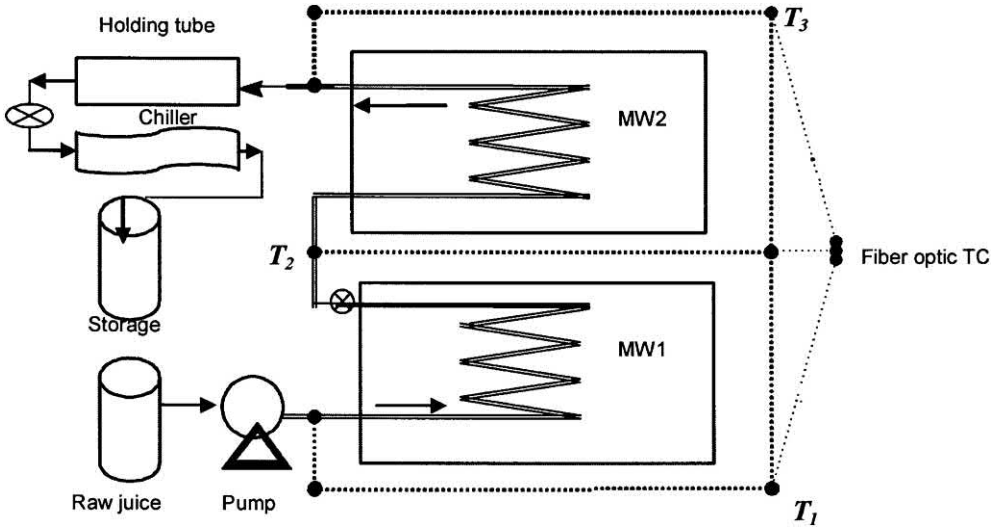

FIGURE 42.1 Continuous-flow microwave pasteurizer.

foods [34, 35]. The current technology differs from an earlier MW-assisted pressurized sterilization system [36, 37]. Recently, researchers from Washington State University (WSU) employed MW heating in combination with hot water immersion in producing higher quality food products, especially ready-to-eat chilled prepared meals. Hong et al. [38] described a 15-kW 915 MHz pilot-scale MAPS for packaged food as illustrated in Figure 42.2. The system is similar to a conventional pasteurization system, which consists of three operating sections, namely, preheating, heating, and cooling. In a continuous process, the products are transported by a conveyor from one section to another. In the preheating section, the packaged food products are loaded and heated in a hot water tunnel to an elevated temperature. In the second section, a pulse of MW energy is introduced to heat the products in combination with hot water immersion and stabilization in a tunnel to raise the internal temperature to a target heating temperature. The pasteurized products are cooled in the cooling section. Water is used for heat transfer, and the residence time in each section is controlled by the speed of the conveyor. It was observed that MW heating improved the heat transfer in the heating section of the MAPS. The difference in the heat transfer values in the packaged products was mostly attributed to the product dimension (mainly thickness) and weight, composition and amount of sauces used, surface area, and dielectric properties of products.

Hong et al. [38] tested MAP for two products, namely, 10 oz. beef meatball in tomato sauce trays and 16 oz. salmon fillet in sauce trays using non-proteolytic *C. botulinum* Type B and *C. botulinum* Type E spores as the target microorganisms for thermal processing. About 57% and 62% of the total lethality for beef meatball and salmon fillet were achieved in the MAH section; the remaining lethality is contributed by the cooling section, whereas the lethality achieved in the preheating section is almost zero The lethality accumulated in the cooling section can be attributed to residual heat and the relatively high temperature in the products as they enter the cooling section. A Monte Carlo simulation indicated that the total lethality of the products follows normal distributions. The simulation showed that more than 98.8% of the process could achieve a minimum of a 5-log reduction of the spores of *C. botulinum* Type B in beef meatball trays against a target lethality of 6-log reductions, and more than 99.1% of the processes achieve >5-log reductions in the spores of *C. botulinum* Type E in salmon fillet trays.

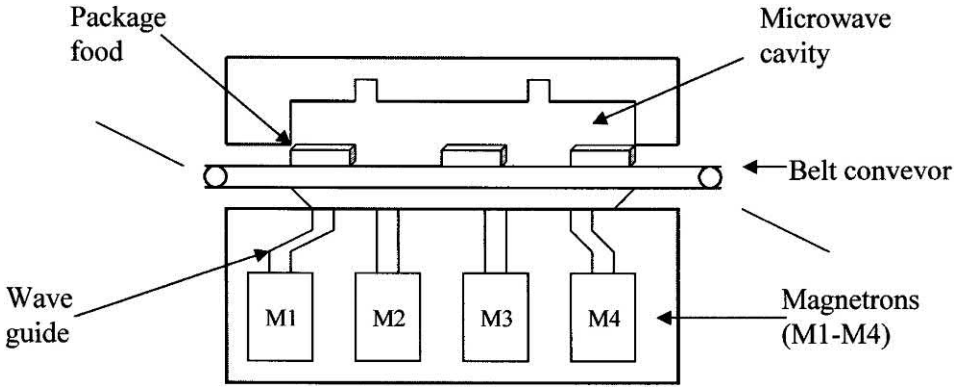

FIGURE 42.2 A typical microwave pasteurizer.

42.8.2.4 MW-Assisted Thermal Sterilization (MATS) System

Researchers from WSU developed a 915 MHz single model MW-assisted thermal sterilization (MATS) system to explore industrial applications of MW volumetric heating in thermal processing of pre-packaged foods [37]. The MATS process of prepackaging mashed potato and salmon fillet has been accepted by the FDA for sterilization of pre-packaged low-acid food in the US.

The pilot MW sterilization system used at WSU is illustrated in Figure 42.3 [37]. The unit consists of two 5-kW 915-MHz MW generators, waveguides, two MW heating cavities, loading and unloading cavities, a sample tray conveyor system, a water circulation system, and a control and data acquisition system. MW power from the generators is transmitted to the MW heating cavities through waveguides during the operation. The food trays are loaded through the loading cavity, which also serves as a pre-heating cavity, and the unloading cavity is used for unloading processed food trays and also works as a cooling cavity. The water circulation system, consisting of two plate heat exchangers, a storage tank, and fixture to provide compressed air to pressurize water, is used to provide temperature-conditioned pressurized water for pre-heating, auxiliary heating to MW treatment, holding, and cooling of food packages. The data acquisition system, data loggers, and custom-built software are used to maintain and collect the operation parameters. The design of the MW applicators in the MW heating section determines heating uniformity and processing time and, thus, is one of the most important parts of a MATS system.

For sterilization, the sample trays were first preloaded on the conveyor mesh belt with a preheating temperature of 60°C with hot water at 122°C in the loading section, and thereafter, the trays were moved through the MW heating cavities and treated by both MW energy and hot water (122°C) with a preset time speed schedule. The sample trays were held in the holding cavity to achieve the desired F_0 after MW treatment. Finally, the trays were cooled to the center temperature of 75°C with tap water and unloaded from the system. *Clostridium sporogenes* (PA 3679, batch No. 307) spores were used in inoculated pack studies for microbial validation of the process. The trays subjected to the target process (F_0 = 6 min) and over-target process (F_0 = 12 min) showed no evidence of gas production during 3 months of incubation. Therefore, the method used in this study was feasible for developing MW processing of inhomogeneous foods, and the developed processing was effective for the sterilization of sliced beef in pre-packaged gravy trays.

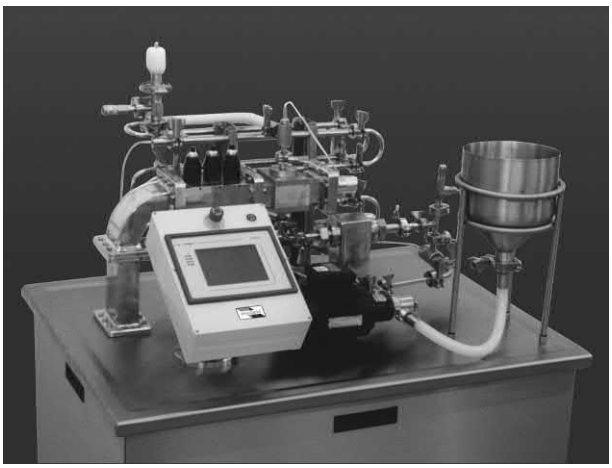

FIGURE 42.3 Multi-mode microwave tunnel cavity for packaged food pasteurization and sterilization.

42.8.3 Application to Food Systems

42.8.3.1 Milk

Milk is traditionally pasteurized in a heat exchanger before distribution. The application of MW heating to pasteurize milk has been well-studied and has been a commercial practice for quite a long time. The success of MW heating of milk is based on established conditions that provide the desired degree of safety with minimum product quality degradation. Since the first reported study on the use of an MW system for the pasteurization of milk [31], several studies on MW heating of milk have been carried out. The majority of these MW-based studies have been conducted to investigate the possibility of shelf life enhancement of pasteurized milk, application of MW energy to inactivate milk pathogens, to assess the influence on the milk nutrients, or to assess the non-uniform temperature distribution during MW treatment [31, 39–44].

Continuous-flow MW treatment has been proposed for milk pasteurization due to its potential advantages over the conventional tubular and plate heat exchangers. Continuous milk pasteurization at 2450 MHz using a simple waveguide heat exchanger was first reported by Hamid et al. [31]. Raw milk was passed through a glass tube fitted across a waveguide, and milk was exposed to MW energy during gravity falling. The plate counts were found to be negative while the temperature reached 82.2°C. Jaynes [39] developed an experimental continuous-flow MW pasteurizer using a Teflon tube (12 cm/0.635 cm) placed across a 2450 MHz MW guide. The system had a 15 s holding time. The adequacy of pasteurization was considered by the inactivation of phosphatase enzymes, standard plate, and coliform counts.

High-temperature short-time (HTST) sterilization of raw milk has also been tested under a MW field at 2450 MHz. A typical MW pasteurizer is shown in Figure 42.4. The process was done in a free-falling stream of milk with pressure application. Heating was reported to be extremely rapid with a temperature rise of 200°C; holding was less than second while the cooling was done by turbulent mixing with cold sterilized milk. However, the process was not considered economically feasible. Kudra et al. [40] used a domestic MW oven for continuous-flow pasteurization of milk and its constituents. The protein in milk was found to be the contributing component in dictating the heating pattern in milk pasteurization while the effects of fat and lactose were considered negligible. Lopez-Fandino et al. [45] reported the effects of thermal treatment of milk in a continuous-flow MW system by studying the

FIGURE 42.4 Microwave pasteurizer.

denaturation of β-lactoglobulin and the inactivation of alkaline phosphatase and lactoperoxidase using a modified MW oven at 2450 MHz. The results were compared with those obtained by conventional thermal treatment in a plate type heat exchanger, and the degree of inactivation caused by the thermal treatment in both cases was found to be similar. MW pasteurization of milk was reported to result in lower levels of denaturation of whey proteins compared to conventional thermal processes, and the denaturation of β-lactoglobulin was similar in both processes [46]. Moreover, the process yielded lower microbial counts and lower lactose isomerization. The sensory characteristics of MW-pasteurized milk were considered comparable to those achieved by traditional pasteurization after 15-day storage.

To overcome the non-uniformity of temperature distribution caused by MW heating, Coronel et al. [47] experimented on continuous-flow MW heating of milk at 915 MHz using a cylindrical MW applicator. The MW field inside the applicator generated a parabolic field distribution inside the tube for a fluid with constant dielectric properties, like those of milk at 25°C. The system was designed in such a fashion that the fastest moving particles reside at the center and would receive maximum power for a shorter period, whereas the slowest moving particles at the wall side would receive minimum power for a larger period. The system was reported to exhibit a relatively even distribution of temperature for milk, in the cross-sectional area of the tube at the exit of the applicator. Temperature distributions data revealed that the hottest temperature was found at the center of the tube while the cooler temperature was close to the walls of the tube.

42.8.3.2 Effect on Milk Nutrients

Milk is a rich source of vitamins, and heat treatment affects some of these nutrients. The effects of MW heating on several vitamins in cows' milk have been studied by many researchers [45]. Most studies report an insignificant loss in vitamin A, β-carotene, vitamin B_1, or B_2 in MW-pasteurized milk while losses of approximately 17% for vitamin E and 36% for vitamin C have been found. Sierra et al. [48] compared the heat stability of vitamins B_1 and B_2 in milk between continuous MW heating and conventional heating having the same heating, holding, and cooling steps. No significant losses in the vitamins were reported during MW heating at 90°C without holding period, while vitamin B_2 was found to decrease by 3–5% during 30–60 s holding. The authors concluded that the MW process does not offer any additional advantage concerning vitamin retentions as compared to a conventional heating process. MW heating of milk does not affect protein or fat components. Volatile components of conventionally treated and MW-treated (continuous-flow) milk have differed significantly.

42.8.3.3 Effect on Microbial Inactivation

The inactivation of *Streptococcus faecalis*, *Yersinia enterocolitica*, *Campylobacter jejuni*, and *L. monocytogenes* in milk by MW energy has been reported by Choi et al. [42, 43]. A complete inactivation was achieved when *Y. enterocolitica*, *C. jejuni*, and *L. monocytogenes* were heated at a constant temperature of 71.1°C at 8, 3, and 10 min using MWs with initial microbial loads of 10^6–10^7 CFU/mL [42, 43].

42.8.3.4 Fruit Puree and Juices

The inactivation of vegetative microflora in fruit products including purees and juices by MW heating, in general, does not pose any serious threat, and can be achieved by processing those products at a high temperature for a short time. However, some reports revealed that a few pathogens, namely *Salmonella enerica*, *E. coli O157:H7*, and *Cryptosporidium parvum*, have been associated with the foodborne illness in fruit juices. Pasteurization of fruit juices is traditionally carried out by a HTST heating process using a plate heat exchanger followed by a brief holding period and cooling. However, fouling is a major problem with the process. Inactivation of microorganisms and enzymes of fruit products, e.g., citrus juices by MW pasteurization, especially in continuous-flow systems, has created interest among juice processors due to lower thermal exposure, elimination of fouling in the pipeline, and retention of juice quality.

In orange juice, pectin methyl esterase (PME), an undesirable enzyme, causes spoilage and cloud loss during storage. Also, the enzyme is more heat resistant than spoilage microorganisms and, therefore, has been considered as an index of the adequacy of pasteurization. Nikdel et al. [49] described a continuous-flow MW system to pasteurize orange juice using PME inactivation and microbial count as indices. However, the work did not consider the time requirement for achieving the MW exit temperature, and come-up time (CUT) and come-down time (CDT) contributions were not considered in these studies. The inactivation of PME and *Lactobacillus plantarum* was found to be more pronounced using MWs as compared to conventional heating. The kinetics of PME inactivation in orange juice during MW heating in continuous as well as batch-mode processes were compared with those during conventional heating by Tajchakavit and Ramaswamy [26, 27], and they found largely enhanced inactivation of PME while employing MW heating. In a batch process, orange juice in glass beakers, with good mixing, was heated in an MW oven for a pre-selected time to achieve the desired

temperature. In the continuous-flow system, the juice was pumped through a helical glass coil placed inside the MW oven under full power heating conditions, and a target exit temperature was achieved based on juice flow rate and initial temperature. Under steady-state conditions, the increment of fluid temperature between inlet and outlet in continuous flow was found to be non-linear along the tube length. Under both batch and continuous-flow MW heating conditions, PME inactivation rate was significantly higher than in conventional thermal treatment at selected temperatures (D values at 60°C: batch MW = 7.37 s, continuous MW = 22 s, and conventional = 150 s). The authors claimed some enhanced-thermal effects during MW heating largely contributing to greater PME inactivation.

MW pasteurization of apple juice has also been investigated by several researchers [19, 45]. Tajchakavit et al. [50] studied the destruction kinetics of *Saccharomyces cerevisiae* and *L. plantarum* in apple juice under continuous-flow MW heating conditions and compared them with conventional batch heating in a water bath. The z values under MW heating for *S. cerevisiae* and *L. plantarum* were found to be 7 and 4.5°C, respectively, while the corresponding batch conventional heating values were 13.4 and 15.9°C, respectively. Microbial destruction thus was much more temperature-sensitive under MW heating than under thermal heating. Based on the computed D values, the authors again suggested some contributory enhanced effects to be associated with MW heating. However, Canumir et al. [51] reported that exposure of *E. coli* to MW treatments at 2450 MHz resulted in a reduction of the microbial population in apple juice and that the inactivation is solely due to heat. The pasteurization was carried out at different power levels (270–900W), and it was reported that a 2–4-log reduction in the microbial population was achieved at 720–900 W for 60–90 s with D values ranging from 0.42 min at 900 W to 3.88 min at 720 W. Recently, Gentry and Roberts [19] developed a continuous-flow MW pasteurizer using helical coils distributed through a large cavity oven to produce uniform and reproducible heating of apple cider. The process lethality of apple cider was verified by inoculation of *E. coli* 25992, and the 5D reduction was reported.

Piasek et al. [52] employed EnbioJet MW Flow Pasteurizer to examine the preservation of plant phytochemicals and bioactivity of anthocyanins-rich aronia and blue-berried honeysuckle juices. The juices were sterilized using the power supply of 63 A/20 kW and the temperature range of 90–135°C. The MW exposure time was 7 s. Compared to thermal treatment, a higher stability of phytocomplexes during processing was observed. In the same batches of juices subjected to heating at 100°C, the sharp decline of anthocyanin content accompanied by lowered antioxidant activity was noticed. The changes in chemical composition were reflected in altered biological activity. Both cytotoxicity and protection of DNA against oxidative damage were higher for microwaved juices than for juices processed by the conventional heating that caused degradation of bioactive phytochemicals.

Marszałek et al. [53] compared the quality and shelf life of strawberry purée processed by continuous MW heating at 90 and 120°C for 10 s to conventional thermal pasteurization at 90°C for 15 min during prolonged storage at 6°C. It was observed that MW heating at 120°C and conventional pasteurization were efficient for total microbial inactivation, which allowed for the storage of samples for up to 52 weeks. However, the sample treated at the lower temperature (90°C) during MW heating did not sufficiently reduce the total microbial counts in strawberry purée which resulted in shortening the shelf life to up to 44 weeks. Contrary to conventional pasteurization, MW heating could not completely achieve the inactivation of polyphenol oxidase (PPO) and peroxidase (POD). Furthermore, it was found that the PPO activity decreased about twofold during the storage of MW-heated samples while POD activity substantially increased in all the samples during 52 weeks of storage.

Benlloch-Tinoco et al. [54] evaluated the use of pasteurization units (PU) (Eqn. (14)) as a measure of the lethal effect during kiwifruit puree processing with the aim of comparing conventional (heating at 97°C) and MW (1000 and 900 W) technologies for POD and *L. monocytogenes* inactivation. The temperature profiles of the samples during processing were determined at different positions. The conventional heating mode required a significantly ($p < 0.05$) higher thermal load to achieve the pre-set level of POD inactivation (90%) in the kiwifruit puree than any of the MW treatments studied, irrespective of whether the comparison was carried out on the coldest or hottest spot of the sample.

$$PU = \int_0^t 10^{\frac{(T(t)-T_{ref})}{z}} dt \tag{42.14}$$

Franco et al. [55] studied dielectric properties and electrical conductivity of green coconut water (GCW) by open-ended coaxial probe technique at temperatures from 0 to 90°C and frequencies between 500 and 3000 MHz. At 915 MHz, ionic conduction shows an important role in MW heating, while both ionic and dipolar mechanisms were found at 2450 MHz, depending on temperature. The addition of sugars had a weak effect on polarization or loss. Component interaction significantly dropped the loss factor by 12% at 915 MHz and 8% at 2450 MHz.

42.8.3.5 Ready-to-Eat Meals

The frozen ready-to-eat food-processing industry is enormous and has been rapidly expanding over the years. The growth of the industry has been generated by the consumer demand for ready-to-eat meals which can be reheated easily before eating. The pasteurization schedule of ready-to-eat meals needs to be established through the same guidelines that are used for commercial sterilization and cannot be simply specified regarding a time–temperature combination. The pasteurization of ready-to-eat meals using MWs to enhance their shelf life has been recognized for many years, and the potential of the method has been verified in pilot-scale systems [56]. Pilot- and commercial-scale MW pasteurizers are available presently for this purpose. However, the adoption of the

technology by the food processing industry has been slow due to the uncertain trends in the markets for chilled foods with extended shelf life and also because of the technical limitations linked to the process. Ideally, the product should be heated to specified levels without over-cooking, then cooled quickly and properly stored and distributed. All along, the product should remain microbiologically safe while its shelf life is extended.

Various procedures for overcoming the technical problems have been considered including the use of a liquid circulating around the packs of food to restrict edge heating, pressurized systems for elevating temperatures or using partially open packs to prevent the bursting of packages, moving the waveguides, hot filling of product components to produce more uniform product temperatures, or incorporating metallic structures into the cavity to modify the field distribution. Many of these changes increase the complexity and cost of the equipment and may impede the flexibility of product types. Improving the design procedures for MW systems, including the design of the MW cavity, food packaging, and food composition, should lead to better processes. An efficient engineering approach requires methods that are capable of predicting the electric and magnetic field and temperature distributions in foods during MW heating. Heat processing at 80–85°C for a few minutes is considered sufficient, with a margin of safety, to inactivate vegetative pathogenic microorganisms such as *Salmonella* and *Campylobacter* but not bacterial spores. However, most bacterial spores do not multiply at low temperatures below 4°C. The growth from spores needs to be considered only when they are known to be present in the product ingredients and prolonged storage periods are expected.

Effect of various combinations of MW ovens (domestic, pilot-scale tunnel) and frequencies (2450, 896 MHz) have been studied for the pasteurization of ready-to-eat spaghetti bolognese meals in retail packaging to extend the shelf life [57]. It was reported that mean product temperatures above 80°C could be achieved using any of the systems but only the tunnel operating at 896 MHz heated all of the products in a pack above that temperature.

Ryynanen and Ohlsson [17] studied the importance of chemical and physical modifications in four-component chilled ready meals during uniform MW heating. The food component placement and geometry of products and packages were reported to play a significant role in providing MW heating uniformity of multi-component food systems. The temperature distribution could be balanced partly by taking advantage of edge and corner heating intensification. In contrast, chemical modifications, such as saltiness, did not notably affect the heating uniformity. However, interaction effects can sometimes be important.

42.9 STERILIZATION SYSTEMS

The pasteurization of packaged bread, pasta, and pizza have been reported. In some European countries, the whole loaf of the packaged bread is treated with MW energy to enhance the shelf life. MW-treated fresh pasta in packs further needs controlled atmosphere storage to increase the shelf life. MW processing for fresh filled pasta became common in Italy in the 1990s, and the technology has been applied to ready-to-eat meals, pasta-based products, and a variety of other foods. Some of the leading global food manufacturers apply the technology, including Unilever and Barilla SpA in Italy and Morinaga in Japan. However, these products have had limited success due to the excessive cost of the process.

In the 1970s Kenyon developed a high-quality shelf-stable ration as a replacement for the U.S. Army's C-ration by using a fiberglass-reinforced polyester pipe which was installed in a 10 kW MW oven. The system was similar to the equipment shown in Figure 14.3. A pair of butterfly valves at the product entry allowed pouches to be introduced into the processing system on a narrow conveyor belt through the MW field. The pouches dropped off at the end of the belt into a cold-water tank from which they could be removed periodically. Radiation heat losses were minimized by wrapping the pouches in MW-transparent insulation. However, the temperature difference from the edge to the center of the pouches was reduced to 5°C or less from 30°C or more. Another contemporary study of MW packaged food carried out by Alfa Laval, Sweden, was found to establish a decreasing temperature gradient from edge to center by introducing a cooling step to lower the temperature at the edges. Another modification of MW sterilizer was carried out based on MW heating of water by conveying packages of products through water; the water temperature was progressively adjusted by conventional heating means to provide edge heating control without expending too much energy in MW heating of the water. The system was installed in a Swedish food plant [6].

HTST processing of pouches by conventional retorting has clearly proven the benefit of such processing on some quality parameters. According to Ohlsson and Bengtsson [58], there is no reason to believe an MW HTST process would be any less successful. The authors [58] made a comparison of canning, retorting foil pouches, and MW sterilization of plastic pouches regarding the cook value (in an integrate value describing the effect of time and temperature on product quality). The quality of a variety of products processed using MW sterilization was superior. Typical commercial MW reheating and sterilization systems are shown in Figures 42.5 and 42.6.

Limited publications of data on processing two- and three-component ready meals are available. Processing meals presents a more complex problem—a differential heating pattern of various components. The problem could be solved by accounting for the energy requirements of each component. Several patented references are available on the topic while public information is lacking. Data available on the effect of storage time at room temperature on the quality factors of MW-sterilized foods are scarce. However, there are some results in which MW-sterilized (2450 MHz) vegetables were compared with foil pouch sterilization at 121°C and a frozen reference. The MW product was comparable with the frozen product for sensory characteristics even after 6 months at 25°C [59]. In another study with chicken à la King, the appearance

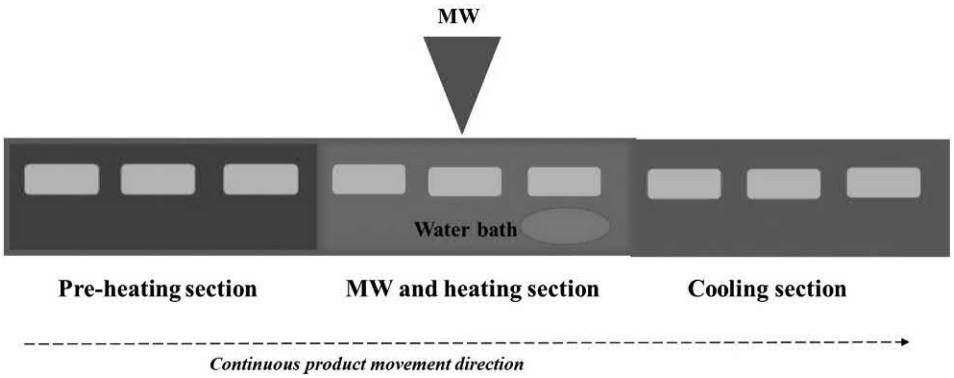

FIGURE 42.5 Pilot-scale MW-assisted pasteurization system (MAPS) for packaged food.

of MW-sterilized product compared favorably with the frozen reference even after 12 months' storage.

42.10 MARKER FORMATION AS AN INDEX OF MW STERILIZATION

Implementation of the MW sterilization process can vary significantly among process design and manufacturers. The application of the process in the food industry especially in the United States depends on the FDA approval of the dielectric sterilization process as a reliable procedure to establish and validate the required lethality for heat treatments to ensure microbiological safety. To design a new thermal process that ensures adequate sterility for shelf-stable foods, it is necessary to locate the cold-spot in packaged foods [60]. Once the cold-spot is determined, accurate time–temperature data can then be gathered from the slowest heated point and used for developing suitable thermal processes.

Numerous biological integrators have been found in the literature, and most of those have been used as relative indicators for food safety. None of those are adequate for the identification of the coldest point of thermally processed foods. Microbiological assays are good indicators to determine the effectiveness of a process; however, the procedure has limitations as the process is time-consuming, expensive, subject to recovery and contamination problems, and requires large population changes as evidence of the process. The use of effective chemical marker techniques developed by United States Army Natick Research Center has been reported to be an alternative technique to quantify the time–temperature history of food products to assess heating uniformity in sterilized foods. Three markers have been in use for food systems, namely: 2, 3-dihydro-3,5-dihydroxy-6-methyl-(4H)-pyran-4-one (M-1), 4-hydroxy-5-methyl-3(2H)-furanone (M-2), and 5-hydroxymethylfurfural (M-3) [51]. The marker yield can be correlated with the time–temperature effect within food systems provided the kinetic information is obtained. The formation of intrinsic chemical markers is described as first-order reaction kinetics, taking into consideration an excess source of either the protein or ribose/glucose precursor in food materials [61]. Since both marker formation and bacterial destruction are functions of the time–temperature profile, verification of calculated marker formation using experimental studies is analogous to verification of bacterial destruction in sterilization. The marker formation kinetics of ham and whey proteins has been well compared to experimental and mathematical models by Zhang et al. [62].

The yield of M-2 in whey protein gels as model foods was used to quantitatively assess the heating uniformity of MWs

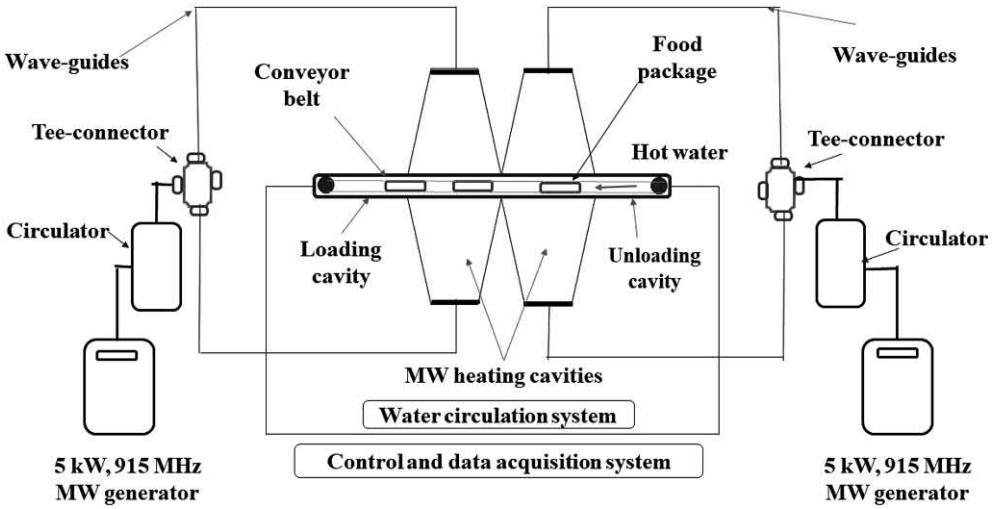

FIGURE 42.6 Pilot-scale MW-assisted sterilization system.

at 915 and 2450 MHz [63]. M-2 well predicted a HTST process, while M-1 was found to be more relevant for longer thermal processes [64]. Kim and Taub [61] evaluated the kinetics of M-1 in broccoli extract at sterilization temperatures (116–131°C) practiced in the food industry. Zhang et al. [62] evaluated the concentration of marker compound formed (M-2) during heating of whey protein concentrate solution and ham, and experimental data combined with numerical analysis were reported to result from an accurate and comprehensive study of the sterilization process. The marker yield increased beyond a temperature of 100°C, and the maximum was at 121°C. Lau et al. [64] studied the chemical marker formation of 4-hydroxy-5-methyl-3(2H)-furanone (M-2) in a model food system (20% whey protein gel) to identify cumulative time–temperature effects in high-temperature-short-time processes at 915 MHz. The formation of M-2 occurs from D-ribose and amines through non-enzymatic browning reactions and enolization under low-acid conditions (pH > 5). M-2 formation follows first-order reaction kinetics and can be used for determining the cumulative heating effect in a model food system subjected to MW heating.

However, the main limitation of using the chemical marker technique in real foods is the inconsistency of food composition in the food system leading to potentially large variations in the measurements of the marker yields. In addition, the heating pattern changes with food materials, placement of foods in ovens, and oven design, and therefore a combination of a coupled thermo-electromagnetic model along with experimental measurement of marker formation could provide a better picture of MW sterilization.

42.11 LIMITATIONS AND FUTURE OF MW HEATING

MW sterilization has been studied extensively for the academic and industrial sectors. However, the commercialization of the process has had only limited success [29]. The major drawback in the MW sterilization is the non-availability of actual temperature profiles. The measurement of temperatures at a few locations does not guarantee the real temperature distribution of the product during MW heating as the heating pattern can be uneven and difficult to predict, and can change during heating. Therefore, researchers in the field have found inconsistent outcomes.

Second, it is not always true that the MW-assisted process results in better quality retention of food products. The degradation kinetics of either quality, sensory, or nutritional aspects depend upon many factors like the nature of the food products, food geometry, dielectric properties, and oven designs as compared to conventional thermal processing. The dielectric properties of the food product significantly vary during heat processing and especially at or above 80°C for protein and starches, and simultaneously the heat absorption process. These changes in dielectric properties could affect the heating pattern qualitatively while such factors are not serious in conventional thermal processing. Coupling of heat transfer and electromagnetics could serve to account for changes in dielectric properties during thermal treatment [62].

The novelty of the MW sterilization process depends on the proper selection of equipment and packaging which could assure its success in food processing industries. Laboratory processing equipment is also essential for process refinement and to study the effect of process and storage time on product quality attributes, and microbiological safety factors. It is well-recognized that MW sterilization can produce high-quality shelf-stable food products. Only the most recent work had the benefit of suitable barrier packaging material. However, the earlier work recognized the need for suitable barrier material. Recently, few packaging material suppliers have shown serious interest in this process.

42.12 RECOMMENDATIONS FOR MW PASTEURIZATION AND STERILIZATION

Based on views and research outcomes of several experts in the field of MW technology applied to food, the U.S. Food and Drug Administration published the following recommendations in 2002 for better heat transfer and temperature management in MW heating:

1. Temperature distribution in food during and after MW heating is different from that using the conventional heating method. Therefore, the temperature should be measured with various techniques for a more reliable record of temperature distribution. The temperature should be measured in as many places as possible to predict more accurate information and time–temperature history of the product during MW thermal processing.
2. Information on the coldest point and its location are of primary importance for the microbial safety of sterilized food. As heating patterns can change dramatically for various food materials, different placements in the oven and different oven designs and, since the patterns can also change during heating, a combination of a coupled thermal-electromagnetic model complemented with experimental measurement of marker formation are needed for a comprehensive and repeatable MW sterilization.
3. To obtain MW heating uniformity of multi-component food systems is dependent on food component placement and geometry of products and packages. Placement has the most significant effect. The temperature distribution should be balanced partly by taking advantage of edge and corner heating intensification.
4. A combination of the thermal-electromagnetic model and marker formation kinetics should be used to describe MW sterilization in a comprehensive way. Coupling of heat transfer and electromagnetics is important to consider for significant changes in dielectric properties during the heating of foods. The model

predictions should be verified by obtained experimental data involving chemical marker yields that are functions of the time–temperature history of the material.
5. The time–temperature history and thus the sterilization vary spatially in a very significant way. Additionally, heating changes the relative spatial variation in sterilization. The spatial non-uniformity of sterilization and its transient changes can be improved significantly by changing the material's dielectric properties, which are a function of its composition. The effect of salt content was found to be particularly pronounced.
6. To improve the MW heating efficiency and desirable sensory characteristics of foods, the combination of MWs with other modes of heating such as infrared heating (IR) and jet-impingement can be used.
7. Applying MW energy at a lower frequency, e.g., 900 MHz, would show higher penetration depths in materials such as foodstuffs.

42.13 CONCLUSION

MW energy has advantages over conventional heating. The application of MW energy for pasteurization and sterilization has been studied for about half a century with some commercial success. Some researchers have claimed non-thermal or enhanced thermal effects to be associated with MW heating on the destruction of microorganisms and inactivation of the enzyme, but the issue remains controversial. Continuous-flow microwaveable pasteurizers could be used for milk and juice processing. MW pasteurization of ready-to-eat meals has also been found to be a commercial success in the European countries while US industries are still reluctant to adopt the technology. The replacement of conventional heating by MW energy source is not possible without fully understanding the real heating and inactivation mechanisms, temperature distribution in multilayered foods, and other critical factors. The qualitative and significant change in heating pattern has to be taken into consideration in the calculations of marker yields by coupling the electromagnetics with energy transfer in MW sterilization. Currently, more emphasis has been placed on the sterilization of solid foods using MW energy. Commercial-size MW equipment is now readily available for pasteurization and sterilization applications. Some reasons cited for the lack of commercial success in operation are complexity, high expenditure, non-uniformity of heating, inability to ensure sterilization of the entire package, lack of suitable packaging materials, and unfavorable economics when compared to prepared frozen foods in developed countries.

43 Ultrasound in Food Processing and Preservation

P. J. Torley, T. T. Truong, and B. Bhandari

CONTENTS

43.1 INTRODUCTION

The effects of high-power ultrasound waves on the physical, biochemical, and microbial properties of foods have attracted a great deal of interest in recent years. This is because ultrasound can produce a variety of effects depending on the ultrasound wave characteristics and product characteristics. Ultrasound can be used to characterize the products as non-destructive or to produce physical transformations. Ultrasound

is important in many situations, including natural systems (e.g. communication between rats at ultrasonic frequencies [1]; echolocation by bats and dolphins; detection of ultrasound signals by fish and moths to avoid predators [2, 3]), engineering design to minimize cavitation (e.g. erosion of impellers in pumps [4], non-destructive evaluation of manufactured products [5], enhancing the efficiency of industrial processes [6, 7]), detection of underwater vessels and oceanography [8], identifying fish stocks [9], medical imaging [10], surgery [11], and physiotherapy [12]. Many of the techniques used in these situations have parallels in food processing, where ultrasound can either be used to monitor processes while minimizing any effects on product characteristics, or to become directly involved in the process, helping to bring about physical transformations in the product. This chapter will focus on the latter aspect, and will include an overview of the history of ultrasound development, the basic principles underlying the effects of sonication on properties of food systems, and the use of ultrasound in food processing, particularly microbial inactivation, heat and mass transfer, and homogenization.

With such a broad range of applications, the history of ultrasound research, development, and application is extremely complex. Systematic studies of physical, chemical, and biological effects produced by ultrasound began in the early 1900s. In 1917, Lord Raleigh developed a mathematical model for cavitation bubble collapse while investigating the problem of high-speed propeller erosion [13]. Also in 1917, Langevin discovered that sound rays killed fish while studying sonar for antisubmarine warfare. The late 1920s was also an important time in ultrasound research with potential applications in the food industry, with a number of important ultrasound effects [14, 15]. During this time various researchers reported that ultrasound could be used to rupture microorganisms, emulsify oil and water, atomize liquids, cause agitation inside individual plant, animal, and amoebae cells, accelerate chemical reactions, and degas liquids. Mechanisms to explain the effects of ultrasound were identified, including heating, agitation, aggregation, and cavitation [14]. There are a number of reviews available that can be consulted for a more complete history of ultrasound development [13–17].

43.2 BACKGROUND

43.2.1 Sound Waves

Ultrasonic waves are similar to sound waves, but their frequencies are far too high for perception by the human ear. Transmission of sound occurs due to ordered and periodical movements of the molecules of the media, with motional energy passed on to adjacent molecules without transfer of matter. Typically, the range of frequencies perceived by humans is 20 Hz to 20 kHz, while ultrasound is from about 20 kHz to 1.2×10^{10} kHz (the highest frequency that can be transmitted by solids or liquids). Ultrasound has the properties of sound waves, such as reflection, interference, adsorption, and scattering, and can be propagated through solids, liquids, and gases [18, 19].

Sound waves can be either parallel or perpendicular to the direction of travel through the material, and are respectively termed as longitudinal and transverse waves (shear waves) (Figure 43.1). In transverse (shear) waves, particle motion is perpendicular to the direction of wave propagation. As liquids and gases do not support shear stress under normal conditions, transverse waves can only propagate through solids. The velocity of these waves depends on the material (Table 43.1) and is relatively low as compared to longitudinal waves.

In longitudinal waves, the direction of particle motion is the same as the wave motion. These waves are capable of traveling in solids, liquids, or gases, and thus are widely used in ultrasonic applications. Longitudinal waves have a short wavelength with respect to the transducer dimensions, producing sharply defined beams, and have a high velocity (Table 43.1). The longitudinal velocity is dependent on the state of the material and so can be used to follow processes such as freezing of orange juice [20], meat [21], or solidification of fats [22]. It is also sensitive to differences in structure, such as fiber orientation in meat [23] and comminute meat composition [24].

43.2.2 Wave Characteristics

The fundamental parameters that characterize ultrasound waves are velocity (c), wavelength (λ), frequency (f) amplitude (A), and intensity (I). Velocity is the propagation speed of a sound in a medium and is related to wavelength and frequency:

$$c = \lambda f \tag{43.1}$$

It depends on the physical properties of the medium through which waves propagate. For solids and liquid, velocity is related to density (ρ) and Young's modulus of a solid, or bulk modulus of elasticity for a liquid (K):

$$c = \sqrt{\frac{K}{\rho}} \tag{43.2}$$

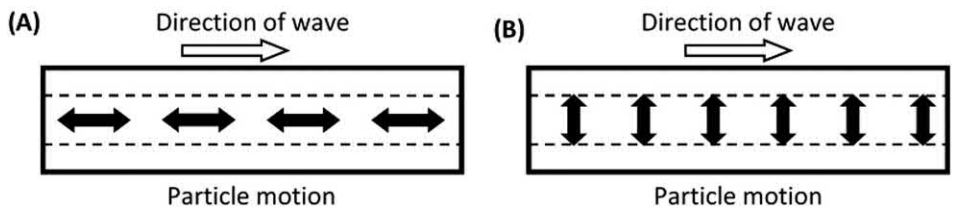

FIGURE 43.1 Types of sound wave: (A) longitudinal waves (B) transverse (shear) waves.

TABLE 43.1
Velocity of Transverse and Longitudinal Sound Waves in Different Materials

Material	Wave Type	State	Velocity (m/s)
Air	Longitudinal	Gas, 20°C	344
Aluminum	Longitudinal	-	6374
	Transverse	-	3111
Water	Longitudinal	Water Vapor	500
		Water, 25°C	1498
		Ice	3760
	Transverse	Ice	2000
Orange juice [20]	Longitudinal	Liquid, 20°C	1540
		Frozen, −20°C	3310
Beef (direction of ultrasound signal either parallel or perpendicular to muscle fiber orientation) [23]	Longitudinal	Warm, 37°C	1595
		Perpendicular	1605
		Parallel	1525
		Chilled, 0°C	1531
		Perpendicular	2870
		Parallel	2930
		Frozen, −9°C	
		Perpendicular	
		Parallel	
Fat content of meat mixtures [24]	Longitudinal	100% lean meat	1543
		50% lean meat/50% fat	1584
		100% fat	1617
Olive oil [22]	Longitudinal	Liquid, 60°C	1490
		Solid, −30°C	1990

For gases, the relationship includes the pressure (P) and the specific heat at constant pressure (C_p) and specific heat at constant volume (C_v):

$$c = \sqrt{\frac{C_p P}{C_v \rho}} \tag{43.3}$$

Wavelength is the distance between adjacent wave crests (Figure 43.2), while frequency refers to the number of wave crests that pass a point in a unit time, and resembles the vibration of the wave generator. The ultrasound wavelength at 20 kHz frequency in water at 25°C is around 7.5 cm, whereas in more dense systems (such as in muscle or bone) it will be higher, and in the air it is around 1.65 cm.

Amplitude is the height of the wave, and it determines the wave strength. Amplitude is related to the energy contained in the wave:

$$E \propto A^2 \tag{43.4}$$

Amplitude refers to the motion of the ultrasonic source, the motion of the receiver of the sound, or the motion of the medium through which the sound wave is passing. Intensity is a measure of the flow of acoustic energy through a unit area of the medium in a unit time. As sound waves pass through any real medium or biological tissue, the intensity of the signal decreases with distance of travel due to scattering of the sound waves and absorption of part of the sound energy

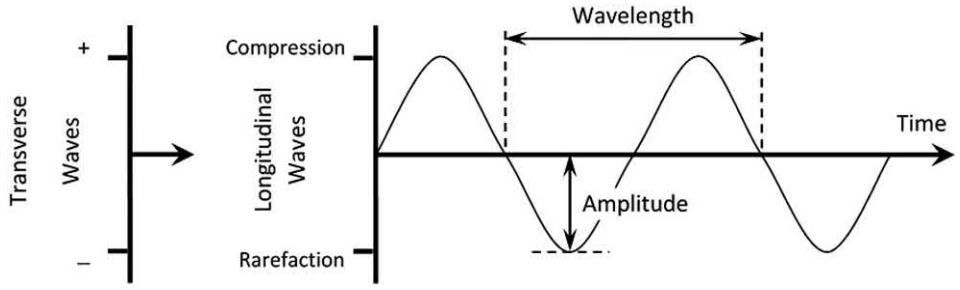

FIGURE 43.2 Transverse and longitudinal wave characteristics.

by the material. The absorption of sound is due to a number of mechanisms: viscous losses, heat condition losses, and losses due to molecular exchange of energy [18]. Scattering is caused by interfaces between materials with differing acoustic impedances (sound reflection properties). The heterogeneity in a material can greatly increase attenuation when there are large differences in the density of the two materials, such as gas bubbles suspended in a starch water gel. The decrease in intensity (I) follows an exponential pattern which depends on the initial intensity at the transducer (I_o), distance from the transducer (x), and the amplitude attenuation coefficient of the material (α):

$$I = I_o e^{-2 \alpha x} \quad (43.5)$$

The sound energy absorbed is converted to heat causing an increase in temperature. The heat production (Q_v) is related to the intensity of the sound (I) and the amplitude attenuation coefficient of the material (α):

$$Q_v = 2 \alpha I \quad (43.6)$$

The amplitude attenuation coefficient varies between materials, and with the frequency of the sound. Generally, the absorption coefficient increases with increasing frequency and in biological systems can vary markedly between materials [25].

43.2.3 Cavitation

In liquid media, the best-known effect of ultrasound is cavitation. When an intense sound wave passes through a liquid, it creates regions of compression (positive pressure) and rarefaction (negative pressure). If the negative pressure during rarefaction is high enough, a cavity or bubble can be formed in the liquid. There are two main types of cavities: transient (also called "inertial") and stable (also called "non-inertial"). Each of them demonstrates a different type of behavior of a gas bubble that is subjected to an ultrasonic field [26].

Transient cavitation occurs when a cavity that is exposed to ultrasound vibration progressively increases in size over a number of compression and rarefaction cycles until it reaches a size where it collapses violently [27]. During cavity collapse, very high, but localized, temperatures, pressures, and cooling rates occur. A theoretical study has estimated the temperature created as being up to 10,000 K, pressures of up to 100 MPa (though an experimental study suggests 0.01 to 0.5 MPa [7]), and cooling rates in the order of 10^{10} K/s [28]. It is also reported that an electrical field can occur at the interface when a cavity is fragmented [29].

Long-lived gas bubbles are called stable cavities and will exist for many compression and rarefaction cycles [30]. They are produced at relatively low ultrasound intensities (1 to 3 W/cm^2) and will oscillate for a number of cycles, often nonlinearly about some equilibrium size without collapsing [31]. While the conditions within stable cavities are not as extreme as transient cavities, relatively high pressures and temperatures (estimated at about 1650 K) still occur, which allows them to influence chemical reactions.

Whether or not cavitation occurs depends on a variety of factors including the frequency of the vibration (increasing frequency increases the power required to produce cavitation), intensity of the vibration (related to amplitude), solvent viscosity, surface tension and vapor pressure, attenuation of the vibration by the medium (greater attenuation at higher frequency), the presence of gas bubbles as cavitation nuclei, and the ambient temperature and pressure [31].

43.2.4 Liquid Flow and Bubble Movement

Both the large and localized agitation produced by ultrasound is of considerable practical importance. Ultrasound agitation is the origin of at least part of the beneficial effect of ultrasound in process, such as heat and mass transfer, emulsification, cleaning of surfaces, and polymer degradation.

Microstreaming occurs due to the growth and shrinkage of the cavitation bubbles during cycles of rarefaction and compression [32]. The rapid movement of liquid caused by changing bubble size causes shear; however, the effect is limited to about one bubble diameter. Microstreamers are bubbles that form at a nucleation site and then move through the acoustic field to a pressure antinode (if the bubble diameter is less than resonance size) or pressure node (if larger than resonance size) [26, 32, 33]. Resonance size is determined by the properties of the liquid and acoustic wave frequency, and it is the size where the applied frequency produces large changes in bubble diameter. Owing to differences in the speed of bubble movement depending on whether they are in the compression or rarefaction part of the acoustic wave, microstreamers are able to move faster than the average liquid velocity.

When a transient cavitation bubble collapses, there is a rapid inflow of liquid from all sides causing high localized shear rates and shockwaves in the surrounding liquid [31]. If a transient cavitation bubble collapses when it is close to a solid surface a micro-jet is formed. In this situation, the solid surface means the liquid will not be able to flow in from all sides, creating a non-symmetrical flow that directs a micro-jet of liquid at the solid surface [26, 31, 34]. The jet of liquid has a relatively high velocity (about 100 m/s), though it is a relatively short-range effect (about a bubble diameter) [32]. Depending on the circumstances, micro-jets may have advantageous effects (e.g. cleaning surfaces, pitting increasing surface area for reaction), while in other situations they may be damaging (e.g. pitting of ultrasound probe tips, erosion of propellers). An analogous situation occurs at the interface between two immiscible liquids, where micro-jets can produce an emulsion.

There can also be movement of bubbles in acoustic fields due to the density difference between the gas bubble and the liquid medium. When the cavity forms, gas can progressively diffuse into it from the surrounding medium, or the bubble

can coalesce with other bubbles, progressively increasing in size until it floats to the surface. This is the basis of ultrasound degassing of liquids [35].

43.2.5 Sonochemistry

Sonochemistry is the term for chemical reactions performed under an acoustic field, commonly ultrasonic. The field has developed as it has been found that ultrasound produces a range of effects on chemical reactions in treated materials, including free radical formation, increased reaction rates, less extreme processing conditions (e.g. lower temperature, pressure), reduced induction period, easier initiation of difficult reactions, improved catalyst efficiency, permitting the use of less refined raw materials, reduced number of processing steps, alteration of the reaction pathway, and sonoluminescence [31, 33, 36, 37]. Sonoluminescence is the light emitted during the collapse of either stable or transient cavities due to the generated pressures and temperatures [38].

Within the collapsing cavity, there are extreme pressures, temperatures, and cooling rates, along with gas or vapor from the liquid medium. These conditions are capable of creating hydroxyl radicals from water, which can react with other chemicals in the cavity, or diffuse into the liquid medium where they can react with other compounds. Other reactions are possible if there is a volatile compound present in the liquid medium. The volatile compound can diffuse into the cavity during expansion, and can undergo chemical reactions during collapse of the cavity.

In addition to chemical reactions caused by the diffusion of reactive species or reaction products into the liquid medium, cavity collapse can affect the chemical reactions in the liquid medium. The high shear created by cavity collapse may also cause breaks in polymer chains, or increase reaction rates due to an increase in the kinetic energy of molecules, or alter interaction within the solvent.

Ultrasound waves can alter chemical processes at surfaces, with different effects depending on whether they are large, small, or liquid surfaces. There can be mechanical damage to the solid material, with shock waves and micro-jets causing surface damage including pitting of solid surfaces, fragmentation of brittle materials, deaggregation of groups of particles, and high-velocity collisions between small particles accelerated by ultrasound causing in some instances abrasion and in others, fusion. Such changes can alter chemical reactivity, for example through increased surface area, the removal of contamination from the solid surface such as oxidation from metals. With immiscible liquids, cavitation at their interface can create emulsions that greatly increase the area of contact between the two materials.

While the main focus of sonochemistry is the cavitation-related effects, the non-cavitational effects of ultrasound can play a role in chemical reactions. Ultrasound agitation of liquids improves mass transfer, and heating of the material due to energy absorbed from the ultrasound waves can increase the rate of chemical reactions.

43.3 ULTRASOUND INSTRUMENTATION

43.3.1 Transducers

A transducer is a device that converts one form of energy into another form. In ultrasonic applications, the transducers are designed to convert mechanical or electrical energy into high-frequency sound. There are two main types of transducers: mechanical and electroacoustic [7]. Mechanical transducers rely on the flow of either a liquid or gas through a siren, rotor, turbine, or whistle to generate ultrasound. Electromechanical transducers are widely used in modern ultrasonic applications and are based on the inherent electrostrictive phenomenon in certain materials to produce piezoelectric or magnetostrictive transducers [7].

43.3.2 Ultrasonic Equipment

There are different types of ultrasonic apparatus commercially available for small- or large-scale power ultrasound applications, including whistle reactors, ultrasonic baths, and probe systems [31, 35]. A whistle reactor uses a mechanical ultrasonic source that relies on the stream of liquid flowing past a metal blade to cause vibration [31, 35]. The frequency of the vibration depends on the liquid flow rate, with flow rates high enough to be able to generate ultrasound which can cause cavitation in the liquid. These sorts of systems can be used for high-power liquid processes such as homogenization, emulsification, and dispersion.

Ultrasonic baths are cheap, simple, and versatile, being made up of a metal bath with one or more transducers attached to the walls of the tank [31, 35, 36]. Items can be directly immersed in the bath for ultrasound treatment, though the maximum power input is generally relatively low (about 1–5 W/cm^2).

Probe systems consist of a metal horn coupled to an ultrasonic transducer, with the metal horn used to amplify the vibration produced by electrostrictive material (normally piezoelectric) in the transducer [7, 27]. Amplifying the vibration produced by the transducer is necessary as the amplitude of waves produced by piezoelectric materials is too small to have a useful effect. An appropriate horn design increases the amplitude of the vibration at the face of the horn. Probe systems have the advantages that they can be placed directly in or against the material being processed, their power can be controlled, and they can produce ultrasound intensities of up to several hundred W/cm^2 [30, 35, 36]. Disadvantages of the probe system include erosion of the horn tip by cavitation, free radical formation, and heating of the material exposed to ultrasound. Tip erosion by cavitation can cause contamination of the material by metal from the horn as well as a gradual change in horn length which will affect its efficiency.

A number of systems have been developed to overcome some of these limitations, including the cup horn, flow cell, and tube reactor. The cup horn system contains an ultrasound probe that incorporates a cooling system [36], with the cooling liquid (typically water) used as the coupling medium to transmit vibrations from the probe tip to the reaction vessel.

This approach allows better temperature control than bath or simple probe systems, though the reaction vessel size is limited and power input into the reaction vessel is reduced compared to a probe placed directly in the material being processed. The flow cell is a continuous system where the ultrasound probe is placed directly in a liquid that is being pumped through a cell, with treatment only occurring while the liquid is inside the cell [31, 36]. This allows high-intensity treatment and control over the temperature rise by controlling the residence time of the liquid. In tube reactors, the liquid is treated with ultrasound as it is pumped through a zone fitted with some form of ultrasound generator [31].

43.4 ULTRASOUND IN FOOD PROCESSING

The application of ultrasound in food processing has been of interest for many years, with researchers investigating its potential as a means of monitoring a process or product, or as a way of altering the properties of a process or product. Low-power, high-frequency ultrasound (<1 W/cm^2; >100 kHz) is normally used to monitor food products or processes. The use of ultrasound monitoring has been evaluated in a wide range of food systems including meat, fats and oils, milk, bread, fruit, and sauces [18, 19, 25], with various parameters, particularly velocity (m/s), attenuation (dB/m), and impedance (kg m/s), or related parameters, used to measure characteristics such as composition, phase changes, and particle size distribution.

High-power, low-frequency ultrasound (10 to 1000 W/cm^2; 20 to 100 kHz) is normally used to alter the properties of a material or affect the progress of a process. It does this through physical, chemical, and mechanical effects (Table 43.2). Ultrasound can affect food properties; however, it is common to use it in combination with other processing technologies to improve the efficiency of the process.

43.5 ANTI-MICROBIAL EFFECTS

The use of ultrasound as an antimicrobial treatment, either alone or in combination, has been of interest for many years for use in food products, or to remove contaminating microorganisms from foods and processing surfaces [39–44]. The antimicrobial effect of ultrasound is largely due to the localized, but extreme, pressures and temperatures produced during cavitation leading to damage to cell walls [41], with possible contributory effects due to direct thermal effects from the localized heating, production of free radicals causing damage to DNA, and microstreaming causing thinning of cell membranes [39, 40, 42].

43.5.1 Sensitivity of Different Microorganisms

Ultrasound treatment has been shown to be an effective antimicrobial treatment, destroying a variety of microorganisms, including bacteria [40, 45, 46], bacterial spores [47–49], yeast [50–52], fungus [45, 53, 54], fungal spores [55], protozoa [56], and viruses [45]. Comparative studies of the sensitivity of different microorganisms show the effectiveness of ultrasound varies widely, with even closely related microorganisms showing differences in sensitivity [57, 58]. In general, spores [46–49, 59] and some viruses [45] are difficult to inactivate with ultrasound. Gram-positive bacteria are less sensitive to ultrasound than Gram-negative bacteria [46, 60, 61], though no difference between Gram-positive and Gram-negative

TABLE 43.2
Some Applications of High-Power, Low-Frequency Ultrasound in the Food Industry

Application	Description	References
Anti-microbial effects	Microbial destruction, microbial removal from surfaces	[39–42, 68, 69, 237–240, 70–73, 75–77]
Heat transfer	Increase the rate of freezing, thawing, and cooking	[178–180, 182–184, 187–189]
Mass transfer	Increase the rate of mass transfer in drying (solid, liquid, and osmotic drying), brining, membrane separation, dewatering, and bed filtration	[78–93, 96–99, 101–105, 109, 115–117, 181, 241, 242]
Meat processing	Meat tenderization	[104, 105, 183, 184, 224–227, 229–231, 243]
Homogenization, emulsification, and encapsulation	Homogenize and emulsify milk, mayonnaise	[35, 63, 207, 219, 220, 244–247]
Fermentation and ageing	Increase rate of fermentation and ageing (e.g. wine)	[248–253]
Crystallization	Control of nucleation and crystal growth	[6, 35, 131, 254]
Cutting	Cut fresh and frozen food products, including composite or multilayer foods	[255]
Defoaming, defrothing, and degassing	Defoam carbonated drinks, beer, and other liquids during canning; defoam microbial fermenters; remove dissolved gasses from liquids	[7, 35, 90]
Cell disruption and extraction	Enhance extraction of compounds (e.g. enzymes, proteins, fruit juices, essential oils)	[13, 53, 256–258]
Enzyme activity and protein denaturation	Enzyme inactivation; protein denaturation; enhance enzyme activity	[196–200, 202, 205–209, 216, 217, 259, 260]
Polymerization and depolymerization	Polymerization and depolymerization of polymers	[28, 30, 261]

bacteria has been found [45]. It has also been observed that rod-shaped bacteria tend to be more susceptible than coccus-shaped bacteria [61], and that larger cells are more susceptible than smaller cells [42].

43.5.2 Effectiveness as an Anti-Microbial Treatment

While ultrasound used by itself can kill microorganisms, it is a relatively inefficient process, with extended processing times required to produce a significant reduction in microbial numbers. As a result, research into ultrasound as an antimicrobial treatment has largely focused on combining ultrasound with other treatments, particularly heat treatment (also termed thermosonication), pressure treatment (manosonication), and combined heat and pressure treatments (manothermosonication) [39, 42, 44], with less attention paid to its use with other treatments such as pulsed electric fields, antimicrobial chemicals, and pH [43, 46].

The lengthy processing required to destroy some microorganisms and particularly spores at temperatures well below temperatures used for conventional thermal treatment makes ultrasound an unattractive treatment. The D value of vegetative *Staphylococcus aureus* treated with ultrasound (20 kHz, 150 W, 40 ml sample volume) was 36.5 minutes at 11.2°C in phosphate buffer, and 187 minutes at 13.5°C when suspended in ultraheat-treated milk [62].

Ultrasound treatment of bacterial spores can have little effect at low temperature, with no reduction in *Bacillus stearothermophilus* spore numbers by an extended ultrasound treatment at 12°C (20 kHz, 120 W, 50 ml sample volume), though there is the release of low molecular weight materials [49]. *Clostridium sporogenes* and *Bacillus cereus* spores suspended in Ringer solution survived sonication (20 kHz, 500 W, 35°C) for 30 minutes, though combining ultrasound and 6% H_2O_2 proved an effective treatment [46]. Ultrasound was also reported to have an insignificant effect on the survival of *Clostridium botulinum* spores in honey [59].

Ultrasound produces a variety of effects that can be applied in dairy processing [63]. One effect that has been examined closely is its ability to inactivate microorganisms when used in combination with a heat treatment to give an effective method for the destruction of microorganisms present in milk [60, 62, 64, 65].

43.5.3 Ultrasound Combined with Heat and Pressure

Combining ultrasound with either pressure, temperature, or pressure and temperature treatments has proven a particularly popular approach as the length of ultrasound treatment can be substantially reduced [39, 42, 44]. Simply combining ultrasound with mild heat treatments has been found to increase the rate of microbial inactivation in a variety of microorganisms. *Streptococcus faecium* and *Streptococcus durans* had D values at 62°C (heat only) of 11.2 and 10.3 minutes respectively, while simultaneous heat and ultrasound (62°C, 20 kHz, 160 W) reduced D values by 84% and 91% respectively [58]. Yeast cells are destroyed more rapidly by a combined ultrasound and temperature treatment [52]. The D time for *Saccharomyces cerevisiae* was reduced by up to 63% by combined ultrasound (20 kHz, up to 180 W, 300 ml sample volume) and heat treatment (50°C or 55°C) compared to heat-only treatment [52]. The combined treatment was also successful with bacterial spores. The D value of *Bacillus subtilis* spores at 100°C was reduced by 38 to 84% (depending on strain and medium) by a combined heat and ultrasound treatment [47].

A limitation of combined ultrasound and thermal processing is that its effectiveness decreases with increasing temperature, as the increase in vapor pressure and the decrease in liquid surface tension and viscosity [47] reduce the cavitation effect [42]. To overcome this problem, processes combining ultrasound and pressure treatment, or ultrasound, pressure, and thermal treatments have been developed [42]. By pressurizing the material, cavitation can occur at higher temperatures, increasing the efficiency of microbial inactivation.

Even at temperatures well below the boiling point of the medium, using pressure during ultrasound treatment will affect microbial destruction. When different bacteria were treated by ultrasound (20 kHz, 117 μm amplitude, 40°C), increasing the pressure from 0 to 400 kPa produced substantially different decreases in D value for *Streptococcus faecium* (D value about 11 minutes at 0 kPa, 5 minutes at 100 kPa, 1.8 minutes at 400 kPa), *Listeria monocytogenes* (3.5, 2, and 0.8 minutes), *Salmonella enteritidis* (2, 1, and 0.4 minutes), and *Aeromonas hydrophila* (1.3, 0.8, and 0.4 minutes) [61]. However, when the results are expressed as a percentage, the variation in the decrease in D value is somewhat smaller, with a decrease in D value of 39 to 55% between 0 and 100 kPa, and 72 and 84% between 0 and 400 kPa [61].

Even closely related microorganisms show some differences in response to combined pressure and ultrasound treatment. When three *Salmonella* serotypes were ultrasound treated (20 kHz, 117 μm amplitude) at 40°C, increasing pressure from 0 to 50 kPa, the D value was reduced by 24 to 48% (depending on serotype), though at higher pressures the variation between serotypes was smaller. Increasing treatment pressure from 0 to 250 kPa decreased D value by 65 to 72% [57].

Combining pressure and thermal treatments further increases the antimicrobial effect of ultrasound. A combined pressure, thermal, and ultrasound treatment (20 kHz, 117 μm amplitude, 175 kPa) of *Salmonella enteritidis* gave D values that were lower than a combined thermal and ultrasound treatment at the same temperature [66]. The improvement from the combined pressure, thermal, and ultrasound treatment gave D values 68 to 91% lower at or below 60°C than the combined thermal and ultrasound treatment, but only 0 to 44% above 60°C.

The sensitivity of bacterial spores can also be increased by combined pressure, thermal, and ultrasound treatment. When *Bacillus subtilis* spores were pressure and ultrasound treated (200 kHz, 117 μm amplitude, 300 kPa) at 55°C and 70°C, only about 20% of the spores survived, while the heat-only treatment saw about 100% survival at the same temperatures [48].

43.5.4 Processing Medium

The processing medium can play an important role in determining the effectiveness of ultrasound as an antimicrobial treatment. When *Staphylococcus aureus* suspended in phosphate buffer received combined heat and ultrasound (20 kHz, 150 W, 40 ml sample volume) treatment, the D value was reduced by 60 to 65.5%, while the same treatment was less effective when suspended in milk, reducing the D value by 41 to 47% compared to a heat-only treatment [62]. A similar effect was seen with *Salmonella typhimurium*, where the number of survivors after ultrasound treatment was substantially higher in liquid egg (50% survival after treatment at 20°C for 15 minutes, 32% at 40°C) than skim milk (87% at 20°C, 19% at 40°C) or brain heart infusion broth (6% at 20°C, 16% at 40°C) [64].

Water activity can affect the effectiveness of ultrasound, with ultrasound proving more effective at higher water activity. When *Salmonella enteritidis* was treated with ultrasound (20 kHz, 117 μm amplitude, 58°C), the D value increased with decreasing water activity, from 0.22 minutes at a water activity above 0.99, to 1.53 minutes at water activity of 0.98 and 4.56 minutes at a water activity of 0.96 [66]. A similar pattern of increasing D value with decreasing water activity was also seen in samples exposed to a combined pressure, thermal, and ultrasound treatment (20 kHz, 117 μm amplitude, 175 kPa) [66]. While the water activity was not reported, incorporating 57% sucrose into the broth used to suspend *Listeria monocytogenes* before pressure and ultrasound treatment (20 kHz, 117 μm amplitude, 200 kPa, 40°C) increased the survival time, though adding 3% NaCl had no effect on survival time [67].

The pH of the medium can alter the effect of ultrasound treatment, with decreasing pH tending to reduce the survival of bacteria and yeasts [43]. Differences in the pH range of the ultrasound medium may help explain the relatively small variation in ultrasound's effectiveness against *Escherichia coli* suspended in UHT milk (pH 6.7), carrot juice (pH 5.9), or phosphate buffer (pH 7.0), and greater variation for *Lactobacillus acidophilus* suspended in either orange juice (pH 3.7) or phosphate buffer (pH 7.0) [65]. The survival of *Listeria monocytogenes* also decreased with a decrease in medium pH when treated with ultrasound (20 kHz, 117 μm amplitude, 200 kPa, 40°C), going from about 3.7×10^5 cfu/ml to 2.6×10^3 cfu/ml at pH 7, and from about 3.8×10^5 cfu/ml to 6.6×10^2 cfu/ml at pH 4 [67]. However, the decrease in pH had a much greater effect on the survival of *Listeria monocytogenes* when the samples were treated with heat (62°C) instead of ultrasound.

Differences in the viscosity of different mediums may explain some of the differences seen. The relatively higher survival of microorganisms in more viscous liquids is observed due to their high viscosity, protecting the microorganism by reducing cavitation. Ultrasound treatment was much less effective at reducing the level of *Salmonella eastbourne* suspended in milk chocolate than in peptone water. Other studies have shown that more viscous media can improve microbial survival, with slower destruction of *Bacillus subtilis* spores in glycerol than milk [47], and in egg than other media [57, 62, 64].

43.5.5 Decontamination of Food Surfaces

Raw fruit and vegetables used in some types of minimally processed foods have spoilage and possibly pathogenic microorganisms adhering to or entrapped in their surfaces. It is common to wash in water or water containing a sanitizer (typically 50–100 ppm chlorine) to reduce this microbial load. However, effective sanitizing is difficult as the bacteria can be difficult to destroy or remove as they are attached or entrapped in the uneven surface of the plant matter. Ultrasound can be incorporated in the sanitizing process to improve the effectiveness of the washing process, with combined ultrasound (32–40 kHz, 10 W/L of water) and chlorinated water giving a larger reduction (1.7 logs) in *Salmonella typhimurium* numbers on iceberg lettuce than ultrasound alone (1.7 logs), chlorinated water alone (1.6 logs), or washing in sterile water (0.7 logs) [68]. Larger-scale trials found that the product (parsley, strawberries, cabbage, and lettuce) and washing medium (water only, chlorinated water, or chlorinated water with a surfactant) had an effect on decontamination, while ultrasound frequency (0 kHz, 1.0 log reduction; 25 kHz, 1.4 logs; 32–40 kHz, 1.3 logs; 62–70 kHz, 1.3 logs) had no effect on decontamination [68].

Ultrasound treatment was found to be effective at reducing the concentration of *Salmonella typhimurium* on chicken breast skin [69]. Decontamination treatments in a chlorine solution (0.5 ppm free residual chlorine) reduced *Salmonella typhimurium* contamination by 0.2 to 0.9 logs, while ultrasound treatment (20 kHz, 100 W) reduced counts by 1 to 1.5 logs. A combination 0.5% ppm chlorine and ultrasound treatment was the most effective, reducing *Salmonella typhimurium* by 2.4 to 3.9 logs.

Combined chemical (acetic acid) and ultrasound treatments (frequency not given; 240 W; up to 320 seconds) have also been used to clean egg shells [70]. The ultrasound and acetic acid treated eggs were as clean as commercially washed eggs, and ultrasound and acetic acid treated eggs had the same sensory properties and foaming ability, and gave cakes with the same height as eggs cleaned in acetic acid without ultrasound.

43.5.6 Decontamination of Processing Surfaces

Cleaning of surfaces used for food processing is also important, as they can be a cause of cross-contamination. Ultrasound treatment can improve the removal of microbial spores from surfaces [71, 72]. However, the effectiveness of ultrasound recovery is affected by factors including the material, treatment time, type of microorganism, and presence of surfactants [71–73]. The material can affect recovery substantially, with the recovery of fungal (*Aspergillus niger*) spores from PVC (50%), frosted glass (60%), and plain glass (80%) being higher than stainless steel (10%) or HDPE (10%) [72, 74]. There was similar variation in the recovery of bacterial

(*Bacillus subtilis*) spores, with high recovery from glass (96%), and lower recoveries from the plastics (polystyrene, 24%; polypropylene, 53%; polyethylene, 41%; polycarbonate, 46%) [71]. Addition of a surfactant (Tween 80) enhanced ultrasound recovery for polystyrene (42%) and polyethylene (75%), but had little effect on glass (92%), polypropylene (51%), and polycarbonate (43%).

Ultrasound treatment has also been shown to be effective at removing protein contamination from knives in abattoirs [75] and milk biofilms on stainless-steel and polypropylene dairy processing equipment [76]. A number of studies have demonstrated the use of ultrasound in cleaning cheese molds [63]. In a practical investigation in a commercial chicken processing plant, ultrasound-assisted cleaning of plastic trays, steel baskets, and steel shackles was effective at reducing microbial and other contamination [77].

43.6 ENHANCEMENT OF MASS TRANSFER

Mass transfer plays an important role in many industrial processes, such as drying, dewatering, filtration, membrane separation, salting, osmotic dehydration, extraction, sonocrystallization, and rehydration. Ultrasound has been shown to improve the efficiency of many mass transfer processes either through a direct involvement in the process (e.g. cavitation, microstreaming, or acoustic streaming causing agitation to improve mass transfer, cavitation creating voids in the material), or supporting the process (e.g. agitation or microjet formation to assist cleaning). There has been substantial research into ultrasound-assisted drying, membrane filtration, osmotic dehydration, and sonocrystallization along with the related processes of cheese brining, meat curing, and rehydration of dairy powders. There has been substantial research into industrial applications of ultrasound-assisted bed filtration and dewatering [78–82], where it has been shown that ultrasound can substantially improve the efficiency of dewatering or filtration systems.

43.6.1 Drying

Drying is a mass transfer process involving the removal of liquid from a material, with the rate of drying dependent on factors such as the structure of the material, temperature, relative humidity of the air, and air velocity. In selecting drying conditions it is necessary to find a balance between conditions that maximize the drying rate and minimizing any undesirable changes these conditions will cause in the product.

As a result of the effects of ultrasound on material properties, incorporating ultrasound into the drying process can increase the rate of drying by reducing external barriers causing agitation in the drying medium close to the solid surface which reduces the thickness of the boundary layer [83] and internal barriers by enhancing internal liquid movement from the core of the material to the surface due to repeated compression and expansion or the creation of micro-channels in the solid that permit liquid movement [83]. Combining ultrasound and air drying has been shown to enhance the rate of drying in various products including carrots slices [84], onion slices [85], potato cylinders [86], wheat [87], corn [87], rice [88], and walleye pollack surimi (washed fish mince) [89].

While ultrasound is normally used with solids or liquids, as they provide a good medium for the propagation of ultrasound, various systems have been developed that will generate ultrasound in gases, such as the Galton whistle or a siren [30], or a piezoelectric transducer with radiating plate. Stepped-plate radiating plate designs have been developed which improve the efficiency of ultrasound generation when compared to conventional flat plate designs [90].

The effectiveness of sound or ultrasound frequency and intensity tend to depend on the particular combination of material, drying conditions, and ultrasound system. For example, in some instances in onion rings, the drying rate increases with an increase in sound frequency from 1.6 to 3.2 kHz (both at 140 dB) [85], while for green rice there was little difference between 12 kHz and 19 kHz, though relatively low intensities were used (132 dB and 128 dB respectively) [88]. With potato cylinders dried with combined hot air (120°F) and sound (0.7 kHz to 10.25 kHz), a sound frequency of 8.1 kHz was found to be most effective [86]; however due to the experimental set-up used, the sound intensity decreased with increasing frequency (142 dB at 0.7 kHz; 102 dB at 10.25 kHz) making the results more difficult to interpret.

The greatest benefit of combining ultrasound and air drying occurs at lower temperatures. In carrot slices, a combination of ultrasound and 60°C air took about 25 minutes to reduce carrot slice weight by 80%, while 60°C air alone took about 35 minutes [84]. By contrast, combined ultrasound and 115°C air drying gave no benefit over drying in 115°C air alone. In walleye pollack surimi, a combined ultrasound and air drying rate reduced the time to dry from 73% moisture to 60% moisture at 20°C from 260 minutes (0 dB) to 70 minutes (155.5 dB), while at 50°C drying time reduced from 100 minutes (0 dB) to 40 minutes (155.5 dB) [89]. A similar pattern, where the benefit from ultrasound treatment (11.7 kHz; 165 dB) decreased with increasing drying temperature, was also seen in whole and crushed wheat and crushed corn [87].

Another application of ultrasound in drying has been to assist the drying of liquid droplets. Incorporating ultrasound in a spray drying tower reduced the maximum temperature of the material during drying and reduced the size of the dried particles [91]. Ultrasound has also been used to further reduce the size of droplets originally produced by spraying a liquid through a nozzle, reducing the drying time required [92].

43.6.2 Osmotic Dehydration

Osmotic dehydration is a food preservation technology that involves soaking food products (generally fruits and vegetables, though also with cheese and meat) in a concentrated solution (e.g. sodium chloride and sugar). In a relatively slow process, water moves from the product into the high-concentration solution, solutes move from the solution into the product and there is movement of solutes from the plant cells into the high-concentration solution [83, 93–95]. Osmotic

dehydration can improve the sugar-to-acid balance, texture, and color stability, and is typically used as a pre-treatment before freezing or drying [93].

Ultrasound treatment has proven to be an effective technique at increasing the rate of osmotic dehydration. When apple cubes were dehydrated in a 70°Brix sucrose solution, the rates of water loss and sucrose gain were higher than in samples agitated in an oscillating water bath [96]. Ultrasound treatment was also able to increase the rate of osmotic dehydration of strawberry halves [97]. In strawberries that had been pre-treated with high pressure, a combination of osmotic dehydration and ultrasound treatment (35 kHz water bath) increased the water loss and solids gain compared to osmotic dehydration alone, though a combination of osmotic dehydration and vacuum was the most effective treatment.

Not all products respond in the same way to ultrasound-assisted osmotic dehydration. Differences in water loss or solids gain in products treated with osmotic dehydration or a combination of ultrasound and osmotic dehydration has been attributed to differences in the structure of the food product [83].

43.6.3 Cheese Brining

The manufacture of some cheeses and cured meats relies on the penetration of brine into the food product, as the salt alters the flavor and texture development, reduces water content, improves microbial safety, and contributes to the maturation of the product [98]. When brining is used with larger items, the process can be time-consuming as mass transfer can be relatively slow. Various methods can be used to improve the rate of brine penetration, such as agitation or tumbling, vacuum, increased brine concentration, increased brining temperature, ratio of brine to product, and needle injection. However, it is important to maintain finished product quality. For example, injection of brine directly into meat using multi-needle injectors is common in meat processing, but the path where the needle penetrated is sometimes obvious in the cooked product.

Ultrasound can improve the brining process in cheese, increasing the rate of water loss and sodium chloride gain from small cheese blocks (cylinders 34 mm in diameter and 30 mm high; parallelepipeds of 60 mm by 25 mm by 12.5 mm) [98]. The benefit of ultrasound occurred over a range of temperatures (5 to 20°C), and was noticeable when compared to static or agitated brining. In larger samples (parallelepipeds of 140 mm by 140 mm by 90 mm), ultrasound treatment increased the initial sodium chloride penetration particularly at the surface [99]. However, the moisture content diffusion rate was lower in ultrasound-treated cheese than conventionally treated cheese, and both ultrasound and conventionally brined cheeses reached a consistent sodium chloride distribution after the same maturation time [99]. The use of ultrasound brining can affect other characteristics, with more rapid formation of free amino acids [100] and free fatty acids [101] during the maturation of acoustically brined cheeses, and differences in the sensory texture, aroma, odor, and taste between ultrasound and conventionally brined cheeses [101], though no differences were found in cheese microstructure [99].

43.6.4 Curing Meat Products

The functional properties of many processed meats rely on the partial solubilization of muscle protein in the raw meat (generally by sodium chloride or a combination of sodium chloride and polyphosphate) in order to increase the cook yield and to hold meat pieces together after cooking. One common approach used to make restructured meat products containing large pieces of meat is to tumble (mix) the meat chunks with the salts (added either as dry salts, or dissolved to form a brine), relying on the mechanical action to distribute the salts through the meat, and to solubilize part of the meat protein. The tumbling process is time-consuming, requiring several hours, and ultrasound has been used to reduce or eliminate the tumbling process.

A combination of treatment with ultrasound and tumbling gives products with equal or higher bind strengths and cook yields than meat tumbled without ultrasound [102, 103]. The increase produced by the combined ultrasound and tumbling treatment varies, with the largest increases occurring in meat with no added salt, with the effectiveness of ultrasound progressively decreasing [102] or disappearing [103] with increasing level of salt addition. Ultrasound also proved effective in meat when used without any tumbling. In meat injected with a brine, either a conventional tumbling process or ultrasound treatment (22 kHz) was used to distribute the brine through the meat [104]. The ultrasound-treated meat was more tender and juicier, with a higher production yield than tumbled meat. In all studies, ultrasound treatment affected the microstructure of the treatment, with greater separation of myofibrils occurring in the ultrasound only [105], or combined ultrasound and tumbling samples [102, 103] than in the tumbling-only samples.

43.6.5 Membrane Filtration

Membrane separation techniques, such as microfiltration, ultrafiltration, and reverse osmosis, are widespread in food processing to concentrate or purify materials for the dairy, beverage, and egg industries [106–108]. A disadvantage of membrane separation techniques is that they show a progressive decrease in flow rate due to fouling and concentration polarization. Fouling is a result of components from the feed being deposited on the surface or pores of the membrane, while concentration polarization occurs due to concentration gradients that develop due to the accumulation of retained components near the membrane [109]. Membrane systems are operated to minimize these problems so that they maintain their flow rate over the course of a day's processing (e.g. periodic flushing to remove fouling, feed flow velocity and turbulence to minimize concentration polarization) [108], and many strategies are employed to clean membrane systems [110]. Ultrasound can be used to improve the efficiency of both the membrane filtration process [111], and cleaning of fouled membranes [109]. Ultrasound-assisted membrane processing has been used successfully with a variety of food-related systems, including solutions of salt, polysaccharides and proteins, and yeast cell suspensions.

Membrane distillation is a process involving the membrane separation of a vapor and a liquid, for example in desalination or concentration of solutions. Ultrasound increased permeate flux during membrane distillation by 5% to 30% compared to the conventional process [112, 113]. In addition to ultrasound's effect on concentration polarization and fouling found in other membrane separations, combining ultrasound with membrane processing also reduces temperature polarization (temperature gradient between bulk liquid and membrane).

The filtration of suspended solids can also be enhanced by ultrasound treatment. There was a higher flux when ultrasound was used in conjunction with microfiltration to dewater yeast cells suspended in water [114]. The benefit of ultrasound decreased as the liquid feed velocity increased, and at 0.53 m/s there was no additional increase in flux due to ultrasound [114]. Ultrasound treatment improved permeate flux during the microfiltration of baker's yeast suspensions with either continuous pump pressure and ultrasound, or intermittent pump pressure and ultrasound, and was also effective at cleaning a membrane that had been fouled during ultrasound processing [115].

The use of ultrasound in preventing or removing fouling of membranes [109] depends on ultrasound parameters (e.g. ultrasound frequency and intensity), the filtration system (e.g. intermittent or continuous ultrasound application during filtration, conditions during cleaning cycle, acoustic properties of the filtration membrane), attenuation of the ultrasound signal by the feed material, size of colloidal particles in the feed material, and the cavitation threshold of the feed material (viscosity, temperature, surface tension, pressure, dissolved gases, concentration). Ultrasound treatment does not affect membrane permeability, rather it helps prevent the decrease in permeate flow rate by breaking up fouling at the membrane surface or reducing the concentration polarization, though it may be less effective at removing material stuck in membrane pores [109].

One limitation of ultrasound in membrane processing is the potential for damage to the membrane through processes such as cavitation-induced erosion, acoustic streaming, and microstreaming. Some studies have shown that ultrasound affects membranes altering both permeability and microstructure, while others have found no effect [109]. This may be due to differences in susceptibility to ultrasound depending on membrane material [116, 117] and ultrasound parameters [117].

43.6.6 Extraction

Extraction is used to separate compounds out of their surrounding matrix. Utilization of ultrasound in extraction has emerged in the food industries due to its benefits in providing comparable effects to other novel extraction technologies (supercritical fluid extraction, high pressure processing, microwave-assisted extraction, and pulsed electric field) [118–122] and minimizing use of harmful solvents (i.e. chloroform, chlorobenzene, methanol, and acetonitrile) compared to the conventional solid–liquid extraction methods [123, 124]. Ultrasound-assisted extraction (UAE) used with non-toxic solvents such as water, ethanol, and sunflower oil has been investigated in a variety of food matrices to extract a range of compounds including carotenoids, phenolic compounds [125], natural pigments [126], oligosaccharides [127], polyphenols [128, 129], and anthocyanins [130].

Upon sonication, ultrasonic cavitation generates massive changes in temperature (2000–10,000 K) and pressure (100–1000 MPa) in the medium, leading to mechanical and cavitational effects on the extraction process. In the first stage, there is shear disruption that causes damage to the cellular matrix and particle size reduction [131]. Physical modification of the matrix surface creates pores that improve solvent penetration into the internal structure by mechanical effects, facilitating the disintegration of intracellular materials. Ultrasonic cavitation also induces the formation of microfissures and microchannels in the matrix surface that further enhances the penetration of the solvent into the matrix. In the second stage, an increase in surface area of the solvent–matrix interface allows a greater dissolution of extracting compounds to the solvent [132]. The mass transfer and diffusion of the target compounds into the solvent are also facilitated by turbulence mixing and acoustic streaming [133].

Process efficiency, extraction yields, and quality of extracting materials using the ultrasound method depend on various factors such as sonication parameter (ultrasonic power and frequency), extraction parameter (extraction time and temperature), solvent properties (polarity, viscosity, vapor pressure, surface tension, etc.), particle size of matrix, the ratio of solvent to matrix, and the interaction between solvent and matrix [134, 135]. For example, when extracting prebiotic oligosaccharides from selected fruits and vegetables using ultrasonic water bath at 40 kHz, the yield of total oligosaccharides increased two- to four-fold compared to that extracted by conventional methods. The optimum yield of total oligosaccharides can be achieved with a sonication temperature of 40°C, sonication time of 10 min, and ethanol concentration of 63% v/v [127]. A previous study performed on the extraction of phenolic compounds from grape pomace reported that the UAE method surpassed the conventional aqueous extraction method with a reduction of extracting time by three- to eight-fold depending on the sonicating temperature (20–50°C) [136]. Attempts have also been made to employ UAE in a solvent-free extraction system using vegetable oils as alternatives to organic solvents for extracting carotenoids in carrot and pomegranate wastes [137, 138]. These studies demonstrated that sonication and the use of vegetable oils improved extraction yield and reduced extraction time [138]. UAE can be combined with supercritical fluid extraction [139], microwave [140], high pressure [141], and enzymes [142, 143] to provide cumulative effects in extraction process.

43.6.7 Sonocrystallization

43.6.7.1 Ultrasound Treatment Alone

The crystallization of food systems can be categorized into supercooled and supersaturated crystallization [144]. Typically, the former involves freezing of food where water

transforms into ice crystals whose size, shape, and distribution can be modulated by the ultrasound technique. The application of ultrasound in the freezing of food is discussed in Section 43.6.1. Supersaturated crystallization is the main mechanism to induce condensation of solute from saturated solution, which plays a pivotal role in the crystallization of sugar, fat, and protein [144]. Conventional supersaturated crystallization (addition of seed crystals and use of an antisolvent) is reported to be time-consuming whereas the use of power ultrasound to assist crystallization or "sonocrystallization" is known to increase nucleation rate in the primary nucleation, induce fragmentation of crystals in the secondary nucleation, and facilitate crystal growth rate [145–149]. These advantages of sonocrystallization are based on the effect of acoustic cavitation bubbles acting as nuclei that accelerate the induction of nucleation and subsequent crystal growth. In addition, the cavitation effect also enhances movement of solutes and subsequent collisions of particles [150]. These effects lead to changes in supersaturation and reduce the metastable zone width whereby a controlled crystallization process can be achieved. The crystal habit (size, shape, and distribution) and product yield obtained by ultrasonic method are attributed to sonication conditions (frequency, power, intensity, pulse mode, and time) and levels of supersaturation (concentration and crystallization temperature) [151–154].

43.6.7.1.1 Lactose

Sonocrystallization of lactose resulted in the formation of smaller size, narrow size distribution [155–157], higher lactose recovery, and higher purity [153, 158, 159].

43.6.7.1.2 Edible Fats/Oils

High-intensity ultrasound (acoustic frequency 20 kHz, electrical power 50 W, and sonication time 10 s) also modified the crystallization behavior of edible fats, such as palm kernel oil, shortenings, and anhydrous milk fat. A decrease in induction time and a generation of smaller fat crystals influenced the polymorphic forms, melting behavior, microstructure, and texture of those fat samples [152].

43.6.7.1.3 Food Protein

When ultrasound (100 kHz and 100 W) was applied to an egg albumin solution, it was found that a sonication time of 10 s increased the nucleation rate whilst longer-term sonication tended to damage the crystal cluster due to excessive irradiation [160].

Apart from lactose, anhydrous milk fat, and egg albumin, the application of ultrasound to crystallization can also be found in other food products such as triglycerides, cocoa butter [161], soybean oil [162], and palm oil [163].

43.6.7.2 Ultrasound Treatment in the Presence of Dissolved Gases

The presence of dissolved gases (e.g. air, oxygen, carbon dioxide) in the food systems has a significant impact on ultrasound treatment, leading to changes in crystal size, number, and distribution. The presence and motion of gaseous bubbles themselves are capable of providing nucleation sites. In addition, any mechanical treatments (i.e. mixing, shaking, sonication, etc.) applied to the system can create nano- to micron-sized gaseous bubbles from the dissolved gas. The tiny gaseous bubbles can act as catalysts under sonication, causing a synergetic effect on crystallization behavior. As a result, the number of nuclei and resultant crystals is greatly increased whereby the physical properties of sonicated foods can be modified.

It has been reported that coupling dissolved oxygen and ultrasound (35 kHz, 1 s, 0.2 W/cm^2) in mannitol solution (10%wt) resulted in a substantial decrease in crystal size whereas uniformity in size of the single crystals was enhanced [164]. Recent studies performed on lactose and anhydrous milk fat have demonstrated that the addition of dissolved carbon dioxide at a concentration of 2000 ppm prior to the application of ultrasound (20 kHz, 1 min) could enhance the effects of sonication on facilitating the initiation of nucleation and the reduction of crystal size. This leads to an increase in lactose recovery with smaller crystal size compared to using ultrasound alone [157].

For lipid systems, the addition of carbon dioxide in sonicated materials can be beneficial for minimizing the lipid oxidation during storage which is accelerated by the presence of hydroxyl and hydrogen free radicals formed during the sonication of fats and oils. A similar effect has also been reported in sonication of carbon dioxide-infused gelatin gel at low frequency (20 kHz, intensity of 0.7 W/cm^2). The combined treatment caused a decrease in freezing time, ice crystal size of the gels, and water loss [165].

43.6.8 Rehydration of Dairy Powders

In order to utilize reconstituted dairy powders for food processing, it is important that they are completely dispersed and dissolved into solution. Thus the solubility of the reconstituted dairy powders is a key influential factor on functionality and product performance. Failure to rapidly achieve complete rehydration will cause economic losses due to time-consuming rehydration, processing difficulties, and decreased productivity [166].

Numerous studies have shown that reconstituted dairy powders enriched with protein and casein-dominant items such as milk protein concentrates (MPC) are prone to poor solubilization [167–169]. The poor solubility of MPC is not fully understood but is assumed to be induced by the formation of a network of crosslinked proteins on the surface of powder particles [170]. The rehydration of dairy powders involves two dissolution steps in which the disruption of primary particles occurs in parallel with the release of materials into aqueous phase [170]. The use of ultrasound is an effective physical approach to increase the dispersibility of poorly soluble milk powders as, owing to its generated cavitation effects, it can break the insoluble agglomerated masses into smaller particles, facilitating the simultaneous discharge of materials into the surrounding medium [171].

It was demonstrated on whey protein powders that low frequency (i.e. 20 kHz) surpasses high frequency in terms of

physical size reduction of primary particles. A considerable reduction in whey protein powder from 30 μm to 1 μm was achieved for the first 10 min of sonication at 20 kHz and 31 W [172]. Kresic and Lelas [173] also reported that sonication treatment at 20 kHz for 15 min increased the solubility of whey protein isolate up to 98.9%. McCarthy and Kelly [174] observed that ultrasonication at 20 kHz for a very short time period (0.5 min; energy density 10.5 J mL^{-1}) was sufficient to dissociate MPC powder particles into smaller ones, yielding 95.6% MPC solubility.

Low-frequency ultrasound also induces complete rehydration of MPC powders after 10 min of ultrasonication whereas mechanical stirring treatment took about 4 h to achieve a comparable solubility (85%) [175]. In contrast, high-frequency ultrasound (213–644 kHz) did not induce any size reduction of whey protein powders at 8% w/w solid concentration [172, 176]. A previous study performed on ultrafiltered and diafiltered milk protein retentates showed that ultrasonication can be used as an additional step prior to spray drying to improve the solubilization of dairy powders. When the milk protein retentates were sonicated at 20 kHz and 12.5 W for 0.5 min, the particle size decreased from 28.45 to 0.13 μm. The sonicated milk protein retentates were subjected to spray drying. The solubility of the resultant powder remarkably increased from 35.78 to 88.30% [177].

43.7 ENHANCEMENT OF HEAT TRANSFER

Sound and ultrasound can be used to enhance the rate of heat transfer during freezing [178-–181], thawing [182], and cooking [183, 184]. In the case of thawing and cooking, sound and ultrasound assist the process by increasing the rate of heat transfer with the surrounding medium and by absorption of sonic energy by the material. By contrast, in samples being frozen, the absorption of energy from sound waves which will reduce the cooling rate needs to be balanced against the improved heat transfer coefficient and also improved product quality produced by increasing ice crystal nucleation.

43.7.1 Freezing

Ultrasound can assist in the freezing process, both through decreasing the time required to freeze the food, and improving the quality of the frozen food [180]. Ultrasound can be used to increase the convective heat transfer coefficient [180, 185, 186] between the food being frozen and the refrigerant. Ultrasound also affects crystallization, increasing the nucleation rate and crystal growth rate [35]. As the freezing of water in food is a crystallization process, ultrasound can alter this process, possibly through cavitation bubbles being nuclei for ice crystal formation, or through collapsing cavitation bubbles shattering existing ice crystals creating more nuclei [179, 180]. Since reducing the size of ice crystals in frozen food helps to reduce damage to the food microstructure and improve the quality of the food when consumed, using ultrasound to assist freezing may improve the freezing rate and quality of the frozen product.

A disadvantage of using ultrasound to improve the freezing process is that ultrasound also generates heat, so the benefits of improved heat transfer and nucleation must be balanced against heating. In a study of freezing potato pieces ($76 \times 17 \times 17$ mm^3) in an ultrasonic bath (25 kHz), a power input of 7.3 W did not substantially affect the freezing rate (compared to no ultrasound), while 15.9 W and 25.9 W both decreased the time to go from 0 to −7°C, though 15.9 W gave a greater reduction in 0 to −7°C time than 25.9 W [179]. The limited effectiveness of 7.3 W was ascribed to the low intensity of agitation produced causing little increase in heat transfer. The greater effect on the cooling rate at 15.9 W than 25.9 W was attributed to the balance between the improved heat transfer between the refrigeration medium and the potato due to greater agitation, and the higher heat production due to greater energy input by the more intense ultrasound [179].

Selecting the appropriate ultrasound intensity also affected the microstructure of frozen potato [178]. The ultrasound treatment found to give the best freezing rate (15.9 W) was also found to minimize microstructural change. Immersion freezing combined with a 15.9 W ultrasound treatment gave tightly packed cells, with no observed cell wall damage, compared to no-ultrasound immersion freezing which caused cell wall damage and caused separation of the potato cells. Compared to the other ultrasound treatments, 15.9 W caused less damage than 7.3 W ultrasound treatment (prominent cell wall separation and intercellular voids), with a 25.9 W ultrasound treatment causing an intermediate level of damage compared to the 7.3 W and 15.9 W treatments [178].

43.7.2 Thawing

Large-scale thawing of frozen food is traditionally done with air or water thawing, though there is interest in emerging technologies such as high-pressure, microwave, ohmic, and acoustic or ultrasonic thawing [182]. Thawing techniques should minimize the thawing time, and minimize the formation of hot spots in the food that can damage quality (e.g. partial cooking, or increased microbial growth) while maintaining product quality.

Early attempts at ultrasound or acoustic thawing were not particularly successful, with the formation of hot spots, poor penetration, and high power consumption [187]. More recently, an improved understanding of the interaction between sound waves and food products has improved the results of acoustic or ultrasound thawing, including using ultrasound either to assist thawing [188], or as the only energy source for thawing [189].

It has been proposed that the absorption of ultrasound energy depends on the thermoelastic relaxation of ice crystals in the food, and is affected by ice crystal orientation and size, impurities present in the ice crystals, and temperature [188]. Studies in meat found differences in ultrasound attenuation depending on food temperature, with greater attenuation in frozen meat than thawed [190], and increasing attenuation as the temperature of frozen meat increased markedly above about −10°C reaching a maximum near its freezing point (about −2°C) before decreasing rapidly at higher temperatures

[191], making ultrasound particularly suitable for controllable thawing of foods [189].

Effective acoustic or ultrasound thawing relies on the selection of an appropriate frequency and intensity to defrost the food efficiently without excessive heating near the surface [189]. When ultrasound was applied directly to meat (beef, pork, or fish) excessive heating near the surface was particularly a problem at high intensities (1 to 3 W/cm^2) and over a range of frequencies (220 kHz to 3.3 MHz), with cavitation causing problems at lower frequencies, while high attenuation caused excessive heating at higher frequencies [189]. A combination of 500 kHz and 0.5 W/cm^2 was found to offer effective thawing while minimizing surface heating.

Acoustic defrosting (1500 Hz) of fish blocks in an agitated water bath (18°C, 3.8 m/s water velocity at block surface) reduced the time to go from –29 to –1°C by approximately 25 to 70% (depending on ultrasound power input level), while larger reductions were seen going from –5 to –1°C (approximately 32 to 82%) [188]. Some rapid thawing techniques can cause excessive heating at the product surface leading to loss of product quality. However, combined acoustic and water bath thawing gave the same surface temperature as water bath thawing alone [188].

43.7.3 Cooking

Some use of ultrasound has been made for cooking of meat, taking advantage of the increase in temperature due to the absorption of the ultrasound energy. Several ultrasound cooking processes have also been developed for meat products [192, 193], and similar processes may be useful with other foods. Ultrasound cooking (1000 W, 20 kHz) of beef samples in a water bath reduced the cooking time (6.7 minutes), reduced energy consumption (0.08 W/g), and gave a higher yield (85.3%) than convection cooking in a broiler (12.3 minutes; 0.22 W/g; 76.1%) [184]. Ultrasound cooking gave similar or better tenderness ratings than convection cooking but had a poorer flavor. An important disadvantage of substituting ultrasound cooking for other methods is the poorer flavor [184]. The flavors formed during dry heat cooking of meat (e.g. roasting, grilling) are an important part of the sensory characteristics, with different volatiles profiles forming during moist cooking (e.g. boiling, microwave) [194, 195].

In addition to using ultrasound in isolation to cook food, ultrasound-assisted water bath cooking is also likely to prove effective, due to the increased heat transfer coefficient produced by ultrasound [185, 186], and the agitation of the liquid by ultrasound mixing helping to ensure an even temperature throughout the cooking medium [184].

43.8 PROCESSING OF PROTEIN FOODS

Ultrasound can be used to enhance the processing of materials containing proteins, such as the tenderization of raw meat, destruction of microorganisms, homogenization, protein extraction from cells, and enhancing membrane filtration. The ultrasound mechanisms that can enhance these processes, such as localized or bulk heating, micro-jet formation, high shear, liquid agitation, polymer chain lysis, and free radical formation, can also denature the proteins present. In some instances, this can be desirable, such as the denaturation of proteins responsible for undesirable texture, color, or flavor changes, while in other situations it can be undesirable, for example giving a cooked appearance to raw meat during tenderization or loss of activity in enzymes being extracted from cells and purified. As a consequence, each process must be developed to maximize or minimize the effect of ultrasound on the proteins present.

43.8.1 Enzyme Inactivation

Ultrasound increases the effectiveness of heat inactivation of enzymes, and has been demonstrated in enzymes derived from plants [soybean lipoxygenase [196]; horseradish peroxidase [196–198]; watercress peroxidase [199]; mushroom polyphenol oxidase [196]; orange pectinmethylesterase [200]; tomato pectinmethylesterase and polygalacturonase [201]]; animal tissues [porcine heart malate dehydrogenase [202]; rabbit muscle L-lactic dehydrogenase [202]; bovine intestinal mucosa alkaline phosphatase [202]; porcine pancreas phospholipase A2, trypsin, and lipase [203]; bovine pancreas α-chymotrypsin [203]; trypsin, [204]], microorganisms [*Pseudomonas fluorescens* lipase and protease [205]; alcohol dehydrogenase and glucose-6-phosphate dehydrogenase from baker's yeast [202]; β-galactosidase from *Escherichia coli* [202]]; and milk [bovine lactoperoxidaase and alkaline phosphatise [206]; alkaline phosphatase, γ-glutamyltranspeptidase, and lactoperoxidase [207]]. The ultrasound stability of individual proteins varies between enzymes [196, 202, 203, 205] and also depends on ultrasound treatment conditions [196, 198, 202, 204, 205, 208], the composition of the treatment medium [196, 198, 200, 202–204, 209], treatment pH [205], and whether they are bound (e.g. membrane-bound proteins) or free (e.g. cytoplasmic proteins). Enzyme inactivation generally increases with increasing ultrasound power, ultrasound frequency, exposure time, amplitude, cavitation intensity, processing temperature, and processing pressure, but decreases as the volume being treated increases [196–200, 202, 204–206, 208].

A combined heat and ultrasound treatment can produce a markedly greater effect on enzyme inactivation than heat alone. Orange pectinmethylesterase in orange juice was inactivated relatively slowly by heat alone (72°C, D value of 500 minutes), while the combined heat and ultrasound treatment (72°C, 20 kHz, 117 μm, 350 kPa) gave a much lower D value (1.2 minutes) [200]. Ultrasound was also effective at a temperature (38°C) where thermal inactivation is insignificant, giving a pectinmethylesterase D value of 11 minutes. The rate of inactivation of tomato pectinmethylesterase was also greatly increased by a combination of heat and ultrasound, with increasing cavitation intensity (measured via H_2O_2 production) dramatically increasing the rate of inactivation [208]. Similarly for *Pseudomonas fluorescens* heat-resistant lipase, a combined ultrasound and thermal treatment (110 to 140°C, 20

kHz, 117 μm, 350 kPa) reduced lipase D values by 25 to 86% (average of 58%) and protease D values by 15 to 67% (average of 42%) compared to the heat-only treatment at the same temperature [205]. Generally, the reduction in D value tended to decrease with increasing treatment temperature. In milk, ultrasound alone is not very effective at inactivating milk enzymes (alkaline phosphatase, γ-glutamyltranspeptidase, and lactoperoxidase) and other milk proteins (α-lactalbumin and β-lactoglobulin), but a combination of ultrasound and heat is more effective than heat treatment alone [207].

Studies with buffers show that making small changes in the treatment medium composition, such as adding calcium salts, or whey protein hydrolysate, can markedly alter the rate at which an ultrasound treatment denatures enzymes [203]. For example, in a salt buffer adding calcium increased the stability of α-chymotrypsin by 62%, while in a whey protein and salt buffer, adding calcium increased the D value by 146% [203]. There was a marked difference between the salt buffer and the whey protein and salt buffer (511% no calcium, 826% with calcium). By contrast, there was little difference in trypsin inactivation between the salt buffer or whey protein buffer either with or without added calcium.

43.8.2 Changes in Protein

Ultrasound-induced changes in milk also affect the characteristics of products made from the milk. Yogurt manufactured from milk processed with ultrasound (40°C, 20 kHz, 2 kg/cm^2, 12 s ultrasound exposure time) took 10 to 20% longer to ferment (slower pH fall), lost less serum, and had a different texture (higher compression force, higher viscosity) than yogurt made from conventionally processed milk [205]. These differences may be due to ultrasound-induced protein modification. In another study, milk treated with ultrasound (20 kHz, 15 to 20°C, 6 minutes ultrasound exposure time) before a yogurt starter culture was added fermented at effectively the same rate (indicated by pH fall) as a conventionally homogenized milk [210]. In contrast, fermentation was faster when samples were treated with ultrasound during fermentation, which may have been due to faster lactose hydrolysis as a result of ultrasound causing the release of β-galactosidase from bacterial cells [211]. Some ultrasound treatments also increased yogurt viscosity, increased water-holding capacity, and reduced syneresis compared to yogurt made with conventionally homogenized milk, which are likely to be the result of changes in protein conformation caused by ultrasound. Some depolymerization of collagen is also reported [212].

43.9 ULTRASOUND AS A PROCESSING AID

Ultrasound has been used to enhance the efficiency of food-related enzymatic processes including enhancing the esterification of glucose [213], hydrolysis of olive oil [214], and proteolysis of casein by α-chymotrypsin [215]. Ultrasound increased the rate of invertase catalyzed hydrolysis of sucrose, α-amylase and glucoamylase hydrolysis of starch, and α-amylase hydrolysis of glycogen [216, 217]. These studies show that ultrasound power levels can be found that give a balance between enhanced rates of enzyme activity while maintaining enzyme activity over an extended period. Ultrasound has also proven effective when lactose in milk is hydrolyzed by fermentation with *Lactobacillus bulgaricus* [211]. Ultrasound increased the rate and extent of lactose hydrolysis, and also altered the hydrolysis process, giving markedly higher levels of residual glucose in the milk. When lactose is hydrolyzed within the cell, the glucose produced is consumed by the bacteria.

43.10 HOMOGENIZATION AND EMULSIFICATION

Homogenization or emulsification is one of the important unit operations in the food industries. Homogenization is a common term used when the size of a non-uniform dispersed system is reduced to a required size and distributed uniformly in the bulk product. In the homogenized product, the particle size distribution of the dispersed phase is narrow. Milk is the food that is most commonly homogenized. In the emulsification process, two immiscible components are mixed and uniformly distributed. The examples are oil-in-water or water-in-oil type emulsions. The equipment used to homogenize or emulsify the product are high-pressure homogenizers and colloid mills. Ultrahigh-pressure homogenizers (can go up to 5000 bars) and microfluidizers are recent techniques that are gaining popularity in the preparation of sub-micron emulsions. Ultrasonication has also been proven to be another way of mixing two immiscible liquids, and has been used successfully in the cosmetic, pharmaceuticals, chemical, and textile industries [131].

Ultrasonic emulsification is mainly driven by cavitation, wherein the bubbles collapse at the interface of two immiscible continuous and dispersed phases. A straightforward way to produce an emulsion by ultrasound is by immersion of a sonotrode either into the mixture of all components or into the continuous phase and adding gradually the phase to be dispersed during sonication. This procedure works well for small batches, but scale-up is difficult [218]. Since the intensity of ultrasound in a liquid decreases rapidly with the distance to the sonotrode, it may be difficult to process larger volumes [218]**.** In some cases, the liquid whistle type of ultrasound device is used [131]. This can give much more throughput (up to 12 000 L/h) than the sonotrodes such as in the case of manufacturing fruit juices, ketchups, and mayonnaise [131]. Ultrasound treatment is also an effective method for homogenizing the fat globules present in milk [207, 210, 219]. Wu and Hulbert [210] reported that high-amplitude homogenization not only gave a good homogenization effect in milk but also significantly improved the water-holding capacity and viscosity and also reduced syneresis of yogurt produced from ultrasonicated milk. The ultrasound was also very effective in producing sub-micron sized emulsion of essential oil (limonene) for the purpose of encapsulation by spray drying. The particle size and distribution were the function of ultrasonication period (Figure 43.3). Ultrasonication was found

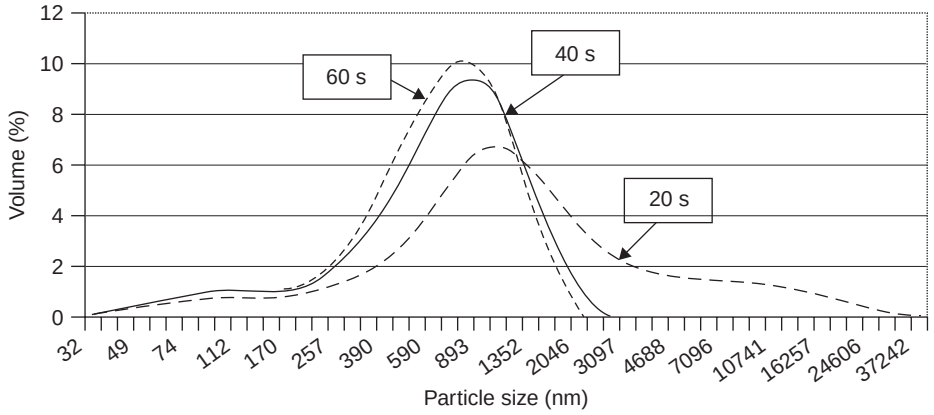

FIGURE 43.3 Size distribution of the emulsion produced by ultrasound at various time periods (dispersed phase-limonene, continuous phase Hi-Cap/maltodextrin mixture aqueous solution). (From Jafari et al. [220].)

much easier to operate, control, and clean as compared to the microfluidizer.

One of the issues of ultrasound emulsion is the critical product contamination of the metal alloys which are used to make the sonotrodes. This contamination can result in oxidation of the product and the development of off-flavor. Attempts have been made to make the device transmit the ultrasonic waves through other materials such as a double jacket filled with pressurized water in a flow-through cell where there will not be direct contact between the sonotrode and product [220].

43.11 MEAT TENDERIZATION

Tenderness is the most important consumer quality attribute in cooked meat [221, 222]. Meat tenderness is influenced by a multitude of factors, including animal characteristics (e.g. genetics, animal age, muscle function), pre-slaughter handling of the animal (e.g. stress, muscle glycogen), and post-slaughter handling of the carcass (e.g. chilling rate, electrical stimulation, carcass suspension technique) [223]. There are myriad techniques available to tenderize meat including many conventional approaches (e.g. aging time, treatment with proteases, injection with salt solutions, mechanical treatment, cooking technique), including some emerging techniques, such as hydrodyne (explosive shock), ultra-high pressure, and injection of calcium salts [223]. Ultrasound also offers potential as a tenderizing treatment in meat as it can be applied without causing the changes in appearance that occur with some other treatments.

The ultrasound conditions used to treat meat vary widely, and correspondingly the effectiveness of ultrasound for meat tenderization varies (Table 43.3). The intensity of ultrasound treatment appears to play an important role in the tenderizing effect, with studies using relatively low intensity (<2 W/cm^2) producing little effect, even though the samples received extended exposure (up to 70 minutes) [224, 225]. Higher-intensity ultrasound proved effective in some cases at tenderizing meat [104, 105, 183, 226–228], though a number of other studies found the treatment conditions to have no effect on tenderness [183, 184, 229, 230] or even to decrease tenderness [183]. The frequency chosen does not appear to be responsible for the variation in results, as these studies have been performed in a narrow range (20 to 47 kHz; most studies between 20 and 30 kHz). The use of high-frequency ultrasound (2.4 MHz) to treat pre-rigor meat initially increased the firmness (compression force) of raw meat compared to untreated or post-rigor ultrasound-treated meat [231]. After 14 days' aging, no difference was found between untreated, pre-rigor, and post-rigor ultrasound-treated meat [231].

The microstructure of ultrasound-treated meat shows that there can be significant disruption to the structure. In beef *Longissimus*, there was greater sarcomere shattering and myofibril disruption from ultrasound cooking than convection, though in the *Pectoralis*, no difference with cooking method was found [184]. This may be due to the greater collagen concentration and differences in connective tissue distribution in *Pectoralis* compared to *Longissimus*. In another study, both *Semimembranosus* and *Longissimus* showed damage to their microstructure caused by ultrasound [228] (Figure 43.4). By contrast, in chicken *Pectoralis* ultrasound treatment did not affect microstructure [227]. There was also greater myofibril damage in ultrasound-treated cured meat products [102, 105].

In beef *Semimembranosus* treated with high-frequency ultrasound (2.4 MHz), pre-rigor ultrasound-treated meat initially had longer sarcomeres than untreated meat, though there was no difference in myofibril fragmentation after 6 days' aging [231]. There were no differences in microstructure between post-rigor ultrasound-treated and untreated samples.

In addition to the physical disruption shown by microstructural studies, ultrasound could increase meat tenderness through an increase in proteolysis, which contributes to meat tenderization during aging [232, 233], for example through increased release of cathepsin (muscle protease) [233]. Ultrasound treatment of lamb muscle fibers was found to activate proteolysis, with SDS-PAGE analysis showing greater appearance of bands around 30 and 83 kDa, and the disappearance of an 87kDa band, in samples that had been ultrasound-treated and aged at 4°C for two days, compared to the much smaller changes in samples that had only been aged at 4°C for two days [234]. However, this effect is not found consistently,

TABLE 43.3
Some of the Studies of the Tenderization of Meat by Ultrasound Treatment

Muscle	Frequency (kHz)	Power Input	Treatment Time (min)	Tenderness Effect	Reference
Horse *Semimembranosus*	22	1500 W	Five sessions totaling 50 minutes	Ultrasound-treated meat had lower shear force (25.2 kg/cm^2) than conventionally processed (injected and tumbled) meat (31.5 kg/cm^2 N)	[104, 105]
Chicken *Pectoralis major*	40	2400 W	15	At 24 hours post-mortem, ultrasound-treated muscles gave a lower shear force (4.4 N) than untreated muscles (5.0 N)	[227]
Beef *Semitendinosus*	25.9	1000 W	Up to 16	Ultrasound-treated meat had lower shear force than untreated at 2 and 4 minutes, but equal or higher after 8 or 16 minutes	[226]
Beef *Longissimus Semitendinosus Biceps femoris*	30–47	0.29–0.62 W/cm^2	Up to 30	Ultrasound did not affect instrumental tenderness	[224]
Lamb *Longissimus*	20	63 W/cm^2	Average of 2.5 per steak	Ultrasound did not affect instrumental or sensory tenderness	[229]

as when beef or lamb muscles were treated with ultrasound, there was no effect on the SDS-PAGE profile, with the appearance of a 30 kDa band (a marker of proteolysis in aged meat) occurring at the same rate in ultrasound-treated and untreated meat [229, 230]. Ultrasound could also damage cell walls and membranes [13], physically disrupt proteins through bubble pulsation, cavitation, and free radical formation [13], including fragmentation of collagen [235]. An effect on collagen in treated meat has been shown, with meat cooked by ultrasound having a lower total and soluble collagen content than

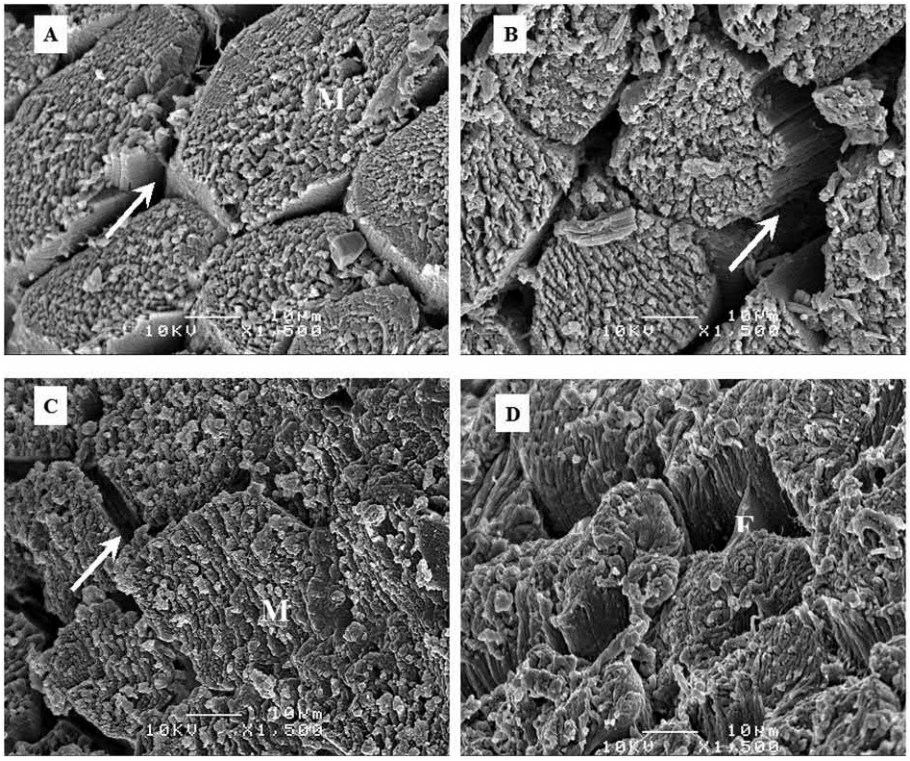

FIGURE 43.4 Scanning electron micrograph of bovine *Semitendinosus* muscle treated with ultrasound (24 kHz) for various treatment times. (From Jayasooriya [236].) (A) 0 s; tightly packaged and intact fiber bundles are shown, (B) 60 s; fiber bundles are intact, but increased spaces between fiber bundles are shown, (C) 120 s; disintegrated fiber bundles are evident, and (D) 240 s; integrity of the fiber bundles are lost, and myofibrils and connective tissue appeared to be denatured. M = fiber bundle; ⟶ = inter-myofibrillar spaces; E = endomysium. (From Jafari et al. [220].)

convection-cooked meat [184], though in raw meat, ultrasound treatment had no effect on total and soluble collagen contents [229, 230] or insoluble collagen [231].

44 Ohmic Heating and Food Preservation

Marybeth Lima and Mohammad Shafiur Rahman

CONTENTS

44.1 OVERVIEW

Ohmic heating (OH), also known as Joule heating, electric resistance heating, direct electric resistance heating, electroheating, and electroconductive heating, is a process in which alternating electric current is passed through food material; heat is internally generated within the material due to its resistance to the applied electrical current. In conventional heating, heat transfer occurs from a heated surface to the product interior by means of convection and conduction and is time-consuming, especially with longer conduction or convection paths that may exist in the heating process. Electro-resistive or ohmic heating is volumetric in nature and thus has the potential to reduce over-processing by virtue of its inside–outside heat transfer pattern.

Ohmic heating is not a new technology; it was used as a commercial process in the early 20th century for the pasteurization of milk [1]. However, the "Electropure Process" was discontinued between the late 1930s and 1960s, ostensibly because of the prohibitive cost of electricity and a lack of suitable electrode materials. Interest in ohmic heating was rekindled in the 1980s when investigators were searching for viable methods to sterilize effectively liquid–large particle mixtures, a scenario for which aseptic processing alone was unsatisfactory. The purpose of this chapter is to present general information about ohmic heating, especially with regard to food preservation and processing.

44.2 GENERAL INFORMATION ON OHMIC HEATING

44.2.1 Advantages

Ohmic heating exhibits several advantages with respect to conventional food-processing technologies (Table 44.1).

44.2.2 Commercial Applications

OH can be applied to a wide variety of foods, including liquids, solids, and fluid–solid mixtures, and it is used commercially to produce liquid egg products in the United States. It is also used in the United Kingdom and Japan for the processing

TABLE 44.1
Advantages of the Ohmic Heating Process

1. Particulate foods up to 1 in^3 are suitable for ohmic heating; the flow of a liquid–particle mixture approaches plug flow when the solids content is considerable (20–70%).
2. Liquid–particle mixtures can heat uniformly (under some circumstances, for example, if liquids and particles possess similar electrical conductivities, or if properties such as solids concentration, viscosity, conductivity, specific heat, and flow rate are manipulated appropriately).
3. Temperatures sufficient for UHT processing can be rapidly achieved.
4. Absence of hot surfaces for heat transfer, resulting in a low risk of product damage from burning or over-processing.
5. Higher temperatures in particulates than liquid can be achieved, which is impossible for conventional heating.
6. Reducing risks of fouling on heat transfer surface.
7. Ease of process control with instant switch-on and shut-down.
8. Reducing maintenance cost (no moving parts).
9. High energy conversion efficiency.
10. Relatively low capital cost.

of whole fruits such as strawberries. Additionally, OH has been successfully applied to a wide variety of foods in the laboratory, including fruits and vegetables, juices, sauces, stews, meats, seafood, pasta, and soups. In 1997, there were 19 plants operating worldwide using ohmic heating technology [2].

The widespread commercial adoption of ohmic heating in the United States depends on regulatory approval by the FDA, a scenario that requires a full understanding of the ohmic heating process. This includes heat transfer (temperature distributions), mass transfer (concentration distributions, which are influenced by electricity), momentum transfer (i.e. fluid flow), and kinetic phenomena (i.e. thermal and possibly electro-thermal death kinetics, and nutrient degradation). Currently, there are no ohmic heating units available for household use.

Larkin and Spinak [3] examined safety considerations for ohmically heated, aseptically processing, multiphase low-acid food products and discussed the need for providing information on equipment design, product specification, process design, and process validation for regulators. Full knowledge of these areas is critical to ensure that the food product receives adequate thermal treatment. Significant research strides toward widespread commercial use are in progress.

44.2.3 Heat Generation

OH devices consist of electrodes, a power source, and a means of confining the food sample (for example, a tube or vessel). Appropriate instrumentation, safety features, and connections to other process unit operations (e.g. pumps, heat exchangers, holding tubes) may also be important. Ohmic heaters can be static (batch) or continuous. Figure 44.1 is a schematic diagram of a static ohmic heating process.

The key to the OH process is the rate of heat generation, the electrical conductivity of food material, and the way the food flows through the heater. The heat generation by electrical energy due to electrical resistance can be written as

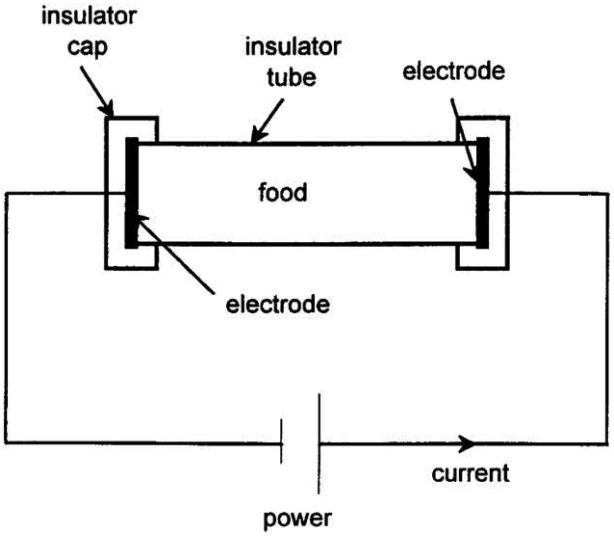

FIGURE 44.1 Schematic diagram of an ohmic heating process.

$$Q = I^2R = \sigma V^2 \tag{44.1}$$

where Q is the heat generation (W), I is the current (A), V is the voltage gradient (volt), σ is the electrical conductivity (S/m), and R is the electrical resistance (ohm). The electrical conductivity and resistivity from Ohm's law can be written as

$$R = \frac{V}{I} \qquad \text{and} \qquad \sigma = \left(\frac{1}{R}\right)\left(\frac{L}{A}\right) \tag{44.2}$$

where L is the length (m), and A is the cross-sectional area (m^2). The rate of heat generation depends on the local electric field strength. When a two-phase mixture is heated electrically, the two phases generate heat at the same rate if the liquid and solid have the same electrical resistance. When the fluid is of a higher electrical conductivity than the particles, non-uniform heating can occur in the fluid surrounding the particles if heating takes place under static conditions. The ratio of heat generation in solid to liquid is

$$\frac{Q_s}{Q_L} = \frac{\rho\sigma_s\sigma_L}{\left(\sigma_s + 2\sigma_L\right)^2} \tag{44.3}$$

where ρ is the density (kg/m^3), σ_s and σ_L are the electrical conductivity of solid and liquid, respectively, and Q_s and Q_L are the heat generation in solid and liquid phases, respectively.

Important design considerations include electrode configuration (current flows across the product flow path or parallel to the product flow path), the distance between electrodes, electrolysis (metal dissolution of electrodes, particularly at low frequencies), heater geometry, frequency of alternating current, power requirements, current density, applied voltage, and product velocity and velocity profile. Additional factors regarding the food system used in an ohmic heater include the type of product and its properties, especially electrical

conductivity and heating rate; others include percent solids, acidity, product viscosity, specific heat, and density, and solid particle size, shape, and orientation to the electric field. Substantial literature has been devoted to these topics [4–12].

Electrode design is a critical factor for the designing of OH processes. At least two or more electrodes are used to impart current in the fluid, and their locations or positions depend on the types of design. Two common designs are either static systems in a vessel, or continuous flow [13]. The open geometry types are easy to clean and reduce the effect of fouling with low damage to the products [14]. OH is usually arranged in one of four different configurations [12]. These are parallel plate configuration (transverse configuration), parallel rod design, collinear design, and staggered rod arrangement. Different conductive electrode materials, such as titanium, stainless steel, platinized-titanium, aluminum, and graphite, have been used for electrode. The selection depended on the price, corrosion resistance, and quality of the products. In addition, stainless-steel electrodes are preferred for quality products, and the frequency of the power supply must be increased to prevent corrosion and metal dissolution [15]. Coated electrodes can minimize or eliminate electrolytic reactions.

Using a 60 Hz sinusoidal alternating current, all the electrode materials exhibited intense electrode corrosion at pH 3.5 compared to other pH values, and titanium electrodes showed a relatively high corrosion resistance. The corrosion rate of other metals at pH 3.5 was about 55 times higher than that of titanium [16]. In the case of pomegranate juice, applying voltage gradients in the range of 30–55 V/cm showed that as the voltage gradient increased, the time of heating and pH decreased [17]. When the frequency of heating sample increased from 50.0 to 10×10^4 Hz, the time required for the heating sample to reach 80°C increased approximately six-fold [18]. Conventional OH under typical low-frequency alternative current of 50 to 60 Hz could cause oxygen and hydrogen evolution due to the electrolysis of water [19].

Temperature measurement remains an area of concern because many measurement methods influence the electric field during OH. A triple-point probe is the most satisfactory thermocouple for OH applications [20]. Some success has been seen with thermocouples that are coated with material, such as Teflon, however non-invasive temperature measurements that do not interfere with the electric field remain a challenge, particularly with regard to temperature measurement inside particles. Flash magnetic resonance imaging (MRI) could be used to determine rapid food particle temperature mapping during ohmic heating [21].

Heat is generated internally during OH, and this heating is not necessarily uniform. Thus, prediction equations to estimate heat generation are an important issue in OH to address questions like (i) where is the cold spot in the medium? (ii) What is the lethal treatment delivered to the cold spot? (iii) How is the lethal treatment ensured? Keys to OH include the rate of heat generation, the electrical conductivity of the food material, and the way in which food flows through the ohmic heater [3].

44.2.4 Cost

The economic analysis could play an important role in understanding the overall cost and viability of the commercial applications [12]. Investigators compared the cost of installation and operation of ohmic food-processing systems to that of conventional retorting, freezing, and heating in a conventional tubular heat exchanger [22]. The components included in the cost analyses were labor, energy, packaging, equipment maintenance and repairs, plant supplies, and interest and depreciation on the processing and filling equipment. Ohmic operational costs were found to be comparable to those for freezing and retort processing of low-acid food products. Though ohmic heating was found to be more costly than conventional methods for processing high-acid foods, still OH is viable considering other advantages.

44.3 PARAMETERS OF IMPORTANCE IN OHMIC HEATING

44.3.1 Electrical Conductivity

The most important parameter of interest in ohmic heating is the electrical conductivity of the food and/or food mixture. Substantial research was conducted on this property in the early 1990s because of the importance of electrical conductivity with regard to heat transfer rate and temperature distribution. The findings of numerous electrical conductivity studies are as follows: the electrical conductivity is a function of food components; ionic components (salt), acid, and moisture mobility increase electrical conductivity, while fats, lipids, and alcohol decrease it. Electrical conductivity is linearly correlated with temperature when the electrical field is sufficiently high (at least 60 V/cm). The increase in temperature increases the electrical conductivity due to the increase in ionic mobility [23]. Non-linear shapes (sigmoidal curves) are observed with lower electrical field strength [4, 18]: (i) electrical conductivity increases as temperature and applied voltage increases, and decreases as solids content increases, (ii) lowering the frequency of alternating current during ohmic heating increases the electrical conductivity, (iii) the waveform can influence the electrical conductivity; though alternating current is usually delivered in sine waves, and sawtooth waves increased the electrical conductivity in some cases, while square waves decreased it [18], and (iv) electrical conductivity increases by heating cycle; preheated samples show increased electrical conductivity as opposed to raw samples when both are subsequently subjected to ohmic heating [24].

The electrical conductivity of solids and liquids during ohmic heating of multiphase mixtures is also critically important. In an ideal situation, liquid and solid phases possess essentially equal electrical conductivities and thus (generally) heat at the same rate. When there are differences in the electrical conductivity between a fluid and solid particles, the particles heat faster than the fluid when their conductivities are lower than the fluid. Solid particulates heat more slowly than a fluid when the electrical conductivity of the solid is higher

than that of the fluid. Fluid motion (convective heat transfer) is also an important consideration when there are electrical conductivity differences between fluids and particles.

The current density (i.e. ratio between the current and electrode surface area) is important in calculating the critical current density, which is used in the design of the electrode dimension [13]. The voltage gradient increases the heat generation per unit time because of the resistance to current passing through the sample at any power applied, and it is related to the sample composition and its electric conductivity [20, 25–27].

Other product properties that may affect temperature distribution include the density and specific heat of the food product. When solid particles and a fluid medium have similar electrical conductivities, the component with the lower heat capacity tends to heat faster. High densities and specific heats are conducive to slower heating. Fluid viscosity also influences ohmic heating; higher viscosity fluids tend to result in faster ohmic heating than lower viscosity fluids [28].

44.4 MODELING OF OHMIC HEATING PROCESSES

44.4.1 Process Considerations

Considerable effort has been expended to model the heat transfer mechanisms and microbial death kinetics involved during ohmic heating. Models are of interest in the analysis and design of ohmic heating processes to provide information about the temperature distribution throughout the process, especially *cold spot*, and to provide accurate predictions of the minimum lethal processing time. Complexities in modeling heat transfer processes during ohmic heating arise when the liquid and particle possess different electrical conductivities, and because electrical conductivity is a (sometimes non-linear) function of temperature and frequency of alternating current. The thermal history and location of the *cold spots* or *cold zones* during OH require special consideration as the current knowledge of conventional heating cannot be extrapolated [23, 29].

Numerous models have been developed based on numerical solutions using transport equations with appropriate boundary conditions, assumptions, and dimensional groupings. These models contribute significantly to the understanding of heat transfer in OH. The voltage field (Laplace) equation for a single solid particle in a static heater has been solved [30]. Numerical solutions and experimental simulations of more complex ohmic heating situations have been developed [31–33]. Thermal-hydraulic aspects of ohmic heating were studied, and it was found that the temperature distribution can vary significantly even when ohmic heating rates are uniform [34]. Davies et al. [35] quantified the effects of a non-uniform electric field on temperature distributions during ohmic heating, while others [8, 36, 37] used magnetic resonance imaging to rapidly map and model the temperature of solid–liquid particle mixtures during ohmic heating.

A particle does not heat uniformly during ohmic heating because of the non-uniform nature of the electric field within the system [3]. Zones of high and low heat generation in a fluid around a particle of low electric conductivity are shown in Figure 44.2. The current is high on the sides of the particle and low in the front of rear regions, since current attempts to bypass the solid. This non-uniformity of heating can be reduced by increasing fluid mixing, reducing the viscosity of fluids, improving the rotation of particles, and the presence of other particles in the medium [38]. Kamonpatana et al. [39] developed mathematical models and microbiological verification of OH of a multicomponent mixture of particles (i.e. five types of particles) in a continuous-flow ohmic heating system with the electric field aligned parallel to flow. A chicken piece was found to be the slowest-heating particle in the worst-case simulation. The developed model and microbiological verification strategy could help to ensure sterility in a continuous-flow ohmic sterilization process for a multicomponent mixture.

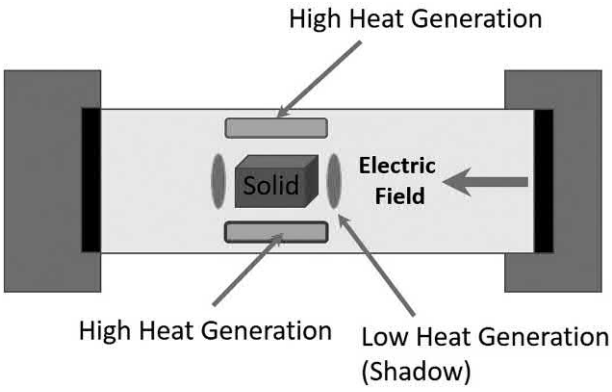

FIGURE 44.2 Zones of high and low heat generation in the fluid around a particle of low electrical conductivity. (Redrawn from Sastry [38].)

A dual cylindrical microwave and ohmic combination heater was developed for the minimization of thermal lags in the processing of particulate foods [40]. Temperature profiles of particle liquid mixtures containing sodium chloride solutions (5–20 g/L); chicken and potato particulates at different mass fractions (10–15 g/100 g) and sizes (0.5 and 1 cm cubes) were compared using a combination of heating modes. In the case of OH, particle size and salt concentration affected temperature variations between solution and particulates. However, the solution temperature in microwave heating lagged the particle temperature up to salt concentration 12.5 g/L regardless of the particle size and mass fraction, whereas the opposite trend observed at 20 g/L (i.e. very high concentration). The maximum temperature lags in the particulates were 7.1, 11.9, and 3.1°C, respectively, for microwave, ohmic, and combined heating, and a developed regression model could be used for the prediction of the temperature gradient as a function of salt concentration, particulate size, and concentration.

44.4.2 Microbial Death Kinetics

In terms of microbial death kinetics, considerable attention has been paid to the following question: does electricity result

in microbial death, or is microbial death caused solely by heat treatment? The challenge in modeling microbial death kinetics is the precise matching of time–temperature histories between ohmic processes and conventional processes. The FDA has published a comprehensive review of microbial death kinetics data regarding OH [41].

Initial studies in this area showed mixed results, though the experimental details were judged insufficient to draw meaningful conclusions [1]. Researchers compared the death kinetics of yeast cells under time–temperature histories as identical as possible and found no significant difference between conventional and ohmic heating except at low temperatures [42] (Tables 44.2 and 44.3). The decimal reduction times of *Bacillus subtilis* spores were significantly reduced when using ohmic heating at identical temperatures [43]. These investigators also used a two-step treatment process involving ohmic heating, followed by holding, followed by heat treatment, which accelerated microbial death kinetics; they hypothesized that electroporation may positively influence microbial death kinetics. The inactivation of yeast cells in phosphate buffer by low-amperage direct current electrical treatment and conventional heating at isothermal temperatures was examined [44]. These researchers concluded that a synergistic effect of temperature and electrolysis was observed when the temperature became lethal for yeast.

Tian et al. [45] performed OH (i.e. high-voltage-short-time (HVST) and low-voltage-long-time (LVLT)) and conventional water bath (WB) heating to identify whether a non-thermal death effect existed in OH. The heating on inactivation and proteome changes of *Escherichia coli* O157:H7 cells at the same endpoint temperature of 72°C (i.e. heating time varied) were measured. The inactivation of HVST was comparable to WB, and the largest inactivation was observed at LVLT, and there was lower intracellular protein content detected in LVLT and HVST samples than those of WB. Quantitative proteomic profiles identified 2626 proteins, and more protein changes in HVST and LVLT samples were mainly attributed to the leakage of intracellular proteins due to the damage of the cell membrane. In addition, bioinformatics analysis indicated that the differential proteins were mainly involved in transcription, translation, cell wall and membrane biogenesis, and amino acid, carbohydrate, and lipid metabolism. It was observed that 34 differential protein pathways were enriched, and five significant pathways were mostly related to the ribosome, terpenoid backbone biosynthesis, glycerophospholipid metabolism, ABC transporters, and folate biosynthesis. Therefore, additional non-thermal effects on the microbial inactivation existed.

Kim et al. [46] applied low-frequency (i.e. 0.06–1.0 kHz) pulsed OH (waveforms: sine, square, triangle, and pulse; titanium electrode) for the inactivation of foodborne pathogens (*E. coli* O157:H7, *Salmonella typhimurium*, and *Listeria monocytogenes*) and bacteriophage MS-2 in buffered peptone water and tomato juice. In the case of pathogenic bacteria, they observed lower sub-lethal injury at 0.06–0.5 kHz than at 1 kHz, however MS-2 phage was inactivated more effectively at low frequencies and was more sensitive to acidic conditions than pathogenic bacteria. The pulsed OH waveform prevented electrode corrosion sufficiently at low frequencies (0.06–0.2 kHz). This process showed no electrode corrosion (pulsed wave) or quality degradation of tomato juice regardless of frequency. The increased electroporation effect at low frequencies was suggested as a reason for the reduced resuscitation level. Kim et al. [47] developed continuous OH (electric field strength 26.7 V/cm; frequency 25 kHz) at 85–100°C for 30–90 s on commercially processed apple juice using five sequential electric fields resulting in the rapid inactivation of *Alicyclobacillus acidoterrestris* spores. They suggested that the OH system is superior to conventional heating for rapid sterilization (30 s) of apple juice to assure microbiological quality without damage to the °Brix and color.

The heating rate and reduction rate of pathogens increased corresponding to decreased flow rate (i.e. higher numbers of pathogens survived at a higher flow rate). Increasing treatment voltage can be an effective way to inactivate pathogens, but the heating rate overly accelerates and adversely affects food quality (for example, color and lycopene retention in tomato juice). Kim et al. [48] proposed to increase the initial temperature by preheating, and this can help inactivate pathogens in the early treatment stage without affecting the heating rate. The flow rate, voltage, and initial temperature are important factors for determining pathogen inactivation performance of continuous-type OH.

Further research regarding microbial death kinetics, survivor counts, subsequent treatment, and the influence of electricity on cell death kinetics are necessary to address regulatory issues. It is commonly assumed that microbial death is

only a function of temperature (heat) results, and this is now an appropriately conservative design assumption.

44.4.3 Vitamin Degradation Kinetics

Limited information exists regarding product degradation kinetics during ohmic heating. Researchers measured vitamin C degradation in orange juice during ohmic and conventional heating under nearly identical time–temperature histories and concluded that electricity did not influence vitamin C degradation kinetics [49]. This study was conducted at one electrical field strength (E = 23.9 V/cm). Others found that the ascorbic acid degradation rate in buffer solution during OH was a function of power, temperature, sodium chloride concentration, and products of electrolysis [11]. The *D*-values of ascorbic acid degradation in acerola pulp during OH were 30.2 and 38.0 h (temperature: 85°C), respectively at electric fields 10 and 100 Hz, and it was 38.6 h in the case of conventional heating [50]. The use of low electric field frequency (10 Hz) led to greater ascorbic acid degradation and higher color changes probably due to the occurrence of electrochemical reactions. Above 100 Hz up to 10^5 Hz (i.e. high electric field frequency) as tested, ohmic and conventional heating processes showed similar degradation rates of ascorbic acid and similar color changes. It was suggested that the ascorbic acid molecule predisposition for hydrogen donation in redox reactions was not affected by the rapidly varying electric field [50].

44.4.4 Mode of Actions

Early research on OH was conducted on heat transfer and the sterilization of liquid–particle mixtures. In executing such studies, investigators observed unanticipated phenomena. For example, OH beetroot resulted in enhanced diffusion of betanin from the beetroot tissue when compared to beetroot tissue heated conventionally [51]. These investigators hypothesized that the enhanced mass transfer could be caused by electro-osmosis.

Investigators expanded on the aforementioned work and found that the diffusion of beet dye from beetroot into a carrier solution was enhanced as much as 40% during heating from 20 to 80°C, and that the concentration of diffused dye was proportional to particle surface area and a linear function of electric field strength [24]. In the case of OH Japanese white radish, the heating rate was influenced by frequency; as the frequency of alternating current decreased, the heating rate increased [52]. These investigators used H-NMR analysis and hypothesized that at low frequency (50 Hz), rapid heating is caused by electroporation of the radish tissue membrane, which resulted in a decrease of electrical impedance. Subsequent studies have concluded that electroporation is the most likely mechanism for enhanced mass transfer effects during ohmic heating [10, 53].

Electroporation is defined as the formation of holes in a cell membrane resulting from the local pressure of ions, which cannot initially permeate the cell membrane but are forced against it by the electric field [54]. The relatively low alternating frequencies employed during OH enable this charge build-up to occur on the cell wall, resulting in the formation of pores. This also suggests that the lower the frequency of OH, the more pronounced the mass transfer effect; this concept has been demonstrated in the literature [55–57]. It was found that direct current resulted in less mass transfer enhancement than low AC frequency OH (at 15 V/cm, 250 Hz < DC < 50 Hz). In addition, it was postulated that a monopolar electric charge (DC) is not as effective as a bipolar electric charge at creating stress on the cell membrane, thus yielding less of an effect than low-frequency alternating current [55]. A moderate electric field enhanced the membrane permeability of potato cells and the electric field strength, temperature, and processing time. The type of plant tissue affected the degree of tissue damage and the extraction yield. It is believed that the electric breakdown and electroporation are the dominant mechanisms for the controlled low temperature, and higher temperature reduces non-thermal impact [58]. Electroporation also occurs in microbial cells [59].

Uniform and quick pH reduction (i.e. acidification) is important to achieve in foods, either treated by heat or low-pH foods. Conventionally, food-grade acids are used to modify the original pH, but it is a slow process. For instance, finished pH is achieved after 10 days [60]. However, vegetable acid-soaking treatments are carried out at refrigerated conditions for more than 24 h to control microbial growth [61]. It is also relatively slow. Blanching in acid solutions is another commonly employed method; however, it results in the leaching out of solutes. Considering these constraints, a combination of vacuum, high pressure, and OH could be used to reduce pH instantaneously and uniformly [62].

Electrically heating foods influences their mass transfer properties. This phenomenon has important implications for food-processing operations that involve mass transfer. In 2001, the FDA reported that "A large number of potential future applications exist for ohmic heating, including its use in blanching, evaporation, dehydration, fermentation, and extraction" [41].

44.5 APPLICATIONS OF OHMIC HEATING

44.5.1 Maintained Texture and Flavor

Sensory evaluation is critically important to any viable food process. Numerous publications have cited the superior product quality that can be obtained through decreased processing times, though few published studies specifically quantify sensory and texture issues. Six stew formulations sterilized using OH before and after three years of storage were analyzed; the color, appearance, flavor, texture, and overall food quality ratings were excellent, "indicating that OH technology has the potential to provide shelf-stable foods closely equivalent to those prepared from scratch." The quality and mechanical properties of hamburgers cooked with a combination of conventional and OH were not different from hamburgers cooked with conventional heating [36, 63].

In the case of OH (45, 60, 80 V at 60 Hz and 10, 100, 1000 Hz with 25 V, 65°C/30 min) of whey acerola-flavored drink, a similar fatty acids profile and volatile compounds were observed as compared to conventional heating. However, their intensity varied as a function of the parameters used (voltage and frequency) and resulted in more viscous beverages [64].

44.5.2 Gelatinization

Starch gelatinization is an important parameter in food processing and can be either advantageous or disadvantageous depending on the desired product formulation. The electrical conductivity of a food product is influenced significantly by starch gelatinization [65]. These investigators found that electrical conductivity decreased with the degree of gelatinization, and suggest that OH can be used in the development of a sensor to detect starch gelatinization. OH was used to maximize the gel functionality of a seafood product [66]. The OH process was superior to the conventional heating process because of rapid heating that deactivated enzymes, which in turn enabled strong gel formation.

44.5.3 Blanching

Because blanching requires large volumes of water during processing and often requires dicing vegetables, studies to increase the efficiency of blanching using OH are important. Wigerstrom [67] found that electric fields enhanced moisture loss during the blanching of potato slices. Mizrahi [68] determined that OH was an effective method for blanching because the rapid, uniform heating exhibited by OH eliminated the need for dicing vegetables. The quick process time and reduction in surface area (no dicing) reduced solute losses by an order of magnitude during blanching. Sensoy and Sastry [69] found that using ohmic heating during the blanching of mushrooms resulted in the shrinking of mushrooms at a lower temperature and with less water use as compared to conventional blanching. Lakkakula et al. [56] showed significant lipase deactivation in rice bran during ohmic heating, with and without a corresponding temperature increase. Taken collectively, these studies show that ohmic heating can increase process efficiency in blanching. Considering OH and conventional blanching (CB) of pumpkin, peroxidase inactivation kinetics and color changes were measured [70]. It was verified that OH accelerated the enzymatic inactivation process; for a reduction higher than 90% (i.e. peroxidase) it took 2 min for OH whereas CB took 4 min with no significant difference in color changes between the processes.

Considering apple juice, OH of polyphenol oxidase inactivation was optimized considering temperature (60–80°C) and voltage gradient (30–40 V/cm) [71]. An improvement in apple juice quality was achieved by using OH at 80°C and 40 V/cm as compared to CH. The total extracted phenolic content was increased by 5.4% with OH and 2.5% with CH as compared to fresh apple juice. The color was improved and loss of ascorbic acid and carotenoids decreased in the case of OH.

However, there was an absence of non-thermal effects of electricity (frequency 10–10^5 Hz; waveforms, sine, square, triangle, and pulsed; voltage gradients, 3.9 and 20.5 V/cm; temperature 75°C for 25 min) on the enzymatic inactivation kinetics of peroxidase and phenolic compounds degradation in the case of sugarcane juice. Selected waveforms promoted higher degradation of these compounds, and color changes were observed when 10 Hz/25 V and 60 Hz/130 V were applied, with higher electric field strength [72].

44.5.4 Peeling

Peeling is one of the most important preparatory steps in the processing of fruits and vegetables for canning and other methods. In the case of OH-assisted lye peeling, it was observed that the concentration of lye (2% sodium hydroxide at 532 V/m and 3% sodium hydroxide at 426 and 479 V/m) can be significantly lowered in the presence of OH to achieve high peeled yields and quality, which is considered the complete removal of peels [73]. In addition, the effects of increasing field strength yielded no significant additional benefits.

44.5.5 Evaporation

Wang and Chu [74] studied the effect of OH on the vacuum evaporation of orange juice and found that the evaporation rate could be increased as much as three times using ohmic heating, resulting in enhanced product quality. The authors concluded that OH could have potential as a fast evaporation method and recommend further development in this area. OH was applied in a seawater desalination thermal process (i.e. water is evaporated from seawater by heating and then condensed to produce pure water) with the advantage that there was no fouling on the conventional heat transfer surface although some issues of color existed [11, 75]. OH was also applied in hydro-distillation, for example, extraction of essential oils and alcohol concentration [76, 77]. The emerging OH distillation method was shown to be a potential alternative to hydro-distillation for the recovery of target components from miscible and immiscible mixtures such as ethanol–water and aromatic herbs–water, respectively. It offers several advantages such as better process control, reduced distillation cost, and shorter process time without adversely affecting the yield and distillate quality [78].

44.5.6 Dehydration

Ohmic heating was used to enhance the drying rate of vegetable tissue. OH of sweet potato prior to dehydration accelerated the hot-air drying rate significantly as compared to raw, conventionally treated, and microwaved samples [79]. Ohmic pretreatment accelerated the vacuum drying rate of sweet potato as much as 24%; and minimal ohmic treatment (electrical field strength of 50 V/cm and an endpoint temperature of 40°C) resulted in the maximal or near-maximal acceleration of drying rate [80].

Lima and Sastry [57] found that the lower the frequency of alternating current used in OH, the faster the hot-air drying rate. Maximum drying benefits were seen when drying

to initial or intermediate moisture contents. These investigators suggested that because OH enhances drying rates and enhances extraction yields, the process could be ideal for the recovery of high-value, heat-labile components from biological materials using unit operations such as supercritical fluid extraction. Moraveji et al. [81] simulated the transport phenomena of the potato drying process in a static system considering electrical field intensity, electrical conductivity, solid heating, liquid–solid conductivity, and predicted the parameters, such as drying rate, moisture content, and temperature changes, on the drying process of potato. It was observed that OH reduced the drying time and accelerated the diffusion in the entire product as compared to other conventional methods. In addition, heat and mass transfers simultaneously occurred nearly at the same rate in both phases (i.e. solid and liquid).

44.5.7 Fermentation

Cho et al. [82] found that mild electrical treatment significantly decreased the lag time of *Lactobacillus acidophilus*, possibly due to electroporation, which could enhance the transport of substrates across the cell membrane. The electricity applied later in the microbial growth cycle proved detrimental, possibly because of the enhanced transport of inhibitory substances across the cell membrane.

44.5.8 Enhanced Growth of Beneficial Bactria

Considering yogurt, OH under sub-lethal conditions presents promising results regarding the enhancement of growth rate (i.e. enhanced metabolism), whey protein structure as a potential carrier of probiotic entities and bacteriocin activity, leading to considerable improvements in the fermentation process [83]. However, Pereira et al. [83] pointed that fundamental knowledge is still required to understand interactions between electric fields and whey protein structures, and the interaction between alternating electric fields and the microorganism is far from being understood.

44.5.9 Extraction

Ohmic heating has been used to enhance the extraction of components from foods. For example, an electric field was used to extract sugar from sugar beets [84] and soymilk from soybeans [85]. OH of apple tissue prior to mechanical juice extraction significantly increased apple juice yields with respect to un-treated apple tissue, and the lower the frequency of alternating current, the higher the extraction yield [57, 86]. Similarly, a significant increase in the extraction of rice bran oil from rice bran (with moisture addition) was observed, especially at low (1 Hz) frequency [56].

Several studies have examined the diffusion of beet dye from beetroot. The diffusion enhancement of beet dye due to ohmic heating was especially pronounced at lower temperatures (42°C vs. 58°C and 72°C) and could be related to the difference in electrical conductivity of beet tissue between conventional and ohmic cases at the same temperature [87]. Kulshrestha and Sastry [53] showed that significant leaching of beet dye occurs with temperature increases of 1–2°C in OH. OH was applied to extract inulin from the wet-milled and dry-milled powders of Jerusalem artichoke tuber, and it was observed that OH provided a higher inulin extraction yield than the conventional heating method. Furthermore, dry milling produced a higher extraction yield and inulin purity than wet milling [88]. The juice yield and bioactive compounds of apple and carrot mashes treated by PEF or OH at different preheating temperatures (40, 60, or 80°C) were increased. A release of total polyphenols from apples into the juice increased in all pre-treated samples compared to the control. This was due to the thermal and electric field-based cell disintegration [89].

Moderate electric field extraction at low and high temperatures offers several advantages, such as enhancing product yield and quality with saving time and energy. Optimizing process parameters, such as treatment time and temperature, electric field intensity, and frequency, can boost the performance of such a system. In addition, the proper selection of raw material and preparation are needed [58]. Non-electroconductive materials such as glass, polyvinyl chloride, acrylic, Teflon, ceramic, and polypropylene were used for the extraction chamber [58].

44.5.10 Emulsion Stability

The stability of iron-loaded double emulsions was monitored under the influence of novel (microwave and ohmic) and conventional heat treatments [90]. Microwave heating led to destabilization and obvious phase separation. Considering iron release and color, conventional heating resulted in greater stability than OH. In addition, OH enhanced lipid oxidation (in yogurt as a model system) and increased iron release as compared to the conventional heating.

44.6 CONCLUSION

OH shows potential in food processing and preservation. The important factors that need to be considered for designing OH are electrode configuration, types of electrodes, electrical conductivity, applied voltage gradient, waveforms, frequency, fluid viscosity, solid–liquid ratio, and direction of fluid flow with respect to current flow. The mechanisms of action are electroporation and change in protein and starch configuration. OH is newly commercially used in many countries. Many applications, such as thermal treatment, bacterial inactivation and growth enhancement, peeling, blanching, drying, evaporation, distillation, and desalination, are now documented in the literature.

45 UV Light in Food Preservation

Mohammad Shafiur Rahman

CONTENTS

45.1 ULTRAVIOLET RADIATION

Ultraviolet radiation (UV) has been known for long as the major factor in the bactericidal value of sunlight. It is mainly used in sterilizing air and thin films of liquid due to low penetration depth. When used at high dosage there is a marked tendency toward flavor and odor deterioration before satisfactory sterilization is achieved. The low level of radiation at carefully applied doses can often usually extend the shelf life of foods without serious change in quality [1]. The technique of UV radiation to kill off bacteria in water is well-known. UV is safe, environmentally friendly, and more cost-effective to install and operate than conventional chlorination. It does not affect the taste of the water as chlorine does. High-intensity UV-C lamps can increase the potential of destroying surface bacteria on food [2]. UV radiation has been used in dairy plants for many years. It is also used in the ice cream industry and in meat and vegetable processing plants [3]. More applications of UV irradiation are presented by Falguera et al. [4]. A cost comparison of UV with the other processes is given in Table 45.1.

45.2 UV MODE OF ACTION

A number of theories have been proposed with regard to the mode of action of UV light. These include indirect lethal action resulting from the production of hydrogen peroxide, and various chemical and physiochemical changes in the constituents of the cell. The production of hydrogen peroxide is not generally considered as the mechanism by which ultraviolet light induces its effect, although organic peroxides may be involved. It has been suggested that substances of the cell nucleus are involved in the destruction action by UV light. UV wavelengths of 200 to 290 nm penetrate cell membranes to disrupt DNA molecules, preventing cell replication [1]. In addition, the degradation of the bacterial cell walls can cause a germicidal effect [5, 6]. Photo-reactivation could also enhance the effect on microbial deactivation and other physicochemical changes.

45.3 UV IN FOOD PRESERVATION AND DETERIORATION

Current UV reactors for juice processing use either very long tubes with UV transparent walls or very thin films to ensure sufficient exposure to UV radiation. The reactor design with long tubes requires turbulent flow and over 38 liters of juice exposed to a large number of UV lamps. In contrast, the design with thin films operates in laminar flow but is restricted to low-viscosity juices with no pulp. Recently a reactor has been designed involving the pumping of fluid through the annular gap between two concentric cylinders. To provide sufficient exposure and to reduce the fluid boundary layer thickness next to the radiation source contained within the outer stationary cylinder, the smaller inner cylinder rotates at a low rpm. Rotation of the inner cylinder establishes a complex flow field called Taylor–Couette flow consisting of laminar vortices that both fill the annular gap of several millimeters and circumscribe the inner cylinder. UV is one of the non-thermal processes capable of providing the FDA requirement of a 5 log reduction in viable pathogens [7]. A numerical dispersed phase model has been developed to describe the particle-phase flow patterns and particle residence times in thin-film UV reactor Cider Sure 1500 [8]. This model was used to simulate the processing of apple cider. UV irradiation is applied commercially in food processing by bactericidal ultraviolet lamps: tenderizing or aging of meat, curing and wrapping of cheeses,

TABLE 45.1

prevention of surface mold growth on bakery products, and air purification in bottling and food processing establishments and over pickle vats [1].

It is generally agreed that the wavelength for maximum germicidal effect is 2600 Å. Low-pressure mercury-vapor lamps have a maximum output at 2537 Å, a value close to the peak wavelength for bactericidal effectiveness. The lethal action varies with the time of exposure and intensity of light. Other influential factors include temperature, hydrogen ion concentration, and the number of organisms per unit area exposed. The relative humidity affects the death rate of bacteria suspended in air, this being most noticeable at relative humidity values greater than 0.50, at which point an increase in relative humidity results in a decreased death rate [1]. Pulsed xenon UV systems can disinfect aerobic bacteria in the absence of manual disinfection [9].

Spores of bacteria are generally more resistant to UV light than vegetative bacteria; *Bacillus subtilis* is reported as five to ten times more resistant than *Escherichia coli*. Molds are more resistant than vegetative bacteria, while yeasts differ less from bacteria in this respect. It has been suggested that some mold species may be protected by fatty or waxy secretions on the cell surface that shield them from the rays. Pigments apparently also afford some protection; dark-pigmented spores are more resistant to UV irradiation than non-pigmented types [1]. Short exposures, even long enough to cover one or more life cycles of the organism, are more efficient than higher radiation intensities for brief periods. This presumably is due to the fact that during certain stages of the life cycle the susceptibility to ultraviolet radiation is increased.

45.3.1 Juice

The lethal action of ultraviolet light on microorganisms has been well-documented. The practical application of this has been controversial because of the type and intensity of radiation, methods of estimating lethality, and other factors. A study of the germicidal powers of UV shows that 30 to 83% of the yeast, and 33 to 72% of the molds, were killed in apple cider through layers varying from 2 to 25 mm in thickness [1]. A greater part of the light was absorbed by coloring matter. Incident energy levels of 254 nm inhibited 90% of *Bacillus megatherium* at 11 kW/m^2 and 90% of *Sarcina lutea* at 198 kJ/m^2 [5]. There was a 90% reduction in the microbial count of apple juice. Coupled with effective refrigeration, this could be of commercial significance. Inactivation of *E. coli* O157:H7 in apple juice showed 2.81 log, 1.95 log, and 1.85 log reduction when exposed to UV-C (254 nm), Far-UV (222 nm), and Far-UV (282 nm), respectively, at the similar levels of fluence of 750 kJ/m^2 [10]. *E. coli* O157:H7 was shown to be acid-resistant, and up to 99.5% of cells survived in apple juice when incubated at 20°C for 24 h, while no reactivation potential was observed in dark incubation phases after exposure to UV light. However, the effect of deactivation by Far UV (222 nm) was higher as compared to UV-C and Far-UV (282 nm) when stored at 37°C.

Maple sap is susceptible to microbial infection, which, when it occurs, lowers the quality of the syrup. Schneider et al. [11] studied the effects on the reduction of living cells of bacteria (*Pseudomonas-25* and *Pseudomonas-11*) and a yeast (*Cryptococcus albidus*) strain suspended in maple sap when exposed to UV radiations of different intensities and for different lengths of time. The two bacterial strains were equally more sensitive than yeast. An increase in exposure time had the same effect regardless of the method of irradiation employed.

Ultraviolet C treatment is an emerging food-processing technology for health-conscious consumers. Freshly squeezed mango juice was exposed to UV-C light (for 15, 30, and 60 min at 25°C) and thermally pasteurized (at 90°C for 60 s) to compare the effect on microbial inactivation, physicochemical properties, antioxidant activities, and other quality parameters. In addition, a shelf life study of juice samples stored at 4°C was conducted for 5 weeks. In the case of mango juice, UV-C treatment and thermal pasteurization (i.e. 90°C for 60 s) showed no significant changes in physicochemical properties. An increase in extractability of carotenoids (6%), polyphenols (31%), and flavonoids (3%) and enhancement of antioxidant activity were observed in the juice exposed to UV-C for 15 and 30 min at 25°C as compared to freshly squeezed juice [12]. Thermal pasteurization and UV-C treatment exhibited a significant reduction in microbial load and prolonged the shelf life of juice. The shelf life of UV-C-treated juice stored at 4°C was extended for at least 4 weeks longer than freshly squeezed juice.

Fresh pitaya juice showed a reduction of 1.81 log cycles of *Zygosaccharomyces bailii* when treated (flow rate 30.3 mL/s and time 30 min) with UV-C light treatment (0.57 W/m^2), while mesophylls showed 1.76 log cycles [13]. The treatment did not affect pH and total soluble solids, while the total color change was slightly affected by the flow rate and treatment time. The phenolic content was not affected by the treatment, while betalain content and antioxidant activity were reduced as the flow rate increased. The color parameters and betalains content of treated juice decreased after 10 days of storage at 4°C, while phenolic compounds remained constant during the entire storage time and antioxidant activity was reduced after 5 days of storage. The mesophylls and yeasts plus *Z. bailii* quasi remained constant during 10 days of storage.

Freshly pressed apple juice or fresh cider contains many microorganisms, which cause deterioration within 2 days

at room temperature unless they are inhibited or destroyed. The microbial population of fresh cider was greatly reduced and storage life was prolonged without affecting the flavor by specially designed UV lamps [14]. Harrington and Hills [14] found that the percentage reduction of microbial activity was affected by the clarity of the cider, the length of UV exposure, and the presence of potassium sorbate. This is very suitable where the initial microbial count is high and there is not adequate refrigeration. Hoyer [15] reported values of UV dose for 90% reduction of *E. coli* ATCC 11229 and *E. coli* ATCC 23958 were 25 and 12.5 J/m^2, respectively, and a value of 15 J/m^2 for a 1 log reduction of *E. coli* O157:H7 in drinking water. UV doses for a 90% reduction in model juices with dose distribution in annular UV reactors were determined and varied from 4.5 to 6.5 kJ/m^2 in a vertical set up [16]. The UV dose distribution must be taken into consideration when calculating the microbial inactivation achieved by the reactor and designing a continuous UV reactor [16].

UV (254 nm, bench-top, batch-scale unit with incident UV intensity of 200 W/m^2) exposure resulted in a more than 90% reduction in PPO activity in mushroom after 5 min of exposure (480 kJ/m^2) [17]. A model system of typical fruit and vegetable juice (glucose, sucrose, and fructose at 10 g/100 mL level, pH 3.5–6.8, and suspended particles 844 NTU) was used to treat PPO. A depth of 1.4 mm with gentle agitation was used. PPO inactivation was accelerated by fructose due to the generation of reactive oxidative species by fructose, while sucrose and glucose showed no effect on the inactivation rate. The inactivation rate was higher at pH 3.5 than at pH 6.8, and suspended particles reduced the inactivation due to the scattering of UV light. Additionally, no reactivation was observed during storage.

In the case of coconut water, 3.1–7.8 log microbial reductions were observed for the inoculated *Lactobacillus rhamnosus*, *Salmonella typhimurium*, and *Saccharomyces cerevisiae* after 10 min of treatment of UV-C light (52–264 kJ/m^2) [18]. The residual effect during storage at 5 and 25°C showed the bacterial decay when stored at 5°C; while 25°C storage showed maximum growth of 1.12 log (12 h storage) and 0.8 log (24 h storage) cycles for *L. rhamnosus* and *S. cerevisiae*, respectively. The residual effect showed that no refrigeration may be required for the storage of coconut water.

Iwanami et al. [19] studied the effect of UV radiation in a lemon flavor composed of lemon oil, water (pH 6 phosphate buffer), and ethanol. Three new compounds of aldehyde, newly identified as photoreaction products of citral, limonene, terpinolene, and nonanal, decreased, while p-cymene increased after UV radiation. Other components, such as sesquiterpene hydrocarbons, citronellal, linalool, and terpineols, were slightly changed. These results suggested that UV radiation is critical for the UV-unstable component in lemon flavor, and the photolysis of citral could affect other components in lemon flavor [20].

45.3.2 Fruits and Vegetables

The effect of UV on bacteria and fungi, such as *Penicilli* and *Aspergilli*, was reported by Kleczkowski [20]. UV inhibits the fungal development in grape berries [21], kumquat, and orange fruits [22]. Moy et al. [23] combined UV and gamma radiation for the preservation of papaya. Combined methods can avoid high doses of gamma and UV radiations. UV irradiation exhibits a hormetic effect in disease resistance and control of diseases for postharvest crops [24].

Lu et al. [25] studied the efficacy of gamma rays (0.1 to 3 kGy), electron beams (0.1 to 5.0 kGy), or UV radiation (0.44 to 7.33 kJ/m^2) to preserve onions for up to four weeks at 20–25°C. UV-radiated onions exhibited the greatest percentage of marketable onions and reduction in postharvest rots. Sprouting was observed with control, UV-, and electron beam-irradiated onions but not with gamma-irradiated onions. No significant total sugar, pH, moisture, ascorbic acid, color, texture, or sensory quality changes were observed with the onions irradiated with UV. The optimum UV doses were in the range of 3.58 to 7.33 kJ/m^2 for onions. In addition, UV is much more economical and safer to use than gamma or electron beam irradiation.

Ranganna et al. [26] studied the efficacy of UV treatment in the control of both soft rot and dry rot diseases of potato tubers for short-term storage of three months and to understand the tuber quality changes. They tried four UV radiation dose levels (7.5, 10.0, 12.5, and 15.0 kJ/m^2), and three incubation levels each for fungi *Fusarium solani* (0, 1, and 2 days) and bacteria *Erwinia carotovora* var. *carotovora* (0, 6, and 12 h). The highest UV dose level was found to be more effective as compared to the other three radiation dosages to control disease caused by the above fungi and bacteria. The visual observations of potato quality showed that there was no significant change in the tuber quality such as firmness and color.

The effect of a hormetic dosage of UV radiation in delaying the senescence of tomato was investigated [27]. Mature green tomato fruits were irradiated (UV-C, 200–280 nm) corresponding to 0, 3.7, and 24.4 kJ/m^2 and were stored at 16°C, under high relative humidity for a period of 35 days. Attributes of senescence such as weight loss, color, texture, respiration rate, ethylene production, and putrescine were monitored periodically throughout the storage period. A dose of 3.7 kJ/m^2 was found to be beneficial (hormetic) in delaying ripening and senescence, while the higher dose impaired ripening and caused abnormal browning, manifested as sunscalding of the fruit's surface. The development of color and softening of tissue were significantly retarded during storage in response to the treatment with the hormetic dose. In addition to a delay in the climacteric response by at least 7 days, the respiration rate and ethylene production of the treated fruit were also reduced. The delay in senescence was attributed, in part, to the maintenance of a high level of putrescine (antisenescence agents exerting an opposite physiological effect to ethylene) [27].

UV-C irradiation could be used as an effective and rapid method to preserve the postharvest life of ripe mangoes without adversely affecting certain quality attributes [28]. This was observed after 10- and 20-min exposure prior to storage for 14 days at 5 or 20°C and a shelf-life period of 7 days at 20°C. Treated fruit maintained better visual appearance,

suppressed decay symptoms, maintained firmness, showed greater levels of putrescine and spermidine, and retained higher levels of sugars and lower levels of organic acids during storage at 5 or 20°C.

Mau et al. [29] found that UV irradiation increased vitamin D_2 content in edible mushrooms. After UV-C irradiation for 2 h, vitamin D_2 contents in common and high-temperature mushrooms increased from 2.20 and 4.01 μg/g of dry weight to 7.30 and 5.32 μg/g, respectively. After UV-B irradiation for 2 h, the vitamin D_2 content in common mushrooms reached 12.48 μg/g. UV-B irradiation resulted in higher vitamin D_2 conversion for common mushrooms. After UV-B irradiation for 2 h, vitamin D_2 contents in shiitake and straw mushrooms increased from 2.16 and 3.86 to 6.58 and 7.58 μg/g, respectively. The increased rates in shitake and straw mushrooms were not as high as in common mushrooms.

The enzymatic browning in fruit and vegetable tissues containing phenolic or polyphenolic compounds is common. A reduction of 58.7% in polyphenol oxidase (PPO) activity was achieved in the first 90 s when UV-Vis irradiation was used, and it was completely inactivated after 35 min of treatment [30]. The melanin pigment was synthesized and absorbed some radiation energy, thus leading to a slower inactivation of polyphenol oxidase.

UV irradiation (6 to 48 h, 13.0–103.7 J/m^2) showed potential for increasing the mechanical strength of casted soy protein films [31]. Besides increasing tensile strength, the appearance of immobile bands in electrophoretic patterns suggested further development of covalent cross-links in UV-treated films. Individual proteins may exhibit different degrees of response to UV radiation due to varying amino acid compositions and molecular structures. UV treatment would not be expected to render soy protein films unsuitable for use as edible films or as food wraps. UV treatment increased the tensile strength of gluten, zein, and albumin films suggesting the occurrence of UV radiation-induced cross-linking within film structures. For caseinate films, UV-curing did not affect tensile strength but substantially reduced total soluble matter. Small but significant decreases in the total soluble matter were also noticed for UV-treated zein and albumin films.

UV irradiation reduced the water vapor permeability of albumin films but did not affect the water vapor permeability of the other types of films. Gluten, albumin, and caseinate films had increased yellowness as a result of UV treatment. In contrast, UV treatment decreased the yellowness of zein films, possibly due to the destruction of zein pigments by UV radiation [32]. The gel strength of minced mackerel with transglutaminase alone at a concentration of 0.47 unit/g was three times greater than that of control [33]. When transglutaminase-supplemented minced mackerel was exposed to UV light for the optimal irradiation time of 20 min, the gel strength could be further increased by 25%. This suggested that UV irradiation accelerated the transglutaminase to catalyze the cross-linking of myosin heavy chains in mackerel actomyosin [33]. With increasing time of exposure to UV radiation, the molecular weight of proteins in water solutions decreased with the excluded volume increases for the two kinds of proteins (pepsin and albumin) as studied by Maciejewska et al. [34]. The denaturation effect of dimethyl sulfoxide on the solid samples of both starch components (amylase and amylopectin) was demonstrated by its spectral similarity [35]. In a study by Fiedorowicz et al. [36], a suspension of corn starch in water was irradiated by UV light with a wavelength greater than 250 nm at 25°C, under a stream of nitrogen or air, for time intervals ranging from 5 to 25 h. They found that molecular size distribution profiles confirmed the photo-degradation to be oxidative in the early stage (up to 5 h), and cross-linking reactions in the later stage (5–15 h) of irradiation under aeration.

The pulsed UV light pretreatment reduced the water content in mangoes, but did not affect the apparent water diffusivity of the subsequent drying process [37]. Vitamin C and carotenoids in dried mangoes increased 10 and 40% (36 and 108 kJ/m^2) as compared to the untreated dried mango, while vitamins B_1, B_3, and B_5 increased by 10 to 25% (36 and 72 kJ/m^2). Vitamin B_6 was highly affected by pulsed UV light, decreasing by 40 to 50% in the pretreated mangoes.

45.3.3 Meat

After killing, meat becomes tender upon storage as a result of enzymatic activity. This process is speeded up at relatively high temperatures, which favor the growth of surface microorganisms. By controlling such growth with ultraviolet light, the advantage of the high storage temperature can be better utilized and result in less loss of meat. In this particular case, irradiation alone is the less likely active factor. The lamps employed emit rays not only in the germicidal 2537 Å range but also in the 1850 Å range. These shorter waves convert atmospheric oxygen to ozone; irregular and shaded areas of an irradiated surface are sterilized by the ozone. UV is also used in storage vats and other tanks, over both conveyers and for final treatment of both caps and stoppers [1].

Putrefaction spoilage of fresh meat can occur in a few hours as a result of the action of spoilage bacteria. UV at a wavelength of 254 nm was effective in destroying surface bacteria on fresh meat by 2 log cycle (99% reduction) after a radiation dose of 1.50 kW/m^2 on smooth-surface beef meat. A further increase in dose level to 50.0 kW/m^2 reduced 3 log cycle. Since UV radiation does not penetrate most opaque materials, it was less effective on rough surface cuts of meat, such as round steak, because bacteria were partly shielded from the radiation. No deleterious effects on color (redness) or general appearance were observed, and UV irradiation of meat carcasses could increase the lag phase of bacteria until adequate cooling of the surface [38].

The physical appearance of a retail product in the display case is the most important factor determining consumer selection of beef products. Reagan et al. [39] mentioned that significant increases in shelf life may be obtained by exposure of beef muscle and fat surface to UV light (max wavelengths 3660 Å for 2 min). UV treatment decreases initial count and/or attenuation of the bacteria present on retail cuts, and

resulted in increased consumer acceptability, higher muscle color ratings, and increased shelf life of beef [39].

Kaess and Weidemann [40] found that continuous UV ($0.2–24 \times 10^{-2}$ W/m^2) irradiation of psychrophilic microorganisms growing on muscle slices at 0°C and 0.993 equilibrium relative humidity resulted in an extension of the lag phase of *Pseudomonas* and of the molds *Thamnidium* and *Penicillium*, but not the yeast *Candida scottii*. A minimum intensity of 2.0×10^{-2} W/m^2 at the meat surface is necessary to prolong storage life substantially. Lower equilibrium relative humidity did not substantially increase UV effects. The relative extension of storage life at 10°C was comparable to that obtained at 0°C. The simultaneous use of UV (0.2×10^{-2} W/m^2) and ozone (0.5 mg/m^3) produced synergistic effects with molds, but not with bacteria [40].

45.3.4 Minimally Processed Fruits and Vegetables

UV-C radiation can be considered a promising tool for maintaining the overall quality of fresh-cut fruits if applied in mild doses [41, 42]. All treatments with UV-C (1.2–24.0 kJ/m^2) imparted the same germicidal effect with a 1–2 log reduction in total viable counts in fresh-cut apple [42]. The loss of compartmentalization of surface apple cells, activating dehydration and oxidative phenomena, was observed with treatments above 1.2 kJ/m^2. Mild treatments resulted in more stability in terms of microbial growth and the development of browning and off-flavors as compared to the untreated. In addition, an edible protective film formed during treatment inhibited microbial growth and hindered dehydration during storage, while this was too thin to be perceived visually. UV-C light (fluency: 0.2–4.8 J/m^2 and 200 J/m^2) did not decrease the initial microbial load of fresh-cut pineapple sticks [43]. However, treated pineapple packaged in conventional PET/EVOH/PE trays and stored at 6°C showed slower (i.e. 2 log cycle lower) yeast and lactic acid bacteria growth up to 15 days. In addition, UV-C light did not promote changes in color and increased consumer preference.

The microbial counts of fresh-cut watermelon reduced just after exposure, and after 11 days at 5°C, mesophilic, psychrophilic, and enterobacteria populations were lower in the UV-C-treated watermelon [41]. Slight changes in color were observed. Considering sensory quality, low-dose (1.6–2.8 kJ/m^2) treated fruit can be stored for up to 11 days at 5°C, while the maximum shelf-life of moderate- to high-dose (4.8–7.2 kJ/m^2) treated fruit was 8 days at 5°C. The untreated and UV-C-treated fruit showed a similar decrease in lycopene after 11 days' storage at 5°C, and the decrease was low at low doses. The vitamin C level remained the same, while total polyphenols content considerably declined throughout the storage period and total antioxidant capacity markedly increased. Higher doses induced slightly higher carbon dioxide production, while no changes in ethylene production were observed, and final gas partial pressures remained the same within modified atmosphere packages.

The water consumption in fresh-cut salad washing can be reduced by UV-C light [44]. Water drained from lettuce was collected and then treated with UV-C light (up to 1.2 kJ/m^2) and reused for up to five washing cycles. A considerable amount of UV-C light can penetrate wash water if its thickness is lower than 1 cm. A dose of 0.4 kJ/m^2 allowed the inactivation of most of the native microflora and the achievement of more than 5 log reductions in inoculated *Salmonella enterica*, *Listeria monocytogenes*, and *E. coli*. In multiple washing cycles up to 5, the treatment resulted in more than 3 log reductions in native microflora in the wash water.

45.3.5 Fish and Seafood

The use of UV radiation is effective in inhibiting the action of spoilage bacteria on fish and seafood [2]. UV at 254 nm and doses of 3.0 kW/m^2 from a photochemical reactor or 48 J/m^2 from a high-intensity UV-C lamp (40 sec at 120–1.8 kW/m^2) reduced the surface microbial count on mackerel by 2 or 3 log cycles [3]. Huang and Toledo [3] mentioned that the shelf life of Spanish fresh mackerel was extended by 7 days over the untreated sample when the skin surface was treated with high-intensity UV and stored in ice at –1°C. When UV irradiated and packed in 0°C ice, surface microbial counts on vacuum-packaged mackerel lagged by 4 days compared to those on mackerel wrapped in 1 mil polyethylene [3].

The use of UV has some disadvantages, such as it does not penetrate most opaque materials and it is less effective on rough surfaces [2]. Huang and Toledo [3] found that rough-surface fish such as croaker and mullet had little bacterial count reduction on its surface with a UV-C-13 lamp with doses of 1.2 to 1.8 kW/m^2 up to 50 s treatment. They found that spray washing with water containing 10 ppm chlorine by itself or in combination with UV was necessary to reduce surface counts on rough-surface fish to the same extent as that on smooth-surface fish.

UV at 260 nm (6 W/m^2) could inactivate mold *Aspergillus niger*, *Penicillium citrinum*, and *Cladosporium cladosporioides* in dried fish products, such as dried filefish fillets without any concomitant changes in the color or sensory qualities [45]. The overall reduction of the spoilage molds ranged from 1 to 2 log cycle (6–18 W/m^2). Hunter color parameters and sensory parameters (color, texture, and appearance) of the fillet did not change (6–18 W/m^2), while flavor and overall acceptability decreased at the dose of 6 W/m^2.

45.3.6 Dairy

A 6 log reduction of the initial microbial population was achieved using 100 kJ/m^2 of pulsed UV when goat milk was inoculated with *E. coli* [46]. Samples irradiated with 50 and 100 kJ/m^2 doses exhibited aromatic changes as compared with the non-irradiated, while no significant differences in the physical or compositional parameters were observed. The inactivation of *E. coli* O157:H7 in bovine milk was higher when exposed to 254 nm UV as compared to 222 and 282 nm at the same fluence of 50, 100, and 200 J/m^2 [47]. The reactivation was increased as the incubation time and temperature (5, 20, 37°C) increased regardless of the UV light sources (i.e. under dark incubation phases), while the reactivation ratios

were lower than those of non-UV-treated cells regardless of the incubation temperature. The lowest reactivation ratios were observed after milk exposure to the UV light at 254 nm and 4°C as compared to 222 and 282 nm exposure.

UV and heat pasteurization treatments caused loss of vitamin C in milk. In the cases of cow and goat milk, pasteurization did not show any significant effect on vitamin B_2. However, UV light treatment decreased the amount of vitamin B_2 after several passes of milk through the UV system. UV light sensitivities of vitamins were C > E > A > B_2, and sensitivity depended on the number of passes, and initial levels before UV treatment [28].

The fat oxidation by photochemical action results in off-flavors, such as rancidity, tallowiness, fishiness, cardboard flavor, and oxidized flavor [48]. Coe and Le-Clerc [49] attributed rancidity to the ultraviolet light range of the spectrum. The defects of milk, such as fishiness [50] and cardboard-like flavor [51], butterfat [20], and processed cheese [52] were caused by light oxidation. Thus, packaging materials with the ability to screen UV have been developed for food products. Processed cheese in normal cellophane wax-coated wrappers becomes oxidized within 12 h, and within 48 h the top slice became inedible [48]. This process can be retarded by incorporating a substituted benzophenone within the wax coating normally applied to certain types of cheese wrappers.

Hirsch [53] mentioned that it is accurate to say that the meaty portion of bacon is subject to fading when exposed to UV light. Fade can be reduced appreciably through vacuum packaging and a UV barrier on the packaging material. A good vacuum-packaging operation will deliver a bacon package with no less than 28 in of vacuum. By incorporating polyvinylidine chloride (PVDC) into the packaging material both oxygen and UV light are screened, and the product survives a considerably longer period of time without fade. Generally, retinoids are very susceptible to oxidation because of their alkyl chains with highly conjugated double bonds [54]. Shimoyamada et al. [54] found that retinol and retinoic acid bound to β-lactoglobulin were less susceptible to light-induced oxidation by UV light irradiation than those which were free or bound to bovine serum albumin. They found a different mechanism of protection against light-induced oxidation compared to enzymatic oxidation. Jung et al. [55] found that the addition of ascorbic acid greatly inhibited the light-induced reduction of all-*trans*-retinyl palmitate and 13-*cis* isomer in skim milks. Ascorbic acid also greatly increased the formation of 9-*cis*-retinyl palmitate in skim milk during light storage.

45.4 UV IN SANITATION

The disinfection (treatment time: 3–60 min) effectiveness of lettuce, tomatoes, and carrots was compared when treated with chlorine (50, 100, and 200 ppm), citric acid (0.5, 1, and 1.5%), UV-C (0.65 and 16 kJ/m^2), and ozone (5 ppm) [56]. Citric acid did not prove effective for the inactivation of *E. coli* ATCC 11775, while UV-C was effective when fluence was higher (i.e. more effective in the smooth surface of tomato, 2.7 log reduction), and ozone was able to inactivate bacteria in tomatoes (2.2 log reduction) after only 3 min. In all treatments, carrots and lettuce showed lower inactivation because of their porous and rough surfaces. UV-C produced most effects on the color, therefore sensory properties need to be considered in addition to the effectiveness of microbial disinfection.

UV rays (non-ionizing radiation) have been used extensively in the disinfection of equipment, glassware, and air by industries for many years [57]. The bactericidal effect of ultraviolet light is widely used for sanitation purposes. It is particularly effective in destroying airborne organisms and consequently has become an important sanitary aid to in-plant installations. It may eliminate detrimental contamination and keep away objectionable invaders. Cerny [58] found that high-intensity UV irradiation may be used in the sterilization of packing materials for aseptic packaging. The penetrating power of ultraviolet rays is very low, so that lethal action is confined to organisms on or near the surface of irradiated materials. Aerial disinfection is severely limited by the presence of dust particles in the atmosphere. Several different UV lamps are available commercially for food industry applications for processing or disinfection.

45.5 PHOTO REACTIVATION

If microorganisms are treated with various dyes (erythrosine, for example), they may become sensitive to damage by visible light. This effect is known as *photoreactivation*. Some food ingredients could possibly induce the same reaction. Such dyes are said to possess photodynamic action [1]. Spores may occasionally fail to show photoreactivation when inactivated with UV light, whereas the corresponding vegetative cells sometimes show photoreactivation. The simplest explanation of these data is to assume that radiation damages genetic material in the spore, and that certain bacteria may produce diploid spores as a result of specific disruptions. Such bacterial spores exhibit two types of radiation inactivation curves: *B. subtilis*, *Bacillus brevis*, and *Bacillus mesentericus* are inactivated in a single-hit fashion, whereas *Bacillus megaterium*, *Bacillus cereus*, and *Bacillus mycoides* are affected by a multiple-hit approach. In all cases, there is no effect on spore survival if the post-irradiation medium is changed from yeast extract to a purely chemically defined medium [1].

When surface microbial contamination is the major cause of spoilage in the case of selected seafood, the application of intense, short pulses of incoherent, continuous, broad-spectrum light can be used to increase the shelf life. The extension is achieved through two processes: (i) by the destruction of spoilage-causing microorganisms, and (ii) by the inactivation of enzymes. This destruction or inactivation is obtained through a complex photothermal and photochemical mechanism mediated by the use of wavelengths less than 300 nm. The pulsed light waves transfer thermal energy to a thin surface layer without raising the interior temperature of the product [2]. Colby and Flick [2] concluded that the increased efficiency is possible to achieve by the use of dyes or other chemical compounds that selectively bind to either

microorganisms or enzymes thereby increasing their susceptibility to the pulsed electromagnetic waves.

Photo-induced (light-induced) off-flavors also result from lipid oxidation and protein degradation. Linoleic acid is highly susceptible to photo-oxidation, and can lead to the formation of high levels of hexanal. Cabbagy, burnt-protein, and burnt-feather notes are associated with protein degradation. Amino acid degradation is catalyzed by riboflavin photo-oxidation and results in thiols, sulfides, disulfides, and 3-methylthiopropance of riboflavin, and oxygen generates methional, which further degrades to methanethiol, dimethyl sulfide, and dimethyldisulfide, all of which contribute to a cabbage or burnt-feather type aroma. Maillard reaction heterocyclic intermediates 2-ethylpyrrole, 2-ethylfuran, and 2,4,5-trimethyloxazole decrease in concentration as a result of photo-oxidation in the presence of chlorophyll [59, 60].

The pH of fructose solution decreased by 5.29% upon exposure to high-intensity pulsed UV light due to the photolysis of fructose when exposed to UV light at 254 nm [61]. UV light (254 nm) exposure of fruit juice with fructose can form furan [62] and accelerate the degradation rates of patulin and ascorbic acid of apple juice [63, 64]. Fructose can be used as a photosensitizer for the accelerated photo-degradation of chlorpyrifos (i.e. insecticide) and diuron (i.e. herbicide) [65]. The reactive oxygen species (ROS), primary species (such as hydroxyalkyl, and hydroxyalkyl acyl radicals), secondary species (hydroxyl, peroxyl, superoxide radicals, and hydrogen peroxide), singlet oxygen, acidic photolysis was generated in the fructose solution when exposed to 254 nm UV light [65–67].

45.6 CONCLUSION

UV rays are extensively used in industry for disinfecting equipment, glassware, air, and water. A low dose of UV usually extends the shelf life of foods without serious changes in quality. However, at high doses marked changes, such as flavor, odor, fat oxidation, and loss of vitamins, are observed before satisfactory sterilization. Mild doses of UV are successfully applied in different food products, such as juice, fresh and minimally processed fruits and vegetables, fresh and dried fish, and dairy products. Photo-reactivation could occur in many food components, such as fructose and color pigments, and could enhance the effectiveness of UV treatment. However, this treatment can cause positive or negative effects on food products, and thus needs to be applied carefully.

46 High-Intensity Pulsed Light for Food Preservation

M. L. Bhavya and H. Umesh Hebbar

CONTENTS

46.1 INTRODUCTION

Urbanization has changed the lifestyles of people and their priorities towards the consumption of processed foods, and the trend is on the rise. Thermal processing of foods ensures prolonged shelf-life and food safety; however, it also contributes to undesirable changes in the food matrix affecting the functionality of foods and their flavor, colors, vitamins, and textural softening [1]. In recent years, consumers' demand for minimally processed foods with nutrients has increased drastically. Simple, cost-effective, and energy-efficient novel alternative techniques are gaining importance in meeting consumers' demands. Many innovative technologies have been developed to inactivate microorganisms, such as pulsed electric field, high hydrostatic pressure, ultrasound, dense phase carbon dioxide, cold plasma, ozone, and pulsed light (PL), and these are gaining popularity in the food-processing sector. These novel technologies have potential in preserving the nutritional and delicate sensory qualities of food and hence can be used for the minimal processing of foods [2]. Among these non-thermal technologies, one of the emerging technologies is light-based processing, which not only reduces the microbial load but also retains the nutrient quality of solid and liquid foods. This novel technology is being employed to decontaminate foods, packaging material, medical devices, and processing equipment related to the food, medical, and pharmaceutical sectors [3–7].

46.1.1 Pulsed Light Technology

PL technology is a novel non-thermal processing, where decontamination of foods is achieved by the application of high-intensity light pulses within a short duration of time. The term PL has been recognized since the year 1980 and was first implemented by the FDA for processing of food in the year 1996 [8]. The PL constitutes a wide wavelength range

of 180–1100 nm, which includes ultraviolet (UV): 180–400 nm, visible (VIS): 400–700 nm, and the near-infrared region (IR): 700–1100 nm [4, 9, 10]. Irradiation with PL of high peak power is used to deliver a spectrum 20,000 times more intense than sunlight at the earth's surface [4, 11]. One of the major benefits of PL is its short-duration energy exposure as compared to the static UV treatment [12, 13]. The foremost advantages of PL are (i) its substantial microbial reduction in very short treatment time, (ii) absence of chemical compounds, (iii) its low impact on the environment [7, 14], (iv) its operation at relatively low costs, and (v) it generally does not affect the characteristics of food matrices [15]. PL has potential applications in food processing by reducing risk to public health from foodborne pathogens, extending the shelf life of the food product, and improving economics during food distribution [16]. Although, PL processing is considered "non-thermal," it has the drawback of heating the sample if prolonged treatment is used. Significant increase in temperature is due to longer pulsed ultraviolet (PUV), and it has an extra thermal effect on microbial reductions [17, 18].

46.1.2 Terminology

The following terminology and units are frequently used in PL treatment [9]: pulse width (i.e. time interval during which energy is delivered, s), fluence (i.e. energy received from the lamp by the sample per unit area during the treatment, expressed as J/m^2), energy dose (i.e. used synonymously in place of fluence), peak power (i.e. pulse energy divided by the pulse duration and measured in Watt, W), fluence rate (i.e. energy received from the lamp by the sample, W/m^2), and exposure time (i.e. duration of the treatment, s).

46.2 PULSED LIGHT SYSTEMS

Batch and continuous systems are used for microbial load reduction in various food products. Most of the batch systems have almost similar constructions with different types of light sources and product cooling mechanisms. Continuous-flow systems are reported to be better suited, as they provide good mixing and enhance the feed handling rate. A few reports on batch and continuous systems for PL processing are discussed below.

46.2.1 Batch Systems

MacGregor et al. [19] used a bench-top PL system for the inactivation of food-related pathogenic bacteria. The chamber was designed to keep the samples at an inclination of 45° to receive equivalent doses of light energy from a xenon lamp, which is placed in the chamber. At the upper level of PL (512 μs), reductions of 6 and 7 log were observed for *Listeria monocytogenes* and *Escherichia coli* respectively. Fine and Gervais [20] used a 3-liter fluidized-bed system with adjustable air nozzles and compressed air to allow the tangential blowing of fluidized food powders. This system uses high intensity with broad spectra white light, whereas a flash lamp was surrounded by a quartz jacket with water circulation to limit lamp overheating and a reflecting cylinder. Sharma and Demirci [21] and Ozer and Demirci [16] decontaminated alfalfa seeds and salmon fish fillets using batch systems. Similarly, Bialka and Demirci [22] also constructed a laboratory-scale, batch PL system for the sterilization of blueberries with a slight alteration in the set-up consisting of a quartz window and a cooling blower. Choi et al. [23] designed a PL system for the sterilization of infant foods that consists of a water bath as a cooling device to dissipate the heat produced during the discharge of PL and an oscilloscope to observe the exponential decay pulse. Luksiene et al. [24] fabricated a high-power PL system with a xenon flash lamp as the light source. Paskeviciute et al. [25] and Luksiene et al. [26] used this unit for chicken, vegetable, and fruits sterilization. Cheigh et al. [27] constructed a lab-scale PL system comprising a xenon lamp used to produce intense pulsed light (IPL) for inactivating *L. monocytogenes* on solid medium and seafoods (Figure 46.1). Hwang et al. [28] designed a batch IPL treatment unit for the microbial inactivation of various liquid samples (mineral water, isotonic beverage, fruit juices, carbonated beverages, milk). The samples were exposed to a xenon lamp placed in a chamber, and to prevent the overheating of samples during processing, an air cooling system was provided on either side of the lamp.

46.2.2 Continuous-Flow Systems

Krishnamurthy et al. [29] conducted PUV treatment in the continuous flow-through system for inactivating *Staphylococcus aureus* in milk. Milk was pumped through a narrow quartz tube exposed to PUV, placed inside a chamber. V-groove reflectors made up of a polished metal surface were provided to enhance the energy absorption by milk. The authors concluded that effective inactivation of *S. aureus* (up to 7.27 log) in milk can be carried out in a continuous-flow system. Pataro

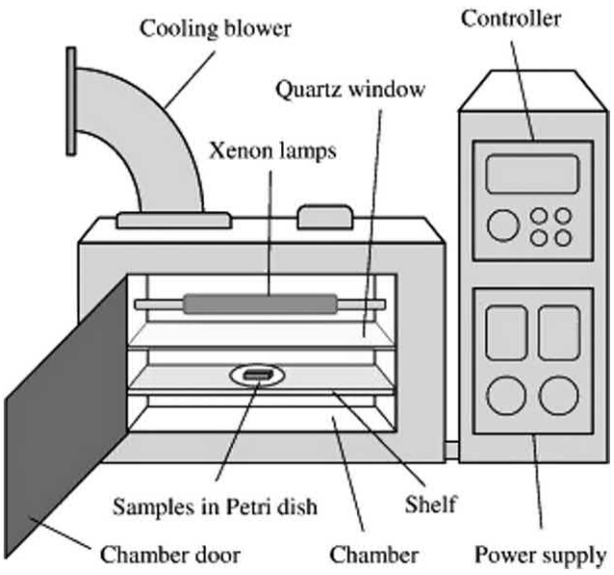

FIGURE 46.1 Schematic diagram of the intense pulsed light (IPL) system. (From Cheigh et al. [27].)

et al. [30] reported their work on bacterial (*Listeria innocua* and *E. coli*) inactivation of fruit juices (apple and orange) in a laboratory-scale continuous-flow PL system. Pre-cooled juice was pumped through two consecutive quartz tubes exposed to xenon lamps (pulse duration of 360 μs), and the heating of the product was controlled through a water–ethylene glycol solution refrigeration system. The present system was able to inactive up to 4 log under optimized conditions of processing. The authors suggested that proper designing of the system is essential to minimize the temperature build-up and to improve treatment homogeneity. Caminiti et al. [31] developed a continuous-flow system to study the impact of a select combination of non-thermal processing technologies, including light-based technology, on the quality of an apple and cranberry juice blend (Figure 46.2). The juice was pumped through two quartz glass tubes and exposed to PUV (360 μs) and cooling assembly prevented heating of the product while flowing through tubes. The unit was able to handle nearly 20.8 ml of juice per min and the authors did not observe any significant difference in appearance, sweetness, or acidity of the juice processed by PUV.

A pilot-scale flow-through system was designed by Chaine et al. [12] for the decontamination of sugar syrup. A xenon flash lamp was fitted inside a stainless-steel tube, using a quartz sleeve, and the sugar syrup was passed through a narrow gap between the steel tube and quartz sleeve. At an optimized flow rate of 5.3 ml/s, at least a 3 log reduction of various microbes was achieved. Based on the result, the authors recommended the use of several parallel modules to increase the volume of feed. Muñoz et al. [32] used a continuous PL system consisting of two quartz tubes for the inactivation of microbes in pre-cooled juice, where a xenon flash lamp with a pulse generator was used for the generation of PL (Figure 46.3). The authors inferred that a combination of PL and thermosonication (prior to PL) is more effective than the individual application. In another study, a similar system was developed to treat apple juice, in which the authors compared the effect of PL with and without the combination with ultrasound (US) treatment on different microbes [33]. Juice was pumped through two consecutive quartz tubes exposed to a xenon lamp and recirculated for the desired degree of exposure, and the product temperature was maintained through an

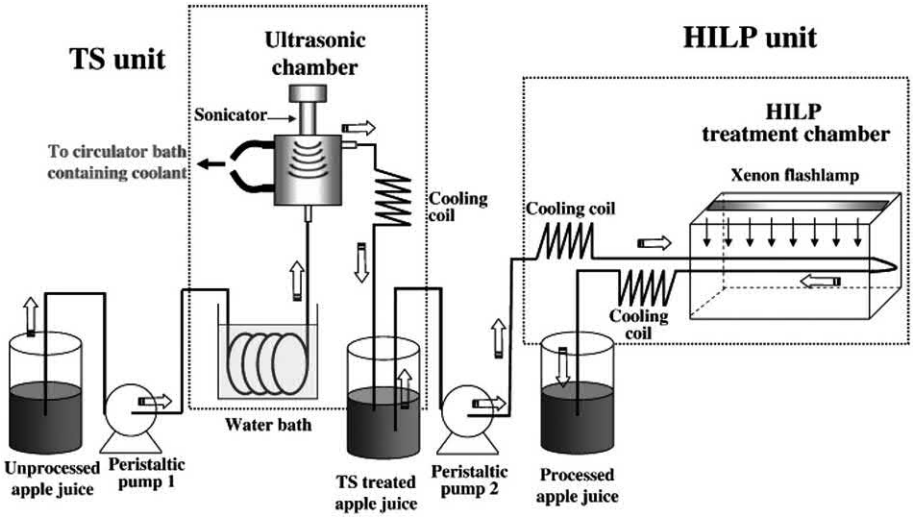

FIGURE 46.3 Schematic diagram of a thermosonication (TS)/high-intensity light pulse (HILP) processing system for reconstituted apple juice. (From Muñoz et al. [32].)

external cooling system. The results have shown that a continuous PL system can be effectively used in combination with other techniques. Yi et al. [34] developed a pilot-scale continuous-flow IPL system (Figure 46.4) to inactivate bacteria and viruses in untreated groundwater. A cylindrical treatment chamber (0.93 m height × 0.31 m diameter) was used to circulate water in the chamber using a pump, and the treatment time was set by controlling the flow rate. Multiple cylindrical xenon flash lamps (15 nos.) with emission spectra ranging from UV to infrared were used in the study. They reported a 2.91–4.70 log reduction of various microbes at different processing times and energy doses. At the optimized rate, the developed unit was estimated to handle 720 L/h of water, and it was suggested that it could be used in the food industry for the treatment of water.

PL-based systems are being manufactured to suit commercial-scale operations. The pioneering company to produce PL equipment for application in water purification and virus inactivation was Purepulse Technologies Inc. (San Diego, California), a subsidiary of Xenon Corp., which commercialized the PureBright™ system [11]. As per literature reports, there are three major commercial companies, namely, SteriBeam Systems from Germany, Xenon Corporation from the United States, and Claranor from France, producing PL-based disinfection systems. The details of various systems used for PL processing are presented in Tables 46.1 and 46.2.

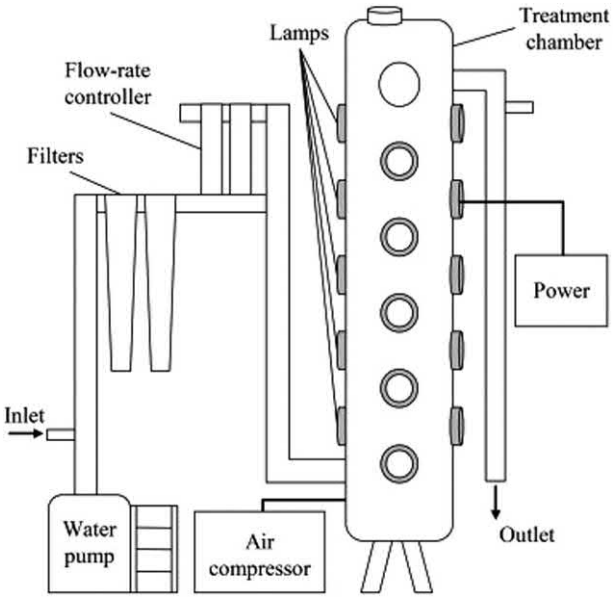

FIGURE 46.4 Pilot-scale continuous-flow PL system. (From Yi et al. [34].)

46.3 PULSED LIGHT FOR MICROBIAL INACTIVATION

46.3.1 Effect on Microorganisms: Bacteria, Fungi, Viruses, and Spores

The susceptibility trend is reported to be Gram-negative bacteria > Gram-positive bacteria > bacterial spores > fungal spores > viruses [35–38]. Gram-positive bacteria, *L. innocua*, are more resistant to PL when compared to Gram-negative bacteria, *E. coli*, which may be due to the distinguished compositional/structural variation in the cell walls of these bacteria [12, 39–41]. In contrast, Palgan et al. [10] found that *E. coli* (4.67 log reduction) was more resistant than *L. innocua* (5.13 log reduction) when inoculated in maximum recovery diluent solution. According to Luksiene et al. [26] and Hilton et al. [42], *Bacillus* was more susceptible than mesophilic bacteria, and *L. innocua* was more resistant than *Pseudomonas fluorescens* to PL at low temperatures and low fluence levels. Higher PL resistance shown by *Listeria* spp. (<1 log reduction), as compared to *Pseudomonas phosphoreum* (5 log reduction) and *Serratia liquefacans* (3.9 log reduction), could be related to the existence of photoreactive substances and protective

PL Processing of Fruits and Vegetables

Product	Processing System/Conditions	Microbial Safety Parameters	Reference
Apple juice	Laboratory-scale continuous-flow PL unit that produces 3 pulses/s with approx. 1.21 J/cm^2/pulse at 1.9 cm from the quartz window surface (SteriPulse-XL 3000)	4 and 2.98 log reduction of *E. coli* and *L. innocua* at 4 J/cm^2	Pataro et al. [30]
Orange juice		2.90 and 0.93 log reduction of *E. coli* and *L. innocua* at 4 J/cm^2	
Commercial apple juice	Continuous-flow PL system (RS-3000B SteriPulse-XL)	4.2, 1.8, and 3.1 log reduction of *S. enteritidis*, *S. cerevisiae*, and *E. coli* at 0.73 J/cm^2	Ferrario and Guerrero [33]
Cucumber slices	Bench-top PL system (RS-3000C SteriPulse- XL)	0.6, 2.2, and 2.8 log reduction of *E. coli* at 4, 8, and 12 J/cm^2 respectively	Tastan et al. [127]
Fresh-cut tomatoes	Automatic flash lamp system (SteriBeam Xe-Matic-2L-A)	4.2 and 3.8 log reduction of mold and yeast count at 6 and 8 J/cm^2 respectively	Valdivia-Najar et al. [82]
Fresh-cut avocados	Automatic laboratory flash lamp system (SteriBeam XeMaticA-2L)	1.05, 0.85, and 1.2 log reduction of aerobic mesophilic count at 3.6, 6, and 14 J/cm^2 respectively	Aguiló-Aguayo et al. [108]
Strawberries	Bench-top PL system (SteriPulse- XL RS-3000)	1.4–2.4 log reduction of *E. coli* O157:H7 at 5.6–63.2 J/cm^2 of WPL treatment	Huang et al. [91]
Raspberries		1.6–4.5 log reduction of *E. coli* O157:H7 at 4.8–53.9 J/cm^2 of WPL treatment	
Mango slices	PL system- XeMaticA-2L (SteriBeam)	3.5 and 2.07 log reduction of *L. innocua*, and yeast and mold count at 8 J/cm^2 respectively	Salinas-Roca et al. [94]
Apple juice	Steri-Pulse XL-3000 PL sterilization system	1.93 and ≥4.7 log reduction of *L. innocua* and *E. coli* at 8 s PL treatment respectively	Palgan et al. [10]
Apple juice	RS-3000B Steripulse-XL system	1.0, 1.6, 2.1, and 2.4 log reduction of *S. cerevisiae*, *L. innocua*, *E. coli*, and *S. enteritidis* respectively at 71.6 J/cm^2	Ferrario et al. [54]
Fresh-cut avocado	XeMaticA-2L system (SteriBeam)	2.97 and 3.33 log reduction of *L. innocua* and *E. coli* respectively at 12 J/cm^2	Ramos-Villarroel et al. [41]
Apple juice	RS-3000B Steripulse- XL system	3.9 and 1.0–2.0 log reduction of *S. cerevisiae* KE 162 cells in commercial and natural apple juice respectively at 60 s PL	Ferrario and Guerrero [63]
Mung bean sprouts	PL chamber with three xenon tube reflector (Claranor)	1.91, 1.55, and 1.65 log reduction of *E. coli*, *L. innocua*, and natural microbiota respectively	Kramer et al. [56]
Endive salad		2.34, 2.54, and 2.46 log reduction of *E. coli*, *L. innocua*, and natural microbiota respectively	
Raspberries	Batch-fed PL system (SteriPulse-XL 3000)	0.4–3.9 log reduction of *E. coli* and 0.3–3.4 log reduction of *Salmonella* at 2.9–72 J/cm^2 respectively	Bialka and Demirci [17]
Plums	PL system (laboratory construction)	1.5 and 1.4 log reduction of mesophiles and *B. cereus* respectively	Luksiene et al. [26]
Tomatoes		1.2 and 1.5 log reduction of mesophiles and *B. cereus* respectively	
Cauliflowers		1.1 and 1.3 log reduction of mesophiles and *B. cereus* respectively	
Sweet peppers		1.3 and 1.8 log reduction of mesophiles and *B. cereus* respectively	
Strawberries		1.1 and 1.5 log reduction of mesophiles and *B. cereus* respectively	
Apple cider	RS-3000C SteriPulse system	1.49 log reduction of *E. coli* ATCC 25922	Sauer and Moraru [13]
Apple juice		1.62 log reduction of *E. coli* ATCC 25922	

(*Continued*)

TABLE 46.1 (CONTINUED)
PL Processing of Fruits and Vegetables

Product	Processing System/Conditions	Microbial Safety Parameters	Reference
Apple juice	SteriBeam XeMaticA-2L system	1.27–3.76 log reduction of *P. expansum* at 4–32 J/cm^2 respectively	Maftei et al. [84]
Commercial apple juice	RS-3000B SteriPulse-XL system	3.0 and 4.4 log reduction of *A. acidoterrestris* spores and *S. cerevisiae* cells at 71.6 J/cm^2	Ferrario et al. [119]
Apple juice	PL mobile decontamination system (Claranor)	3.0 and 2.7 log reduction of *L. brevis* and *L. monocytogenes* at 17.5 J/cm^2	Ignat et al. [87]
Raspberries	RS-3000C SteriPulse system	4.5 log reduction of *Salmonella* at 28.2 J/cm^2	Xu and Wu [65]
Fresh-cut mushrooms	SteriBeam XeMaticA-2L system	3.03 and 2.66 log reduction of *E. coli* and *L. innocua* respectively at 12 J/cm^2	Ramos-Villarroel et al. [40]

compounds, which contribute to the antimicrobial efficiency of PL [43]. PL caused reduction of *E. coli*, *L. monocytogenes*, *Salmonella typhimurium*, and *Vibrio parahaemolyticus* in agar by 5.8, 6.1, 6.0, and 5.4 log units respectively at 0.525 J/cm^2 [44]. A single PL (0.6 J/cm^2) was sufficient to reduce *Bacillus subtilis* by 8.7 log units in suspension [45]. McLeod et al. [46] observed a 5–7 log reduction of microbes tested on agar in petriplates, and found higher resistance of *L. monocytogenes* (4 log reduction) to PUV treatment at low fluence of 1.25 J/cm^2. Ganan et al. [47] reported that *S.* Typhimurium

PL Processing of Meat, Marine, and Poultry Products

Product	Processing System/Conditions	Microbial Safety	Reference
Egg pasta	PL system (Claranor) with dose from 0.13 to 1.75 J/cm^2/pulse and experiment was carried out at 25°C	2.5 log reduction of *S. enterica* 9898 DSMZ at 0.7 J/cm^2	Manzocco et al. [90]
Skinless chicken fillets	Semiautomated intense PUV system (SteriBeam system)	Reduction range: 0.9–2.4 log for *S. enteritidis*, 1.1–2.0 log for *L. monocytogenes*, 1.3–3.0 log for *S. aureus*, 1.7–3.0 log for *Pseudomonas spp.*, 1.3–3.0 log for *B. thermospacta*, and 1.3–2.8 log for *E. coli* when treated at 1.25–18 J/cm^2	McLeod et al. [46]
Ham slices	Steribeam SBS-XeMatic-2L-A device (SteriBeam system)	1.78 log reduction of *L. monocytogenes* at 8.4 J/cm^2	Hierro et al. [97]
Bologna slices		1.11 log reduction of *L. monocytogenes* at 8.4 J/cm^2	
Eggs	Steribeam SBS-XeMatic-2L-A device (SteriBeam system)	0.14–2.49 log reduction of *S. enteritidis* at 2–12 J/cm^2 respectively	Hierro et al. [99]
Shrimp	Lab-scale PL system	2, 2.2, and 2.4 log reduction of *L. monocytogenes* at 0.7, 6.3, and 12.1 J/cm^2 respectively	Cheigh et al. [27]
Salmon		1.8, 1.9, and 2.1 log reduction of *L. monocytogenes* at 0.7, 6.3, and 12.1 J/cm^2 respectively	
Flatfish		1.6, 1.7, and 1.9 log reduction of *L. monocytogenes* at 0.7, 6.3, and 12.1 J/cm^2 respectively	
Eggs	Steribeam SBS-XeMatic-2L-A device (SteriBeam system)	3.3 and 5 log reduction of *Salmonella* at 0.35 and 2.1 J/cm^2	Lasagabaster et al. [100]
Beef *carpaccio*	Steribeam SBS-XeMatic-2L-A device (SteriBeam system)	1.2, 1.0, and 0.8 log reduction of *E. coli*, *S. typhimurium*, and *L. monocytogenes* respectively at 11.9 J/cm^2	Hierro et al. [44]
Tuna *carpaccio*		1.0 and 0.7 log reduction of *V. parahaemolyticus* and *L. monocytogenes* respectively at 11.9 J/cm^2	
Egg shells	SteriPulse XL-3000 PUV system	2.0 and 7.7 log reduction of *S. enteritidis* at 1.2 and 35.3 J/cm^2 respectively	Keklik et al. [116]
RTE Sausages	RS-3000C SteriPulse system	1.37 log reduction of *L. innocua* at 9.4 J/cm^2	Uesugi and Moraru [14]
Salchichon	Steribeam SBS-XeMatic-2L-A device (SteriBeam system)	1.81 and 1.48 log reduction of *L. monocytogenes* and *S. typhimurium* respectively	Ganan et al. [47]
Dry cured loin		1.61 and 1.73 log reduction of *L. monocytogenes* and *S. typhimurium* respectively	

is more resistant than *L. monocytogenes*. The effectiveness PL treatment is independent of temperature for *E. coli* and *P. fluorescens* in clear liquid substrates within the temperature range of 5 to 40°C, but a modest synergistic effect of temperature and PL was observed for *L. innocua* at 50°C [42]. IPL sensitivity in microorganisms may be related to differences in bacterial cell wall composition due to their protective and effective mechanisms to repair against the damage [48]. Gomez-Lopez et al. [5] demonstrated that the degree of inactivation of *L. monocytogenes* achieved by PL treatment was independent of the successive flashing, i.e. the microbe did not show any resistance to PL treatment. PL induced sublethal injury in *Saccharomyces cerevisiae* cells at low doses up to 12 J/cm^2, showing that the recovery of cells is dependent on the medium [49]. This treatment causes sublethal damage, which makes cells more sensitive to stress in subsequent stages, such as storage at low temperatures [50]. In contrast, PL did not induce any sublethal damage to the bacterial cells, such as *L. monocytogenes*, *E. coli*, *V. parahaemolyticus*, and *S.* Typhimurium [44]. *Salmonella* and *Listeria* were unable to repair the cell damage induced by PL through the photoreactivation mechanism [25].

The PUV inactivated *B. subtilis* spores in aqueous solution by >5 log cycles at a fluence of 60 mJ/cm^2 [51] and 5 log reduction on agar and treated at 1.24 J/cm^2 PL [37]. Spores are more resistant to PL than vegetative cells [52]. For a cell density of 10^7 cells/ml, fluence of 0.5 J/cm^2 induced >5 and 3 log reductions of vegetative cells and spores of *B. subtilis*, respectively. A 7.9 log reduction of *B. subtilis* spores in suspension was observed at 12 J/cm^2 PL application, and lower total fluences (0.3–5.5 J/cm^2) had no influence on germination, but retarded vegetative growth [53]. Ferrario et al. [54] found that *S. cerevisiae* was more resistant to PL treatment than *E. coli*, *L. innocua*, and *Salmonella* Enteritidis in PL-flashed apple juice. In contrast, Nicorescu et al. [45] have reported that bacteria is more resistant than yeast for PL treatment. *Aspergillus niger* was the more resistant microorganism to UV-C compared to *B. subtilis*, *Geobacillus stearothermophilus*, *Alicyclobacillus acidoterrestris*, and *S. cerevisiae* [12]. The vegetative cells are more sensitive to PL than spores [5]. Marquenie et al. [55] observed that conidia of *Botrytis cinerea* and *Monilinea fructigena* was reduced by 3 and 4 log units, respectively, and single light pulse did not lead to the development of any resistance to PL treatment. Inactivation of *B. cinerea* conidia was higher on nutrient agar as compared to that in suspension [55]. The PL-treated bacterial populations were decreased by 8 log units and fungal counts by 4.5 log units, after 1000 light pulses of the higher UV intensity light [35]. *Aspergillus niger* was more resistant in spore form as compared with *Fusarium culmorum* to PL, and this resistance can be attributed to UV absorbance associated with the dark pigment present in *A. niger* [35]. When UV-C and PL were applied sequentially, regardless of the fluence or duration of treatment, inactivation of *B. cinerea* conidia was increased and the maximal reduction was obtained at the highest doses (0.10 J/cm^2 and 120 s). Combined thermal treatment (45°C for 10 min) and PL (120 s) caused *B. cinerea* conidial reduction of 3.5 log units, an increase of 1 log unit compared to the sum of individual treatments [55]. Viruses were found to be more resistant to PL treatment as compared to bacteria [36]. Murine norovirus (MNV) was inoculated in phosphate-buffered saline solution, and it was observed to reduce by 2.59, 3.77, and 6.69 log units, respectively, when treated (i.e. laboratory-scale IPL system for 30 s) at 0.64, 1.45, and 3.43 J/cm^2, respectively. Inactivation of MNV in water was observed at 3.35 log units after 89 s treatment (4.30 J/cm^2) in a pilot-scale IPL system [34].

46.3.2 Mode of Action

A few studies have reported that VIS or IR region did not contribute any antibacterial effect, while the UV region was proved to be responsible for the inactivation of pathogens [56–58]. Both *Listeria* and *Salmonella* were susceptible to PL (6.5–7.0 log reduction, respectively), and no antibacterial effect was observed when UV light was filtered [25]. Reports are also available indicating that both VIS and IR regions in combination having high peak power also contribute to the destructive effect on microorganisms [4]. The antimicrobial efficacy of UV light on bacteria is due to the absorption of radiation by conjugated carbon–carbon double bonds in proteins and nucleic acids, photochemical dimerization of nucleic acids, and consequent inhibition of transcription and replication, thus resulting in DNA structural changes/cellular inactivation [9, 40, 59]. Sublethal injury caused to bacterial cells by PL processing confirmed that membrane damage is one of the major reasons for bacterial inactivation [30]. Ferrario et al. [49] studied the effect of PL on *S. cerevisiae* through transmission electron microscopy (TEM) and revealed that the loss of viability initiated by PL treatment not only caused membrane damage but also provoked significant disorder in the inner cells.

Cheigh et al. [27] identified the cell damage in *L. monocytogenes*, treated with UV-C and IPL, with the help of TEM analysis. UV-C-treated *Listeria* cells had a similar structure as untreated cells, except for a blurry and indistinct cell wall. In contrast, IPL-treated cells exhibited damage to cell wall structures, cytoplasm shrinkage, and rupture of internal organization leading to leakage of cytoplasmic content and ultimately to cell death [27]. Studies by Takeshita et al. [60] and Krishnamurthy et al. [61] concluded that formation of thymine dimer is the most important reason for inactivation as compared to damage through different mechanisms listed by other researchers. The internal cellular structure collapsing could also contribute to the inactivation of cells by PL and PUV treatment (Figure 46.5). Kramer and Muranyi [62] confirmed that the loss in cell viability by PL application is attributed to oxidative stress associated with DNA damage which results in photochemical inactivation of microbes, apart from its effect on the cell membrane or intracellular enzyme. The TEM studies on *S. cerevisiae* treated with PL revealed that the inactivation process in cells is due to alteration in cell shape, vacuolization, membrane permeabilization, and coagulation of inner cell contents and cell wall [60, 63].

Cheigh et al. [64] reported that IPL application exerted milder photochemical effects on cells than the UV-C

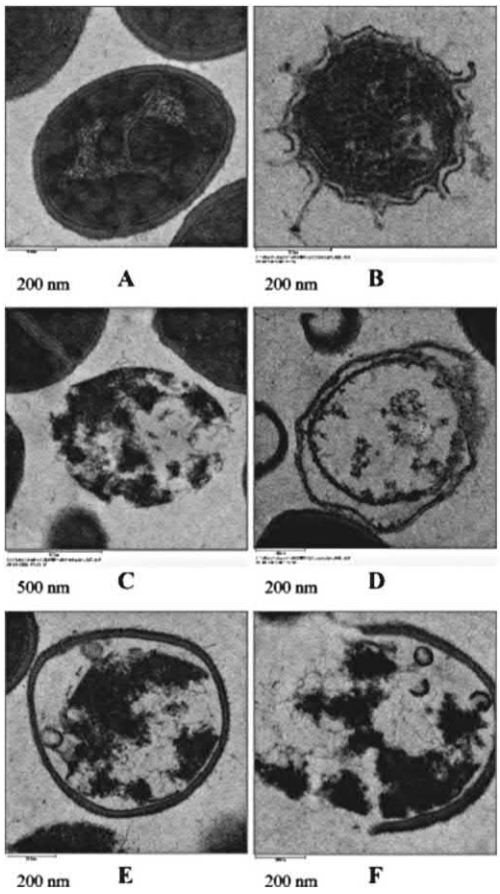

FIGURE 46.5 Evaluation of pulsed UV light (12-ml sample treated for 5 s at 8 cm below quartz window) induced damages in *S. aureus* by TEM: (a) control sample, (b) cell wall rupture, (c) lack of cell wall, (d) cytoplasm shrinkage and cell wall damage, (e) cytoplasm shrinkage and membrane damage, and (f) cell wall damage and cellular content leakage. (From Krishnamurthy et al. [61].)

irradiation, and inactivation of microbes was attributed to other factors, in addition to RNA or DNA damage (Figure 46.6). Nicorescu et al. [45] evaluated the effect of PL on the structural differences in *B. subtilis* inoculated on powdered spices and in suspension with the help of scanning electron microscopy (SEM). The cell membrane was disrupted clearly and formed deep craters in the cell wall after PL treatment on spices. However, in the case of *B. subtilis* treated in suspension, only deformation of the cell wall was observed. The cell wall disruption can be attributed to photothermal stress and germicidal action caused by the PL having a UV component. PL altered the DNA structure by decreasing supercoiling of DNA and further breaking into a single strand, leading to cell death [45]. Treating *E. coli* with PL caused structural changes in membrane integrity leading to flattening of cells, which is attributed to absorption of UV light, that in turn leads to overheating, intercellular water vaporization, and subsequent membrane disruption [65]. The research findings have shown that PL processing involves (Figure 46.7) photothermal/photophysical and photochemical effects, which cause alteration of cell membrane integrity and damage to chromosomal DNA [40, 45, 61, 64, 66].

46.3.3 Inactivation Kinetics

When illustrating microbial inactivation kinetics, the first-order model is widely accepted, especially for thermal treatments. However, it has been shown that the inactivation curves are clearly nonlinear and the use of first-order inactivation kinetics is not suitable for PL inactivation [13, 27, 68–70]. The shape of inactivation curves and lethality of PL treatment depend on the energy dose applied, the absorption properties of the liquid treated, and the types of microorganism [30, 43, 71]. *E. coli* was more sensitive than *L. monocytogenes* to UV-C treatment, and the Weibull model fitted better as compared to the first-order kinetics [17, 72]. The most resistant bacteria, i.e. *L. innocua*, *Pseudomonas*, and *Brochothrix thermosphacta*, displayed typically sigmoidal inactivation curves, with an initial shoulder followed by an exponential loss of cell viability down to the maximum detectable inactivation. However, in the case of the most sensitive species (*Photobacterium phosphoreum*, *Serratia liquefaciens*, and *Shewanella putrefaciens*), no initial shoulder was observed due to the PL treatment (0.053 J/cm^2) [43]. According to Uesugi et al. [68] the nonlinear Weibull model can be used to quantitatively describe microbial inactivation by PL [13]. This model has been used to predict microbial inactivation [13, 33, 42, 46, 56, 68, 73, 74]. The Weibull model (Equation 46.1) is a non-mechanistic model that uses a power function to explain the relationship between inactivation level and dose of the IPL [28, 56, 68, 72]:

$$\mathrm{Log}(N/N_0) = -\alpha * F^{\beta} \tag{46.1}$$

where N is the number of survivors after PL treatment (CFU/g); N_0 is the number of *E. coli* before PL treatment (CFU/g); α is the scale parameter; β is the shape factor, which describes the shape of the curve; and F is the PL fluence (J/cm^2). Inactivation curves exhibited a marked upward concavity, which indicates that the PL process became less efficient for higher doses in the case of commercial and natural juices (Figure 46.8). In commercial apple and natural melon juices, a Weibull-type model was suitable for survival data, except for the *S. cerevisiae* response for which a biphasic model showed better fit [75]. Hilton et al. [42] confirmed that the Weibull model was able to predict the inactivation kinetics of three microbes, namely, *E. coli*, *L. innocua*, and *P. fluorescens* in clear liquids, at sublethal temperatures and fluence below 12 J/cm^2. The Weibull kinetic parameters for PL inactivation in *L. innocua* showed a synergism between temperature and PL inactivation,; a significant temperature dependency of the shape (*n*) and scale (*b*) was observed. However, another study reported that PL inactivation of *E. coli* and *P. fluorescens* was independent of temperature [42]. Ferrario and Guerrero [33] mentioned that the Weibullian model was appropriate for representing survival data, showing higher coefficient of correlation values (95.0% and 99.1%). No differences in the Weibullian-related statistics corresponding to *E. coli* were observed between commercial and natural apple juice

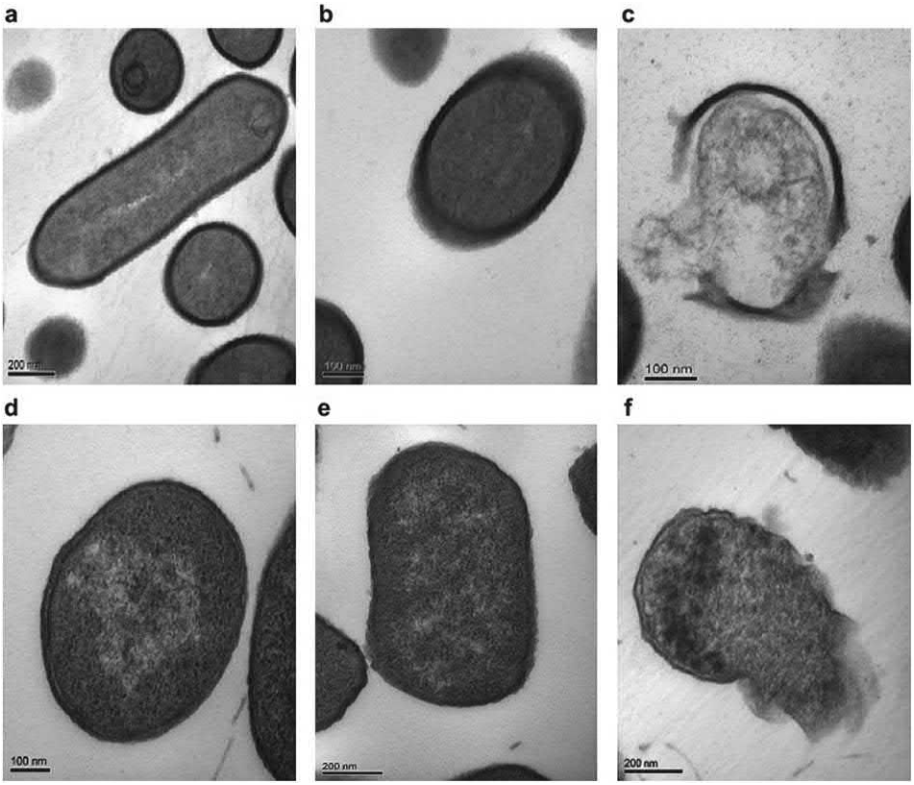

FIGURE 46.6 Transmission electron micrographs of *L. monocytogenes* (a, b, c) and *E. coli* O157:H7 (d, e, f). Images: (a) and (d) untreated control cells, (b) and (e) UVC treatment for 600 s, and (c) and (f) IPL treatment for 180 s at 376 W/m^2. Bars correspond to 100 nm (b–d) and 200 nm (a, e, f). (From Cheigh et al. [64].)

demonstrating that applied treatments exhibited similar effectiveness in both matrixes.

Zenklusen et al. [76] observed that the survival curves of *Aspergillus carbonarius* and *Aspergillus flavus* were non-log linear: the fungal counts steeply reduced (1.2–1.7 log cycles) up to 5–15 s (6–8 J/cm^2) PL treatment. Cheigh et al. [27] used a log-linear model, Weibull model, and modified Weibull model for the inactivation of *L. monocytogenes* (total fluence: 0–17.2 J/cm^2) and the modified Weibull model showed good fitting performance with concave, convex, or linear curves followed by a tailing effect. Common models based on log reduction values for all the species tested on chicken fillets gave a good fit for the majority of the species, but for *L. monocytogenes* exposed to both UV-C and PUV light, reduction was overestimated. It is reported that the Weibull model fits well when the curve is convex, which indicates that exposed cells were destroyed and shows that more resistant cells or those cells sheltered from exposure were left undamaged [46]. The shape of the inactivation curves of *B. subtilis* exposed to PL was dependent on its physiological state. For spores, inactivation curves were typically sigmoidal, showing an initial shoulder followed by an exponential loss of cell viability and a final tailing tendency. The "log-linear with shoulder and tail" model [77] was used to fit the inactivation kinetics of *B. subtilis* spores. In contrast to those found for spores, inactivation curves without a shoulder were shown for vegetative cells. The occurrence of a shoulder or tailing in the inactivation curves could be attributed to differences in cell resistance and/or high absorption in the UV region [52, 75]. Valdivia-Nájar et al., [78] used the modified Gomperz's model on fresh-cut tomato slices during cold storage and mentioned that it provided a good fit to the experimental data with $R^2 > 0.930$. Yi et al. [79] applied the double Weibull model and suggested that this method is suitable for assessing the performance of IPL treatment.

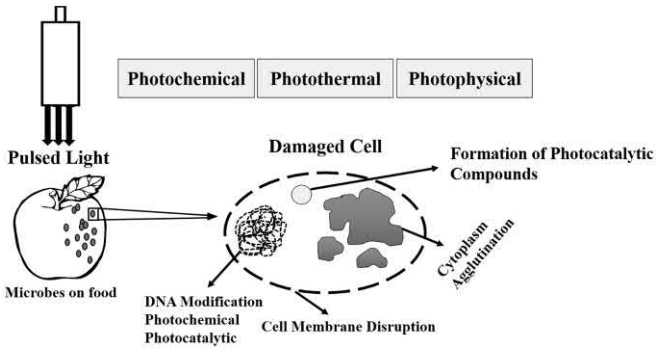

FIGURE 46.7 Mechanism of PL.

46.4 MICROBIAL INACTIVATION BY PULSED LIGHT PROCESSING IN FOODS

46.4.1 Fruits and Vegetables

PL processing has been attempted for various vegetables, fruits, spices, and other products of plant origin for the

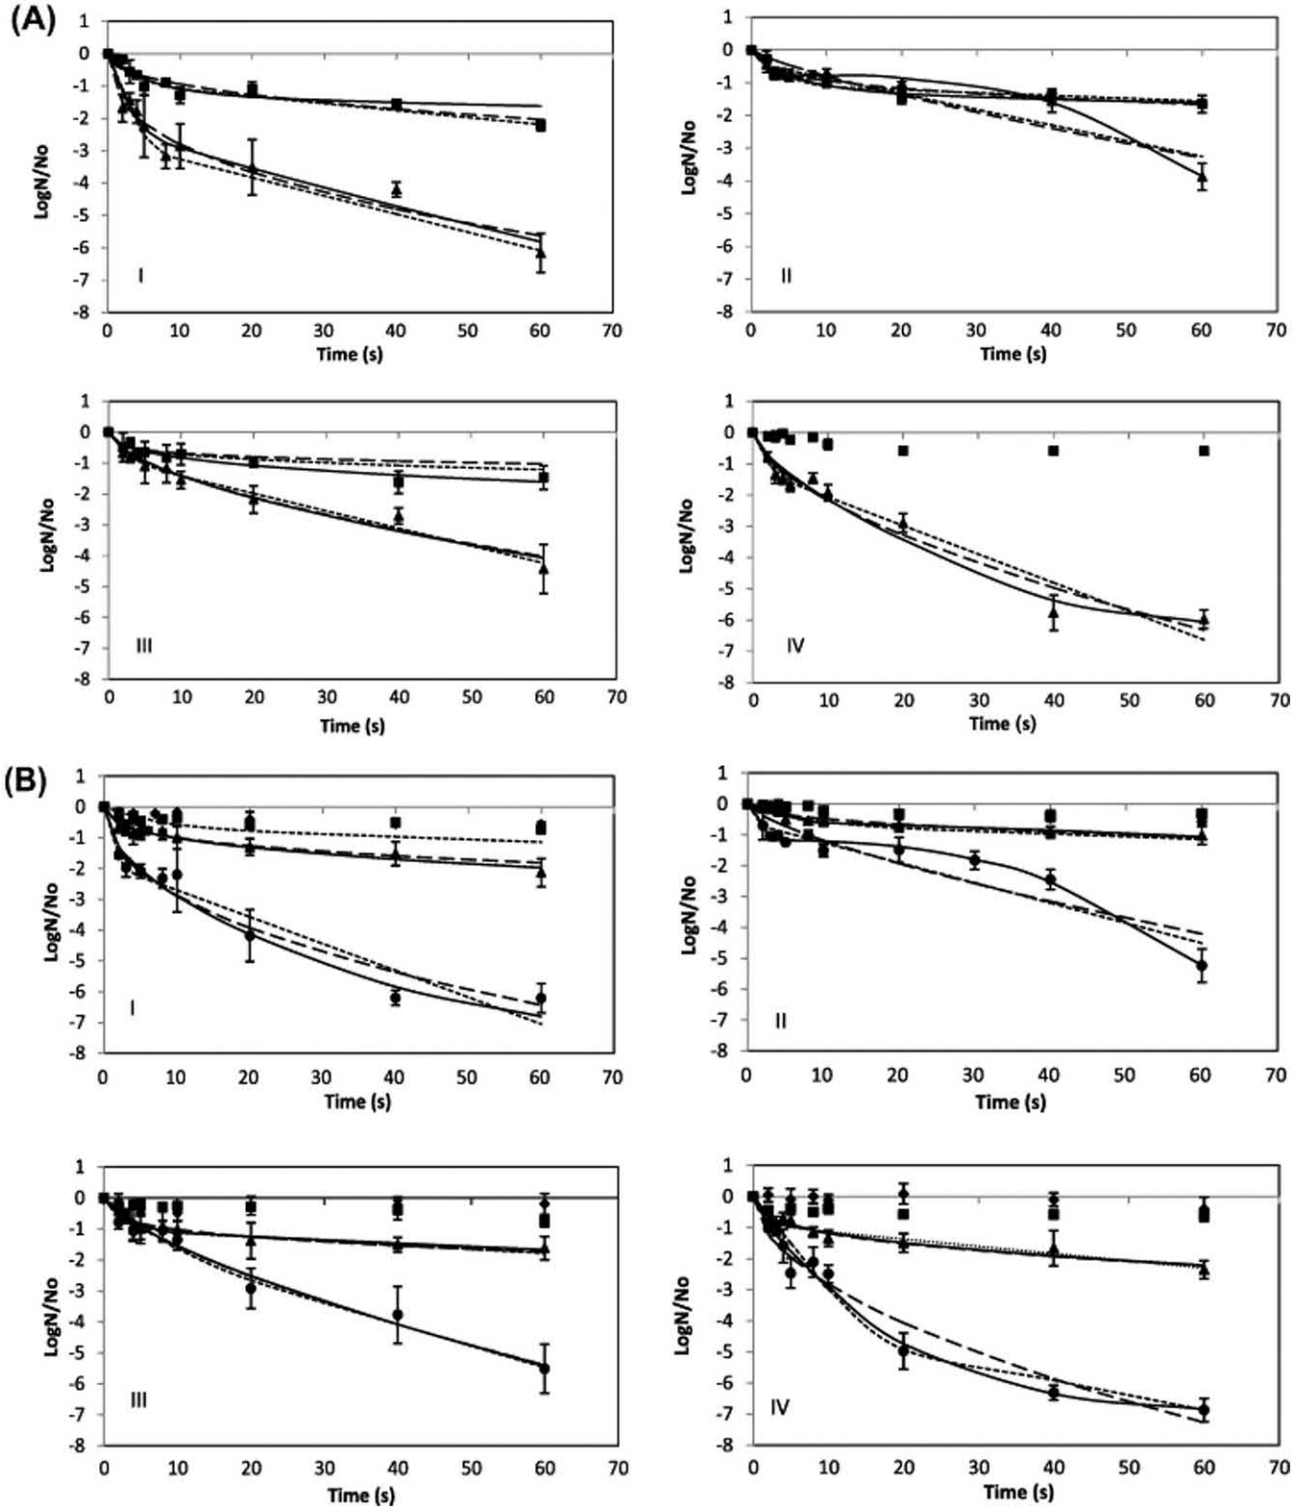

FIGURE 46.8 Experimental survival curves (points) and fitted values derived from Weibull (dashed line), biphasic (dotted line), and Coroller (solid line) models for *E. coli* (I), *S. cerevisiae* (II), *L. innocua* (III), and *S. enteritidis* (IV) in apple (▲); melon (●); orange (■); and strawberry (♦) juices treated with PL. (A) commercial juices; (B) natural juices. (From Ferrario et al. [75].)

decontamination of foodborne pathogens. Literature reports on the inactivation of these pathogens in different fruits, vegetables, and their products are presented in Table 46.1. In order to increase the safety of fruit and vegetable juices, US FDA regulation requires a 5 log reduction process for pathogens [80]. *E. coli* and *Salmonella* populations in blueberries treated with PL decreased with increases in fluence and time. Further, *Salmonella* showed a higher resistance to PL treatment as compared to *E. coli*, when inoculated on the skin of blueberries [18]. The treatment of apple juice with PL reduced *E. coli* counts by 3.1 to 4.9 log CFU/ml, when treated at energy levels of 4.03 to 5.10 J/cm^2 [32]. *E. coli* and *L. innocua* counts were reduced in apple juice treated with PL at 28 J/cm^2, and even after 48 h, there was no subsequent recovery of the cell [10]. With PL application, molds on strawberry fruits were decreased by 16–42% with applied fluence ranging from 2.4 to 47.8 J/cm^2 [81]. Valdivia-Najar et al. [82] observed that when tomato slices were treated with PL (4–8 J/cm^2), psychrophilic bacterial count reduced to 0.7–1.8 log CFU/g from an initial count of 7 log CFU/g.

The efficiency of PL treatment is affected by the type of microbe, microbial population, volume of suspension, and inoculation site [5, 18, 34, 83, 84]. The antimicrobial effect of PL decreased as the population density increased, for both vegetative cells and spores of *B. subtilis* and *G. stearothermophilus* [52]. Decontamination of dip-inoculated was tougher than spot-inoculated samples (by 3.6 log reduction difference at 15 s dry PL) due to penetration of *E. coli* into the open surface structures of the produce [85]. The inactivating effect of PL treatment (16 J/cm^2) against *Penicillium expansum* inoculated in apple juice prominently depended on the microbial population, i.e. 1.30 and 3.2 log reductions for 3×10^5 and 2.3×10^4 CFU/ml, respectively [84]. The inactivation varied based on the growth phase of microbes; for example, reduction was more significant during lag and early stationary phase of growth [5]. The effectiveness of microbial inactivation was influenced by the properties of foods, such as intrinsic transparency, turbidity, absorptivity, reflection coefficient, thickness, color, viscosity, moisture content, the presence of particulate material, and the flow rate of the product [10, 23, 33, 54, 86]. Ferrario et al. [49] stated that both pH and absorbance of the matrix had impact on the PL efficiency, but the absorbance was the most effective factor.

Furthermore, the distance between the sample and light source, treatment time, volume of the sample, sample depth, geometry of the treatment chamber, orientation, and lamp design were the critical factors to be optimized to achieve maximum effectiveness of the PL treatment [9, 29, 65, 87, 88]. The sterilization effects of IPL treatment on *L. monocytogenes* showed significant inactivation compared to UV-C treatment due to the higher penetration depth and emission power of IPL [27]. The inactivation of microbes decreased with the distance when the sample was kept directly below the lamp, but increased at the shelf borders [5]. Efficiency of PL in microbial inactivation is directly dependent on the energy dosage absorbed by microbe, which is affected by the light transmittance through the liquid food [28, 30, 84]. PL has very limited penetration depth in opaque media and is capable of targeting the surface microorganisms [84, 88]. Nearly 5 log and 3.5 log reductions were observed for agar seeded and suspension of *S. aureus* cells, respectively, at 16.8 J/cm^2. In order to achieve a higher microbial inactivation rate in opaque liquids, a high dosage of light is required along with a longer treatment period [28]. The sample depth of suspension cells greatly influences the inactivation level due to the poor penetration capacity of PUV light [86, 88]. Efficiency of PL treatment for the inactivation of *P. expansum* intensely decreased from 3.21 to 1.58 log CFU/ml, when the depth of apple juice was increased from 6 to 10 mm [84]. The inactivation rate of *S. cerevisiae* was higher in a peptone water system than in apple juice possibly due to an increased absorptivity of juice that decreased the effective interaction between microbes and light photons [49]. Another study also showed that PL effectiveness was negatively influenced by the higher absorbance values of liquids in the UV-C region [75].

The properties of the food surface have an impact on the decontamination efficacy of IPL [28, 74]. Studies have proven that physiochemical parameters such as chemical composition, total soluble compounds, pH, and light absorbance (especially due to compounds such as carotenoids) affect the degree of microbial inactivation [49, 78]. The beverages with higher transparency like apple juice, carbonated drink, and plum juice displayed 7 log reductions of *Pseudomonas aeruginosa* with the application of 12.2–24.3 J/cm^2 [28]. While, in the case of milk, grape juice, and coffee, a lower reduction value of 1–1.9 log CFU/ml was observed with a PL dose of 29.2 J/cm^2. Similarly, due to the differences in the transparency of the medium (1 mm thick), lower inactivation levels of *E. coli* and *L. innocua* were also reported by Palgan et al. [10] in milk (1275.2) and orange juice (79.7) when compared to apple juice (5.81) and maximum recovery diluent (0.74) with lower absorption coefficients (ε) (Figure 46.9). PL was more effective in the apple juice system with lower turbidity as compared to orange and strawberry juices, and this signifies that higher turbidity of juices weakens the PL efficiency [54]. One of the important factors that govern the effectiveness of PL is the fluence level applied to the sample [40, 71]. The dose applied and inactivation of microbes are proportional, thus confirming that the PL treatment with higher intensity and pulse number inactivates the microbes to a greater extent [7, 13, 19, 41, 58, 84]. As the distance between the sample and the lamp decreases, the temperature of the product increases drastically [55, 89]. When the spectral range of the PL treatments, particularly the UV component, was altered (normally using filters), the inactivation of *E. coli* and *L. innocua* was also lowered (Ramos-Villarroel et al., 2012). The degree of reduction of *E. coli* and *L. innocua* on fresh-cut avocado flashed with PL containing a UV component (2.74 and 1.35 log CFU/g, respectively) was greater than that treated with PL without UV spectrum (0.83 and 0.68 log CFU/g, respectively) [40]. Other studies have also shown that the UV part of PL contributes more to the inactivation of microbes and is more effective in the case of thin-layer products [56, 90]. Among the spectrum of UV, UV-C was more effective in inactivating

FIGURE 46.9 **a**. (From Palgan et al. [10].)

vegetative cells and spores [37, 56, 59]. It was reported that a 266 nm dose of 0.42 J/cm^2 inactivated *E. coli* in suspension by 7 log units, whereas a 355 nm dose of 16.7 J/cm^2 inactivated *E. coli* by 4 log units only [83].

During long PL treatments, the heating effect has an important role in the quality changes of the product. A lower product temperature ensures better retention of nutrients, since bioactive components present in food may be degraded during the sample heating process. Product heating and browning due to PL treatment have been reported as a major limiting factor for its application in the processing of foods [18]. There was a strong linear relationship between temperature attained and PL treatment time for apple juice, orange juice, and milk with average temperatures of 36.2, 40.6, and 40.1°C, respectively [10]. Product temperature depends on the treatment time, number of pulses, and distance from the PL source [5, 33, 88, 89]. Further, to dissipate the temperature changes due to product heating, integration of the cooling systems in the equipment can be implemented that confines the heating rate and reduces the final temperature of the product [30]. Dry PL (DPL) treatment for 60 s increased the blueberry surface temperature to 64.8°C, whereas it reached only 34°C with wet PL (WPL) [18]. Raspberries and blueberries were submerged in agitated water to remove the excess heat produced by PL, and the WPL process provided the benefits of conserving sensorial and nutrition quality by decreasing sample heating, uniform PL exposure, and physical removal of microbes due to the agitation of water [91]. For spot inoculation on blueberry, DPL and WPL treatments decreased *Salmonella* by 0.9 and 4.4 respectively (Figure 46.10), whereas for dip inoculation, *Salmonella* reduction was 0.6 and 0.8 log units respectively [92]. Thus, PL and washing process showed a synergistic effect on the inactivation of *Salmonella* spot inoculated on blueberries. For the decontamination of berries, WPL processing was reported to be one of the possible non-chemical substitutes for chlorine washing as it had greater effectiveness and an environmentally friendly process [91]. WPL treatment showed time-dependent log reduction for spot-inoculated green onions, whereas WPL treatment had practically no influence on treatment time for dip-inoculated ones [85]. *E. coli* inactivation in green onions by DPL at 5 s was more effective than 60 s WPL treatment (>4 log reduction) [85]. Therefore, light-based technology with a slight modification by the addition of cooling systems in order to reduce the thermal effect can be a promising technique to inactivate the microbes in vegetables and fruits (solid and liquid foods) by retaining the quality of foods and increasing the shelf life of the products.

PUV and PL were found to be more effective than continuous UV treatment for both aqueous suspensions and surfaces [51, 64, 93]. The turbulence has a distinctive effect on microbial inactivation, and PL efficacy enhanced considerably with increased turbulence [13, 45, 74]. Continuous flow-through PL of apple juice was more effective in inactivating microbes than batch-mode PL [32, 33, 75]. The inactivation of microbes (*E. coli*, *Salmonella*, and *S. cerevisiae*) was 1.8–2.4 log cycles in apple juice treated with continuous-flow PL (0.73 J/cm^2), whereas it was 0.4–1.7 log cycles in juice treated with batch PL (2.4 J/cm^2) [33]. In apple juice, a maximum reduction of 7.3 log CFU/ml was noticed for *E. coli* with high turbulence (3000 rpm) compared to 4.5 and 2.7 log reduction for the treatment with low turbulence (500 rpm) and static treatment respectively. For the same high turbulence treatment, inactivation counts of *E. coli* in apple cider were 5.5 log units higher than low turbulence and about 3.2 log CFU/ml greater than static treatment [13]. Inactivation of microbes also depends on the distribution of fluence on the sample surface, and location of microbes [10, 94]. The shielding of microbes from incident light by suspended matter is one of the major limiting factors in PL treatment for liquid substrates [13]. The surface topology of the product plays an important role in PL treatment, as microbes can lodge on irregular surfaces and thus inhibit the effect of PL on the target organism. Kaack and Lyager [95] noticed that PL application reduced the amount of inoculated yeast cells on carrot slices by about three to four cycles, whereas Gómez et al. [67] reported 1.6

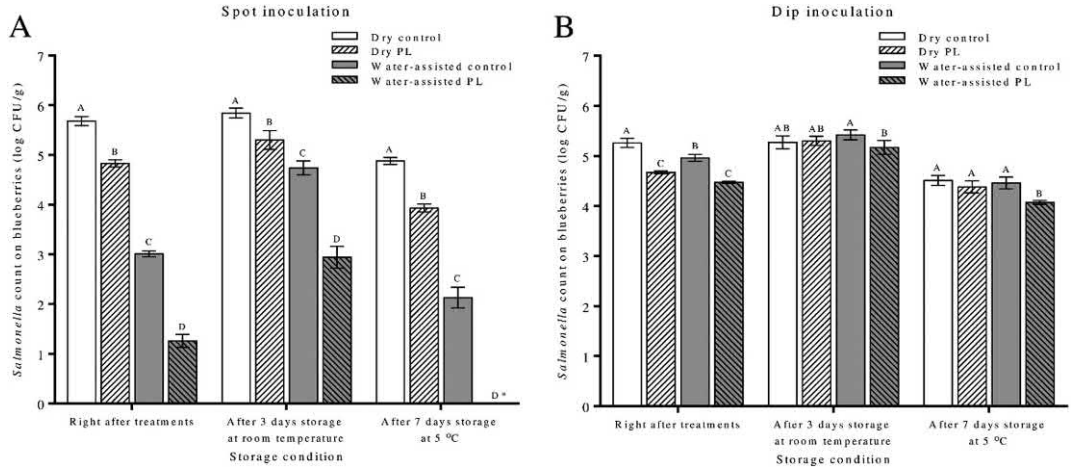

FIGURE 46.10 Counts of *Salmonella* spot-inoculated (A) or dip-inoculated (B) on blueberries after treatments and after 3 days of storage at room temperature or 7 days of storage at 5°C. Dry control blueberry samples and samples washed with tap water or treated with dry or water-assisted PL treatments were stored at room temperature for 3 days or 5°C for 7 days. (From Cao et al. [92].)

log cycles in apple discs, which can be due to the shielding of microorganisms by rough apple surface and internalization into apple tissue [96]. Likewise, the reduction in the native microflora was lesser than *L. innocua* and *E. coli* inoculated on spinach samples flashed with PL due to internalization of endogenous microorganism [73]. Raspberry and strawberry treated with PL at 5.4 J/cm^2 inactivated *E. coli* by 3.0 and 2.3 log CFU/g, *Salmonella* by 3.4 and 3.9 log CFU/g respectively, and this variation in inactivation can be attributed to the difference in the surface of the fruits [17]. The difference in efficacy of PL against *E. coli* and *Salmonella* inoculated on blueberry skin (>6.7 and 5.7 log reduction respectively) and calyx (4.3 and 4.1 log reduction respectively) was due to the rougher surface of calyx that allows more shadowing effect [18]. Xu et al. [85] also observed a difference in the inactivation efficacy of PL on *E. coli* inoculated on the stems (4.9 log CFU/g) and leaves (5.2 log CFU/g) of green onions. Similarly, Huang et al. [36] found that the reduction of *E. coli* and *Salmonella* on blueberry (5.7 and 4.2 log reduction respectively) was higher compared to that on strawberry (2.1 and 1.9 log reduction respectively) at 22.5 J/cm^2. The presence of achenes on strawberry could possibly shade bacteria from the PL beam leading to incomplete decontamination compared to blueberries with smooth skin [36]. Cauliflower, being the most irregularly surfaced vegetable, was less disinfected by PL than other fruits and vegetables, and thus the antimicrobial efficiency of PL exhibited clear dependence on surface irregularity [26]. The irregular surface of the matrix protects the hidden microorganisms from IPL so that microbial decontamination becomes limited, irrespective of the fluence applied [45, 56, 71, 84, 97]. Koh et al. [98] studied the effect of cut type on fresh-cut cantaloupe treated with PL and found that sphere samples had significantly lower microbial count compared to cuboid and triangular prism-shaped samples. The increasing microbial growth was attributed to a higher area/volume ratio which causes more wounds on the product, thus leading to higher electrolyte leakage and in turn higher microbial growth [98]. A higher degree of microbial inactivation (about 50%) was observed in sphere-shaped cantaloupe compared to that of cuboidal or triangular prism ones. This difference could be due to the decreased scattering of light around the edges of the sphere and reduced shielding influence due to lower initial microbial load [98]. At the end of the 10th day of storage, *Salmonella* counts were lower (2.3 and 2 log CFU/g) in raspberries treated with PL at 14.3 and 28.2 J/cm^2 respectively, as compared to control (5.0 log CFU/g) [65]. PL processing showed its ability to decontaminate and promote higher microbial stability during storage, thus increasing the shelf-life of the product [78, 87, 96]. PL processing could inactivate microbial growth and, thus, extend the shelf life of treated fresh-cut cantaloupe samples by 8 days [98]. Ramos-Villarroel et al. [41] concluded that PL can extend the microbial shelf life of the fresh produce, but PL in combination with appropriate packaging systems along with the application of firmness stabilizers and anti-browning agents retain the physical and chemical quality of the treated samples.

46.4.2 Meat, Marine, and Poultry Products

Microbial decontamination of animal products such as meat, poultry, and dairy products for improving safety and shelf-life has been reported, and key findings are presented in Table 46.2. The sliced ham lost less moisture when placed far away from the lamp than when located near the lamp, and there was a 6°C temperature increase with every 10 s of PUV light treatment [89]. PUV treatment also affected the tissue structure of ham, which may be due to the destruction of the network and changes in myofibrillar proteins [89]. PL-treated vacuum-packaged ham extended the shelf life by an additional 30 days compared to the vacuum-packaged-only ham [97]. Further, the inactivation of *Listeria* and *Salmonella* on chicken breast surface was found to be 0.8–0.9 log reduction at 0.8–1.1 J/cm^2 and 2–2.4 log reduction at 5.4 J/cm^2 respectively. At 5.4 J/cm^2 fluence of UV light, reduction by 2, 2, and 2.4 log CFU/ml was observed for *Listeria*, aerobic plate count, and *Salmonella* respectively on the chicken surface [25]. The reduction in microbes was similar for both chicken fillets that are unpacked and modified atmosphere packaging (MAP) packed, and treated with PUV at higher fluence (10.8 and 18.0 J/cm^2). When MAP chicken fillets were treated with lower fluence of 1.2 and 3.6 J/cm^2, they showed lower (0.9 and 0.7 log, respectively) reductions [46]. A minor elevation of temperature was noted by about 0.5–2.5 and 2.5–3.5°C when PUV at fluence of 10.8 and 18 J/cm^2, respectively, was applied to chicken samples [46]. They also found a limited dose-response effect on chicken fillet treated with PUV, due to the shading effect of uneven surface structures of the samples. The reduction of *Salmonella enterica* was lower in the case of cells inoculated in the dough before sheeting when compared to those inoculated on the surface of egg pasta after sheeting [90]. High doses of PL reduced *Salmonella* as a result of egg pasta heating or sample heating rather than the germicidal effect of the UV component of light [90]. Egg decontamination efficiency by PL could also depend on the washing process before the processing. Higher *Salmonella* decontamination was achieved in unwashed eggs than washed eggs, which could be due to damage of egg cuticle that acted as a protective shielding against PL. The washing procedures could damage the cuticle and, therefore, enable microbial cell penetration into pores, that in turn protect bacteria from being affected by PL [99]. In contrast, a 5 log reduction in *Salmonella* population was detected in both washed and unwashed eggshells flashed at 2.1 J/cm^2 PL [100]. They used a different washing procedure for eggshells (immersion in 70% ethanol) and stated that washing has no effect on the antimicrobial efficacy of PL on the surface of eggshells without any *Salmonella* penetration into egg content. *Salmonella* inoculated on eggshell was found to have photoreactivation capability, and hence it was advised to store eggs that are PL-treated away from light [99]. Meanwhile, the photoreactivation capability of *L. monocytogenes* inoculated on ham and bologna was not observed [97].

46.4.3 Milk and Milk Products

In milk, after PL treatment of 7–28 J/cm^2, *E. coli* was decreased by 0.6–1.1 log CFU/ml and for *L. innocua*, it was

0.5–0.8 log CFU/ml respectively [10]. A high fluence of 26.2 J/cm^2 resulted in 3.2 log reduction in the total microbial count, and concomitantly, milk temperature was increased to 55°C which indicated a combined effect of photochemical and photothermal damage of natural microflora by PL in raw milk [101]. The milk with different total solids (9.8, 25, and 45 %) treated with PL of 2.1 J/cm^2 reduced *E. coli* by 0.21, 0.13, and 0.03 log units, respectively [74]. No significant difference in inactivation of *E. coli* was observed when milk with different fat levels (skim, 2% fat, and whole milk) was treated with PL. The inactivation levels of *E. coli* decreased by 2.0, 0.6, and 0.4 log CFU for 9.8, 25, and 45% total solids, respectively, as the total solids in reconstituted milk increased. PL treatment efficiency was hindered by the presence of milk fat due to the scattering of light by fat globules [74]. Increasing levels of oil and protein reduced the killing efficiency of IPL, since proteins have high absorption at about 280 nm and lipids absorb a higher wavelength of the UV-B region, thus decreasing the effective radiation dose on microbes. Since starch did not show any negative impact on the decontamination of microbes, foods such as fruits and vegetables, which are high in carbohydrates, but poor in fats and proteins, seem to be more appropriate for IPL processing [102]. The use of turbulence enhanced the inactivation of *E. coli* in reconstituted milk by PL treatment [74]. Thus, turbulence with thin layer flow can significantly improve the effectiveness of PL treatment, presumably by maximizing exposure of microbial cells to the incident light, and could disintegrate the clusters of microbial cells that lead to the increase of microbial inactivation. A 3 log reduction of *L. innocua* was found on Gouda cheese samples flashed with just 0.9 J/cm^2, whereas a 1 log reduction was found for Manchego cheese slices [103]. The difference in decontamination magnitude between types of cheese was noticed, and this could be described by their different topography (i.e. the porous nature in Manchego vs smoothness of Gouda-type cheeses) [103]. A *L. innocua* reduction of 3 log CFU/slice was observed in cheddar and processed cheese slices treated with 9 J/cm^2 [104].

46.4.4 Other Foods

The inactivation of *L. monocytogenes* in infant meals was effective (3 log reduction at 4800 μs), but lower than infant beverages (5 log reduction at 3500 μs) which is due to the product characteristics [23]. Greater PL treatment time (75 s) significantly impaired seed viability by 54 ± 17 and 46 ± 9% in dry and wet barley grains respectively [76]. These results indicated that the decontamination efficacy of IPL is also closely interrelated to the moisture content of the product [23]. A significant reduction of *B. subtilis* spores (4.2) was obtained with a fluence of 1.5 J/cm^2 PL in 65°Brix sucrose syrup [12]. This study also indicated that the increase in depth of sugar syrup from 3 to 10 mm did not significantly affect the *B. subtilis* spore inactivation. Hwang et al. [71] reported a 0.99 log reduction of inoculated microorganism (80% bacteria + 20% molds and yeast) on sesame seeds when IPL treatment was applied, whereas a 7 log reduction of *P. aeruginosa* was noticed in inoculated mineral water [28]. This large change in reduction is mainly due to the matrix type: all sides of sesame seeds could not be exposed to IPL because of the shadowing effect. The addition of a mixing step during IPL treatment of sesame seeds reduced the microbes by 1.02 log units at 39.85 J/cm^2 compared to 0.86 log reductions without a mixing step [71]. Likewise, Moreaua et al. [105] showed that the reduced efficiency of PL in the case of peppercorn decontamination compared to that of inactivation of *B. subtilis* on glass marbles could be attributed to the non-uniform surface of the spice. The rough rice treated with PL (84.4 J/cm^2) exhibited a reduction of aflatoxin B_1 (AFB_1) from 132 to 32 ppb (75% reduction) and aflatoxin B_2 (AFB_2) from 45 to 27 ppb (39% reduction) [106]. However, in rice bran irradiated with PL of 16.1 J/cm^2, the degradation of AFB_1 and AFB_2 reduced by 90.3 and 86.7%, respectively, which was higher than rough rice due to the thinner structure of rice bran. AFB_1 was found to be more susceptible to PL degradation than AFB_2 probably due to the presence of C_8–C_9 double bond in the furan ring of AFB_1, which is liable and vulnerable to photodegradation [106]. Meanwhile, it is noteworthy that UV wavelength spectrum and PL intensity are major factors that affect the degradation of aflatoxins and the rate of degradation was greater for PL treatment as compared to conventional UV treatments [106]. A significant inactivation of *S. cerevisiae*, *A. niger*, *B. subtilis*, *G. stearothermophilus*, and *A. acidoterrestris* spores (5.4, 1.3, <4, and 3 log reduction respectively) was obtained with a fluence of 1.6–1.9 J/cm^2 PL in 65°Brix sucrose syrup [12]. Ground caraway and ground black/red pepper flashed with PL of 10 J/m^2 reduced *B. subtilis* by 0.86–1.0 log units [45].

46.5 Effect of Pulsed Light on Physicochemical Characteristics of Food Products

46.5.1 Physical Properties

The external appearance of grapes was not affected by the application of PL before crushing, whereas after crushing, the pulp was slightly darker than control, due to the diffusion of anthocyanin into the berry [107]. Immediately after the PL treatment, no significant change in color was noticed on fresh-cut avocado treated at 6 J/cm^2, but there were signs of browning in samples treated at 12 J/cm^2 [41]. The net color changes of fresh-cut avocados treated with PL were higher than the control ones and were closely related to the fluence applied; thus the intense application of PL has a more noticeable impact on the color of the samples [41]. Fresh-cut avocados treated with PL did not seem to avoid enzymatic browning, but maintained better hue angle values over time compared to untreated avocado pieces. Meanwhile, chlorophyll content after PL application (6 J/cm^2) on fresh-cut avocados was 1.3-fold higher than in untreated samples [108]. The lightness of the PL-treated fresh-cut avocados decreased throughout the storage period (15 days) and was lower than that of untreated samples [41, 58]. However, variation in color by a shift in a*

values of the endive salad, and fresh-cut avocados treated with PL was more distinct as the fluence applied intensified [56], leading to browning during storage and firmness was also significantly affected [41]. In contrast, PL had no adverse effect on the color of mung bean sprouts, and rather had a positive effect on overall appearance which may be because of lower microbial population [56]. Meanwhile, UV spectra affected the color and texture of fresh-cut mushroom and cut avocados and, therefore, treating fresh produce with quality-stabilizing agents (anti-browning and texture stabilizers) before PL flashing can be recommended for extending the shelf life of a product [40, 58]. Weight loss and browning of apple slices were observed with higher PL treatment (17.5 J/cm^2) due to rupture of membrane and loss of turgidity [87]. Fresh-cut apples treated with PL exhibited a slight decrease in L* values, were susceptible to surface browning, and had lower firmness values when compared to untreated apple samples [96]. Apple slices exposed to PL turned darker and less green than the control, and this influence was more evident as PL dose and storage time increased, probably initiated by browning reactions enhanced by temperature increase during irradiation [67]. PL induced degradation of biopolymers in cell wall, affecting the pectin present in the cell wall, and cells appeared collapsed with ruptured membranes, thus causing a rupture, and folding of cell walls. This membrane damage would increase enzymatic browning reactions due to the loss of functional cell compartmentalization and tissue damage [67]. PL treatment did not affect pH, °Brix, and non-enzymatic browning index, whereas it slightly affected the color of apple juice [32]. Fresh-cut mangoes flashed with PL maintained the color and firmness during 7 days of storage as the control [109]. Green onions treated at 30 s and 60 s DPL were observed to have an alteration in quality with softer and shrunken tissue, color, and smell [85]. Raspberries treated with PL showed a decrease in brightness and did not substantially change the redness of the fruit during storage, and instability of firmness of the fruit was also observed [65]. The DPL treatment degraded the blueberry wax and resulted in a burnt appearance with severe discoloration of blueberries. Color discoloration was coupled with sample heating when blueberries were treated with DPL for 60 s when compared to WPL [18]. The L* value of blueberries treated with WPL, decreased during the storage period (3 and 7 days at room temperature and 5°C, respectively) by losing the surface glossiness and formation of white bloom on the surface [92]. However, color was not negatively affected by PL treatment for fruits and vegetables [26, 87, 98].

PL treatment at 2.1 J/cm^2 decreased the redness and increased the lightness of ham, but in bologna samples, PL at 4.2 J/cm^2 decreased the lightness and increased the yellowness [97]. No significant change in color and total score values was observed in beef samples treated with PL [110]. PL considerably affected the yellowness and redness of the beef *carpaccio* when treated with ≥8.4 J/cm^2, but lightness was not altered between PL-treated and untreated samples. During shelf-life studies, beef and tuna *carpaccio* showed significant, remarkable differences in color and odor when treated with PL at 4.2 J/cm^2 and above [44], whereas Tomašević [110] found the difference in odor of beef samples at 3.4 J/cm^2. When *salchichon* was flashed with 11.9 J/cm^2 fluence, there was no significant difference in color, odor, and flavor, but for dry-cured loin, all these quality parameters changed [47]. Color parameters were not dramatically modified by PL treatment in these ready-to-eat (RTE) dry-cured products, which may be attributed to the greater stability of the cured pigments in comparison to those of fresh meat [47]. The sliced ham flashed with PUV showed a slightly darker color, and decreased both a* and b* values compared to control at the end of 14 days of storage [89]. The vacuum packaging of chicken frankfurters did not have any effect on the log reduction of *L. monocytogenes* (maximum of 1.5 log CFU/ cm^2) with UV treatment (60 s at 8 cm); however, color and quality changes in products were observed [111]. A higher dose of PL (>1.75 J/cm^2) treatment had a slight effect on the appearance and color and enhanced the formation of non-enzymatic browning products and in turn, increased the oxidative stability of egg pasta [90]. Cheddar cheese flashed with PL maintained a stable lightness value L* and lipid peroxide value over 30 days of refrigerated storage [112].

External damage was not observed on strawberries treated with PL (250 s), and the firmness of the treated fruit was similar to that of control berries [55]. Strawberries flashed with PL did not display any pronounced softening when compared to untreated samples even after 8 days of storage at 6°C, and cell wall strengthening of fruit was induced by PL stress [81]. Meanwhile, TEM studies also showed that the internal tangential walls strengthened as did the integrity of the walls of hypodermis cells of fruit by PL stress, whereas the loss of cell assembly was observed in untreated stored strawberry fruits [81]. DPL- and WPL-treated blueberries exhibited shrinkage at the stem of the fruit, showing probable moisture loss during the PL treatment [92]. WPL-treated blueberry samples exhibited significantly lower firmness values than the DPL and water-assisted control samples [92]. Contrastingly, PL at fluence of 8 J/cm^2 drastically affected the texture of fresh-cut tomatoes (55.7% loss). The firmness of the PL (4 J/cm^2) treated fresh-cut tomatoes did not show any significant modifications immediately after the treatment, whereas throughout the storage period (20 days) the firmness values decreased at a higher rate of about 72% [82]. Mango slices treated with PL decreased in firmness of the sample after processing more than untreated ones [94]. Firmness values of fresh-cut avocado treated with IPL decreased intensely compared to control samples immediately after processing, displaying that the UV portion of IPL affected the softness of the fruit [58]. The use of PL (14 and 28 J/cm^2) dramatically affected the textural quality of fresh-cut mushrooms by increasing the toughness of the product, dehydration, and major textural modification [113]. Thus, PL treatment affected the textural properties and firmness of fruit and vegetables [26, 65, 87, 96]. Firmness retention was also observed in PL-treated fresh-cut cantaloupe compared to untreated samples during storage, which may be due to the thickness of the sample (~3 cm) as the effect of PL is restricted to the surface of the product [98, 114]. But contrarily, the adverse effect of single PL treatment at 11.7 J/cm^2

on tissue structure of fresh-cut cantaloupes under chilled storage was minimized by applying repetitive PL (RPL) treatment at 0.9 J/cm^2 every 48-h interval leading to increased microbiological quality, and retention of firmness and ascorbic acid content [114]. Further, firmness was higher for fresh-cut cantaloupes treated with RPL compared to the untreated fresh-cut cantaloupes throughout storage, which may be due to lower CO_2 concentration in treated samples, which could otherwise de-compartmentalize the enzyme and its substrates and then act on cell walls of fruit tissue leading to rapid deterioration [114]. It was also noticed that the PUV-treated sliced ham decreased hardness over the storage time (14 days) which may be due to destruction of the network of tissues that resulted in softening [89].
